The discovery of incidental or secondary findings is not unique to genetic testing; however, the application of next-generation sequencing (NGS) methods to broad population screening programs presents new opportunities to detect clinically-significant findings unrelated to the intended scope of testing. In the context of preconception carrier screening, the detection of pathogenic variants in either a homozygous or compound heterozygous state may represent an incidental disclosure of a disease status unknown to the patient or referring physician, particularly for conditions associated with reduced penetrance or variable presentation. To investigate the frequency of cases reported with a molecular diagnosis, 73,885 sequencing results from three carrier screening panels were reviewed to identify cases harboring at least two pathogenic or likely pathogenic variants in the same gene with demonstrated phasing in the trans configuration. A total of 464 such cases were identified. The variants observed within this cohort involved 13 genes and are predicted to result in at least 16 distinct Mendelian disorders of varying severity. The majority of these cases (398/464, 86%) had variants associated with asymptomatic or milder disease presentations. Excluding alpha thalassemia trait (n=300) and Duarte galactosemia homozygosity (n=93) resulted in a subset of cases (66/71; 93%) enriched for deleterious variants associated with moderate to profound, highly-penetrant conditions. These data indicate that a small percentage of individuals undergoing preconception screening will have an incidental finding that may require clinical evaluation.

PrgmNr 3081 - Non-invasive diagnostic testing for uterine fibroids: A cell-free DNA approach

View session detail

Author Block: **C. Lee**[1], G. Rivera-Cruz[2], L. J. Johnson[1], M. Seshan[1], R. M. Anchan[1], D. R. Armant[3], C. C. Morton[4]; [1]Brigham and Women's Hosp., Boston, MA, [2]Boston Children's Hosp., Boston, MA, [3]Cradle Genomics, San Diego, CA, [4]Brigham & Women's Hosp, Boston, MA
Disclosure Block: **C. Lee:** None.
Leiomyomas, or uterine fibroids (UF), are diagnosed in almost 70% of self-reported white women and over 80% of self-reported black women by the age 50. Approximately 25% of UF are symptomatic, causing heavy menstrual bleeding and anemia, pain, infertility and recurrent pregnancy loss. Therefore, UF are the leading cause of morbidity and hospitalization for benign gynecological issues among reproductive-aged women. The recent bill introduced in the Senate last summer by Senator Kamala Harris, S.4397: Uterine Fibroid Research and Education Act of 2020, has empowered research institutes to advance fibroid research.
Uterine fibroids are often diagnosed by ultrasound, the current non-invasive diagnostic tool that has its own limitations, especially when deciding the appropriate management. The possibility of uterine leiomyosarcoma (ULMS) among UF further complicates disease management and emphasizes the need for a high quality non-invasive diagnostic tool.
Advances in sequencing technologies and understanding of the genetic/genomic landscape of UF are providing new tools to address this knowledge gap and develop robust diagnostics for UF. Heterozygous somatic mutations in *MED12* are present in 70% of UF. Utilizing cell-free DNA (cfDNA) approaches as a non-invasive diagnostic tool has steadily been gaining attraction especially in the prenatal and oncology setting. Liquid biopsies containing cfDNA shed from cancer cells can harbor genetic biomarkers that aid in not only diagnosing a patientâ□□s neoplasm but also in disease management and prognosis. *MED12* somatic variants associated with UF can be assessed in rare cells present in these accessible specimens by deep sequencing technologies. Compared to peripheral venous blood, cells shed from UF are more concentrated in effluents from the uterus, including menstrual blood (MB) and cervical fluid (CF) and may be identified utilizing *MED12* variants as a valuable biomarker.
In this study, we are recruiting women of reproductive age diagnosed with uterine fibroids who are scheduled for surgery (n=100). IRB approval has been obtained. We will collect cfDNA from various biological samples utilizing a menstrual disc with the aim to detect common *MED12* variants. This novel idea highlights the non-invasive approach of diagnosing uterine fibroids. We will compare the data with women without a medical history of fibroids, endometriosis, or adenomyosis (n=30). A cfDNA approach could overcome limitations posed by current diagnostic tools and contribute to innovative precision medicine approaches with a quality of life impact for management of women with UF.

PrgmNr 3082 - Optical Genome Mapping for Constitutional Postnatal SV, CNV, and Repeat Array Sizing: A Multisite Clinical Validation Study

View session detail

Author Block: **N. Sahajpal**[1], V. Rodriguez[2], L. Kanyo[2], A. A. Stence[3], J. R. Hackman[3], A. Mondal[1], A. Bossler[3], P. L. Nagy[2], R. Kolhe[1]; [1]Augusta Univ., Augusta, GA, [2]Praxisgenomics, Atlanta, GA, [3]Univ. of Iowa Hosp. and Clinics, Iowa, IA
Disclosure Block: **N. Sahajpal:** None.
Current cytogenetics methods, such as FISH and karyotyping are time-consuming, labor-intensive, and low throughput. While chromosomal microarrays (CMAs), commonly used in clinical diagnosis, are fast and high throughput, they cannot detect translocations and inversions. Optical genome mapping (OGM) generated by the Bionano Saphyr platform provides a direct, high-resolution view of intact, long DNA molecules, which are then assembled *de novo* to reconstruct the native structures of chromosomes. OGM can detect germline structural variants (SVs) ranging from 500bp insertions and deletions to complex chromosomal rearrangements. Here, we perform a multi-site, multi-operator, multi-instrument validation study to determine the robustness and sensitivity of OGM in detecting SVs and copy number variants (CNVs) associated with constitutional genetic disorders. In the current pilot phase of this IRB approved study of a total of 30 samples comprising 13 whole blood samples of patients with several clinical features of neurodevelopmental disorders and with pathogenic CNVs detected by clinical CMAs, 7 Coriell cell lines with known CNVs, SVs, *FMR1* repeat expansions, and *DUX4* repeat contractions, and 10 whole blood samples from phenotypically normal human volunteers were tested by two clinical diagnostic laboratories. The operators and analysts were blinded to the known genetic abnormalities; and only received the clinical phenotype information. A standard operating procedure (SOP) was devised to enable analysts to systematically and efficiently select for rare (

PrgmNr 3083 - To report or not to report: The power of curating gene-disease relationships with limited evidence for rare disease

View session detail

Author Block: **A. Clause**[1], J. P. Taylor[1], R. Rajkumar[1], K. Bluske[2], E. Thorpe[1], D. R. Bentley[1], R. J. Taft[1], D. L. Perry[1], A. J. Coffey[1]; [1]Illumina, Inc., San Diego, CA, [2]Illumina, Inc, San Diego, CA
Disclosure Block: **A. Clause:** Salary/Employment; Illumina, Inc.. Other; minor shareholder in Illumina, Inc..
The Illumina Clinical Services Laboratory uses the ClinGen Gene-Disease Validity framework to support reporting for the TruGenomeâ□¢ Undiagnosed Disease clinical whole genome sequencing (cWGS) test for patients with suspected rare and undiagnosed genetic disease. Gene-disease relationships (GDRs) of interest are reactively curated during case analysis. Between Oct. 2018 and Feb. 2021, we curated 292 GDRs to support interpretation and reporting for 638 families. Of these GDRs, 243 (83%) had sufficient evidence to support reporting a variant as a potential diagnostic finding (Moderate, Strong, or Definitive GDR), whereas ten were classified as Disputed or No Known Disease Relationship. Variants in genes that lack an established disease relationship are also of value to report provided there is evidence that the GDR is relevant to the probandâ□□s phenotype and supportive of variant pathogenicity. Such variants can be reported as research candidates, highlight a possibly novel diagnosis, or act as a flag for future reanalysis as new evidence emerges.
Thirty-nine GDRs (13%) were considered of uncertain significance, with 36 classified as having Limited evidence and three as No Known Disease Relationship - Animal Model Only. Variants of uncertain significance were returned in 26 of these genes. Most often, the decision to report was due to compelling overlap in phenotype between the proband and previous cases. For example, variants in the *ENTPD1* gene were reported in a proband with similar features to three unrelated individuals described in the literature. For the remaining 13 GDRs, close scrutiny of the evidence led to a decision not to report a variant due to weak or non-specific overlap between the phenotype of the proband and previously described cases, a mismatch in potential mechanism between the probandâ□□s and reported variants, or because variants in the literature lacked sufficient evidence of pathogenicity. For example, missense variants in the *TNIK* gene were not reported in a proband with a complex phenotype because the lone previous report was a homozygous stop-gained variant in a consanguineous family with non-specific intellectual disability.
Careful evaluation of genes helps to deliver the full promise of cWGS, particularly for individuals with rare disease, whose chance of receiving a potentially informative finding should not be constrained by the absence of large numbers of previously described cases. Gene curation provides a principled means to fully consider all GDRs and allows reporting of variants with valid, albeit limited, evidence of their potential significance.

PrgmNr 3084 - *Kmt5b* is highly expressed in the developing brain and may regulate other known autism risk genes and processes

View session detail

Author Block: **H. Stessman**, R. Wickramasekara, B. Robertson, J. Hallgren; Creighton Univ., Omaha, NE
Disclosure Block: **H. Stessman:** None.
Sequencing of neurodevelopmental disorder (NDD) cases has identified lysine methyl transferase 5B (*KMT5B*) as a high confidence risk gene. We have previously characterized developmental and behavioral phenotypes associated with mouse *Kmt5b* haploinsufficiency revealing social and repetitive grooming phenotypes in females and significant growth and developmental defects in males. KMT5B is an enzyme that di-methylates the lysine 20 residue of histone protein 4 (i.e., H4K20me2). This chromatin mark is thought to function in chromatin compaction/gene silencing and resolution of DNA double stranded breaks; although, its function in the brain is largely unknown. This study aimed to (1) catalog the expression pattern of *Kmt5b* over developmental time and (2) identify genes, pathways, and processes impacted by *Kmt5b* loss. Wild-type mice (C57BL/6N) were time mated to produce embryos and pups for the temporal detection of *Kmt5b* transcripts using RNAScope chromogenic *in situ* hybridization. Whole-mount embryos were collected and fixed at embryonic days (E) E11.5, 12.5, 13.5, 14.5, and 16.5, and whole brains at postnatal days (P) 1-2, 10, and 42. RNAScope revealed strong *Kmt5b* expression across the developing central nervous system that was highest during embryonic development and reduced postnatally. To better understand how KMT5B regulates global gene expression, we performed RNA-sequencing (RNA-seq) at E14.5 on whole brain homogenates. *Kmt5b* haploinsufficiency was modeled using a gene trap mouse ($Kmt5b^{gt}$). HET ($Kmt5b^{+/gt}$) x HET pairs generated litters of WT (*K*mt5b+/+), HET, and KO (*Kmt5b*gt/gt) embryos. Three brains of each genotype (WT, HET, and KO) and sex were collected for analysis. The primary effect of *Kmt5b* loss was gene upregulation; the only gene downregulated across all HET and KO conditions was *Kmt5b*. While only ten differentially expressed genes (DEGs) were identified between WT male and female brains, the impact of *Kmt5b* loss appeared more severe in males (more cell stress and death) than females identified through gene set enrichment analysis (GSEA). These analyses also indicated that DNA damage may be a significant source of cell stress and cell cycle delays in HET and KO brains. Finally, we identified a significant enrichment between our upregulated DEGs and known *CHD8* downregulated DEGs (q=0.025). Of the genes that contributed to this enrichment, many are known to regulate cell population proliferation (Stringdb; GO:0042127; FDR q=1.23e-05). These results are particularly interesting given that *CHD8* haploinsufficiency has been associated with overgrowth, and we have identified undergrowth in our *Kmt5b* mouse model.

PrgmNr 3085 - *TRAPPC10* mutation is associated with a microcephalic TRAPPopathy disorder in humans and mice

View session detail

Proteins and other macromolecules are sorted throughout the cell in membrane bound vesicles in a process known as membrane trafficking. Defects in this process are associated with various human disorders. The highly evolutionarily conserved transport protein particle (TRAPP) complexes (TRAPP II and III) perform fundamental roles in subcellular trafficking pathways. This study aims to assess the effect of two homozygous variants in *TRAPPC10*, a component of the TRAPP II complex, in individuals with a microcephalic neurodevelopmental disorder. Here, we present comprehensive genetic, clinical, and functional data to assess the effect of these variants on membrane trafficking and ciliogenesis. Molecular studies revealed a reduced interaction between mutant TRAPPC10 and its putative adaptor protein TRAPPC2L. Studies of patient lymphoblastoid cells revealed an absence of TRAPPC10 as well as an unexpected absence of TRAPPC9, another key TRAPP II complex component associated with a clinically overlapping neurodevelopmental disorder. The TRAPPC9/10 reduction phenotype was recapitulated in TRAPPC10$^{-/-}$ knockout cells, which also revealed a membrane trafficking and ciliogenesis defect. Notably, both the reduction in TRAPPC9 levels and the trafficking defect could be rescued by wild type but not mutant TRAPPC10. Studies of *Trappc10*$^{-/-}$ knockout mice revealed significant neuroanatomical brain defects and microcephaly, paralleling those seen in the human condition as well as in a *Trappc9*$^{-/-}$ mouse model. Together these studies confirm *TRAPPC10* gene mutation as a cause of human disease and define TRAPP-mediated pathomolecular outcomes of importance to TRAPPC9/TRAPPC10 mediated neurodevelopmental disorders in humans and mice.

PrgmNr 3086 - Advanced Diagnostics and Genotype-Phenotype Resolution using Functional Genomics in >500 Neuromuscular and Neurological Disorder Patients

Background: 50-70% of inherited rare neuromuscular disease (NMD) patients remain undiagnosed even after DNA testing, a barrier for clinical trial enrolment. Recently, using a muscular-dystrophy next-generation-sequencing panel on 4656 congenital/limb-girdle muscular dystrophy (CMD/LGMD)-suspected patients across the US and using exome sequencing on 207 genetic myopathies across the Indian subcontinent, and investigating hereditary NMDs and peripheral neuropathies at CHOA, we identified the major hurdles were: a) lack of genotype-phenotype correlation, b) high prevalence (72%) of variants of uncertain significance (VUSs), c) >30% of all patients had pathogenic variant(s) or VUSs in â¥2 genes (multi-genic), and d) the lack of less-invasive biomarker-driven approaches. **Methods:** Here, we used high-throughput clinical-grade RNA-Seq with a proprietary tiered analytical pipeline, and co-immunoprecipitation combined with mass-spectrometry proteomics, and other targeted assays on muscle/skin/blood biopsy-tissues to resolve VUSs and multi-genic cases to enhance molecular diagnostics, and to resolve genotype-phenotype relationships. **Results:** Using targeted RNA-Seq analysis and other assays with genotype-clinical-data correlation on 548 cases, we achieved 64% diagnostic yield and 88% diagnostically informative results. Besides VUS reclassification, we identified variant mechanisms acting either by abnormal splicing/allele/gene-expression/protein-stability/function levels or causing defects in pathways. For example, an 8-year old child with proximal weakness, dystrophic changes on muscle biopsy with normal immunohistochemistry including alpha sarcoglycan stains harbored two variants (pathogenic: c.229C>T, likely pathogenic: c.957-11C>G) *in trans* in *SGCA*. This genotype-muscle biopsy discrepancy was resolved using above-mentioned technique by identifying normal mRNA and protein expression for all Sarcolgycans in muscle even with c.957-11C>G causing both exons 6-7 and 6-8 skips, and that the variantsâ pathogenicity acting at protein function level. Furthermore, the novel application helped discover a new gene, *DRGX*, associated with bilateral hand weakness, finger flexor contractures and sensory motor polyneuropathy in a teenager. Additionally, using enzyme assays and RNA-Seq, we reclassified 20 *GAA* (Î±-glucosidase) gene VUSs as pathogenic variants to resolve undiagnosed Pompe disease cases. **Conclusions:** Our results show the importance of using a multi-tiered approach that includes omics platforms, biomarkers and genotype-phenotype correlation not only for diagnostics but also for better trial-readiness.

PrgmNr 3087 - Cell culture GWAS identifies common genetic variants that influence lithium induced neural progenitor proliferation

View session detail

Disclosure Block: **J. Wolter:** None.
Lithium is highly effective in the treatment of bipolar disorder, partly through its ability to induce neural progenitor cell (NPC) proliferation and adult neurogenesis. Yet a substantial portion of patients do not respond to lithium, and recent evidence suggests that genetic variation plays a role in lithium sensitivity. Combining genome wide association studies (GWAS) with experimental perturbations in genetically diverse human primary cell lines is an emerging and powerful approach to reveal pharmacogenomic interactions in a tightly controlled setting. Here, we use a library of 84 genetically diverse primary human neural progenitor cell lines to identify genetic variation which modulates lithium induced proliferation. We identified a region on chromosome 3 which modulates proliferation from a therapeutically relevant dose of lithium. This locus correlates with change in proliferation rate, and not baseline proliferation, suggesting a bona fide pharmacogenomic interaction. This locus has previously been implicated in GWAS for bipolar disorder, lithium responsiveness in bipolar patients, and general intelligence. Within this gene dense region, we identified one gene, *GNL3*, which is responsive to lithium treatment. We used a polymorphism in *GNL3* to quantify lithium induced allele specific *GNL3* expression, finding that increased levels of *GNL3* correlated with increased proliferation. Increasing *GNL3* expression with dCas9:VP64 induced NPC proliferation, and decreasing *GNL3* expression with dCas9:KRAB reduced lithiumâ□□s effect on proliferation. Looking forward, these experiments motivate the exploration of predicting bipolar patient responsiveness, and modulating *GNL3* expression to affect lithium responsiveness *in vivo*.

PrgmNr 3088 - Characterization of molecular effects of a novel *GNAQ* mutation identified in Sturge-Weber Syndrome

View session detail

Author Block: **F. Galeffi**[1], D. A. Snellings[2], S. Wetzel-Strong[2], J. Bullock[2], C. Gallione[3], N. Kastelic[1], P. E. North[4], D. A. Marchuk[3]; [1]Duke Univ. Med. Ctr., Durham, NC, [2]Duke Univ., Durham, NC, [3]Duke Univ Med Ctr, Durham, NC, [4]Med. Coll. of Wisconsin, Milwaukee, WI
Disclosure Block: **F. Galeffi:** None.
Sturge-Weber syndrome (SWS) is a sporadic, congenital, neuro-cutaneous disorder characterized by a capillary vascular malformation with or without brain lesions. This syndrome is caused by a somatic-mosaic, activating mutation in *GNAQ* that encodes the G protein subunit alpha-q protein. Although the missense mutation R183Q is the sole *GNAQ* mutation identified thus far in affected tissues of ~ 90% of SWS patients, the most common *GNAQ* mutation in cancer is the constitutively-activating Q209L mutation. The restricted mutation spectrum for SWS and related capillary malformations suggests that Q209L might not be tolerated in vascular development. In this study, we sequenced skin biopsies of affected capillary malformations from an additional 10 SWS patients and as expected, found the R183Q mutation in 90% of SWS patients. However, one sample exhibited a Q209R mutation in 113/681 reads (16.6%), which is a rare variant (1.2% of *GNAQ* mutations) in the COSMIC database. To compare the effect of the Q209R mutation on downstream G protein signaling with other relevant *GNAQ* mutations, we performed Luciferase reporter assays in human embryonic kidney cells (HEK293T) transfected with a *GNAQ*-responsive luciferase reporter co-transfected with either *GNAQ* WT, R183Q, Q209L, Q209R, or C9X (premature termination codon representing a null allele). Expression of Q209R induced a 20-fold increase in luciferase activity compared to either WT or null alleles, while Q209L and R183Q induced increases of 50- and 10-fold, respectively. These results confirmed the activating role of Q209R, which was similar to R183Q, but significantly lower than Q209L (***pGNAQ variants. All of the R183 and Q209 missense variants caused extensive dysregulation of a broad range of transcripts compared to the WT or null allele, confirming that these are all activating mutations. However, the missense variants exhibited few differentially expressed genes (DEGs) when compared to each other. These data suggest that these mutations differ in magnitude of activation, but have similar downstream effects. KEGG analysis of DEGs between WT and Q209L revealed several dysregulated signaling pathways including TNF, IL-17, and NF-kappa B, suggesting an inflammatory response to *GNAQ* activation. Gene set enrichment analysis of these DEGs implicates signaling through EGFR, KRAS, and MTOR, consistent with some of the known downstream effectors of *GNAQ* signaling.

Background: Congenital disorders of glycosylation (CDG) are an increasingly recognized group of disorders due to inborn errors of glycosylation. Over 150 types of CDG due to impaired lipid or defective protein glycosylation have been reported, but precise diagnosis can be challenging because of clinical heterogeneity. Loss of MOGS activity does not block all subsequent *N*-glycan processing, as a Golgi-localized endo-Î±-mannosidase can cleave a tetrasaccharide (Glc_3Man) from the glucosylated branch to allow continued glycan processing. While the majority of CDGs can be identified through carbohydrate deficient transferrin (CDT) testing in blood, some CDGs, including MOGS-CDG, will not be reliably detected using this methodology. We aimed to describes the clinical heterogeneity of this multisystem disorder, doubling the total number report to gain insights in twelve cases of MOGS-CDG, combining biochemical and molecular testing to diagnose. **Methods:** Individuals with biallelic variants in *MOGS* were identified by exome sequencing and targeted arrays through an international, multicenter collaboration. Phenotypes and associated biochemical findings were assessed to determine the pathogenicity of individualsâ□□ genetic variants. Confirmatory biochemical assays were performed on serum and urine. **Results:** Biallelic variants in *MOGS* were identified in 12 individuals from 11 families, including 10 unreported individuals. The clinical heterogeneity in MOGS-CDG was delineated, and the neurologic, immunologic, and skeletal phenotypes were described in detail. Urine oligosaccharide analysis was consistently abnormal for all affected probands, whereas biochemical analysis of serum glycosylation was not consistent. **Conclusions:** The clinical phenotypes of MOGS-CDG include multisystemic involvement with variable severity. Molecular analysis, combined with biochemical testing, is important for diagnosis. In MOGS-CDG, urine oligosaccharide analysis can be used as a reliable biochemical test for screening and confirmation of disease.

PrgmNr 3090 - CRISPR engineering of a dystonia-specific allelic series of *THAP1* mutations reveals transcriptional profiles associated with myelination and neurodevelopment

Disclosure Block: **A. Domingo:** None.

The dystonias are a group of neurologic disorders characterized by disturbances in volitional movement. Its genetic architecture is heterogenous, and genetic forms are associated with diverse variants in multiple genes; whether there are shared molecular pathways across mutations/genes remains uncertain. Here we integrated disease modeling using CRISPR-modified induced pluripotent stem cells (iPSCs) with transcriptomic analyses to investigate the molecular consequences of variation in the gene *THAP1*, where dystonia-associated mutations that localize to specific domains are thought to alter gene function differently. We engineered an allelic series of eight variants in a common iPSC background and differentiated these lines into a panel of near-isogenic neural stem cells (n = 94 lines). The mutant lines thus harbored one of pathogenic N12K, S21Thet/hom, P26R or C54Y mutations in the DNA-binding domain, or an R146fs in the nuclear localization sequence (NLS), an M143V variant predicted to be benign, or a deletion of the entire *THAP1* coding region. These were compared to CRISPR-targeted unedited cells and untargeted iPSC lines to discover common differentially expressed genes (DEGs). Each mutation model induced significant (FDR9.6-fold enrichment for shared DEGs compared to null expectation models. Given this, we derived a joint DEG list using weighted Z-scores to define the 871 genes consistently altered by mutations in these domains (FDRThap1-disruptive alleles (C54Y and exon-2 deletion) and detected significant changes in myelin gene expression on targeted expression assays and reduction of myelin structural integrity using staining (PTHAP1 mutations.

PrgmNr 3091 - Distribution and allele frequency of the*Gln3060X*variant present in the*ASPM*gene associated to microcephaly and related disorders in Puerto Rico

View session detail

Author Block: **J. Ã□vila PagÃin**; Univ. of Puerto Rico: MayagÃ¼ez Campus, San SebastiÃin, Puerto Rico
Disclosure Block: **J. Ã□vila PagÃin:** None.
Distribution and allele frequency of the *Gln3060X* variant present in the *ASPM* gene associated to microcephaly and related disorders in Puerto Rico. Microcephaly is a disorder that affects brain-development, resulting in neonates with a smaller head-circumference than expected, generally 3-4 SD below the mean depending on age and gender. The main focus of this research project is the condition Primary Hereditary Microcephaly (MCPH), microcephaly discovered before birth that is commonly caused by genetic factors. Although many genes have been identified as risk factors for MCPH, mutations in the *ASPM* gene are known to be the biggest risk factor associated with primary microcephaly. The *ASPM* gene is known to play a very important role in mitotic division during neurogenesis in a developing brain. Therefore, a mutation in this gene could be the cause of Microcephaly or conditions commonly related to it. The particular variant being studied is *Gln3060X*, a missense variant of the *ASPM* gene previously associated with primary microcephaly. A general population study in Puerto Rican population was done using an array of 625 DNA samples from healthy individuals evenly divided by 30 municipalities around Puerto Rico. The variant was tested using the ViiA 7 Real Time PCR system, using TaqMan and the particular SNP (rs137852994) for the *Gln3060X* variant. Among these 625 samples, 62 mutated individuals were found; 61 heterocigotes (G/A) and 1 homocigote (A/A). In total, this study found an approximate 5% allelic frequency of the *Gln3060X* mutation in Puerto Rican population. Therefore, we can confirm the presence and prevalence of this mutation in Puerto Rico, mainly concentrated among North and East regions of the Island. Furthering the project, patients that suffer from Microcephaly and related conditions will be collected to participate in the study to prove allelic frequency in patients that suffer from them, meanwhile associating this variant with the development of Microcephaly and other conditions in Puerto Rico.

PrgmNr 3092 - Enhancement of CHRNA5 mRNA expression by upstream polymorphisms associated with preserved cognition and lessened neuropathology in an aged human population

View session detail

Author Block: **J. Rybnicek**[1], Y. Chen[2], D. A. Bennett[3], P. L. De Jager[4], H-U. Klein[5], S. Tripathy[2], D. Felsky[2], E. K. Disclosure Block: **J. Rybnicek:** None.

Single nucleotide polymorphisms (SNPs) in cholinergic system genes have been previously linked to Alzheimerâ□□s disease (AD). However, the genetic and cellular mechanisms of these associations remain unexplored. The identification of SNP effects at the level of gene expression and AD-related neuropathologies in human brain could provide evidence for the stratification of AD subjects into molecular subtypes and inform novel treatment strategies. We analyzed *ante-mortem* cognition and *post-mortem* neuropathology data from 1,050 elderly human subjects from the Religious Orders Study and Memory and Aging Project cohorts. All subjects had matched genotypic and *post-mortem* RNA sequencing data from prefrontal cortex (PFC), and 24 had PFC single-nucleus data available. Using general linear models, we replicated a previously-described positive effect of a six-SNP haplotype in an upstream region of *CHRNA5* on levels of *CHRNA5* mRNA in PFC bulk-tissue and single-nucleus data. *CHRNA5* codes for the Î±5 subunit of the nicotinic receptor, which has been previously linked to nicotine dependence and attention deficits, but not AD. Upon further investigation, we identified a novel, sex-dependent association of this regulatory *CHNRA5* haplotype with preserved cognitive status at death as well as lower levels of beta-amyloid and phosphorylated tau in brain. Together, our findings suggest a neuroprotective role for elevated *CHRNA5* expression in brain, and ongoing work is investigating closely-associated cellular and molecular pathways.

PrgmNr 3093 - Functional characterization of haplotype surrounding *TOMM40*-523â repeat to assess differential risk effects on European ancestry *APOEÉ3* haplotypes

View session detail

Author Block: **M. Lipkin Vasquez**, P. Bussies, F. RAJABLI, K. L. Hamilton-Nelson, A. J. Griswold, M. A. Pericak-Vance, J. Young, J. M. Vance, K. Nuytemans; John P. Hussman Inst. for Human Genomics, Miami, FL
Disclosure Block: **M. Lipkin Vasquez:** None.
Introduction: Reports on involvement of *TOMM40*, a gene neighboring *APOE*, in Alzheimer Disease (AD) risk have been inconsistent. Recently, we showed that the length of a poly-T repeat in *TOMM40* (*TOMM40*-523â) is associated with AD risk in individuals carrying *APOEÉ3*, the most common *APOE* haplotype in the general population, on European local ancestry (LA). âVery longâ repeat lengths (VL, >29T) have a protective effect compared to âshortâ repeat lengths (S, APOE*É3* or *APOEÉ4* haplotypes in either ancestral background. Therefore, we hypothesized that variants in linkage disequilibrium (LD) with *TOMM40*-523â on the European LA *APOEÉ3* haplotype can modify risk for AD, potentially through *APOE* regulation. Methods: We used the short tandem repeat detection bioinformatics algorithm HipSTR to type S and VL repeats in whole genome sequencing data of individuals homozygous for the *APOEÉ3* European LA haplotype from the Puerto Rico AD Initiative (PRADI) project. Frequency of variants on 16 S and 14 VL independent haplotypes were compared to determine variants in LD with the repeat. HaploView was used to determine the LD structure of the repeat and surrounding variants. Results: We identified a 16kb LD block surrounding *TOMM40*-523â harboring 21 variants in strong LD (r^2>0.9) with the repeat (hg19, chr19:45,395-45,411k). This region includes the putative *APOE* promoter (harboring LD variants rs405509, rs449446 and rs769450) and a *TOMM40* intronic region with previously reported enhancer activity (harboring LD variants rs157580, rs2075649 and rs157584). Assessment of combined regulatory function of variants in LD with the repeat on S or VL haplotypes in the *APOE* promoter and *TOMM40* enhancer region is currently ongoing using luciferase reporter assays in AD-relevant cell types (i.e. astrocytes, microglia and neurons). Discussion: The identification of clearly distinct S and VL haplotypes on *APOEÉ3* European LA background support importance of the surrounding variants in the risk effect observed in the association analyses. The LD analyses data suggest that *TOMM40*-523â LD variants could directly affect *APOE* expression through presence in the promoter itself and/or in an identified enhancer region in *TOMM40*. The follow-up functional data will pinpoint the driving regulatory element(s) and *TOMM40*-523â LD variants for the observed different AD risk effects in European ancestry *APOEÉ3* carriers. Long term, treatments targeting these regulatory regions may be relevant to a large amount of people given *APOEÉ3*âs frequency in the general population.

PrgmNr 3094 - Identification of candidate genes for alcohol use disorder using RNA-seq data

View session detail

Author Block: **A. Q. Nato**[1], H. Ata Ul Mustafa[1], H. G. Sexton[1,2], S. D. Moore[3,4], J. Denvir[1], D. A. Primerano[1], M-L. Risher[1,2,3]; [1]Dept. of BioMed. Sci., Joan C. Edwards Sch. of Med., Marshall Univ., Huntington, WV, [2]Hershel â□□Woodyâ□□ Williams Veteran Affairs Med. Ctr., Huntington, WV, [3]Dept. of Psychiatry and Behavioral Sci., Duke Univ. Med. Ctr., Durham, NC, [4]Durham Veteran Affairs Med. Ctr., Durham, NC

Disclosure Block: **A.Q. Nato:** None.

Alcohol use disorder (AUD) is a chronic psychiatric disorder with complex etiology. Individuals with AUD usually have intense drinking patterns that result in acute and long-term effects on the brain. Binge drinking results in high alcohol intake, which is common among adolescents and young adults, and is associated with increased risk of developing AUD. Here, we analyze RNA-seq data from hippocampus of Sprague Dawley rats (*Rattus norvegicus*) to investigate temporal variations in gene expression in the presence or absence of ethanol. We used a rodent model of binge drinking (adolescent intermittent ethanol (AIE)) to identify candidate genes that may contribute to the long-term effects on brain function and AUD development. At postnatal day (PND) 30 (adolescence), rats received chronic intermittent ethanol (5g/kg intragastrically (i.g.) 10 times across 16 days). RNA extracted from hippocampal tissue was collected at three time points: 1) 24 hours after 4th dose (PND35), 2) 24 hours after last dose (PND46), and 3) 24 days after last dose (PND70; adult), and sequenced. We processed RNA-seq data (TrimGalore), compiled gene counts (HTSeq), and performed differential expression analysis (DESeq2). We performed fast gene set enrichment analysis (fgsea) using the effect size estimate (log2 fold change) and gene sets of Reactome and KEGG pathways accessed through these databases and MSigDB. We also employed gene graph enrichment analysis (GGEA) using the same data. We visualized the results using the Cytoscape pathway analysis package and identified subnetworks of genes enriched by higher interaction, through the Cytoscape clusterMaker app, which implements Markov CLustering Algorithm (MCL). Using these results, we focused on genes with particular functions, cell types, or diseases such as addiction, neuronal/synaptic remodeling, immune response, inflammation, blood brain barrier, and aging. Candidate genes determined from these analyses may provide clues to the underlying mechanism for detrimental effects of AIE exposure that contribute to the development of AUD.

PrgmNr 3095 - Influence of *APOE e4*in neuropathologic lesions of Alzheimer disease and related dementias

Disclosure Block: **D. Godrich:** None.

Background. Alzheimer disease (AD) is a highly heritable disease that is partially driven by genetics, though much of it is still unexplained. The strongest known genetic risk factor for AD is the *APOE* Îµ4 allele. However, this risk has mostly been shown with the endpoint of clinically diagnosed AD. To get closer to the underlying genetics, it is important to investigate the pathological changes seen at autopsy in the AD brain including neurofibrillary tangles (NFT), neuritic plaques (NP), and diffuse plaques (DP). Moreover, it is uncommon for AD lesions to occur in isolation; instead, they often appear comorbidly with AD related dementia (ADRD) lesions including Lewy Bodies (LB), cerebral amyloid angiopathy (CAA), arteriolosclerosis (ARTE), hippocampal sclerosis (HS), vascular brain injury (VBI), and TAR DNA-binding protein 43 (TDP-43) inclusions. Uncovering genetic factors underlying AD/ADRD lesions using genome-wide association studies (GWAS) may help fill in the gaps of the unexplained genetics. Herein, we report on the influence of the *APOE* Îµ4 status on different AD/ADRD lesions as a first step in the investigation of the genetic architecture of AD/ADRD neuropathologic lesions.

Methods. We used the National Alzheimerâ□□s Coordinating Center (NACC) database, identifying 4,972 autopsied individuals with a neuropathology assessment and *APOE* Îµ4 genotyping. Lesions were ranked as ordinal endpoints based on increasing severity. *APOE* status was categorized as 0, 1, or 2 copies of the *APOE* Îµ4 allele. Correlation between lesions and *APOE* Îµ4 was assessed. Associations between *APOE* Îµ4 and neuropathologic lesions were analyzed using ordinal logistic regression models adjusting for age at death and sex.

Results. *APOE* Îµ4 showed moderate correlations to the three AD lesions and CAA, and minor negative correlations with ARTE and VBI. Ordinal logistic regression models showed that carrying one or more copies of *APOE* Îµ4 is associated with presence of more severe neuropathologic lesions of NFT (OR = 2.13, p-value**Conclusions.** *APOE* Îµ4 is associated to severity of AD lesions, CAA, LB, and TDP-43, but not associated with severity of other ADRD lesions like ARTE, HS, and VBI. These data show that not all ADRD lesions are associated with *APOE* Îµ4 and suggest that there is a need to search for genetic factors underlying ADRD lesions. To expand on these preliminary findings, we are conducting a GWAS on AD/ADRD neuropathologic lesion endpoints to search beyond *APOE* Îµ4 for novel genetic factors.

PrgmNr 3096 - Molecular mechanisms of autism-associated variants in KCNQ3 channel

View session detail

Author Block: **D. M. Dykxhoorn**, A. Hinojo-Perez, J. Rogers, M. A. Edmond, R. Barro-Soria; Univ. of Miami, Miami, FL
Disclosure Block: **D.M. Dykxhoorn:** None.
Background: Autism spectrum disorders (ASDs) comprise a constellation of clinically and genetically heterogeneous neurodevelopmental disorders that affect 1 in 54 children in the US and are characterized by communication deficits, restrictive social interactions, and repetitive behaviors. Genetic analyses have identified loss- or gain-of-function variants in genes coding for several ion channels, including voltage-gated potassium (Kv) channels. Kv channels are widely expressed in the central nervous system (CNS) where they set the resting membrane potential, shape the duration of action potentials, and regulate neuronal firing. Kv channel dysfunction is a major factor in excitatory/inhibitory (E/I) disequilibrium and network impairment. Specifically, recent studies have identified ASD-associated variants in the voltage sensor (S4) of Kv7.3 channel (R227Q, R230S, R230H, R230C, R230L, and R236C) encoded by the KCNQ3 gene.**Methods:** We use voltage clamp fluorometry (VCF) to measure both S4 and gate movement in wild type and ASD-associated Kv7.3 variants expressed in Xenopus oocytes to determine how mutations affect the movement of these domains in Kv7.3 channels. We are also studying the functionality of the Kv7.3 channel in induced pluripotent stem cell (iPSC)-derived inhibitory neurons bearing these variants.**Results:** We found that the R230C mutation in the S4 of Kv7.3 channels caused voltage-independent channels by shifting the S4 movement to strong negative voltages such that the channel remains open at physiological voltages. Similarly, the mutations R230S and R230L removed voltage-independent gating, resulting in enhanced channel function compared to wt Kv7.3 channels. In contrast, R236C shifted both the channel opening and S4 movement towards positive voltages compared to wt Kv7.3 channels. In R227Q, R230C, R230H, and R236C the time course of the fluorescence and channel re-opening follow each other. However, while R230H had faster activation time course, R236C had a slower activation time course compared to wt Kv7.3 channels. Constructs have been derived for the ASD-associated variants and transduced into control iPSC-derived cortical neurons that are being evaluated for their electrophysiological properties.**Conclusions:** Although these variants have been associated with autism, they alter the functionality of the Kv7.3 channel in different ways. The variants (R227Q, R230C, and R230H) and R236C shift the channel opening and S4 movement in opposite direction, thereby causing a gain- and loss-of Kv7.3 channel function. The results of these studies suggest that these ASD-associated variants might alter neuronal network function.

PrgmNr 3097 - Multi-region single-cell dissection of brain vasculature changes in Alzheimerâ□□s Disease

View session detail

The blood-brain-barrier (BBB) is crucial to maintaining the environment of brain homeostasis through avoiding the entrance of pathogens and hazardous substances in the circulating blood into the brain and supplying neuronal and glial cells with oxygen, nutrients and energy molecules. Impaired BBB function is associated with multiple neurodegenerative diseases, including Alzheimerâ□□s disease (AD). The vascular hypothesis of AD thought the brain vascular damage is the initial event to cause the BBB dysfunction and eventually neuronal injury and amyloid-beta (Ab) accumulation in the brain. However, human cerebrovascular cells remain poorly characterized due to their sparsity and dispersion, and their transcriptional changes in response to neurodegenerative diseases and disease predisposition remain unknown. Here, we report a comprehensive single-cell characterization of the human cerebrovasculature using post-mortem in-silico sorting of human brain tissues. We capture 22,514 cerebrovascular cells across 11 subtypes, including three subtypes of endothelial cells, two subtypes of pericytes, two subtypes of smooth muscle cells, three distinct subtypes of perivascular fibroblasts and ependymal cells, across 440 control and AD individuals, and across 6 brain regions. We determine previously-uncharacterized cell type-specific markers and detect brain-region specific gene expression patterns. We identify 2,676 differentially-expressed genes in total (306 on average) between control and AD individuals at sub-cell-type resolution. Among the top 70 most differentially-expressed genes, we find several genes directly linked to AD-associated genetic variants through both physical and correlation-based enhancer-gene links, and through both tissue-level and brain vasculature-specific eQTLs. These include well-studied AD risk-locus genes ABCB1, SLC14A2, PICALM, which we hypothesize play causal roles in AD through the brain vasculature. We also predict the communications between cerebrovascular cell types and vascular/neuronal/glial cell types, by combining covariation information across individuals, ligand-receptor pairs, and functional association data. Notable examples include dysregulation of the interaction between capillary endothelial cells and pericytes, mediated by DLL4-NOTCH3 signaling, which suggests dysregulation of pericyte survival as a molecular underpinning of AD. Overall, our biological insights and our comprehensive resource molecular atlas of the human cerebrovasculature can help guide future biological and therapeutic studies for AD and other brain disorders.

PrgmNr 3098 - Patterns of gene expression variation in large families carrying developmental delay-associated 16p12.1 deletion

View session detail

Author Block: **A. Tyryshkina**[1], M. C. Jensen[2], L. Pizzo[3], C. Smolen[4], M. Das[5], E. Huber[1], A. Krishnan[6], S. Girirajan[7]; [1]The Pennsylvania State Univ., State College, PA, [2]Pennsylvania State Univ, University Park, PA, [3]University Park, PA, [4]Pennsylvania State Univ., State College, PA, [5]The Pennsylvania State Univ., University Park, PA, [6]Michigan State Univ., East Lansing, MI, [7]Pennsylvania State Univ., University Park, PA

Disclosure Block: **A. Tyryshkina:** None.

The 16p12.1 deletion is associated with complex neurodevelopmental disorders, but the presence of the deletion does not adequately explain the phenotypic variability seen in deletion carriers. Previous studies suggest that additional rare variants in the genome may contribute to phenotypes seen in individuals that carry the deletion. However, the mechanisms of how these rare variants contribute to phenotypic variability remain unknown. To investigate this, we performed whole-genome sequencing, RNA sequencing of lymphoblastoid cell lines, and deep clinical phenotyping on 32 individuals in five large families that carry the 16p12.1 deletion. We found that 1,569 transcripts were differentially expressed between deletion carriers and non-carriers, including the brain development genes *FOXP1*, *ANK3*, and *MEF2*. Differentially expressed transcripts were enriched for genes that are preferentially expressed in the late fetal thalamus (FDR=1.18Ã□10^{-3}), hippocampus (FDR=1.73Ã□10^{-3}), striatum (FDR=0.036), and ventrolateral frontal cortex (FDR=8.21Ã□10^{-3}). We observed additional expression changes in severely-affected children that were either unique or overlapped with their parents, which were enriched for biological functions that matched with 33/41 observed developmental phenotypes in the children. We next tested for enrichment of 25 classes of rare variants towards genes with expression changes, such as outlier expression or alternative splicing. For example, five classes of variants were more likely to be located near genes with outlier expression, including loss-of-function and splice-site variants (FDRZEB2, a gene associated with speech impairment, had elevated expression of *ZEB2* compared to the rest of the cohort, and both siblings presented with speech delay. Finally, we found that genes with â□□second-hitâ□□ variants were more closely connected to genes with expression changes in a brain-specific interaction network compared with permuted networks (p=4.88Ã□10^{-4}). These results suggest that the 16p12.1 deletion and other rare variants in the genome jointly contribute to developmental phenotypes by altering gene expression patterns.

PrgmNr 3099 - Plasma membrane injury may trigger DUX4 expression in FSHD

View session detail

Author Block: **A. Bittel**, Y-W. Chen; Children's Natl. Hosp., Washington, DC
Disclosure Block: **A. Bittel:** None.
Background: Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant neuromuscular disorder caused by the pathological expression of the double homeoprotein 4 (*DUX4*) transcription factor in mature skeletal muscle fibers. *DUX4* activates a number of germline genes and alters RNA and protein metabolism, leading to increase immune responses, apoptosis, and progressive myopathy. We previously demonstrated that immortalized myoblasts from individuals with FSHD demonstrate significant impairments in plasma membrane repair when compared to their unaffected siblings. Rapid repair of the plasma membrane injury is essential for muscle health and involves the activation of cellular pathways that have been shown to contribute *DUX4*expression. However, it is unclear if plasma membrane injury itself triggers *DUX4* expression. **Objective:**To determine if plasma membrane injury leads to *DUX4*expression. If so, to determine the time-course of DUX4 expression during the recovery from injury. **Approach:** We utilized a scrape injury approach to induce membrane injury in thousands of cells simultaneously. Briefly, immortalized myobalsts isolated from the biceps of an individual with FSHD and their healthy sibling were scraped with a cell scraper while incubated in cell-impermeant FITC-Dextran dye. This was followed by a brief incubation in propidium iodide (PI), which binds to double stranded DNA, but is excluded from cells with intact plasma membranes. Using confocal microscopy, we identified cells that were injured and successfully repaired their membranes (Dextran (+), PI(-)), and cells that were injured and failed to repair (Dextran(+), PI(+)). We quantified the percentage of Dextran(+) cells that are injured as a measure of injury susceptibility. Percentage of PI(+) cells was used as marker of recovery capacity. qRT-PCR was used to assess for *DUX4*expression, and expression of its downstream target *ZSCAN4,* 6- and24-hours post-injury. **Results:**Confirming our previous findings, FSHD myoblasts were more susceptible to membrane injury - evidenced by the greater percentage of cells that failed to repair (p<.05 however we did not observe any difference in the percentage of cells that failed to repair pi between fshd and healthy cell lines. also observed significantly increased>DUX4expression at 24 hours post-injury (p<.05 and elevated non-significant>ZSCAN4expression at the same timepoint in FSHD myoblasts. **Conclusion:**The results suggest that membrane injury may contribute to *DUX4* expression and could therefore be an important mechanism of disease progression.

PrgmNr 3100 - Re-analysis of regulatory non-coding promoter/enhancer regions of known congenital myasthenic syndrome genes to identify disease-causing variants

View session detail

Author Block: **K. Polavarapu**[1], R. Thompson[2], L. Matalonga[3], A. Topf[4], S. Laurie[5], Solve-RD DITF-EURO-NMD, SNV-indel WG, J. Ribeiro[6], A. Nalini[7], H. Lochmuller[1,8]; [1]CHEO Res. Disclosure Block: **K. Polavarapu:** None.
Promoter and enhancer non-coding regions are among the primary regulatory elements which contain crucial transcription factor binding sites (TFBS). These regulatory regions play a key role in the regulation of gene expression at various levels of transcription and translation. Through targeted sequencing and functional analysis we have previously identified a small number of patients with congenital myasthenic syndrome (CMS) harboring disease-causing variants in the promoter region N-box or in micro-RNA binding site of the 3â□□-UTR. In this study we aimed to analyze these regulatory regions in known CMS genes to identify potential disease-causing variants not previously identified by exome and genome analysis in unsolved cases. Using the GeneHancer database we identified 40 promoter/enhancer regions in 29 known CMS genes. Regions were selected based on gene association score, distance from transcription start site and regions overlapping TFBS sequences with previously reported mutations or having functional evidence. Analysis of regulatory regions was performed in 747 unsolved Neuromuscular disease patients as part of programmatic re-analysis through Solve-RD project. Rare variants with gnomAD and internal MAF A in the regulatory promoter region of the *VAMP1* gene having multiple *RBFOX1* binding sites and another reported frameshift mutation. In another patient with childhood onset ocular onset CMS, we identified likely compound heterozygous variants in *CHRNE* with a nonsense variant and another intronic variant c.500+40G>C affecting a *STAT3* binding regulatory region. In two other suspected CMS patients, regulatory region variants in rare CMS-associated genes *LAMB2* and *PLEC* were identified with partial phenotype correlation requiring further analysis and segregation. This approach of including relevant GeneHancer promoter/enhancer regions might be a relevant addition to the analysis pipeline when no or only single-hit significant coding region variants are detected.

PrgmNr 3101 - Sex bias in neurodevelopmental defects due to differential effects of gene dosage and genetic interactions

Neurodevelopmental disorders have significant sex-bias skewed towards males and are influenced by comorbid features, indicating a complex genetic interplay towards sex-biased phenotypic risk and disease trajectory. Using RNA interference and the UAS-GAL4 system in *Drosophila melanogaster*, we tested the effects of reduced gene dosage and genetic interactions towards differential neuronal, developmental, and behavioral outcomes in males and females. We performed >1100 crosses to test homologs of 136 human genes, including 75 autism and X-linked intellectual disability genes, 32 genes within the neurodevelopmental-associated 3q29, 16p11.2, and 16p12.1 deletions, 29 transcriptional targets of 16p11.2 genes, and 570 pairwise knockdown models using tissue- and neuronal cell type-specific drivers and background specific controls. We used quantitative assays to test sex-specific effects of individual or pairwise knockdown of genes, including neuronal and cellular defects in the fly eye (using *GMR-GAL4* driver), lethality, lifespan, motor defects, seizure susceptibility, and sleep/circadian defects (using *Elav-GAL4* and *nSyb-GAL4* neuronal drivers). We then fine mapped significant sex-biased nervous system defects to distinct neuronal subtypes, including neuroblasts and dopaminergic and glutamatergic neurons. For 6/136 genes (4%), including homologs of *CHD8*, *FMR1*, and *CTNNB1*, more severe developmental and neuronal phenotypes were observed in males. We further tested for interactions of homologs of CNV genes with each other and with genes in neurodevelopmental pathways to identify interactions with biased effects on severity in males and females. Using a multiplicative model, we found additive (18/301, 6%) and synergistic effects (121/301, 40%) of pairwise knockdowns leading to sex-biased severity. For example, male-biased effects were identified with pairwise knockdown of homologs of *KCTD13* and *GRIA3*, while only knockdown of *GRIA3* showed severity in females. Similarly, independently knocking down *PPP4C* and *UBE2A* did not confer any bias in severity, but a strong male-biased effect was observed with combined knockdown of both genes. The sex-biased fly genes have multiple homologs in humans compared to genes with no sex-bias (p

Huntingtonâ□□s disease (HD), spinocerebellar ataxias (SCAs), C9orf72-ALS/FTD, and myotonic dystrophy type 1 (DM1), are caused by the expansion of tandem repeats in a disease-specific gene. Larger repeat expansions are associated with earlier age-of-onset and increased disease severity. Mounting evidence implicates a spontaneously elevated DNA damage response (DDR) in the absence of exogenous damage contributing to disease in HD, SCAs, and C9orf72-ALS/FTD. Here we determined whether an abnormal DDR is also present in DM1. Myotonic dystrophy type 1 is divided into classical DM1 and congenital (CDM1) subtypes, with CDM1 being the most severe due in part to a larger CTG tract. Interestingly, there are rare classical DM1 cases where a contracted CTG is transmitted to the next generation, showing delayed disease onset and reduced disease severity. We assessed the spontaneous DDR through gamma-H2AX levels in fibroblasts derived from patients with the various forms of DM1. Greater gamma-H2AX levels were evident in classical DM1 and CDM1 relative to unaffected controls, with the highest in CDM1. In contrast, contraction individuals and their children were not significantly different from controls. An elevated DDR was not repeat length dependent as contraction families had similar repeat sizes relative to classical DM1 and CDM1 cells, and some classical DM1 patients had larger expansions than CDM1 patients. Our findings reveal a spontaneous DDR previously observed in other repeat expansion diseases also exists in DM1, and gamma-H2AX levels correlate with disease severity, rather than repeat size.

PrgmNr 3103 - Variant analysis in Gaucher sibling pairs discordant for parkinsonism to identify secondary genetic risk factors for *GBA1*-associated Parkinson disease

View session detail

Author Block: **N. Tayebi**, E. G. Woo, G. Lopez, B. Stubblefield, E. Sidransky; NIH/NHGRI, Bethesda, MD

Disclosure Block: **N. Tayebi:** None.

Parkinson disease (PD), caused by complex interactions between genes and/or environmental factors, is characterized by the cytoplasmic accumulation of misfolded SNCA protein in specific brain regions. A milestone genetic finding was that variants in *GBA1,* the gene encoding lysosomal glucocerebrosidase (GCase), confer an increased risk for PD. Mutations in *GBA1* cause the rare autosomal recessive lysosomal storage disease, Gaucher disease (GD). However, most GD patients and carriers with *GBA1* mutations do not develop parkinsonism, implicating additional risk factors including other genetic variants, aging genes, genetic background, environment, and epigenetics. In this study we sought to identify secondary genetic risk variants by performing exome sequencing on DNA samples from nine sibling pairs with GD discordant for PD, adding additional family members in two informative nuclear families. Six of the sibling pairs had Ashkenazi Jewish ancestry and three European backgrounds. Exome data was annotated with Annovar. Quality variants (MPG Score â¥ 10, Score/Coverage â¥ 5) were filtered to include those with a gnomAD v2.11 exome allele frequency â¤ 0.05 and predicted to be damaging or likely damaging by at least two out of three in silico predictors: SIFT, PolyPhen, and MutationTaster. To identify variants, genes, and pathways serving as potential secondary risk factors for parkinsonism, variants were compared within each family to identify those found only in the GD sibling with PD. Among the nine pairs, we also evaluated variants found in at least one GD/PD individual and no GD individuals. Six variants were shared by the GD/PD only siblings in three families and seventy variants were shared by the GD/PD siblings in two families. Interestingly, these shared variants included compound heterozygous variants in two genes, *PCDHB8*, found in the GD/PD sibling in two families with European background, and *ZNF737*, found in two Ashkenazi Jewish families. Furthermore, in the two extended nuclear families, variant analysis uncovered two additional genes of interest only in the PD sibling. Protein-protein network analysis demonstrated that some of the identified genes were linked to SNCA and GCase. Identified candidate variants and genes will be validated in a larger GD/PD cohort. This data confirms the utility of Gaucher sib-pairs and nuclear family studies in identifying the risk factors in a complex disease. This approach likely incorporates factors such as epigenetics, genetic background, predisposition of gene variants, and even chromosomal shuffling in a family or population, providing advantages over pooled heterogeneous samples from different populations.

PrgmNr 3104 - X-linked recessive mutations in *PDZD4* are likely associated with neurodevelopment delay and autism spectrum disorder

View session detail

Author Block: **M. Sandler**[1], J. Serra-Vinardell[1], J. Stephen[1], N. Balanda[1], P. Houston[1], S. Nampoothiri[2], W. A. Gahl[1,3,4], M. V. Malicdan[1,3,4]; [1]Section of Human Biochemical Genetics, Med. Genetics Branch, NHGRI, NIH, Rockville, MD, [2]Dept. of Pediatrics, Amrita Inst. of Med. Sci. and Res. Neurodevelopmental disorders (NDD), a group of diseases that affect the development of the central nervous system, can occur from due to a multitude of genetic predispositions and environmental factors. Despite the high frequency of NDDs in children, little is understood about the mechanism by which they occur. Genetic abnormalities are considered the strongest risk factors for NDD and have been demonstrated to affect multiple facets of brain development and function. Functional genomics is attempting to determine the roles of various genes that may be involved in NDD. In this study, we describe a pediatric proband who presented with learning disability, autistic features, and developmental delay. Exome sequencing re-analysis identified a hemizygous truncating nonsense variant in *PDZD4* that segregated with disease by Sanger sequencing. We also confirmed decreased mRNA expression of *PDZD4* gene in proband fibroblasts compared to controls. While we know that PDZD4 protein and mRNA are expressed highly in brain tissue, little is known about *PDZD4* function, except that it shares a common PDZ domain with other protein faÂÂmilies that are abundant and essential in signal transduction systems. PDZ-domain-containing-proteins have been linked to processes such as ion-channel signaling, transport, and neuronal development. Essential information on how these domains influence synapse biology, however, remains unknown. For these reasons, we chose an in vitro human model to investigate the phenotype of the neural network and examine communication among neurons. We used CRISPR to investigate the functions of *PDZD4*, knocking down genes in i^3N, an induced pluripotent cell (iPSC) line that has an inducible Neurogenin-2 expression, allowing for a scalable production of glutamatergic neurons. Using this cell model, we successfully knocked down the transcription of *PDZD4* by up to 95% and performed RNAseq on the iPSC-derived neurons. RNA seq analysis when compared to control showcased over 600 differentially expressed genes. Using pathway analyses, we observed that many of these genes are involved in central nervous system processes, including synaptogenesis and axonal guidance signaling, highlighting the importance of *PDZD4* in nervous system development. Using epitope tagging technology, we are investigating the localization of this gene in neurons. We anticipate that this experimental approach will be useful in establishing the functional impact of X-linked variants in *PDZD4* identified in NDD patients. Our work will be useful in elucidating the role of the *PDZD4* gene and may provide a better understanding of NDD.

PrgmNr 3105 - Cross-disorder study of neuropsychiatric CNVs and polygenic scores in a large health system-based population

View session detail

Author Block: **M. T. Oetjens**[1], R. K. Linner[1], J. Gudknecht[1], J. B. Leader[1], Regeneron Genetics Center, D. H. Ledbetter[2], C. L. Martin[2]; [1]Geisinger, Danville, PA, [2]Autism & Dev.al Med. Inst., Geisinger, Lewisburg, PA

Disclosure Block: **M.T. Oetjens:** None.

Genetic investigations of neuropsychiatric disorders (NPD) including autism spectrum disorder (ASD), intellectual disability (ID), and schizophrenia (SCZ), have implicated rare copy number variants (CNVs) as important contributors to disease. There is significant variability in how NPD manifest between individuals (i.e., variable expressivity) in the presence of a rare CNV. The uncertainty in risk across NPD can be problematic for genetic counseling of probands and their family members. While these rare CNVs are of large individual effect size, heritability analyses of ASD and SCZ have demonstrated that common variants explain most of the overall genetic liability. Biases associated with case ascertainment and differences in experimental design across studies complicate a cross-disorder characterization of rare CNVs and polygenic scores (representing common variants) from the scientific literature. In this study, we investigated the cross-disorder risk of 31 NPD-related recurrent CNVs and six polygenic scores of cognitive traits or psychiatric disorders in 122,370 patient-participants from DiscovEHR, a large health system-based population with paired exome, genotype, and electronic health data. CNV calling from exome data using the CLAMMS algorithm identified a CNV in ~0.8% (N = 933) of the cohort. Five NPD were examined in this cross-disorder study: attention-deficit/hyperactivity disorder (ADHD; 3,779 cases), autism spectrum disorder (ASD; 450 cases), bipolar disorder (BPD; 6,678 cases), intellectual disability (ID; 676 cases), and schizophrenia (SCZ; 920 cases). We observed several well-known associations with specific CNVs and NPD, including 22q11.2 deletion and SCZ (odds ratio [OR] = 27.59, 95% CI: 7.43-102.38) and 16p11.2 deletion and ID (OR = 31.82, 95% CI: 14.96-67.68). Additionally, we identified novel associations and important replications of previous findings, including 17q12 deletion and ADHD (OR = 13.71, 95% CI: 5.96-31.52) and 16p11.2 duplication and BPD (OR = 2.56, 95% CI: 1.35-4.87), respectively. The effect sizes of polygenic scores were smaller per standard deviation (max OR = 1.36, 95% CI: 1.26-1.48) and across percentiles relative to the CNVs, yet they jointly explained more of the population variance in ADHD, BD, and SCZ than the rare CNVs combined. However, rare CNVs explained more variance for ASD and ID. In conclusion, results from our cross-disorder study of individual CNVs provide more precise estimates of NPD risk and may aid in genetic counseling of these variants. Furthermore, our study reveals that polygenic scores are not yet able to identify individuals at risk for an NPD equivalent to a CNV of large effect size.

PrgmNr 3106 - Infant with PMM2-CDG(CDG-1a) masquerading as infectious pericarditis

View session detail

Author Block: **X. Newman**[1], Y. Martinez[1], P. Jayakar[2]; [1]Nicklaus Children's Hosp., Miami, FL, [2]Miami Children's Hosp., Miami, FL
Disclosure Block: **X. Newman:** None.
PMM2-CDG(CDG-1a) is a disorder of protein N-glycosylation caused by mutations of the phosphomannomutase-2(PMM2) gene. It is by far the most frequent Congenital Disorders of Glycosylation (CDG). In this report we described an unique case of PMM2-CDG with early cardiac manifestation which was masqueraded as infectious pericarditis. The patient is 5 month old Hispanic male with unremarkable birth history. He initially presented to the ED due to a febrile seizure at 2 months old age, patient had full sepsis work-up and was found to have positive RPP for rhino-enterovirus, UA positive for leukesterase, followed by urine culture positive for E.coli. LP performed, CSF fluid normal and culture negative. Cardiomegaly was noted on CXR, BNP elevated, normal Troponin. On auscultation, muffled heart sounds, no heart murmur, EKG normal. The echocardiogram demonstrated large pericardial effusion requiring pericardiocentesis. He was treated with steroids for pericarditis and antibiotics for UTI. Pericardial effusion recurred after two days, requiring second pericardiocentesis and placement of cardiac catheter in the pericardial space to continue drainage, fluid re-accumulated and patient developed tamponade physiology, which resolved after repositioning of the catheter. Pericarditis was suspected to be secondary to viral infection. Patient developed thrombosis of left common iliac, external iliac and femoral arteries, treated with Lovenox. On follow up as outpatient, he was noted to have poor weight gain, severe hypotonia, facial dysmorphism, inverted nipples and abnormal fat pads, global delay and recurrent pericardial effusion needing admission. Brain MRI revealed prominence fissures in the posterior fossa suggesting Cerebellar atrophy. Ophthalmology exam was normal. The NGS panel showed two Pathogenic variants, c.357C>A (p.Phe119Leu) and c.422G>A (p.Arg141His), in PMM2 gene. These variants are on opposite chromosomes. The patient fits into PMM2-CDG (CDG-1a). In conclusion, the clinical manifestation of PMM2-CDG showed a very broad spectrum and multi-organ involvement, cardiac manifestation like pericardial effusion and cardiomyopathy are more common in infancy. However this presentation can be misdiagnosed for more common causes of pericarditis, like post infectious pericarditis. We therefore highly suggest that CDG disorders should be considered in the differential diagnosis of children with early onset multisystem presentation, involving neurological, gastrointestinal and cardiac systems.

PrgmNr 3107 - A scalable bioinformatic approach to recover variation in camouflaged gene regions in whole genome sequencing data from the UK Biobank

View session detail

Author Block: **H. A. Hejase**[1], B. A. J. Sarver[1], K. Y. He[1], L. De Muynck[2], E. A. Khramtsova[1], Q. S. Li[3], B. Smets[2], A. Parrado[1], I. Royaux[2], S. Li[1], M. Black[1], S. Lovestone[2]; [1]Janssen Res. & Dev., Spring House, PA, [2]Janssen Res. & Dev., Beerse, Belgium, [3]Janssen R&D, LLC, Titusville, NJ
Disclosure Block: **H.A. Hejase:** None.
The human genome contains >12,000 gene regions that share a high degree of sequence similarity. Short-read aligners have difficulty mapping reads to such non-unique regions, resulting in low coverage, that are often referred to as â□□camouflagedâ□□. As standard copy number variation (CNV) approaches cannot be utilized in camouflaged regions, we developed a bioinformatics workflow that utilizes short-read datasets to recover these regions and confidently call CNV-based allotypes. In our methodologic approach, camouflaged groups were identified by flagging all the highly similar regions to any given gene body region. Reads with mapping quality score Complement Receptor Type 1 (*CR1*), a gene known to be associated with Alzheimerâ□□s Disease (AD), in whole genome sequencing (WGS) data from the UK Biobank. We assessed our ability to recover CNV-based allotypes of differing length in *CR1* by applying this workflow to WGS data from a total of 556 UK Biobank participants representing age- and sex-matched cases (AD defined as any hospital ICD-10 code: F00, F00.0, F00.1, F00.2, F00.9, G30, G30.0, G30.1, G30.8, G30.9) and controls (individuals without clinical diagnoses, self-reported history, or family history of mental, behavioral, and neurodevelopmental disorders and diseases of the nervous system). We recovered the *CR1* camouflaged region and grouped the samples into clusters putatively recovering three *CR1* allotypes: S homozygote, F homozygote, and S/F heterozygote. We further explored the robustness of this approach by replicating our findings in an independent, internal short-read WGS dataset generated using BGIâ□□s DNBseq technology on 544 AD samples. We found that the frequencies of the S, F, and S/F allotypes ranged depending on their ancestry between [0.05, 0.12], [0.56, 0.7], and [0.24, 0.31], respectively. These estimates are consistent with those previously reported but warrant further validation (i.e., long-read sequencing). Our scalable approach can be generalized to call camouflaged CNVs in large-scale sequencing datasets, thereby recovering variation underlying disease etiology that was previously precluded from investigation.

PrgmNr 3108 - Accurate assignment of disease liability to genetic variants using only population data

Widespread use of next-generation sequencing for diagnostic and research purposes has highlighted the challenge of determining the clinical significance of genetic variation. The American College of Medical Genetics (ACMG) and the Association of Molecular Pathology (AMP) devised a hierarchical scoring approach to estimate pathogenicity using diverse data elements and predictive tools. Availability of variant frequency in public repositories prompted us to test the accuracy of predicting pathogenicity using population data alone. Under the *a priori* assumption that pathogenic or benign variants represent separate groups, we applied a Bayesian method to assign variants to one of two distributions using their counts in samples from affected and apparently healthy groups. This approach, termed BayPR, enabled assignment of probabilities to all variants, regardless of frequency, predicted functional effect or presence in general population databases. Application of BayPR to 103 *cystic fibrosis transmembrane conductance regulator* missense variants with pathogenicity assigned by functional testing produced an area under the receiver operating curve (AUC) of 0.99, which exceeded ten commonly used algorithms (AUC range: 0.54 to 0.97). Application of BayPR to expertly curated variants in eight genes associated with seven Mendelian conditions (autosomal recessive: cystic fibrosis, phenylketonuria, and interstitial lung disease; autosomal dominant: Marfan syndrome and Loeys-Dietz syndrome; X-linked: adrenoleukodystrophy and Barth syndrome) assigned â□¥80% disease-causing probability to 1,350 of 1,374 (98.3%) pathogenic or likely pathogenic variants, while 22 of 23 (95.7%) benign or likely benign variants had predicted probabilities â□¤20%. Using *only* variant count data in affected and unaffected population samples, BayPR can accurately estimate disease liability of rare and private variants responsible for Mendelian disorders, thereby facilitating interpretation in situations commonly encountered in clinical settings.

This work is posted as a pre-print on bioRxiv as of 19 April 2021:

PrgmNr 3109 - Alternative polyadenylation quantitative trait loci (APA-QTLs) in chronic obstructive pulmonary disease

View session detail

Author Block: **A. Saferali**, W. Kim, J. Yun, Z. Xu, R. Chase, M. H. Cho, P. Castaldi, C. P. Hersh; Brigham & Women's Hosp., Boston, MA
Disclosure Block: **A. Saferali:** None.
Rationale: Genome-wide association studies (GWAS) have identified numerous genetic variants associated with complex disease. Alternative polyadenylation (APA) plays an important role in posttranscriptional regulation by allowing genes to shorten or extend 3â□□UTRs which may contain cis-regulatory elements including microRNA or RNA-binding protein binding sites. Here, we investigate SNPs that are associated with alternative polyadenylation (APA-QTLs) to identify novel functions for GWAS variants in chronic obstructive pulmonary disease (COPD).**Methods:** RNA sequencing was performed on whole blood from 3743 subjects in the COPDGene Study and integrated with whole genome sequencing data from the NHLBI TOPMed project. DaPars2 was used to identify and quantify usage of APA sites. Associations between all SNPs within 1000 kb of a gene (cis-) and APA levels were tested using tensorQTL, adjusting for gender, library prep batch, principal components of APA quantifications and principal components of genetic ancestry. A total of 11,869,333 SNPs were tested for association with 32,849 APA sites. COPD-associated SNPs were ascertained from a published GWAS (Sakornsakolpat et al., Nat Genet 2019;51:3).**Results:** In COPDGene whole blood, we identified 32,849 APA sites corresponding to 8,661 unique genes present, after filtering out APA sites with low usage. Genes containing APA sites in blood were enriched for Reactome pathways of interferon signaling, mRNA splicing and antigen processing. We found that a total of 8,881 APA sites were associated with at least one SNP with q-valueHSPA4), G protein subunit alpha 12 (*GNA12*), and GM2 ganglioside activator (*GM2A*). **Conclusions:** Many SNPs were associated with alternative polyadenylation in peripheral blood. Ten lead variants associated with COPD were APA-QTLs, suggesting that analysis of APA in whole blood and other relevant tissues can provide novel insights into disease mechanisms. Colocalization analysis and fine mapping will be important next steps to refine the causal variants involved.

PrgmNr 3110 - Analysis of splice site variation using PEX-DETEX indicates an enrichment of poison exons in individuals with developmental brain disorders

View session detail

Author Block: **A. E. HARE-HARRIS**, K. Kelchner, C. Buoy, S. Kerper, R. Tuttle; Bloomsburg Univ., Bloomsburg, PA
Disclosure Block: **A.E. Hare-harris:** None.
Developmental brain disorders (DBD) encompass a range of neurodevelopmental disorders that exhibit shared genetic etiologies and overlapping symptoms. Whole exome sequence studies have identified pathogenic loss of function variants within the coding regions of more than 500 genes in DBD cases. However, the role of intronic variation in DBD has been largely understudied. Splice site variants (SSVs) that disrupt the dinucleotide sequence (GT) at the splice donor site can disrupt the normal pattern of mRNA splicing by retaining an intron in the mature mRNA transcript. In the case that the retained intron contains a stop codon, a truncated protein product is produced, often resulting in nonsense mediated decay (NMD). This NMD-causing intron is called a poison exon (PE). PEs have been identified in targeted analyses of DBD genes, specifically among individuals with Dravet Syndrome who have SSVs in *SCN1A*. However, to date, no large scale analysis of the prevalence of PEs in DBD cases has been conducted. This study aims to develop and use an automated algorithm, Poison EXon DETEction (PEX-DETEX), to identify and assess the prevalence of PEs in known DBD genes in two large genomic datasets. PEX-DETEX is a scalable automated algorithm designed to identify SSVs that cause a PE from VCF datafiles. The PEX-DETEX pipeline utilizes the neural network SpliceAI, to identify SSVs that are predicted to result the retention of an intron in the mature mRNA transcript. The algorithm incorporates the SSV, retained intron sequence, and any alternative splice sites predicted by SpliceAI into the original transcript sequence. PEX-DETEX translates this sequence to identify PEs by detecting premature stop codons within the alternative transcript. PEX-DETEX is currently being used to compare the prevalence of PEs in 517 DBD genes in case and control individuals from ClinVar and gnomAD (v3.1), respectively. Using known PE variants in *SCN1A* as a confirmatory analysis to validate the efficacy of the algorithm, PEX-DETEX was able to identify PEs with strong accuracy. PE predictions were also validated via visual inspection in the UCSC Genome Browser of SSVs in *PTEN, ARID1B,* and *BRCA2*. Overall, analysis of the prevalence of PEs indicates that ClinVar cases are enriched for PEs in DBD genes compared to control individuals. As seen with *SCN1A,* the results of this study may provide new avenues for functional analyses of PE transcripts as potential pharmacological targets. Furthermore, use of PEX-DETEX in genomic studies has broad implications for the assessment of SSVs that are often categorized as uncertain clinical significance and elucidating the role of intronic variation in human diseases.

PrgmNr 3111 - CNV-Disease Curation and Role of Metabotropic Glutamate Receptors Optimized for Neurodevelopmental Disorders with ParseCNV2

View session detail

Author Block: **J. Glessner**[1], M. Khan[1], J. Li[1], X. Chang[2], Y. Liu[3], P. M. Sleiman[2], H. Hakonarson[4]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]CHOP, Philadelphia, PA, [3]The children's Hosp. of philadelphia CHOP, Philadelphia, PA, [4]Children S Hosp. of Philadelphia, Philadelphia, PA
Disclosure Block: **J. Glessner:** None.
We first discovered significant metabotropic glutamate receptor (mGluR) copy number variation (CNV) associations in ADHD and autism. Whether the singular base, 98% accuracy based on Taqman validation. Comprehensive genomic variant detection and evidence-based assay content and processing optimization is emphasized. The mGluR network constitutes 273 genes from first and second degree protein-protein interactors of the 8 mGluR genes, 4 of which achieved individual statistical significance in our previous studies (Elia et al, 2011). Subsequent analysis found associations to phenotypes including anxiety, depression, mood disorder, Tourette's, anorexia, conduct disorder, oppositional defiant disorder, and schizophrenia of mGluR CNVs compared to control subjects. ParseCNV2 was launched to address CNV burden, known syndromic region querying (CNV GWAS database) and rare recurrent association. CNV detection has remained an area of heavy emphasis for algorithm development; however, both CNV curation and disease association remains in its infancy. ParseCNV2 allows fast and easy curation and association of CNVs in both population and family-based disease settings. Comparable software to ParseCNV2 are benchmarked based on runtime and results. ParseCNV2 starts with a comprehensive quality control pipeline of both samples and individual CNV calls. Beyond deletions and duplications, complex SV (ALU, LINE1, CNV(multiallelic), SVA, INV, INS) parsing is supported. We additionally implemented the DeepCNV algorithm, a deep learning CNV plot validation automatic scoring and the MONTAGE algorithm for Mosaic CNV detection. While many variant call file (VCF) parsers exist, few if any support the variety of VCF presentations and interpretations of CNV genotypes. mGluR genes have been especially pivotal hubs of psychiatric gene association networks. Here we explore the phenotypic and genotypic spectrum of psychiatric disorders in regards to targeted drug therapies. A refined mGluR gene network was introduced to model the most prevalent CNVs in the ADHD population demonstrating the greatest treatment response in neuropsychiatric symptoms to the mGluR modulator fasoracetam. We present a next-generation approach to CNV association by natively supporting the popular VCF specification for sequencing derived variants as well as SNP array PennCNV format. The ParseCNV2 software is available at https://github.com/CAG-CNV/ParseCNV2.

PrgmNr 3112 - Evaluation of splicing in *F9* and *ADAMTS13* Exonic Synonymous Variants

View session detail

Author Block: **K. Jankowska**[1], U. Katneni[1], D. Meyer[1], N. Hamasaki-Katagiri[1], D. D. Holcomb[1], J. Kames[1], C. Kimchi-Sarfaty[2]; [1]FDA, Silver Spring, MD, [2]FDA CBER, Silver Spring, MD
Disclosure Block: **K. Jankowska:** None.
Synonymous single nucleotide variants (sSNVs) are increasingly recognized as contributors to disease phenotype of multiple disease conditions. Splicing dysregulation is considered the primary phenotype inducing mechanism of sSNVs. Additional contributing mechanisms include altered mRNA folding/stability, miRNA binding, translation rate, and co-translational folding. Our models are *F9* and *ADAMTS13* genes: deficiency of FIX, the *F9* product, may cause hemophilia B and deficiency of ADAMTS13 may cause thrombotic thrombocytopenic purpura (TTP). In addition, low ADAMTS 13 plasma levels are predictors of mortality in COVID-19 patients. Previously, we analysed 6 disease-associated and 56 neutral *F9* sSNVs for their effect on splicing using a series of *in silico* splice site prediction tools, splicing regulatory element (SRE) prediction tools, and *in vitro* minigene assays. In this analysis, the use of prediction tools for both splice site and SRE in tandem provided better prediction but those predictions were not always in agreement with the minigene assays. The net effect of variants on splicing dysregulation is context dependent and can be difficult to predict only by *in silico* prediction tools. In this respect, minigene assay could be a straightforward and reliable tool to assess novel variants for potential splicing effects. Currently, we are performing comprehensive *in silico* evaluation of 367 neutral *ADAMTS13* sSNVs. Our preliminary results indicated that some sSNVs change mRNA folding energy/stability, alter mRNA splicing, disturb miRNA binding sites and impact synonymous codon usage. These results suggest that some sSNVs may affect ADAMTS13 function as SNP or in a haplotype and contribute to the large variability in expression and function levels of ADAMTS13 in normal individuals. In conclusion, our results demonstrate that sSNVs are not silent and may contribute to changes in expression and function without affecting the proteinâ□□s amino acid sequence.

PrgmNr 3113 - Exploring the genotypic and phenotypic significance of *KCNJ1* variants in UK Biobank data using REVEAL: Biobank

View session detail

Author Block: **N. Nguyen**[1], S. Sarangi[2], J. L. Brodsky[1], Z. Pitluk[2]; [1]Univ. of Pittsburgh, Pittsburgh, PA, [2]Paradigm4, Waltham, MA
Disclosure Block: **N. Nguyen:** None.
Elevated blood pressure (hypertension) affects one billion people worldwide and is the most common risk factor for cardiovascular disease. Despite its high heritability, the relative contributions of the vast majority of genetic factors to hypertension have yet to be defined. Major regulators of hypertension include the salt-handling transporters in the kidney, among which the renal outer medullary K^+ (ROMK) channel is of particular interest. ROMK, which is encoded by *KCNJ1*, is an integral membrane potassium channel in the kidney. Loss-of-function mutations in ROMK cause a rare salt-wasting disorder, Bartter Syndrome type II. These mutations lead to the premature degradation of ROMK soon after it is synthesized in the cell. Interestingly, heterozygous carriers of these same mutations are protected from hypertension. We therefore hypothesize that polymorphisms in ROMK that result in channel hyperactivity might predispose these individuals to hypertension. To test this hypothesis, we are utilizing REVEAL™: Biobank, a software analytics platform built upon an array-native computational engine, SciDB, to explore the 200K Whole Exome Sequence data from the UK Biobank (Application ID: 51518) . Our goal is to find associations between relevant phenotypes (e.g., blood pressure, urinary sodium and potassium levels) and *KCNJ1* variants using the gene association algorithms, SAIGE and REGENIE. We are also examining correlations between the variants and linkages and relevant blood pressure-lowering medications. Based on these initial analyses, we have begun to select polymorphisms and examine the efficiency of the corresponding proteins to mature and function in yeast and mammalian cells. Preliminary data using the yeast model indicate that two polymorphisms at two different positions in the ROMK sequence that were identified in the UK Biobank and the NIH TOPMed database differentially affect ROMK activity. Our results indicate that relatively subtle amino acid substitutions result in significantly different phenotypes, which may in turn result in a net increase or decrease in blood pressure. In this era of ever-expanding human genomic databases, the consolidation of whole-genome analysis and candidate-based experimental approaches to systematically evaluate the functional impact of human variants is vital. Moreover, as ROMK has emerged as a new target for antihypertensives that lack negative effects on serum potassium, this project may aid in the development of therapeutic strategies to treat heart disease.

PrgmNr 3114 - Genetic control of mRNA splicing is affected by purifying selection and may be linked to incomplete penetrance

View session detail

Author Block: **J. Einson**[1,2], T. Lappalainen[2], D. A. Glinos[2]; [1]Columbia Univ., New York, NY, [2]New York Genome Ctr., New York, NY

Disclosure Block: **J. Einson:** None.

Common variants affecting mRNA splicing are typically identified by splicing quantitative trait locus (sQTL) mapping and have been shown to be enriched for GWAS signals by a similar degree to eQTLs. However, the specific splicing changes induced by these variants have been difficult to characterize, making it more complicated to analyze the effect size and direction of sQTLs.Furthermore, sQTLs may affect the dosage of LoF variants in their target exons. This scenario is a potential driver of incomplete penetrance. To test our model, we first catalogued sQTLs using RNA-seq and WGS data from GTEx v8, using each exonâ□□s percentage spliced in (PSI) metric as a quantitative phenotype. PSI is an interpretable way of assessing an sQTLâ□□s effect size and direction. In total, we identify 5,196 genes with at least one significant exon across at least 1 of 18 GTEx tissues. With this set of sQTLs, it is more common that the derived alleles decrease (n=2,744) rather than increase (n=2,185) the inclusion of their target exons, but have a lower allele frequency distribution compared to sQTLs that increase exon inclusion (K.S. test $p=1.998Ã□10^{-15}$). This suggests purifying selection is acting on sQTL variants based on their regulatory properties.We also performed colocalization analysis between sQTL and GWAS loci across 18 tissues and 114 GWAS studies. We found many examples of sQTL variants colocalizing with GWAS hits, and found some evidence that sQTL effect size, direction and other properties influence the likelihood of a significant colocalization event. Finally, we tested whether sQTLs modifying inclusion of their target exons may modify the penetrance of rare coding variants on the same haplotype. To this end, we analyzed signs of purifying selection by looking for depletion of high penetrance haplotype configurations in a general population. We tested for depletion of high penetrance haplotypes first using all 838 individuals in GTEx v8 with WGS, and then in the larger Trans-Omics for Precision Medicine (TOPMed) project, which includes whole genome sequencing from 63,420 individuals of European descent. The larger sample size allows us to probe penetrance patterns in ultra-rare variants, more common variants, and in genes with multiple rare variants across individuals. Ultimately, we provide insights into the multiple mechanisms how genetic effects on splicing contribute to patterns of genetic variation in human populations and genetic disease risk for common and rare diseases. This technique could improve our interpretation of the risks associated with genetic variation beyond the exome.

PrgmNr 3115 - Identification of discriminative gene-level and protein-level features associated with gain-of-function and loss-of-function mutations

View session detail

Author Block: **C. Bayrak**; Icahn Sch. of Med. at Mount Sinai, New York, NY
Disclosure Block: **C. Bayrak:** None.

Identifying whether a given genetic mutation results in a gene product with increased (gain-of-function; GOF) or diminished (loss-of-function; LOF) activity is an important step toward understanding disease mechanisms as they may result in markedly different clinical phenotypes. Here, we generated the first extensive database of all currently known germline GOF and LOF pathogenic mutations by employing natural language processing (NLP) on the available abstracts in the *Human Gene Mutation Database*. We then investigated various gene- and protein-level features of GOF and LOF mutations by applying machine learning and statistical analyses to identify discriminative features. We found that GOF mutations were enriched in essential genes, autosomal dominant inheritance, protein binding and interaction domains, whereas LOF mutations were enriched in singleton genes, protein-truncating variants, and protein core regions. We developed a user-friendly web-based interface that enables the extraction of selected subsets from the GOF/LOF database by a comprehensive set of annotated features, and downloading up-to-date versions (https://itanlab.shinyapps.io/goflof/). These results could ultimately improve our understanding of how mutations affect gene/protein function thereby guiding future treatment options.

PrgmNr 3116 - Identification of polyadenylation signals relevant to Mendelian disease variant interpretation

View session detail

Author Block: **H. Shiferaw**[1], C. Hong[2], J. J. Johnston[3], L. G. Biesecker[4]; [1]NIH, Gaithersburg, MD, [2]Natl. Inst.S OF HEALTH, BETHESDA, MD, [3]NIH, Rockville, MD, [4]Bethesda, MD
Disclosure Block: **H. Shiferaw:** None.
Polyadenylation is essential in maintaining nascent mRNA stability. Variants in polyadenylation signal (PAS) hexamers can cause reduced polyadenylation at the normal polyA sites and lead to reduced gene expression or expression of transcripts with aberrant 3â□□ UTR sequences. Only 34 PAS hexamer variants in 20 genes have been associated with Mendelian disorders. Of the 20 genes, 12 have at least one PAS hexamer variant as damaging assertion (â□□DMâ□□) in HGMD. We hypothesize that this is under-representative of this class of variants. Here, we aimed to comprehensively identify clinically important PAS hexamers, which are most commonly AATAAA, but other PAS hexamers are included. Clusters of polyadenylated 3â□□ UTRs in ESTs were identified from the PolyA Site 2.0 and examined for dominant polyA site usage activity (defined by >50% of overall EST representation). We filtered for inclusion of polyA sites with PAS hexamers closest to -21 nucleotides relative to the polyadenylation site. We identified 15,212 PAS hexamers for further examination. To understand constraint in the identified PAS hexamers, we compared the number of variants in the AATAAA and ATTAAA PAS hexamers of interest vs. control sequences in 3â□□ UTR by examining variants in gnomAD population. For quality control, we included regions with â□¥20x coverage in >90% of gnomAD samples and removed regions of low complexity and mappability. The AATAAA and ATTAAA PAS hexamers were significantly more constrained than control nucleotides found upstream of our PAS hexamers (p Â® individuals with variants in these hexamers. Twenty-five of 64 genes with PAS hexamer variants showed alternative polyadenylation, which suggests that variants in PAS hexamers can lead to reduced gene function. Additionally, of the 15,212 PAS hexamers, 4,532 were in disease-associated genes, suggesting that PAS hexamer variants may lead to aberrant transcripts in these genes with clinical implications. Further analyses are ongoing to investigate the clinical effects of PAS hexamer variants. These data reinforce that PAS hexamer sequences are critical in polyadenylation and that variants in these sequences are candidates for pathogenic, disease-associated variation.

PrgmNr 3117 - Integrated analysis of co-expression and exome sequencing to prioritize susceptibility genes for cutaneous melanoma

View session detail

Author Block: **S. L. Yepes Torres**, M. A. Tucker, T. Zhang, H. Koka, Y. Xiao, K. Jones, A. Vogt, L. Burdette, W. Luo, B. Zhu, A. Hutchinson, M. Yeager, B. Hicks, N. D. Freedman, K. M. Brown, S. J. Chanock, A. M. Goldstein, X. R. Yang; NIH/NCI, Bethesda, MD

Disclosure Block: **S.L. Yepes Torres:** None.

The application of whole-exome sequencing (WES) has led to the identification of novel high and moderate-risk variants that contribute to melanoma susceptibility. However, confirming disease-causing variants after the initial discovery remains challenging, mainly due to the lack of recurrent variants in multiple families and the presence of genetic heterogeneity. To address this challenge, we applied a gene co-expression network analysis to prioritize candidate genes identified from WES analysis of 34 melanoma-prone families with at least three affected members sequenced per family (n=119 cases), hypothesizing that genes organized on tissue-specific co-expression network may be functionally related. Co-expression network was constructed from GTEx (sun-exposed and non-exposed skin tissue), skin melanoma from the Cancer Genome Atlas (TCGA), and primary melanocyte cultures from 106 newborns using the Weighted Gene Correlation Network Analysis (WGCNA) approach. We performed module-specific enrichment and focused on modules associated with pigmentation processes since they are the best-studied and well-known risk factors for melanoma susceptibility. We found that pigmentation-associated modules across the four expression datasets examined were enriched for well-known melanoma susceptibility genes plus genes with uncharacterized role in melanoma susceptibility. We also used network properties (gene significance, module connectivity, and network representations) to prioritize genes within pigmentation modules as likely susceptibility genes. Integrating information from co-expression network analysis and variant prioritization (allele frequency, pathogenicity, and disease co-segregation), we identified 37 genes (such *DCT, TYR, TYRP1, TPCN2, TRPM1,* and *EPHA5*) as potential melanoma risk genes in our families. The network analysis approach also allowed us to link families with â□□privateâ□□ gene mutations based on gene co-expression patterns and thereby may provide an innovative analysis perspective in gene identification in high-risk families.

PrgmNr 3118 - Loss-of-function tolerance in human disease genes

View session detail

Author Block: **S. Gudmundsson**[1,2,3], M. Singer-Berk[1,3], K. J. Karczewski[1,3], N. Watts[1], E. G. Seaby[1,2,4], S. Baxter[1], Genome Aggregation Database Production Team, Genome Aggregation Database Consortium, D. G. MacArthur[1,5,6], A. Databases of human population genetic variation, such as the Genome Aggregation Database (gnomAD), are generally expected to be depleted from variation with severe effects on health. Predicted loss of function (pLoF) variants, including stop gained, essential splice, and frameshift variants, are rare, highly disruptive, and have important implications in disease biology. The gnomAD dataset provides a valuable opportunity to improve our understanding of the effect of pLoF variants and further elucidate reasons for evasion of pLoF.

Previous analysis revealed that at least 28.7% of all high-quality homozygous pLoF variants from 125,748 exomes and 15,708 genomes (1,245 out of 4,336) were unlikely to cause biological LoF. The most common underlying causes for evasion included presence in a weakly expressed exon, rescue by secondary variants disrupting the nonsense trinucleotide code (multi-nucleotide variants) or frame-restoring indels, and splice variants predicted to be rescued by nearby alternative splice sites. The variants still predicted to result in LoF were found in 1,815 genes where homozygous LoF appears to be compatible with life, defined as â□□LoF-tolerantâ□□ (Karczewski et al., 2020). We further explore the disease-relationship of these genes to improve our understanding of LoF evasion.

Of the 1,815 predicted LoF-tolerant genes, 8.7% (n=158) are associated with autosomal recessive or X-linked phenotypes (AR) in OMIM. Reassuringly, 81% (n=128) of the phenotypes are compatible with presence in individuals in gnomAD, confirming that the list largely consists of genes that are LoF-tolerant. However, 32 variants across 30 genes are associated with severe and lethal phenotypes not expected in gnomAD. Deep re-curation identified further possible reasons for evasion of pLoF, mainly deletion of in-frame an exon that does not alter the reading frame, and possible splice site rescues not predicted by splice prediction tools. In summary, guidelines to identify pLoF variants that are unlikely to result in LoF are important in variant interpretation. Investigation of pLoF variants in the gnomAD dataset in recessive disease-genes reveals common mechanisms of escape. Future analysis aims to reveal additional mechanisms of LoF evasion by curation of pLoF variants in dominant disease genes in gnomAD.

PrgmNr 3119 - LUSTR: A powerful and user-friendly tool to call germline and somatic short tandem repeat variants from short read next-generation sequencing data

View session detail

Author Block: **J. Lu**[1], E. Heinzen[1], M. B. Harms[2], C. De Araujo Martins Moreno[2]; [1]The Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Columbia Univ. Irving Med. Ctr., New York, NY
Disclosure Block: **J. Lu:** None.
Short tandem repeats (STRs) are DNA sequences composed of identical or highly similar short repetitive 1-6 base pair units. STRs incomprise > 3% of the human genome and are present in 90% of human genes. STRs mutate in high rates, and may result in either germline or mosaic STR variants. Pathogenic STR expansions are known to associate with several human neurological disorders, including Huntington disease, amyotrophic lateral sclerosis, fragile X syndrome, and beyond. Next-generation sequencing (NGS) technology now allows STR variant calling using purely computational methods. However, challenges still remain. First, perfect information of target STR loci is often required, which can be difficult to infer, especially in the presence of imperfect repeats. Second, STR variant calling is still limited by the structural complexity of the STR and the length of sequenced reads. Third, most existing tools call only germline STR variants. Although pathogenic mosaic STRs have been reported, post-zygotically acquired pathogenic STR variations remain underinvestigated.

Here we introduce LUSTR as a powerful and user-friendly tool to call both germline and somatic STR variants from short read NGS data. LUSTR improves upon existing STR calling software tools in two major ways. First, LUSTR allows flexible input information for target STR loci diminishing the impact of imperfect inputs. This allows for easier user customized target lists, unbiased compilations of known STRs for genome-wide scans, or in any user interested reference sequence. Second, by applying a two-module strategy that first realigns and annotates every single read found to overlap with target STR loci, LUSTR then estimates both size and allele fraction at each STR locus in the outputs to enable subsequent somatic variant analysis. In the simulation tests with reads generated from C9orf72 STR locus incorporating mimic sequencing errors, LUSTR realigned >99.9% of the simulated reads and estimated both size and allele fraction matching expectations. LUSTR also successfully called variants at 13 tested STR loci in short reads sequenced samples from Genome in a Bottle project. Furthermore, by in silico mixing samples, we proved that LUSTR is able to call somatic STR alleles with fraction down to 5%. We propose application of LUSTR will reveal more details and facilitate further investigation into pathogenic somatic STR variants in human neurological disorders.

PrgmNr 3121 - Rare variants affecting multi-omic measurements of gene regulation implicated in EKG traits

View session detail

Author Block: **T. Li**[1], M. Arvanitis[1], B. J. Strober[1], B. Ni[1], V. Wang[1], J. K. Bonnie[1], R. Keener[1], H. J. Lin[2], J. I. Rotter[2], J. A. Brody[3], S. R. Heckbert[3], N. Sotoodehnia[3], D. E. Arking[4], A. Battle[1], NHLBI TOPMed consortium; [1]Johns Hopkins Univ., Baltimore, MD, [2]Lundquist Inst., Harbor-UCLA Med Ctr, Torrance, CA, [3]Univ. of Washington, Seattle, WA, [4]Johns Hopkins Sch. of Med., Baltimore, MD
Disclosure Block: **T. Li:** None.
Biobank-scale whole genome sequencing has identified molecular pathways relevant to disease that are disrupted by rare coding variants. However, interpretation of non-coding rare variants (RV) is still challenging. RVs have been implicated in complex diseases such as atrial fibrillation (AF). AF variants can be analyzed with electrocardiogram (EKG) traits, but mechanisms of associations remain elusive. Here, we leveraged transcriptomic, proteomic, and methylomic data from Multi-Ethnic Study of Atherosclerosis (MESA) in the TOPMed consortium, to evaluate functional RVs that affect EKG traits through expression of nearby genes in each omic signal. For a subset of 1816 European ancestry individuals, we calculated multi-omic z-scores after regressing out confounders. We observed enrichment of RVs near RNA, protein, and methylation signals with outlier z-scores. We used a hierarchical Bayesian model, Watershed, to prioritize functional RVs and assign posterior probabilities of functional effects for each triplet (gene, individual, RV; 104M analyzed). Compared to WGS annotations, our model significantly improved prediction of multi-omic outlier status for individuals with shared RVs (AUROC = 0.65). The model learned genomic features that predict outlier expression (e.g. TF binding for RNA, frameshift variants for protein). There was good correlation between z-scores of nearby genes and corresponding posteriors for RVs shared with GTEx. Watershed improved risk stratification for diverse polygenic traits over common variants. To study contributions of RVs to EKG traits, we built a framework to evaluate the excess of functional RV burden per gene on 5 EKG traits representing cardiac depolarization and conduction (PR, QRS); repolarization (QT, JT); and rate (RR interval). Multi-omic posteriors prioritized complementary genes associated with extreme EKG values. Extreme QRS intervals were associated with protein outliers of *CFC1*, a risk gene for congenital heart disease, and with mRNA outliers of *STUB1*, a ubiquitin ligase in the heart and striated muscle. A Cox proportional-hazards model showed that extreme values in all EKG traits, except JT, were significantly associated with poorer survival. In a mediation model, 40 genes had outlier protein levels potentially associated with poorer survival through extreme QRS values - for example *ARCN1*, part of the coatomer complex involved in developmental disorders. Our comprehensive survey of RVs and multi-omic outlier signals in a European cohort yields mechanistic insights into EKG traits. These methods are a framework for prioritizing functional RVs in precision medicine studies.

PrgmNr 3122 - Regional missense mutational tolerance in 316,810 exomes

View session detail

Author Block: **K. R. Chao**[1,2], K. E. Samocha[3,2,1], K. J. Karczewski[1,2], gnomAD Consortium, A. H. O'Donnell-Luria[1,2,4], H. L. Rehm[1,2], D. G. MacArthur[5,6,1], G. Tiao[1], M. J. Daly[1,2,7]; [1]Broad Inst. of MIT & Harvard, Cambridge, MA, [2]Massachusetts Gen. Hosp., Boston, MA, [3]Wellcome Sanger Inst., Hinxton, United Kingdom, [4]Boston Children's Hosp., Boston, MA, [5]Garvan Inst., Darlinghurst, Australia, [6]Murdoch Children's Res. Inst., Melbourne, Australia, [7]Inst. for Molecular Med. Finland, Helsinki, Finland
Disclosure Block: **K.R. Chao:** None.
Missense variation contributes to the genetic burden in common and rare disease, but missense variants produce dramatically different effects depending on their location and specific amino acid substitutions, complicating their interpretation. Most existing tools that assess missense variant deleteriousness (e.g., SIFT, PolyPhen-2, CADD) focus on the effects of the amino acid substitution and specific site without accounting for the characteristics of the surrounding region. The missense badness, PolyPhen-2, and constraint (MPC) score was developed to incorporate information about both missense depletion within a gene and variant-level metrics to provide a more informative prediction of missense variant deleteriousness.

Here we describe an update to the MPC score and regional missense constraint (RMC) metrics calculated on the gnomAD v2.1 dataset (125,478 exomes). We describe two major refinements to the RMC methods: an improved model of expected missense variation which accounts for DNA methylation and incorporates per-base coverage correction, and increased breakpoint resolution (moving from per-exon to per-base breakpoints). We also test our improved method on the UK Biobank (UKBB) dataset (191,062 exomes) and find similar RMC results between the two datasets. The code for the new RMC pipeline will be released in an open source GitHub repository, and we will upload the updated regions of missense constraint and MPC scores to the gnomAD browser.

The updated gnomAD constraint metrics show 2,671 transcripts with evidence of RMC. Over half of these transcripts (1,426, 53%) overlap the 2700 transcripts found to have evidence of RMC using the ExAC dataset (60,706 exomes). In addition, the updated results include 1,069 new transcripts exhibiting regional missense depletion and remove 1,212 transcripts previously thought to have RMC due to inadequate coverage correction. Furthermore, a larger proportion of the gnomAD results have multiple regions of varying missense constraint: 36% of the previous 2700 transcripts vs 56% of the updated 2671 transcripts have three or more regions of varying missense constraint.

The increased resolution of the RMC results increases the specificity of the MPC score and helps identify variants that fall within previously unappreciated constrained regions. In addition, the updated results aid in clinical interpretation of missense variants, particularly of variants falling within regions of intermediate missense depletion or within regions previously erroneously identified as constrained.

PrgmNr 3123 - Transcription factor analysis across 3,604 GWAS uncovers novel pathway-specific associations

View session detail

Author Block: **C. Breeze**[1], Q. Lan[1], N. Rothman[1], N. Franceschini[2], S. I. Berndt[3]; [1]Natl. Cancer Inst., Bethesda, MD, [2]Univ North Carolina at Chapel Hill, Chapel Hill, NC, [3]Natl. Cancer Inst., Rockville, MD
Disclosure Block: **C. Breeze:** None.
Background: Single nucleotide polymorphisms (SNPs) from genome-wide association study (GWAS) are known to preferentially intersect with active regulatory elements in cell types relevant to disease aetiology. However, aside from a few well-studied SNPs, little is known about transcription factors (TFs) and their binding sites impacted by disease-associated variants. In-depth characterization of TF-specific associations is anticipated to yield new insights into GWAS-mediated disease pathology. However, high false positive rates in TF binding site mapping and a deluge of available epigenomic datasets can hamper researchers working to identify TF-related associations. An organized and efficient analysis strategy is needed to consistently and reliably identify TF-specific associations for GWAS SNPs.
Results: To yield insights into the genetic mechanisms underlying common diseases, we developed FORGE2-TF, an automated web tool for the analysis of TF-specific signal across different GWAS and epigenomic datasets (https://forge2-tf.altiusinstitute.org/). We first used FORGE2 to analyse 3,604 GWAS from the NHGRI-EBI GWAS catalogue using data for DNase I hotspots, 5 histone mark categories and 15 hidden Markov model chromatin states to yield 2,395 tissue-specific enriched GWAS. Of these, 2,363 presented significant trait- or disease-TF enrichments via FORGE2-TF, including > 500 enrichments for immune traits, > 50 enrichments for cardiovascular traits, and > 35 enrichments for neural traits. Importantly, we demonstrate that FORGE2-TF analysis can establish key pathways associated with GWAS-mediated disease aetiology via combined TF and PANTHER pathway analysis adjusting for TF models employed. In addition, a range of newly-associated GO categories were detected, extending our knowledge of tissue-specific regions in GWAS-mediated disease aetiology.
Conclusion: In short, we give a complete list of TF analyses across 3,604 published GWAS, revealing previously unreported associations, pathways and mechanistic insights. Furthermore, we have implemented a straightforward, easy-to-use web tool and browser for TF analysis of further GWAS.

PrgmNr 3124 - Transcriptome-wide association studies and fine-mapping at cell-type resolution

View session detail

Author Block: **H. Shi**[1,2], M. J. Zhang[1,2], K. M. Siewert-Rocks[1,2], S. Gazal[3], A. O. Pisco[4], A. Nathan[5,6,2], S. Raychaudhuri[5,6,2,7], A. L. Price[1,2]; [1]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [2]Broad Inst. of MIT and Harvard, Cambridge, MA, [3]USC, Los Angeles, CA, [4]Chan Zuckerberg Biohub, San Francisco, CA, [5]Brigham and Womenâ□□s Hosp., Boston, MA, [6]Harvard Med. Sch., Boston, MA, [7]Univ. of Manchester, Manchester, United Kingdom

Disclosure Block: **H. Shi:** None.

Transcriptome-wide association studies (TWAS) integrating gene expression predictions from cis SNPs with GWAS summary statistics have identified thousands of genes associated to diseases (Gusev et al. 2016 *Nat Genet*, Wainberg et al. 2019 *Nat Genet*). However, TWAS generally use gene expression predictions for bulk tissues, and cannot leverage fine-grained cell-types.

Here, we introduce a powerful approach for performing TWAS at cell-type resolution, leveraging large sample sizes for bulk tissues (GTEx Consortium 2020 *Science*) and high-resolution mouse scRNA-seq data (Tabula Muris Consortium 2020 *Nature*) and the observation that expression of most genes are conserved between human and mouse. We infer cell-type-specific gene expression for each GTEx sample with respect to each Tabula Muris cell type under an empirical Bayes framework, enabling cell-type-specific gene expression prediction and TWAS in each cell type. We also extend gene-level TWAS fine-mapping (Mancuso et al. 2019 *Nat Genet*) that leverages gene expression co-regulations to fine-map causal gene-cell type pairs and to compute posterior mean causal effect sizes in addition to posterior causal probabilities.

We applied cell-type TWAS to GWAS summary statistics for 52 diseases and complex traits (average N=345K), analyzing 343 Tabula Muris cell types from 29 tissues. Across diseases/traits, cell-type TWAS identified a median of 44% more independent gene-disease associations at transcriptome-wide significance (FDRCACNA1C expression in neuronal stem cells with schizophrenia ($P=7Ã□10^{-13}$, vs. $P=3Ã□10^{-8}$ in brain cerebellum in tissue-level TWAS). Although other brain cell types were also significant, TWAS fine-mapping strongly prioritized *CACNA1C* expression in neuronal stem cells over other cell types (posterior causal probability = 1.00, gene expression-disease effect size = -0.02 (s.e. 0.0006)), consistent with known biology. We also identified biological pathways curated in KEGG and Reactome that were associated to diseases using cell-type TWAS. Across diseases/traits, cell-type TWAS identified a median of 30% more pathways (FDRNature).

PrgmNr 3126 - Why do males die? Uncovering the genetic connections causing COVID-19 disease severity

View session detail

Author Block: **M. Hoch**, K. Cardoza, F. Montz, B. Froeschke, K. P. Dobrinski; Univ. of Tampa, Tampa, FL
Disclosure Block: **M. Hoch:** None.
SARS-CoV-2, a randomized killer across global populaces, seems to cause higher death rates within the male population. In an attempt to answer why, this study examines associations with single nucleotide polymorphisms (SNPs) that increase gene expression associated with viral infection and proliferation. ACE2 is believed to be assisted by co-receptors ENPEP and ANPEP with TMPRSS2 serving to cleave the viral protein into two subunits allowing for viral binding to the ACE2 receptor. Due to ACE2 being located on the X chromosome, its expression could potentially be increased or decreased depending on the sex of the COVID-19 patient. The ACE2 gene has SNPs which increase the expression of ACE2. These SNPs were found at frequencies greater than 50% in all male populations analyzed. This could account for the increase in male deaths. Females would undergo X-inactivation for the SNPs and thus have protection from the increased ACE2 expression in all their cells. Population specific SNP patterns were found for ACE2, ENPEP and TMPRSS2 genes which may play a role in increased prevalence of disease among certain populations. Males at higher risk for disease severity would be ones with SNPs for alternate alleles causing increased expression of the ACE2 receptor. Meanwhile, males with the ancestral allele, which is not common globally, would have a decreased expression for the ACE2 receptor which could lead to decreased disease severity. This analysis begins to elucidate the role of personalized medicine in understanding COVID-19 disease susceptibility and severity.

PrgmNr 3127 - CRISPR activation at a trait-associated SNP reveals *trans* effects on gene expression

View session detail

Author Block: **C. J. Cardinale**, X. Chang, H-Q. Qu, X. Wang, C. N. Vaccaro, H. Hakonarson; Children's Hosp. of Philadelphia, Philadelphia, PA
Disclosure Block: **C.J. Cardinale:** None.
There is currently considerable interest among complex trait geneticists in methods for finding the target genes of trait-associated SNPs discovered in GWAS. We developed a method using CRISPR activation (CRISPRa) in order to find differential gene expression induced by the SNP rs10833518, which we showed is associated with the age-of-onset of type 1 diabetes. We produced capped-and-tailed messenger RNA encoding nuclease-dead Cas9 fused to the histone acetyltransferase domain of p300 (dCas9-p300) by in vitro transcription. This mRNA was electroporated along with synthetic single-guide RNAs (sgRNA) directed to the rs10833518 SNP, or a non-targeting control, in primary human T cells. Total RNA was collected from the cells 3 days post-transfection and subjected to RNA-seq. Although we did not observe cis effects on differential gene expression at the chromosome 11 locus, we did detect trans changes in ODC1 and ARRDC3 messages at approximately 1.5-fold. ODC1 encodes a metabolic enzyme, ornithine decarboxylase. ARRDC3 encodes alpha-arrestin, a signaling mediator that interacts with G protein-coupled receptors. These results show that CRISPRa can reveal modifications to the transcriptome in cases where eQTL or epigenetic analysis of a GWAS locus are unsuccessful.

PrgmNr 3128 - Insights into Molecular Pathways Associated with Juvenile Myositis through Single-Cell Transcriptome Profiling

View session detail

Author Block: **C. Kao**[1], A. Doostparast[1], M. Gonzalez[1], K. Wang[1], H. Hakonarson[1,2]; [1]Ctr. for Applied Genomics, Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Dept. of Pediatrics, Perelman Sch. of Med., Univ of Pennsylvania, Philadelphia, PA

Disclosure Block: **C. Kao:** None.

Inflammatory myopathies (IM)-including dermatomyositis (DM), polymyositis (PM), and inclusion body myositis (IBM)-are a group of rare autoimmune diseases most often characterized by chronic muscle inflammation leading to progressive skeletal muscle weakness and loss of function, where cutaneous involvement may be present (in DM) and systemic problems occur in severe cases. IM presentation is heterogenous, where amyopathic forms (without apparent muscle involvement) can manifest. Juvenile-onset IMs are generally considered distinct but closely related clinical entities from their adult-onset forms. The etiology of IM is unknown, although there is a clear genetic/heritable component. Steroids and other immunomodulatory agents have been transformative, but some cases remain difficult to treat/manage. We are collecting a biobank of samples from families with juvenile IM cases, with the aim of using 'omics' technologies to find potentially informative biomarkers to guide use of existing and possibly new therapies.A number of autoimmune diseases, including DM and PM, show a prominent type I IFN expression 'signature' (~300 genes) which can be tracked in affected tissues and in blood. We previously profiledthe type I IFN signature in blood cells from a group of juvenile IM subjects. Generally, type I IFN activity correlated with disease activity, but a few appear to have persisting disease activity despite a low IFN signature. We performed whole blood RNASeq and single-cell RNASeq on a subset of cases to find potentially informative signals beyond the type I IFN signature. We focus in particular on the mTOR pathway, which has been shown to differentially regulated in monocytes in another autoimmune disorder, Castlemanâ□□s disease, and where targeting mTOR therapeutically (i.e. with rapamycin) is known to be effective in a subset of patients. A number of genes in the mTOR pathway are also differentially expressed in different cell types in juvenile IM, and the potential implications for biomarker development and therapeutic targeting is discussed.

Biochemistry, Oslo Univ. Hosp., Oslo, Norway, [3]Lovisenberg Diakonale Sykehus, Unger-Vetlesen Inst., Oslo, Norway, [4]Broad Inst. of MIT and Harvard, Cambridge, MA

Disclosure Block: **F. Yu:** None.

Accelerated bone loss in older adults increases the risk of osteoporotic fracture, disability, and mortality; and causes a global burden of public health. Proteomics has emerged to be an effective approach to reveal the pathophysiological mechanisms of bone diseases. However, the majority of previous human proteomics studies are on serum/plasma samples. Only a few population-based studies measured proteomics in disease-relevant tissues/cell types. To study proteomics in osteoporosis as well as osteoporotic fracture, we did a comprehensive comparative analysis of proteomes in the pilot samples of a cohort of 200 subjects. Three bone-biopsy samples at three different skeletal sites (caput, collum, and trochanter) and plasma have been collected from each of the three participants with hip replacement surgery or fracture surgery in Oslo University Hospital, Oslo, Norway. The whole proteome of each sample was measured by the high-throughput data-independent acquisition (DIA) liquid chromatography-mass spectrometry (LC-MS/MS). We found that bone samples contain a more diverse proteome compared to plasma samples. The average number of proteins detected are 2069 (caput), 2732(collum), 2721 (trochanter), and 632 (plasma). Each bone site contains a set of unique proteins that are not found in other skeletal sites or plasma samples (percentage of site-specific proteins: 6.7% (caput), 12.2% (collum), 11.8% (trochanter). Bone unique proteins are enriched in some important pathways that are less well-represented by the plasma proteins, including ribosome, Parkinsonâ□□s disease, carbon metabolism, oxidative phosphorylation, etc. Several most abundant bone-classic proteins account for one-third of the total protein mass in bone samples (excluding albumin and hemoglobin), namely, collagen chains, actin, serotransferrin, and vimentin. For the 1775 proteins that are commonly detected in all three bone sites, we performed ANOVA of mixed model and identified 28 proteins that are differentially expressed in specific bone site, including *LRP1*, *NT5E*, and *CS*. In conclusion, by performing the proteomics study in bone samples, we intend to build human bone tissue proteomic atlas that will provide novel insight into the pathophysiological mechanisms of bone health-relevant consequences.

PrgmNr 3130 - Single-cell and spatial transcriptomics of reovirus induced myocarditis

View session detail

Disclosure Block: **M. Mantri:** None.
A significant portion of unexplained deaths in people aged 35 and younger is thought to be due to viral myocarditis, an inflammatory disease of the heart caused by viral infection. The viral and host factors that give rise to injury of the heart following viral infection remain challenging to study, given the heterogeneity of host-pathogen interactions in complex cardiac tissue. Here, we studied the heterogeneous and cell-type specific innate and adaptive immune responses involved in reovirus-induced myocarditis using single-cell and spatial transcriptomics. We infected neonatal C57BL/6 mice with reovirus type-1-lang (T1L) strain (WT) and a mutant strain that does not cause myocarditis (K287T), and applied single-cell and spatial transcriptomic technologies to cells isolated from cardiac, intestinal (primary site of infection) and spleen tissue at three time points post infection. An integrated and time-resolved analysis of single-cell and spatial transcriptomic data revealed stark differences in basal interferon response and innate immune response post infection in cardiac cell types. Pathway enrichment analysis identified a significant upregulation of basal interferon response and innate immune responses four days post infection in endothelial cells. These results demonstrate the importance of endothelial cells lining the cardiac vasculature in initiating host defense to viral infection. Single-cell transcriptomics analysis further revealed a novel Cxcl9-high endothelial cell population involved in the recruitment of T-cells using the Cxcl9-Cxcr3 axis in infected cardiac tissue. Spatial transcriptomics analysis confirmed the co-localization of these signaling cardiac cells and immune cells within the myocarditic patches in the infected tissue. We furthermore found an enrichment of Cxcl9-high endothelial cells as well as Ccl2+ fibroblast cells in WT-infected as compared to K287T mutant infected hearts seven days post infection. This enrichment of signaling by cardiac cells further explained the increased infiltration of immune cells including dendritic cells, T-cells, NK cells, Neutrophils, and eventually, an increased degree of tissue damage in the WT-infected as compared to K287T mutant infected hearts. Together, our results help clarify the role of host-pathogen interactions in reovirus induced myocarditis.

PrgmNr 3132 - ACME: An Affinity-based Cas9 Mediated Enrichment method for targeted nanopore sequencing

View session detail

Author Block: **S. Iyer**[1,2], M. Kramer[1], S. Goodwin[1], W. R. McCombie[1]; [1]Cold Spring Harbor Lab., Cold Spring Harbor, NY, [2]Stony Brook Univ., Stony Brook, NY
Disclosure Block: **S. Iyer:** None.
Structural variations (SV), tend to be recurrent and have been associated with several cancer types. Next-generation sequencing (NGS) is mostly blind to large SVs, lacking sensitivity with false positive rates up to 89% in SV detection. Long-read sequencing generates read lengths of tens of thousands of bases and has helped identify thousands of genomic features pertinent to cancer that were previously missed by NGS. However, the throughput and coverage offered by whole genome long-read sequencing makes it infeasible to conduct large-scale genomic studies. Targeted sequencing significantly improves accuracy and coverage by offering the depth necessary to detect rare alleles in a heterogenous population of cells. Using nanopore Cas9-targeted sequencing (nCATS), a PCR-free enrichment system from Oxford Nanopore Technologies (ONT), we targeted 10 important cancer genes in MCF 10A and SK-BR-3 breast cell lines. However, we observed that the number of reads generated for targets longer than 30 kb were not sufficient to accurately call SVs. To further enhance this approach, we developed an Affinity-based Cas9-Mediated Enrichment (ACME) step, that uses HisTag Dynabeads™ to pulldown non-target reads. With ACME we achieved ~ 75-fold enrichment of the *BRCA2* region and 35-65x coverage of this ~90 kb target on our panel. We observed an increase in enrichment and coverage of other genes on the panel as well, with enrichment as high as 5000-fold for some genes. Across all genes on our panel, we found that ACME helps increase the number of single contiguous reads that span the entire target, which ultimately helps with better alignment and SV detection. ACME could detect all SVs within our target regions that have been previously inferred by PacBio and ONT whole-genome sequencing, but with higher depth. This allows for rare variant detection, making it an effective long-read targeting platform. We are currently testing ACME + native barcoding, to enable targeting a panel of genes across multiple samples, further bringing down per sample sequencing costs. While further optimization is underway, initial testing of this combined approach gave us a mean target coverage of 10-30x. Though unsupported by ONT for the nCATS approach, we have successfully expanded ACMEâ□□s use to the PromethION high throughput device and have observed a 4-fold increase in coverage when compared to a GridION run using the same sample and mass for library prep. With the optimization of the native barcoding approach for ACME, our goal is to perform high throughput long-read targeted sequencing on >15 samples per PromethION flowcell, helping this approach meet production level needs that are currently unmet.

PrgmNr 3134 - Classification of Super populations based on multidimensional scaling analysis of SNP array data

View session detail

Population stratification is an important step in genome-wide association studies and researchersâ initial cohort selection often includes a race criteria. In our centerâs in-house web-based information search system - Analyst portal, we implemented classification of super populations (East Asian, South Asian, African, European, American) based on our samplesâ whole genome SNP array data. PLINK 1.9 was used to calculate identity-by-state (IBS) distance matrix and perform multidimensional scaling (MDS). Support Vector Machine (SVM) classifier was used for the downstream super-population classification. Our SNP array datasets were merged with SNP array data from 2,504 individuals in the 1000 Genomes Project (phase 3). We observed that SNP minor allele frequency in the merged datasets had big impact on the final MDS results as visualized by scatter plots. Inclusion of rare SNPs resulted in super population structure not being captured first. Increase in SNP array dataset size increased the computer memory requirement and computation time, and also interfered what the first MDS dimensions actually capture. We set minor allele frequency of 0.1 and chose batch size of SNP array data at 500 samples per batch. We found that the 5 super populations were and accurately separated by the SVM classifier using the first 3 MDS dimensions. The MDS scatter plots remain virtually the same for different data batches genotyped on different SNP arrays. The predicted super population label is used along with self-reported race information from clinical systems, surveys and registries, to make study cohort selection more accurate and flexible.

PrgmNr 3135 - Genomic assessment of single bacteria with Primary Template-directed Amplification for deconvolution of microbial diversity

View session detail

Author Block: R. Carter[1], J. Zawistowski[2], D. Arvapalli[1], **I. Salas-Gonzalez**[1], J. Blackinton[1], J. West[2]; [1]BioSkryb, Raleigh, NC, [2]BioSkryb, Inc., Durham, NC
Disclosure Block: **I. Salas-Gonzalez:** Salary/Employment; BioSkryb.
Taxonomic identification and genomic profiling of individual bacteria within a population provides a level of resolution not possible with metagenomic analysis and has far-reaching applications including host-microbiome interaction, defining species diversity in non-culturable environmental samples, and bioprocessing. A bottleneck to the genomic profiling of single bacteria has been the availability of a robust technology to faithfully amplify the femtogram quantities of DNA of a single bacterium. Here we employ Primary Template-directed Amplification (PTA), a whole-genome amplification technology, to interrogate the genomes of single bacteria isolated by FACS. PTA yields unprecedented genomic coverage uniformity and prevents error propagation by attenuating the size of amplicons, consequently redirecting primers to the primary template and limiting recopying of amplification products. Following lysis of single bacteria, PTA generated 50-200 ng of amplification product with an average amplicon size of approximately 1 kb, for the creation of sequencing libraries by direct adapter ligation of PTA product. We initially verified the ability of our lysis conditions coupled to PTA to yield quality genome assemblies from both gram positive (*B. subtilis*) and gram negative (*E.* coli) bacteria. Contigs assembled from individual *E. coli* cells averaged 100 kb in length while *B. subtilis* contigs averaged 500 kb, highlighting the ability of PTA amplification product to aid the generation of significantly longer contigs relative to multiple displacement amplification (MDA). We next tested the ability of PTA to jointly recover complete high-quality genome assemblies from multiple cells of a mixed culture comprised of *E. coli* and *B. subtilis* cells that were co-lysed and co-amplified. The resulting sub-assemblies of each species from the joint assemblies had cumulative contig lengths that approximated the average genome lengths of the given subspecies, with little evidence for chimeric contigs. In addition to the assembly approach, a phylogenetic marker-based approach also verified the quality of the single-cell genome assemblies. We currently are extending genomic assessment of single bacteria to environmental and clinical microbiome samples. These data demonstrate that PTA can be used to reliably assemble both individual bacterial cells and to jointly assemble small numbers of pooled bacterial cells. This approach enables high-throughput profiling of bacterial populations with the ability to accurately measure granular taxonomic diversity of the population and to characterize the genomic content of individual bacterial species within.

PrgmNr 3136 - Improved first-strand cDNA synthesis kits incorporating qScript Ultra, a novel, engineered, thermostable reverse transcriptase enabling full-length synthesis of cDNA over 20 kb in 10 minutes

View session detail

Author Block: **R. Heller**, D. Schuster; Quantabio, Frederick, MD
Disclosure Block: **R. Heller:** None.

First-strand cDNA synthesis is an indispensable step that underpins many methods for RNA analysis including monitoring changes in gene expression levels, profiling noncoding RNA, RNA pathogen quantification and sequencing of full transcriptome or RNA viruses. Despite the pivotal role of reverse transcriptase (RT), most commercially available RTs have limited speed, processivity, are adversely affected by sample matrix, or lack activity at temperatures sufficient to relax RNA secondary structure. These deficiencies typically result in incomplete and biased cDNA synthesis. Through a program of directed mutagenesis and enzyme variant screening, we have engineered a novel RNase H(-) RT called qScript Ultra that displays superior velocity and processivity with elevated activity over a broad range of temperatures.

The qScript Ultra Flex kit provides qScript Ultra RT in an optimized and stabilized master mix format that delivers efficient full-length cDNA synthesis with maximal yield at temperatures as high as 60Â°C. The enhanced velocity and processivity enables rapid and efficient conversion of long transcripts at elevated temperatures, critical for capturing RNA with high GC-content or regions of secondary structure. These properties are demonstrated by RT-PCR of 20-30 kb fragments using a brief 10-minute RT time, whereas reactions using other engineered RTs produced little to no product. We show linear and consistent cDNA synthesis over a broad range of RNA input quantity and quality, including picogram levels of RNA from FFPE tissues, and samples containing inhibitors derived from extraction chemicals, blood, plant, and animal tissues. qScript Ultra Flex kit provides separate solutions of anchored oligo(dT), randomers, and an enhancer for use with gene-specific primers solutions for flexibility in choice of cDNA priming.

For RT-PCR applications that demand the highest consistency, reproducibility, and unbiased representation of the transcriptome in cDNA product we developed qScript Ultra cDNA SuperMix. Incorporating both anchored oligo(dT) and randomers, this highly stabilized SuperMix contains all required components for cDNA synthesis except RNA template. The improved speed, processivity, and expanded thermal activity profile of qScript Ultra provides linear conversion of RNA to cDNA from 2.5 Âµg to 1 pg of total RNA in a 10-minute reaction at 55-60Â°C. Compared to other cDNA kits, we demonstrate higher conversion efficiencies and reliable RT-qPCR of low abundance transcripts and low copy viral RNA, even in the presence of high levels of carrier RNA.

PrgmNr 3137 - Learning single-cell embeddings for bulk tissue cellular deconvolution

View session detail

Author Block: **S. Sue**[1], M. Huang[1], C. Nagy[1,2], G. Turecki[3], Y. Li[1]; [1]McGill Univ., Montreal, QC, Canada, [2]Douglas Hosp. (McGill Univ.), Montreal, QC, Canada, [3]Mc Gill Univ, Montreal, QC, Canada
Disclosure Block: **S. Sue:** None.

A challenge in studying complex diseases is dissecting its heterogeneity. Part of this challenge is understanding the impact of different conditions on multiple cell types, since it is known that certain cell types are more sensitive to disease. Therefore, the underlying determinants of disease may be partly attributed to changes in cell type composition within the affected tissues. Existing methods such as single-cell RNA-sequencing (RNA-seq), flow cytometry, and immunohistochemistry are generally used as cell counting methods. However, these methods tend to introduce biases during the preparation and processing steps, and tend to be costly when measuring a substantial number of samples. Thus, to address these problems, computational methods have been developed to determine cell proportions using gene expression data. Here, we present our model scETM-Decon, a supervised deep generative model for determining cell type proportions from bulk RNA-seq data by using single-cell RNA-seq data as a reference. The model architecture includes a fully-connected neural network encoder followed by a linear decoder. The linear decoder has a matrix tri-factorization design, comprising of gene, topic, and cell embeddings. The reference single-cell data is used to determine cell type-specific gene signatures, known as our gene embeddings. scETM-Decon is trained on the single-cell data and gene embeddings to learn the encoder network, topic, and cell-specific embeddings. scETM-Decon further accounts for batch-effects in the data as well as gene-specific effects by learning linear intercepts, making the model robust. The trained model is fed the bulk RNA-seq data to determine the resulting bulk cell embeddings. Cell type proportions are then computed by multiplying the single-cell topic embeddings by the bulk cell embeddings as the single-cell topic embeddings tell us how the cell types are represented by each topic while the bulk cell embeddings show how the subjects are represented by each topic. When applied to human pancreatic islet expression data, scETM-Decon outperforms existing state-of-the-art deconvolution methods in accuracy. Preliminary data from deconvolving the human brain prefrontal cortex also show competitive results, suggesting that scETM-Decon will be a reliable and powerful tool for deconvolution. scETM-Decon allows for a more comprehensive understanding of disease, with potential to identify cellular targets that can be used for diagnosis, prevention, and treatment of complex diseases.

PrgmNr 3138 - Long read sequencing reveals extensive structural variation in diverse mouse genomes

Author Block: **A. Ferraj**[1,2], P. A. Audano[2], P. Balachandran[2], I. A. Walawalkar[2], A. Czechanski[3], L. G. Reinholdt[3], C. R. Beck[1,2]; [1]Univ. of Connecticut Hlth.Ctr., Farmington, CT, [2]The Jackson Lab. for Genomic Med., Farmington, CT, [3]The Jackson Lab., Bar Harbor, ME
Disclosure Block: **A. Ferraj:** None.
Structural variants (SVs) are genomic rearrangements that are larger than 50 bp in length. SVs consist of insertions, deletions, duplications, inversions, and complex combinations of these events; they collectively have implications in the pathology of cancer, Mendelian diseases, phenotypic variation, and evolution. Whole genome discovery and characterization of SVs has primarily utilized Illumina short-read sequencing, which can lack sensitivity in GC-rich regions and repetitive regions and can falter in the detection of some SVs, including inversions, complex SVs, and insertions. With mobile element polymorphisms, short reads cannot resolve the internal structure and sequence of these events when they are identified. Short reads have been used to study SVs in thousands of human and mouse genomes. In recent years, it has been shown that long-read sequencing excels at identifying many SVs, particularly insertions and duplications; these technologies can also resolve the nucleotide sequence of longer insertions. While the Human Genome Structural Variation Consortium (HGSVC) has released the most complete SV call sets to date, similar long-read efforts have not been applied to mouse strains, which leaves a gap in our understanding of a model organism critical to basic and clinical research. With Pacific Biosciences (PacBio) long-read sequencing, we are annotating and characterizing SVs in 13 widely-utilized inbred laboratory mouse strains. With an ensemble of long read SV calling algorithms, we have identified 495,452 SVs which occur at unique sites across the current mouse reference assembly, cumulatively affecting 10% (300Mb) of the mouse genome. We find that SVs account for over 5x the number of nucleotide changes between strains when compared to single nucleotide variants. Most of novel SVs found (90%) were specific to long-read detection. Furthermore, we have detected strain-specific as well as inter-strain SVs that exhibit high impact consequences, including over 2,300 coding sequence variants, 300 frameshift events, and insertion variants that dramatically affect the transcripts that they occur within. Our data comprehensively identify the extensive SVs present in diverse mouse genomes and strongly suggest that SVs contribute to inbred mouse genomic and phenotypic diversity.

PrgmNr 3139 - MERSCOPE™ reveals the transcriptional organization of the mouse brain

View session detail

Author Block: **G. Emanuel**, J. He, J. L. He; Vizgen, Cambridge, MA
Disclosure Block: **G. Emanuel:** Salary/Employment; Vizgen.
Biological systems are comprised of numerous cell types, intricately organized to form functional tissues and organs. Building molecular atlases to fully understand the structure and function of each cell within the brain is now a key aspect of neuroscience research. Atlas initiatives using single-cell RNA sequencing can characterize cell types based on their RNA expression profiles. However, the tissue organization is lost when cells are dissociated for single-cell sequencing, making it difficult to study how the cellular heterogeneity is contributing to the function of the tissue. Furthermore, accurately characterizing each cell within the brain is challenging due to the low expression of many functionally important genes such as nonsensory G-protein coupled receptors (GPCRs). A true spatial transcriptomics technology with high detection efficiency and single-molecule resolution is required to build accurate and complete molecular atlases. Vizgenâ□□s in situ genomics platform MERSCOPE™ enables the direct profiling of the spatial organization of intact tissue with subcellular resolution. MERSCOPE is built on multiplexed error robust in situ hybridization (MERFISH) technology that uses combinatorial labeling, sequential imaging, and error-robust barcoding to provide the highest detection efficiency and resolution available for spatial genomics. In a single experiment, hundreds of thousands of cells can be spatially profiled with high accuracy and reproducibility. To demonstrate the power of MERSCOPE, we mapped 483 genes across three full mouse brain coronal slices. We constructed a panel of canonical cell type markers and nonsensory GPCRs to spatially profile nonsensory GPCR expression across the brain with cellular context. Nonsensory GPCRs in the brain mediate signaling and may play vital roles behind brain ageing and neurodegenerative disorders but are difficult to analyze. Our experiment successfully detected multiple lowly expressed GPCRs including Oxtr, Tshr, and Insr. The mouse brain receptor map demonstrates MERSCOPE as a leading tool for molecular atlassing, enabling scientists to find greater insights into healthy versus diseased tissue.

PrgmNr 3140 - Normalizing UDI Library Construction for Sensitive Genomic Applications

View session detail

Author Block: **M. Costello**, D. Bays, M. Rahardja, J. Smith, J. Pavlica, J. Leonard, G. Rush, J. Mellor; seqWell, Inc., Beverly, MA
Disclosure Block: **M. Costello:** None.
For a wide range of genomic applications, the ability to sensitively discriminate sequencing reads between different samples is a critical requirement to reduce the effects of noise and index contamination in NGS data. Generally, the method of unique dual-indexing addresses this by adding two sample-specific sequence indices that are unique to each sample. Most available methods that employ UDIs do so by incorporating indexing in the library amplification stage, prior to purification and pooling of libraries for multiplexed sequencing. This represents a high workflow burden because individual libraries have to be carried separately through library construction, amplification, purification, and QC adding significantly to handling time and cost.
Here, we describe a novel approach for UDI library construction that permits pooling of samples immediately after dual-indexed transposase tagging, allowing samples to be purified, amplified, and prepped for sequencing as normalized UDI-tagged multiplexed pools. This new method utilizes a novel decoy-based normalization technology during indexed tn5 transposition that generates uniform quantities of library molecules across a 10-fold range of input DNA from 3 to 30 nanograms, a working range of DNA input amount that is suitable for many common genomic workflows and applications. The 10 bp UDIs were designed to be both greater than two errors and two indels away from any other index in the set and were rigorously screened for performance across multiple sequencing chemistries.
We demonstrate the suitability of this new library construction method on a range of sample types and compare the indexing, normalization, and workflow performance to other commonly used UDI library methods. We anticipate that the method will have wide applicability to NGS workflows that have significant multiplexing requirements that also require the sensitivity and performance benefits of unique dual-indexing.

PrgmNr 3141 - Outcome of 1500 matches through the Matchmaker Exchange for rare disease gene discovery: The 2-year experience of Care4Rare Canada

View session detail

Author Block: **M. Osmond**[1], T. Hartley[1], D. Dyment[1,2], K. D. Kernohan[3], M. Brudno[4,5], O. Buske[6], A. M. Innes[7], K. M. Boycott[1,2]; [1]Children's Hosp. of Eastern Ontario Res. Inst., Ottawa, ON, Canada, [2]Dept. of Genetics, Children's Hosp. of Eastern Ontario, Ottawa, ON, Canada, [3]CHEO, Ottawa, ON, Canada, [4]Hosp Sick Children/Univ Toronto, Toronto, ON, Canada, [5]Techna Inst., Univ. Hlth.Network, Ottawa, ON, Canada, [6]Phenotips, Toronto, ON, Canada, [7]Alberta Children's Hosp, Calgary, AB, Canada
Disclosure Block: **M. Osmond:** None.
Genomic matchmaking, the process of identifying multiple individuals with similar phenotypes and genetic variants of interest, has become an essential practice for discovering novel disease-causing genes in undiagnosed rare disease (RD) patients. The creation of the Matchmaker Exchange (MME), a federated networks of rare disease databases, has made matchmaking more accessible to rare disease stakeholders (like geneticists, genetic counsellors, researchers, and patients), yet little data currently exists on outcomes from using the MME. This study summarizes Care4Rareâ□□s experiences with the MME over the past two years, and highlights lessons that can be applied for future matchmaking endeavors. Patients enrolled as part of the FORGE Canada and Care4Rare Canada research programs over a two year period had their exome sequencing data reanalyzed by a multidisciplinary research team. Compelling variants in genes not previously associated with a human phenotype were flagged for matchmaking, and were submitted through the MME node PhenomeCentral. The genotypes and phenotypes of matched records returned by the MME were reviewed, and unresolved matches were contacted by email for additional comparisons. From July 2018 to July 2020, 194 novel candidate genes were submitted to the MME, resulting in 1514 matches and led to collaborations for 29 genes (15%). About half of these collaborations were due to matching with an already established, unpublished cohort of patients immediately after MME submission. GeneMatcher matches (82% of all matches) almost always required email follow-up due to little information available upfront, while over half of matches from other MME nodes could be ruled out on initial review. Only 56% of these follow-up emails sent for unresolved matches received a response. This study demonstrates that matchmaking through the MME is an effective way to investigate novel candidate genes for undiagnosed RD patients. However, it remains a laborious process, especially when investigating a large number of genes. With most genes in the MME receiving at least one match, more sophisticated approaches to matchmaking will be needed to reduce back-and-forth between users. Such new approaches must therefore emphasize the importance of sharing phenotypic and genotypic data directly with matchmaking platforms.

PrgmNr 3142 - sparQ RNA-Seq Kit: Improved RNA sequencing with 4.5 hr library prep using a novel, integrated ribo-globin depletion technology

View session detail

Author Block: **M. Ait-Ichou**, K. Conley, D. Schuster; Quantabio, Frederick, MD
Disclosure Block: **M. Ait-Ichou:** None.
RNA-seq studies carried out using high-throughput sequencing of cDNA have provided tremendous insight into cellular transcripts studies on a large and more comprehensive scale. However, technical challenges such as laborious and lengthy workflows, affordability, compromised accuracy, read coverage biases, and limited transcript diversity have impeded implementation of the technology in many labs. Here we introduce the sparQ RNA-Seq Kit that integrates RNA fragmentation and depletion of abundant ribosomal and globin transcripts from multiple species (human, mouse, and rat) into a single step, and tube. The proprietary, highly optimized enzymes and streamlined workflow generates high quality directional transcriptome NGS libraries from either intact or degraded RNA samples, with key improvements for low input and FFPE samples, in under 4.5 hours. sparQ RNA-seq libraries were prepared from 1 - 1000 ng of intact total RNA and 10 - 300 ng of FFPE and degraded RNA from blood samples. Library yield, transcript coverage, strand specificity, rRNA and globin depletion rates and gene expression levels were determined and compared with libraries prepared by various RNA-seq kits. The results indicate high correlation between the level of gene detected between high and low input RNA and uniform transcript coverage especially for FFPE and degraded RNA at low RNA input. sparQ RNA-seq libraries also show equivalent or superior performance with regards to library yield and sequencing quality metrics, as well as increased detection of GC-rich transcripts, when compared to libraries prepared by kits from other suppliers. The sparQ RNA-Seq Kit is a RNA-seq library prep kit, with integrated ribo-globin depletion technology, that is affordable, and easy to execute. It enables fastest time to result (4.5 hours), minimal hands-on time (33% less), and less pipetting steps while generating high quality transcriptomic data regardless of sample input, such as cells, FFPE, tissue and whole blood.

PrgmNr 3143 - *TRPC6* gain-of-function in doxorubicin-induced heart failure

View session detail

Author Block: **N. Norton**[1], B. M. Necela[1], X-L. Wang[2], T. Lu[2], H-C. Lee[2]; [1]Mayo Clinic FL, Jacksonville, FL, [2]Mayo Clinic, Rochester, MN
Disclosure Block: **N. Norton:** None.
Introduction: Missense mutations in the non-selective calcium channel, *TRPC6* have previously been shown to be causative of familial focal segmental glomerular sclerosis (FSGS) by gain-of-function. More recently common and rare *TRPC6* variants were associated with doxorubicin-induced cardiomyopathy (CM) and heart failure (HF) in cancer patients, but the mechanism is unknown. A very rare variant, N338S, identified in a single cancer patient with dox-induced HF has not previously been identified in FSGS patients. **Methods:** The mutation of *TRPC6* N338S was introduced using the QuickChange site-directed mutagenesis kit. *TRPC6* wild type (WT) and *TRPC6* N338S mutant were transiently transfected into HEK293 cells using the Effectene transfection reagent kit. After 48-h transfection, whole-cell currents of *TRPC6* WT and N338S mutant were continuously recorded at 30-s intervals from a holding potential of -60 mV to a voltage clamp protocol -100 mV to +100 mV using patch clamp technique. Intracellular Ca^{2+} concentration, $[Ca^{2+}]i$, was measured by Ca^{2+}-sensitive fluorescent dye (fura-2) and intracellular Ca^{2+} imaging system. **Results:** The *TRPC6* N338S mutant showed significantly higher inward and outward current density at voltages of -100 mV and +100 mV respectively, as well as $[Ca^{2+}]i$ in HEK293 cells. Application of 1-oleoyl acetyl-sn-glycerol (OAG, 50 uM) robustly increased the current density and $[Ca^{2+}]i$ of *TRPC6* N338S mutant, compared to those of WT controls. Moreover, a 24-h preincubation with doxorubicin (Dox, 0.5 mM) potentiated the effects of *TRPC6* N338S on $[Ca^{2+}]i$, which were abolished by incubation with 1 uM BI-749327 (a TRPC6 inhibitor). **Conclusions:** Rare missense variants at *TRPC6* may cause doxorubicin-induced heart failure by gain-of-function through increased electrical current and intracellular calcium levels. Inhibitors of TRPC6 are a potential cardioprotective therapy for cancer patients with TRPC6 risk variants should they require doxorubicin.

PrgmNr 3144 - Paradigm Shift from Disease PRS to PGx PRS for Drug Response Prediction using PRS-PGx Methods

View session detail

Author Block: **S. Zhai**, H. Zhang, J. Shen; Biostatistics and Res. Decision Sci., Merck Res. Lab., Merck & Co., Inc., Rahway, NJ
Disclosure Block: **S. Zhai:** None.
Polygenic risk score (PRS), by combining many small prognostic genetic effects, has shown promise in predicting human diseases and complex traits. In efficacy-based pharmacogenomics (PGx) studies, the current practice is to apply such PRS built from disease GWAS directly to PGx data from randomized clinical trials for drug response prediction and patient stratification. However, this approach relies on the assumption that every variant selected for constructing PRS has a constant ratio between its genotype main and genotype-by-treatment interaction effects, which largely may not be true in real PGx data. A violation of such assumption will make disease PRS explain less heritability of drug responses and thus reduce power in predicting them. Here, we propose the paradigm shift from disease PRS to PGx PRS approaches by simultaneously modeling the prognostic and predictive effects and constructing both PRSs for drug response prediction in PGx. We make this paradigm shift possible by developing a series of novel PRS-PGx methods, including PRS-PGx-unadj (unadjusted), PRS-PGx-CT (Clumping + Thresholding), PRS-PGx-L, -GL, -SGL (Lasso-, Group Lasso-, Sparse Group Lasso-based penalized regression), and PRS-PGx-Bayes (Bayesian regression). In the framework of Bayesian regression, we propose a polygenic prediction method that infers posterior prognostic and predictive effect sizes of SNPs simultaneously using PGx genome-wide association summary statistics and an external linkage disequilibrium (LD) reference panel. By introducing global-local continuous shrinkage priors on SNP effect sizes, our proposed PRS-PGx-Bayes method is more robust to varying relationships between the genotype main and genotype-by-treatment interaction effects. Extensive simulation studies show that PRS-PGx methods generally outperform the current disease PRS (PRS-Dis) methods across a wide range of genetic architectures and PRS-PGx-Bayes is superior to all other PRS-PGx methods. We further apply the PRS-PGx methods to the IMPROVE-IT PGx GWAS data by constructing PGx PRSs via 5-fold cross-validation to predict low-density lipoprotein-cholesterol. The drug response prediction results demonstrate the great improvement of PRS-PGx-Bayes in both prediction accuracy and the capability of capturing the treatment-specific predictive effects over alternative methods.

The use of genetics in identifying individuals at risk for adverse drug reactions, toxicity or poor response to medication is a growing area of precision medicine and vital to efficient healthcare delivery. Among genes with known or predicted impact on drug responses, *CYP2D6* is a commonly cited biomarker in the US Food and Drug Administration (FDA) drug labels. Genetic variations can alter CYP2D6 enzyme function. These specific alleles and haplotypes can be classified based on the amount of the encoded enzyme activity. Given their allele combinations, an individual is phenotyped as one of the following metabolizer types: ultrarapid, normal, intermediate, poor, or unknown. The frequency of the various CYP2D6 alleles vary globally and show population-specific distribution. Many resources are available to assess individual variant frequencies, but translating these into actionable pharmacogenetic alleles for clinical application is rarely straightforward. Resources from PharmGKB and PharmVar offer data on specific alleles and drug-gene interactions, but this information is of limited use if the individualâ□□s genotype is unknown. Knowledge of the metabolizer phenotype frequencies in specific populations can assist with deciding whether to test an individual. However, searching the biomedical literature on population-specific allele frequencies for each individual is time consuming. Medical Genetics Summaries (MGS) at the National Center for Biotechnology Information (NCBI) now offers allele-specific data for CYP2D6 phenotype frequencies, curated from the published literature, and a centralized list of reference material for additional allele frequency resources. This resource supplements the MGS on over 50 drugs and the genes involved in individual drug responses. The MGS *CYP2D6* reference page provides an overview of the protein function, genotype-to-phenotype translation from pharmacogenomics authoritative sources, links to additional resources, and brief summaries of published literature on phenotype and genotype frequencies. This information will help clinicians identify those individuals at a higher risk of metabolizer alleles that greatly impact how they respond to a drug and what alleles to prioritize in diagnostic testing. When pharmacogenetic testing is warranted, clinicians can select appropriate test options through the linked resources at the NIH Genetic Testing Registry (GTR). This gene-centric resource aims to provide the busy clinician with a single-site resource to improve the adoption of personalized medical care of individuals at risk for adverse or poor reactions from a wide range of medications.

PrgmNr 3146 - Pharmacogenomic polygenic risk score for clopidogrel responsiveness among Caribbean Hispanics

View session detail

Author Block: **j. Duconge**[1], E. Santiago[2], D. Hernandez[1], M. Monero[1], J. Renta[1], P. GonzÃ¡lez[1], H. NÃºÃ±ez[1], K. Melin[1], S. Scott[3], G. RuaÃ±o[4]; [1]Univ. of Puerto Rico Med. Sci. Campus, San Juan, PR, [2]Univ. of Puerto Rico - Med. Sci. Campus, San Juan, PR, [3]Stanford Univ. Med. Ctr., Palo Alto, CA, [4]UConn Hlth., Farmington, CT

Disclosure Block: **J. Duconge:** None.

This multicenter clinical study was aimed at conducting a targeted pharmacogenomic association analysis of residual on-clopidogrel platelet reactivity in 474 Caribbean Hispanic patients. Platelet reactivity was measured using the VerifyNow P2Y12 assay and clopidogrel resistance was defined as P2Y12 reaction units (PRU) â¥208. Genotyping was performed using the whole-genome InfiniumÂ® MEGA BeadChip array. An ancestry-adjusted, weighted polygenic risk score (*w*PGxRS) was developed to account for the effect of multiple variants on PRU and compared between clopidogrel responders and non-responders. The mean PRU across the study cohort was 173.8Â±68.5 and 33.5% of patients were defined as clopidogrel resistant. Multivariate linear regression showed that 19% of PRU variability was attributed to nine independent predictors, with *CYP2C19**2 (rs4244285) accounting for ~7% of observed PRU variation (*p*PON1 rs662, *ABCB1/MDR1* rs2032582, *PEAR1* rs12041331 carrier status and the interaction between African ancestry and rs12041331 carriers also predicted PRUs in participants (*p*â¤0.05). A clear gene-dose effect was seen between PRU and *CYP2C19**2 genotypes, consistent with previous studies in European patient populations, as well as rs12777823. Importantly, a significant positive correlation was detected between the identified *w*PGxRS (five variants) and PRU among the Hispanic patient population (r_p=0.35, *p*wPGxRS discriminated between non-responders and responders (*p*=0.003), indicating that this multigene-based score is a useful predictor of clopidogrel resistance among Caribbean Hispanics. Findings from this work are expected to help close the gap of knowledge about clopidogrel pharmacogenomics and its clinical implementation in this underrepresented population.

PrgmNr 3147 - Results of a Real-world implementation of a pharmacogenetic-empowered comprehensive medication management (CMM) program

Real-world implementation of pharmacogenetic-empowered comprehensive medication management (CMM) can be a useful tool to deal with polypharmacy issues, a common concern in actively aging populations. For over three years, we have been providing a turnkey, population-scale CMM program that combines genetic testing with expert pharmacy review to ensure safe and effective medication use for Medicare eligible members of a state-run retirement system. We tracked pharmacist interactions with patients through their utilization of GeneDose LIVEâ□¢, a clinical decision support (CDS) tool that displayed medication risks including pharmacogenomic test results, provided in silico testing of alternative medications, and recorded and reported the pharmacist notes and actionable information for a patient and their healthcare providers. Specifically, for each patient, pharmacists created a Medication Action Plan (MAP) in the CDS to communicate recommendations to change a drug regimen or specific medication; to monitor drug effectiveness, side effects, or specific laboratory results; and to be aware of potential future medication-related risks due to pharmacogenetic test results with implications for the risk/benefit profile of commonly prescribed medications. In addition, the medication risks identified by the CDS included drug-drug interactions, contraindications, Beers criteria, anticholinergic burden, FDA â□□black-boxâ□□ warnings, and lifestyle factors. The MAPs contained free-text notes and fielded instructions which were analyzed. Evaluation of data from more than 5,000 consented program participants demonstrated that a significant number (72%) of MAPs created by pharmacists were actionable by the memberâ□□s healthcare provider. Of actionable MAPs, 26% contained immediate discontinuation, substitution, or change in medication administration recommendations. Notably, more than 82% of enrollees with MAPs were taking a medication known to be impacted by pharmacogenomics, and of these, about 60% of MAPs contained actionable information specifically related to pharmacogenomic assay results. A propensity score matched difference-in-difference analysis of administrative medical and pharmacy claims data to assess changes in resource utilization following program implementation is ongoing. The results of the impact of this PGx-empowered CMM program on total medical and pharmacy costs will be presented along with results from a full program evaluation.

PrgmNr 3148 - Haplotype-aware inference of human chromosome abnormalities

Extra or missing chromosomes---a phenomenon termed aneuploidy---frequently arises during human meiosis and embryonic mitosis and is the leading cause of pregnancy loss, including in the context of in vitro fertilization (IVF). While meiotic aneuploidies affect all cells and are deleterious, mitotic errors generate mosaicism, which may be compatible with healthy live birth. Large-scale abnormalities such as triploidy and haploidy also contribute to adverse pregnancy outcomes, but remain hidden from standard sequencing-based approaches to preimplantation genetic testing for aneuploidies (PGT-A). The ability to reliably distinguish meiotic and mitotic aneuploidies, as well as abnormalities in genome-wide ploidy may thus prove valuable for enhancing IVF outcomes. We developed a statistical method for distinguishing these forms of aneuploidy based on analysis of low-coverage whole-genome sequencing data, which is the current standard in the field. Our approach overcomes the data sparsity by leveraging allele frequencies and linkage disequilibrium (LD) measured in a population reference panel. The method, which we term LD-informed PGT-A (LD-PGTA), retains high accuracy down to coverage as low as 0.05x and at higher coverage can also distinguish between meiosis I and meiosis II errors based on signatures spanning the centromeres.

After evaluating our method via simulation, we applied it to PGT-A data from 8154 IVF embryos. This allows us to refine original diagnoses of trisomies, identifying 448 chromosomes as possessing a haplotype signature of meiotic error that is enriched among chromosomes 16 and 22. In addition, we demonstrate the use of our method for mapping of meiotic crossovers on trisomic chromosomes, which manifest as transitions between distinct haplotype signatures. This will aid future studies investigating associations between aberrant recombination and aneuploidy. We then continued by uncovering genome-wide abnormalities in ploidy (11 haploid embryos and 12 triploid embryos) that were entirely hidden from standard coverage-based analysis. This finding is particularly important given the major contribution of triploidy to cytogenetically abnormal miscarriages.

In summary, our method complements current approaches for PGT-A, while also offering insight into the origins of chromosome abnormalities in human development.

PrgmNr 3149 - Human milk oligosaccharides protect lung health in breastfed infants of the CHILD Study

Breastfeeding provides many indisputable health benefits but its impact on lung health and disease remains unclear. Previous studies typically considered breast milk and breastfeeding as a single homogeneous exposure, which fails to acknowledge the complex and dynamic interactions of the mother-breastmilk-infant â□□triadâ□□ as a co-adapted system where variations in each component will influence the others. Breastmilk contains a myriad of bioactive components such as human milk oligosaccharides (HMOs), which vary in concentration among nursing mothers. This study investigates the modulating effects of HMOs on risk of recurrent wheeze and asthma among breastfed infants. A total of 19 HMOs were quantified using high-performance liquid chromatography in the breastmilk samples of 980 lactating mothers, collected 3-4 months postpartum in the CHILD Cohort Study. Genome-wide single nucleotide polymorphisms (SNPs) were genotyped for mothers and their children using the Illumina HumanCoreExome BeadChip and imputations were performed on the Michigan Imputation server using the Haplotype Reference Consortium data. In the mothers, we conducted genome-wide association studies (GWAS) as well as association analyses of maternal exposures (e.g., diet, birth mode, feeding practices) to identify both genetic and non-genetic determinants of HMOs. In the infants, we used gene-environment interaction analyses to investigate how maternal HMOs affect risk of recurrent wheeze and asthma among breastfed infants.We report that HMO concentrations are associated with known loci on chromosome 19 and novel associations on chromosomes 3 and 10 (*P*-8). In addition, we determined that non-genetic factors such as birth mode, prior children, and feeding practices are associated with HMOs (*P*PP = 0.002). In conclusion, our study reports both genetic and non-genetic determinants of HMOs and that specific breastmilk components potentially modulate the risk of respiratory outcomes during early childhood.

PrgmNr 3150 - Impact of maternal nutrition on transcriptome changes over time during fetal liver development

View session detail

Author Block: **K. D. Zimmerman**[1], J. E. Chan[1], P. W. Nathanielsz[2], M. Olivier[3], L. A. Cox[1]; [1]Wake Forest Sch. of Med., Winston-Salem, NC, [2]Univ. of Wyoming, Laramie, WY, [3]Wake Forest Univ. Sch. of Med., Winston-Salem, NC

Disclosure Block: **K.D. Zimmerman:** None.

Maternal nutrition during pregnancy has been well-documented to impact fetal development. Poor maternal nutrition is a major contributor to adverse pregnancy outcomes and development of intrauterine growth restriction (IUGR). However, the molecular mechanisms underlying IUGR are not well-understood, particularly in humans, because they are challenging to study in pregnant women. Here we study a well-established nonhuman primate model of maternal nutrient restriction (MNR) to study the effects of maternal nutrition on the transcriptome of the developing fetus. Fetal liver tissue was collected at caesarean section at 90 days gestation (dG), equivalent to the midpoint of gestation, 120 dG, 140 dG, and 165 dG. At each of the 90 and 165 dG time points, 8 control samples and 8 MNR samples were collected. At each of the 120 dG time points, 6 control samples and 6 MNR samples were collected. Each group had an even number of males and females. Total RNA was isolated from each sample to prepare RNA-Seq libraries, which were sequenced (2x100 base) on the HiSeq 2500 Sequencing System. Data pre-processing, normalization, and differential expression analysis was computed with *limma-voom*. We modeled gene expression as a function of sex (covariate), MNR status, dG (centered), dG squared, and the interactions between dG (or dG squared) and MNR status. When contrasting the linear interaction between time point and MNR status, *KCTD13* but not the other genes you list demonstrated an increase of mRNA expression over time in the MNR group while expression slightly decreased in the control group (FDR p-value = 0.093). *KCTD13* is involved in purine metabolism and overexpression of this gene has been previously associated with microcephaly and may also play a role in oncogenesis. When contrasting the quadratic interaction between time point and MNR status, *MBTD1*, *DPYS*, *HADHB*, and *ST6GAL1* all demonstrated increased expression during the from 90-20 dG and then decreased between 140-165 dG in the control group while the opposite expression pattern was observed in the MNR group (FDR p-value = 0.075). *HADHB* plays a role in mitochondrial beta-oxidation. ST6GAL1 appears to play a role in carbohydrate metabolism. These results highlight some transcriptional changes during development in fetal liver tissue that are potentially associated with decreased growth subsequent to a nutrient poor intrauterine environment, and may impact long-term health outcomes in the offspring.

PrgmNr 3151 - Increased number of *de novo* mutations in craniofacial regulatory elements in trios with orofacial clefts

Disclosure Block: **S.W. Curtis:** None.

Orofacial clefts (OFCs) are the most common craniofacial birth defect, affecting 1 in 700 births. Like other structural birth defects, de novo mutations (DNMs) in coding regions are enriched among OFC probands, especially among genes expressed in craniofacial tissues. A role for noncoding variants is supported by functional follow-up of GWAS signals, but the contribution of noncoding DNMs to the formation of OFCs is not well understood. Therefore, we called and analyzed noncoding DNMs using the whole genome sequencing data in 759 trios in the Gabriella Miller Kids First Research Program with either a cleft lip) or a cleft lip and palate. After calling and filtering DNMs for quality, there were 51,170 DNMs, with an average of 67.4 DNMs per trio. To determine the potential impact, these DNMs were annotated using functional information based on genome-wide epigenetic marks in human embryos 4.5-8 weeks post-fertilization, the critical window for facial development. As a control, DNMs were also called in 329 trios from the 1000 Genome Project (1000GP). While the 1000GP trios had on average more DNMs called (84.3; p

PrgmNr 3153 - Multi omics integration in placenta identifies candidate functional genes for birthweight

View session detail

Author Block: **F. Tekola-Ayele**[1], X. Zeng[1], S. Chatterjee[1], M. Ouidir[1], M. Tesfaye[2], T. Workalemahu[3], R. J. Wapner[4]; [1]Natl. Inst. of Child Hlth.and Human Dev., NIH, Bethesda, MD, [2]NIH, Bethesda, MD, [3]Univ. of Utah, Salt Lake City, UT, [4]Columbia Univ. Irving Med. Ctr., New York, NY
Disclosure Block: **F. Tekola-Ayele:** None.
Abnormal birthweight, in part due to placental dysfunction, has been linked with cardiometabolic and neurological diseases in later life. Genome wide association studies (GWAS) have identified genetic variants associated with birthweight, but the functional mechanisms of the variants remain unclear. The placenta is functionally critical in fetal growth but is still missing from many genomics databases including the Genotype-Tissue Expression portal (GTEx). The goal of this study was to provide functional mechanistic insight into the causal pathway from a genetic variant to birthweight by integrating placental methylation and gene expression with established GWAS loci for birthweight. Placental multi-omics data including genotype, methylation, and RNAseq were obtained from the NICHD Fetal Growth Studies- Singletons (n=301). First, we determined whether birthweight GWAS variants regulate nearby placental gene expression (i.e., expression quantitative trait loci; *cis*-eQTL) and methylation (i.e., methylation quantitative trait loci*; cis*-mQTL). Next, we performed mediation and Mendelian Randomization analyses on variants exhibiting both *cis*-eQTL and *cis*-mQTL to determine causal relationships among the variants, methylation, and gene expression in placenta. Lastly, we applied multi-trait colocalization to investigate whether all three traits (i.e., birthweight, placental methylation, and gene expression) share the same causal variant and to identify candidate genes for functional follow-up. We found that 57.9% (158/273) birthweight GWAS variants were *cis*-mQTL in placenta and 9.5% (26/273) were *cis*-eQTL; 23 variants had co-occurring *cis*-mQTL and *cis*-eQTL effects (false discovery rate WNT3A, *CTDNEP1*, and *RANBP2*) such that the birthweight GWAS variant alters methylation, which in turn causally influences gene expression in placenta. Multi-trait colocalization analysis identified *PLEKHA1*, *FES*, *CTDNEP1*, and *PRMT7* as likely functional effector genes for birthweight (PPA â¥0.75). Our results underscore that placental epigenetic and transcriptomic changes underpin the functional interpretation of several genetic loci associated with birthweight, and potentially inform early origins of diseases in later life.

PrgmNr 3154 - The Effect of Variable Hormonal Replacement Therapies (HRT) on Neurocognition in School-aged Males with 47,XXY

View session detail

Author Block: **M. Brooks**[1], C. A. Samango-Sprouse[2,3,4], M. Hamzik[1], T. Sadeghin[1], A. L. Gropman[5]; [1]The Focus Fndn., Crofton, MD, [2]The Focus Fndn., Davidsonville, MD, [3]George Washington Univ. Sch. of Med. and Hlth.Sci., Washington, DC, [4]Florida Intl. Univ., Dept. of Human and Molecular Genetics, Miami, FL, [5]Children's Natl. Med Ce, Washington, DC
Disclosure Block: **M. Brooks:** None.
Introduction 47,XXY is the most commonly occurring sex chromosome aneuploidy (~1:600 live male births) and is characterized by reduced androgen levels, language-based learning difficulties, speech and motor delay, and executive dysfunction. Recently, hormonal replacement therapy (HRT) has been shown to potentially mitigate some of the endocrine and neurodevelopmental deficiencies associated with a supernumerary X, though optimal administration has remained elusive. The purpose of this study is to delineate the effect of variable HRTs on neurocognitive abilities in a large cohort of school-aged males with 47,XXY. ***Methods*** One-hundred and forty-three prenatally diagnosed school-aged males with 47,XXY (CA: 130 months) were administered HRT based on their pediatric endocrinologistâ□□s assessment: EHT (Early Hormonal Treatment; three intramuscular shots of 25mg testosterone enanthate within the first year of life), HBT (Hormonal Booster Treatment; three shots of 50mg testosterone enanthate from 5 to 8 years of age) and/or TRT (regular low-dose testosterone administration beginning at puberty and continuing thereafter). Each subject received comprehensive neurodevelopmental testing including the Wechsler Intelligence Scale for Children, 4^{th}/5^{th} Edition (WISC-IV/V). Subjects were grouped by HRT status: 43 No-T, 15 EHT, 25 HBT, 22 TRT, 25 EHT-HBT, and 13 EHT-HBT-TRT. A one-way ANOVA and Tukey HSD were utilized to determine differences between treatment groups, if any. ***Results*** A one-way ANOVA revealed there were indeed differences between groups on the WISC-IV/V. Tukey HSD tests revealed significantly higher FSIQ scores among the EHT-HBT-TRT (M=124.00, SD=16.03), EHT-HBT (M=115.77, SD=12.99), and EHT (M=118.27, SD=13.17) groups compared to the No-T group (M=103.68, SD=15.85) (p=0.0002, p=0.02, and p=0.04 respectively). The EHT-HBT group performed significantly better than the No-T group on the Verbal Comprehension (p=0.02) and Processing Speed Indexes (p=0.04). Additionally, the EHT-HBT-TRT group scored significantly higher on the Working Memory Index than the No-T and TRT groups (p=0.00001 and p=0.03, respectively). ***Conclusion*** Consistent with previous findings, males treated with EHT and HBT showed improved working memory capabilities compared to untreated males. Our findings of elevated scores among males treated with any combination of HRTs including EHT suggest this treatment may be essential in optimizing neurodevelopmental outcome in males with 47,XXY. Further research is warranted to delineate the effect of variable HRTs on other neurodevelopmental aspects in this population.

PrgmNr 3155 - The Longitudinal Effect of Early Hormonal Treatment (EHT) in Males with 47,XXY

View session detail

Author Block: **C. A. Samango-Sprouse**[1], M. Brooks[2], S. Song[2], T. Sadeghin[3], A. L. Gropman[4]; [1]George Washington Univ., Washington, DC, [2]The Focus Fndn., Crofton, MD, [3]The Focus Fndn., Davidsonville, MD, [4]Children's Natl. Med Ce, Washington, DC
Disclosure Block: **C.A. Samango-Sprouse:** None.
Introduction 47,XXY is the most frequently occurring sex chromosome aneuploidy, affecting approximately 1 in every 600 males. It is characterized by androgen deficiencies and a variable neurodevelopmental profile including speech and motor delay, language-based learning disabilities, hypotonia, tall stature, and executive dysfunction. Previous research suggests Early Hormonal Treatment (EHT) may improve several aspects of neurodevelopment in infants and young children with 47,XXY. This study investigates whether these positive associations are continued into school-aged males with 47,XXY. ***Methods*** Eighty prenatally diagnosed males with 47,XXY between the ages of 80 and 143 mos were followed through yearly comprehensive neurodevelopmental evaluations. Each was administered assessments based on chronological age including the Wechsler Intelligence Scale for Children 4th/5th Edition (WISC-IV/V), Expressive and Receptive One Word Picture Vocabulary Tests, 4th Edition (EOWPVT-4 and ROWPVT-4), and Leiter International Performance Scale, 3rd Edition (LIPS-III). For statistical analysis, the participants were bifurcated by treatment status: No-T (CA: 101 mos, N=54) and EHT (CA: 108 mos, N=26). Two-tailed t-tests were used to determine statistical differences between groups on each assessment. ***Results*** On the WISC-IV/V, the EHT group scored significantly higher on the Verbal Comprehension Index, Working Memory Index, and FSIQ than the No-T group (p=0.04, p=0.03, and p=0.003 respectively). The EHT group scored an average FSIQ of 116.75 whereas the No-T group scored an average of 102.48. The No-T group (M=109.65, SD=10.85) showed significantly reduced scores on the EOWPVT-4 when compared to the EHT group (M=117.50, SD=6.67) (p=0.03). There was also a significant effect of treatment observed on multiple domains of the LIPS-III including Figure Ground (p=0.001), Classifications & Analogies (p=0.02), Visual Patterns (p=0.05), and Non-Verbal IQ (p=0.05). ***Conclusion*** This is the first study to demonstrate a potential sustained positive impact of early-course androgen treatment on neurodevelopmental capabilities in males with 47,XXY. Consistent with findings in young children, we observed improved expressive language skills in those who received EHT. Overall, our findings elucidate the need for early detection in this population, as neurobiological treatment during critical periods of development may optimize their outcome. With time, more data will become available and studies on the impact of EHT in young adults with 47,XXY may be investigated.

PrgmNr 3156 - Trans-ethnic meta-analysis of genome-wide association studies identifies novel loci for gestational duration

View session detail

Author Block: **S. Chatterjee**[1], J. Wu[1], M. Ouidir[1], K. L. Grantz[1], F. Tekola-Ayele[2]; [1]Epidemiology Branch, Div. of Intramural Population Hlth.Res., Natl. Inst.S OF HEALTH (NIH), BETHESDA, MD, USA, Bethesda, MD, [2]Epidemiology Branch, Div. of Intramural Population Hlth.Res., Natl. Inst.S OF HEALTH (NIH), BETHESDA, MD, USA, BETHESDA, MD
Disclosure Block: **S. Chatterjee:** None.
Shorter gestational duration and preterm birth is the leading cause of morbidity and mortality among neonates. Despite strong evidence that the burden of preterm birth in the United States is disproportionately higher among African Americans, large scale genome-wide association studies (GWAS) are lacking in diverse ancestries. To date, only six loci have been identified in Europeans. To bridge this gap, we performed trans-ethnic GWAS meta-analysis of gestational duration in pregnant women of African (n=637), East Asian (n=238), European (n=622), and Hispanic (n=568) ancestries who participated in the NICHD Fetal Growth Studies. GWAS was conducted in each ancestry on ~ 10 million genotyped and imputed single nucleotide polymorphisms (MAF â¥2% in each population) adjusted for sex, maternal age and five genotype principal components. GWAS summary statistics of each population were combined using trans-ethnic approaches based on random effects accounting for potential genetic effect heterogeneity across diverse populations. The median gestational duration was ~39.4 weeks across all ancestries. Trans-ethnic meta-analysis identified eight genome-wide significant (*P* -8) loci in the maternal genome (*C3, C1QBPP, C4orf36, AFF1, SGCD, CYB5R4, LINC02884, LOC112268135*) associated with gestational duration with consistent effect directions in two or more ancestries. The hits at the complement system-related loci, *C3* and *C1QBPP*, are clinically relevant given prior suggestions that serum *C3* can predict preterm birth. At these loci, each additional minor allele was associated with up to 1-week shorter gestational duration. We also replicated (*P*EBF1 locus identified in a previous study. The loci identified in our study also have annotations implicated in cell differentiation, bone development, cell cycle progression, tumor progression, cardiometabolic traits, and central nervous system development disorders. This study identified novel loci associated with gestational duration via trans-ethnic meta-analysis, including genes encoding the complement system proteins in which maternal serum levels have been associated with preterm birth. Functional follow-up on the loci identified may give clues on clinically relevant molecular intervention targets.

PrgmNr 3157 - Whole mitochondrial genome analysis of a single trophectoderm biopsy - heteroplasmy dynamics and selection in human embryos

View session detail

Disclosure Block: **A. Aggarwal:** None.
Objective: Heteroplasmy (Het) is cellular coexistence of mutated and normal mtDNA copies. Knowledge of effects of mtDNA variants on human embryo development is limited, due to availability of human embryos for research and only recent technology for low DNA input genomic analysis. Whole genome amplification (WGA) is integral to preimplantation genetic testing (PGT); however, it may introduce variant errors and uneven coverage bias, leading to false detection of low-level Mt-Het. We optimized sequencing and analysis of human embryonic mtDNA from a small trophectoderm (TE) biopsy and determined a threshold for detection of heteroplasmy. Our objective was to apply this pipeline to a set of 6 familial cases with maternal-embryonic-fetal mtDNA and study patterns of heteroplasmic variation at the embryonic and fetal stage.**Materials and Methods:** We studied 23 samples from 6 cases. Each case included maternal DNA (blood/granulosa cells), embryonic DNA (WGA DNA from TE biopsy of blastocysts undergoing PGT-A), and fetal DNA of miscarried embryos (product of conception tissue). Illumina DNA Prep with Enrichment using whole MtDNA probe capture by ligation (Twist Biosciences) and Next Seq 550 was used for data generation. Dragen Enrichment was used for analysis. Optimized Het detection threshold of 5% was applied for variant analysis.**Results:** Mt-genome was sequenced at mean depth ~5700x (100% at 50x). 487 variants were identified at 147 sites. 165 Het were detected across 23 samples, and 104 were present at high levels (80%4216T>C in two cases and c.*15928G>A* in one case, both associated with repeated miscarriage on MitoMap. **Conclusions:** Our optimized pipeline allowed detection of low Het variants in human embryonic mtDNA. High variant frequency present in the embryonic mt-genome and is transmitted through a severe germline bottleneck of 27 estimated units. We found a decrease in allele frequency for NS variants from mom to fetus, which is indicative of purifying selection. We are expanding these findings on a set of ~500 embryos. These finding may have key implications for understanding variants in early embryos and their significance in human embryo development.

PrgmNr 3158 - *TESLA*: super-resolution Tumor Edge Structure and Lymphocyte multi-level Annotation from spatial transcriptoms

View session detail

Author Block: **J. Hu**[1], L. Wang[2], M. Li[1]; [1]Univ Pennsylvania, Philadelphia, PA, [2]The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX
Disclosure Block: **J. Hu:** None.
Cancer development is a multistep process involving the accumulation of genetic modifications, which results in the expression of tumor antigens that trigger innate and adaptive antitumor immune responses to eliminate cancer cells. The description of tumor-infiltrating lymphocytes and their metastases is highly related to therapy and survival of patients, which unambiguously demonstrated the importance of the tumor microenvironment (TME) in cancer control. Recent advances in spatially resolved transcriptomics (SRT) technologies have enabled comprehensive characterization of gene expression patterns in the context of the tissue microenvironment. However, experimental methods for SRT can only measure spatial gene expression in discrete spots located apart from each other, leaving large areas unmeasured and limiting their usefulness in studying detailed structure in TME. To overcome this limitation, we present TESLA, an approach for Tumor Edge Structure and Lymphocyte multi-level Annotation at the same resolution as the histology image using SRT data. TESLA integrates morphology information on histology image as well as the gene expression information to annotate different cell types directly on the histology image. Based on the colocalization of some immune cell types, TESLA has the compacity of detecting tertiary lymphoid structures, which is a surrogate marker of a brisk anti-tumor immune response. In addition, TESLA is able to characterize intra-tumor heterogeneity and find genes enriched in the core or edge region of a tumor, representing a promising avenue for understanding the tumor microenvironment.

PrgmNr 3159 - A fast and robust Bayesian nonparametric method for prediction of complex traits using summary statistics

View session detail

Author Block: **G. Zhou**[1], H. Zhao[2]; [1]Yale Univ., New Haven, CT, [2]Yale Univ. Sch. of Publ. Hlth., New Haven, CT

Disclosure Block: **G. Zhou:** None.

Genetic prediction of complex traits has great promise for disease prevention, monitoring, and treatment. The development of accurate risk prediction models is hindered by the wide diversity of genetic architecture across different traits, limited access to individual level data for training and parameter tuning, and the demand for computational resources. To overcome the limitations of the most existing methods that make explicit assumptions on the underlying genetic architecture and need a separate validation data set for parameter tuning, we develop a Summary-statistics based Dirichlet Process Regression method SDPR that does not need to tune parameters. In our implementation, we refine the commonly used likelihood assumption to deal with the discrepancy between summary statistics and external reference panel. Through simulations, we show that SDPR is adaptive to different genetic architectures and robust to heterogeneity of per SNP sample sizes. In real data analysis, we compared the performance of SDPR with 7 recently developed or current state of art methods (PRS-CS, SBayesR, LDpred, P+T, LDpred2, lassosum and DBSLMM) on 6 quantitative (height, BMI, HDL, LDL, total cholesterol and triglycerides) and 6 binary traits (coronary artery disease, breast cancer, IBD, type 2 diabetes, schizophrenia and bipolar). SDPR achieved the best performance for 6 traits (height, BMI, HDL, LDL, total cholesterol, breast cancer), and top tier performance for 4 additional traits (IBD, type 2 diabetes, schizophrenia, bipolar; within 0.003 of AUC difference compared with the top method). Furthermore, SDPR is able to fit the model in 15 minutes when executed in parallel, significantly faster compared with 2-5 hours for PRS-CS, LDpred and LDpred2. Taken together, we believe that SDPR has the potential to be widely used given its competent performance on real traits, easiness to use and excellent computational efficiency. SDPR is freely available at https://github.com/eldronzhou/SDPR.

PrgmNr 3160 - A fresh look at the role of Hardy-Weinberg disequilibrium in association testing

View session detail

Author Block: **L. Zhang**[1], L. J. Strug[2], L. Sun[3]; [1]Univ of Toronto, Toronto, ON, Canada, [2]Hosp for Sick Children, Toronto, ON, Canada, [3]Univ. of Toronto, Toronto, ON, Canada
Disclosure Block: **L. Zhang:** None.
Current guidance for Hardy-Weinberg equilibrium (HWE) screening in case-control genome wide association studies (GWAS) is incoherent. First, there is no universal agreement on the HWE p-value threshold as it depends on sample size. Recommended thresholds vary in the literature, ranging from 10E-7 in controls alone (Anderson et al., 2010), 10E-6 in controls and 10E-8 in cases (Marees et al., 2018), and 10E-10 per n=4,000 participants for the UK Biobank study (Bycroft et al., 2018). Second, a truly associated SNP could reasonably be out of HWE in both the case and control groups, even if it is in HWE in the whole population. The degree to which there is Hardy-Weinberg disequilibrium (HWD) due to true association is typically not large but detectable with UK Biobank-type sample size. Consequently, HWE-based quality control may mistakenly screen out truly associated SNPs.
Instead of HWE-based screening and variant removal, we propose a new case-control association test that (a) is robust to genotyping error, (b) leverages HWD attributed to true association to increase power and (c) is easy-to-implement at the genome-wide level. The proposed robust allele-based (RA) joint test expands the recent RA-regression model for conducting robust allelic association analysis (Zhang and Sun, 2021), incorporating the *difference* in HWD between the case and control groups into the traditional association measure. We provide the asymptotic distribution of the proposed test under the null hypothesis of no association. We demonstrate type 1 error control of the RA test at the genome-wide significance level of 5E-8, in the presence of HWD that is attributed to factors unrelated to phenotype-genotype association such as genotype error.
Finally, through a GWAS of meconium ileus in 3,161 individuals (569 cases and 2,592 controls) with cystic fibrosis, we show that the proposed method can (i) robustly analyze SNPs with genotype error, (ii) replicate previous genome-wide significant loci, and (iii) identify novel genome-wide significant loci that were missed by the traditional GWAS approach.

PrgmNr 3161 - A novel regression-based method for X-chromosome-inclusive Hardy-Weinberg equilibrium test

View session detail

Author Block: **L. Sun**[1], L. Zhang[1], Z. Wang[2], A. D. Paterson[3]; [1]Univ. of Toronto, Toronto, ON, Canada, [2]Fudan Univ., Shanghai, China, [3]Hosp for Sick Children, Toronto, ON, Canada
Disclosure Block: **L. Sun:** None.
Prior to conducting a genome-wide association study (GWAS), a critical part of the data quality control step is testing the assumption of Hardy-Weinberg equilibrium (HWE), because severe departure from HWE typically indicates genotyping error. The HWE test for an autosomal SNP is straightforward in an independent sample: Contrast the observed genotype counts with the expected under the assumption of HWE and apply the standard Pearsonâ□□s Chisq test for goodness of fit.
How to best perform HWE test for an X-chromosomal SNP, however, is not clear, even using a sample of unrelated individuals. One simple strategy is to use female data only and apply the same Pearsonâ□□s Chisq test. Alternatively, Graffelman and Weir (2016) proposed a 2 d.f. test that includes the deviation of male genotype counts from the expected based on pooled allele frequency estimate using both male and female data.
Instead of the Pearsonâ□□s Chisq-based test, we propose a new regression-based method that (a) analyzes both autosomal and X-chromosomal SNPs, (b) adjusts for covariate effects if needed, (c) analyzes related individuals, (d) includes the existing tests as special cases, and (e) leads to development of new tests. The proposed method builds from the recent robust allele-based (RA) regression model for conducting allelic association test (Zhang and Sun, 2021).
First, we show that a 2 d.f. score test derived from the proposed RA regression includes the test of Graffelman and Weir (2016) as a special case. Second, we show that the 2 d.f. Pearsonâ□□s Chisq test of Graffelman and Weir (2016) can be reformulated as simultaneously testing sex differences in allele frequency, and HWE in female group alone. Thus, we can then develop new HWE tests that do not assume that sex differences in allele frequency are due to genotyping error. These new tests would be more suitable for analyzing, for example, variants that differ in allele frequency due to sex-specific selection. Finally, as the regression approach adjusts for covariate effects, it can analyze samples from multiple populations jointly.
We illustrate the method by application to both phase 3 and high coverage whole genome sequence data from the 1000 genomes project.

PrgmNr 3162 - A sparse high-dimensional generalized varying coefficient model for identifying genetic variants associated with regional methylation

View session detail

Author Block: **K. Zhao**[1], Y. Yang[1], K. Oualkacha[2], C. M. Greenwood[3,1]; [1]McGill Univ., Montreal, QC, Canada, [2]UniversitÃ© de QuÃ©bec Ã MontrÃ©al (UQÃM), Montreal, QC, Canada, [3]Jewish Gen. Hosp., Montreal, QC, Canada

Disclosure Block: **K. Zhao:** None.

DNA methylation is an essential epigenetic modification that regulates gene activity and contributes to tissue differentiation and disease susceptibility. Notably, DNA methylation variation has a vital genetic component. Loci harbouring genetic variants that influence methylation levels are called methylation quantitative trait loci (mQTLs). Identifying mQTLs can provide important insight into the underlying molecular events within multiple human tissues and thus enhance our understanding of the genetic basis of disease development. We have recently proposed a novel varying coefficient model, SOMNiBUS, to analyze regional bisulfite sequencing-derived methylation data, enabling comprehensive and simultaneous estimates of covariate effects that are smoothly varying along genomic positions. However, SOMNiBUS shows important limitations when applying to mQTL analysis because we routinely face hundreds or thousands of candidate SNPs within or near a regulatory region, and SOMNiBUS cannot cope with high-dimensional feature spaces. To address this problem, we propose a high-dimensional varying coefficient model, imposed with a composite penalty term that encourages both sparsity and smoothness for the varying coefficients. We then present an efficient proximal gradient descent algorithm to estimate our model. A comprehensive simulation study has been conducted to evaluate the performance of our approach in terms of estimation, prediction and selection accuracy. We show that our procedure can simultaneously select important mQTLs and estimate their corresponding varying effects across a methylation region of interest with excellent accuracy. An R package called sparseSOMNiBUS that implements our method is freely available on GitHub.

PrgmNr 3163 - AFA Computationally efficient Ancestral Frequency estimation in Admixed populations: the Hispanic Community Health Study/Study of Latinos

View session detail

Author Block: **E. Granot-Hershkovitz**[1,2], S. Browning[3], Q. Sun[4], M. Argos[5], T. Sofer[1,2,6]; [1]Harvard Med. Sch., Boston, MA, [2]Brigham and Women's Hosp., Boston, MA, [3]Univ of Washington, Seattle, WA, [4]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [5]The Univ. of Illinois Chicago, Chicago, IL, [6]Chan Sch. of Publ. Hlth., Boston, MA

Disclosure Block: **E. Granot-Hershkovitz:** None.

Background: Estimation of ancestry-specific allele frequencies in admixed populations is especially relevant for modern-day populations that are becoming increasingly genetically admixed. These allele frequencies are important for prioritizing ancestry-enriched variants for genomic association analyses, inferring demographic histories of populations, interpreting sequence variants, and determining susceptibility to disease. Existing methods for estimating ancestry-specific allele frequencies from an admixed population are time-consuming and limited to a small number of ancestries and, therefore, cannot be applied at scale. **Methods:** We developed a computationally efficient method, Ancestral frequency estimation in Admixed populations (AFA), to estimate the frequencies of bi-allelic variants in admixed populations with an unlimited number of ancestries. AFA uses maximum likelihood estimation by modeling the conditional probability of having an allele given proportions of genetic ancestries, with no need for phased data. It can be applied using either Local ancestry interval proportions encompassing the variant (LAFA) or Global proportions of genetic ancestries (GAFA), which are easier to compute and are more widely available. We evaluated the performance of our proposed method in simulations mimicking admixed populations and implemented the method using the NHLBI BioData Catalyst Powered by SevenBridges, on data from the Hispanic Community Health Study/Study of Latinos (HCHS/SOL), an admixed population with three predominant continental ancestries: Amerindian, European, and African. **Results:** Simulations demonstrate that ancestral allele frequency estimation accuracy improves with higher minor allele frequency and larger effective sample sizes of the ancestry of interest. Comparing the HCHS/SOL European and African estimated allele frequencies to their respective gnomAD ancestry frequencies shows high correlations. We defined HCHS/SOL ancestry enriched variants as variants with a minor allele frequency (MAF) of â¥5% in the ancestry of interest and â¤1% in the other two ancestries. Overall, we identified 20,777 Amerindian enriched variants, 135,639 African enriched variants, and 15,063 European enriched variants in chromosome 1. **Conclusion:** Our method can be applied to modern-day admixed populations, enhancing genetic discoveries and personalized genomic health for these understudied populations. We will provide a publicly available code and a dataset of the estimated three ancestral allele frequencies in HCHS/SOL for all available variants with an estimated MAF of â¥5% in at least one of the ancestral populations.

PrgmNr 3164 - Applying Recurrent Weighted Replanting to detect gene-gene interaction in case-parent trios

View session detail

Author Block: **Q. Li**[1], A. Musolf[1], J. E. Bailey-Wilson[2]; [1]Computational and Statistical Genomics Branch, NIH/NHGRI, Baltimore, MD, [2]NIH/NHGRI, Baltimore, MD
Disclosure Block: **Q. Li:** None.
To improve the power to detect causal variants in genomic datasets, a novel procedure called Recurrent Weighted Replanting (RWR) is proposed based on the Random Forest (RF) method. In the past, our group developed trio Random Forest (trioRF) to detect gene-gene interactions in case-parent trio data. TrioRF uses cases and random samples of variant calls from the set of matched pseudo controls, and utilizes a proper classification criterion to detect the difference in variant calls between the pseudo controls and cases. The importance score for each feature is calculated based on permutation tests.
Although trioRF can be scaled up and include a large number of features (SNPs here) in one run to fit a classification tree, the chance of including multiple SNPs in interaction within one run is proportional to the total number of SNPs. As a result, for millions of SNPs, we need to increase the number of trees and improve power. Therefore, we propose to implement RWR for trioRF. We run trioRF multiple times. The initial step is to obtain the importance scores for each SNP (feature). Then we use importance scores from the initial step to select subsets of SNPs to include in subsequent runs and novel weights to adjust the probability that each SNP is available for splitting, a procedure denoted as RWR trioRF. At the final stage, the importance scores from the multiple RWR trioRF runs are calculated. We conducted simulation studies to demonstrate the power of RWR trioRF.

PrgmNr 3165 - Approaches for detection of epistatic interactions of causal variants in genome-wide data: Comparison of Recurrent Weighted Replanting with other machine learning methods

View session detail

Author Block: **J. E. Bailey-Wilson**[1], J. D. Malley[1], A. M. Musolf[2]; [1]NIH/NHGRI, Baltimore, MD, [2]NIH, Baltimore, MD

Disclosure Block: **J.E. Bailey-Wilson:** None.

Much effort is being expended to detect the causes of â□□missing heritabilityâ□□ of complex traits, including effects of rare, moderate to high penetrance risk variants and epistatic interactions. Many machine learning (ML) methods can produce strongly predictive models when the number of potential predictive variables (features) is very large compared to sample size and in the presence of complex interactions between the predictors. However, identifying which of the predictor variables are important in the prediction and therefore biologically important in genetic studies, is not possible for many ML methods. Of those methods that can detect interacting predictors, many do not scale well to analysis of extremely large numbers of features such as millions of genotypes. We have developed r2VIM, based on Random Forests (RF), and have now extended it to Recurrent Weighted Replanting (RWR) to improve power to detect causal variants, with an emphasis on detection of predictors involved in interactions since this is a question of great interest to human geneticists. RWR is a multi-step procedure that runs r2VIM iteratively, using r2VIM importance scores from prior steps to select subsets of features (SNPs here) to include in subsequent runs and novel weights to adjust the probability that each feature is selected as available for splitting (mtry parameter) in any given tree of each RF. At the final stage, r2VIM importance scores are calculated and features that pass a threshold based on importance score variance are selected as important. We simulated case-control data based on a variety of pure epistasis and polygenic plus epistasis models for disease risk, where the interacting features had no main effects since this is the most difficult type of interaction to detect with standard statistical methods such as logistic regression. RWR is powerful and can detect variants involved in epistatic interactions with no marginal effects on the trait (power over 80% across a wide variety of simulated models with 5000 cases, 5000 controls, 100,000 SNPs). We compare these results with observed power from other machine learning methods including RF, r2VIM, Boruta, Vita and TEAM; in general RWR has equal or better power.

PrgmNr 3166 - Characterizing homozygous loss of function variants in 454,782 whole exome sequences from the UK Biobank

View session detail

Author Block: **C. Willis**[1], M. M. Parker[1], A. Deaton[1], L. D. Ward[1], A. Flynn-Carroll[1], R. Hoffing[1], M. Plekan[1], G. Hinkle[1], P. Nioi[2]; [1]Alnylam Pharmaceuticals, Cambridge, MA, [2]Alnylam, Cambridge, MA
Disclosure Block: **C. Willis:** Salary/Employment; Alnylam Pharmaceuticals.
Objective Homozygous predicted loss of function (pLOF) mutations which are expected to inactivate protein-coding genes are valuable when evaluating the therapeutic potential and safety of drug targets. We aimed to characterize high confidence homozygous pLOF variants from 454,782 exomes in the UK Biobank. **Methods** We identified individuals that are either homozygous or heterozygous carriers of pLOF variants (stop-gained, frameshift, or splice donor/acceptor) in 454,782 whole exome sequences from the UK Biobank. Additional variant-level quality control filters were applied to validate both variant calls and functional prediction of LOF including average read depth â¥10, > 98% call rate, and Hardy-Weinberg P-value > $1.0e^{-10}$. Additionally, we only considered autosomes in our analyses. To predict with high certainty whether variants cause loss of function in a gene, only those flagged âhigh confidenceâ by the Loss-Of-Function Transcript Effect Estimator algorithm (LOFTEE) in either the Ensembl MANE (Matched Annotation between NCBI and EBI) or canonical transcript were included. **Results** We identified 3,474 homozygous pLOF variants within 2,260 genes and 618,052 heterozygous pLOF variants in 16,405 genes. The majority of homozygous pLOFs were rare (75% were observed in â¤10 subjects) and nearly half (43%) were only observed in one subject. These unique variants were observed at much higher rates in Southeast Asian (4.3%), African (2.7%), and Chinese (1.9%) ancestry populations than in the European (0.2%) ancestry population. The majority (83%) of identified homozygous pLOF variants were also identified in the gnomAD database with highly correlated allele frequencies (R^2=0.98). More frequent homozygous pLOF variants (n carriers > 1) were more likely to be in a gene that was tolerant to loss of function mutations (pLI = 0). We cross-referenced identified putative knockouts in the UK Biobank with FDA approved drug targets according to the DrugBank database and found 28 genes that overlap. **Conclusions** We identified 2,260 genes with high confidence putative human knockouts in 454,782 exome sequences from the UK Biobank, including known drug targets. Characterization of these knockouts will aid in evaluating the safety and efficacy of genetically defined medicines like RNAi therapeutics.

PrgmNr 3167 - Conditional resampling improves calibration and sensitivity in single-cell CRISPR screen analysis

View session detail

Author Block: **T. Barry**[1], X. Wang[1], J. A. Morris[2], K. Roeder[1], E. Katsevich[3]; [1]Carnegie Mellon Univ., Pittsburgh, PA, [2]New York Genome Ctr., New York, NY, [3]Univ. of Pennsylvania, Philadelphia, PA
Disclosure Block: **T. Barry:** None.
The majority (>90%) of GWAS-implicated loci are thought to lie in *cis*-regulatory elements (CREs). The functional role of most CREs, including the gene or genes through which they exert their effect, is unknown. A central challenge over the coming decade, therefore, is to unravel the *cis*-regulatory landscape of the genome across diseases and cell types.
The most promising technology for mapping candidate CREs to their target genes at genome-wide scale are high multiplicity-of-infection (MOI) single-cell CRISPR screens. Despite their extraordinary promise, high-MOI single-cell screens pose substantial statistical challenges. All published methods designed to analyze data produced by high MOI screens suffer from significant calibration issues, creating excesses of false positive and false negative discoveries. In our work we make two key contributions: we (i) identify core statistical challenges at play in high-MOI single-cell CRISPR screens and (ii) present a novel analysis methodology designed to address them: SCEPTRE (code available at timothy-barry.github.io/sceptre/). SCEPTRE is based on the conditional randomization test, an intuitive and powerful statistical methodology that, like parametric methods, enables simple correction for technical factors such as sequencing depth and batch, and like nonparametric methods, is robust to expression model misspecification. SCEPTRE demonstrated excellent calibration and sensitivity on two recent, large-scale, high MOI single-cell CRISPR screen datasets, revealing hundreds of new regulatory relationships, vigorously validated through a variety orthogonal functional assays.
In a parallel work we combined biobank-scale GWAS data, pooled CRISPR screens, single-cell sequencing, and SCEPTRE to dissect the *cis* and *trans* effects of noncoding variants associated with qualitative blood traits. SCEPTRE confidently mapped 37 noncoding variants to their *cis* target genes â in some cases identifying a causal variant among a set of candidate variants in strong LD â and illuminated several *trans* effects networks. Overall, SCEPTRE is well-positioned to become the method of choice for the wave of noncoding genetic screens likely to be conducted over the next few years.

PrgmNr 3168 - COVID19 symptoms vary by *HLA* haplogroup in a well typed crowd cohort

View session detail

Author Block: **N. M. Pearson**[1], J. Rosenfeld[2], C. Sexton[3], M-L. Endale[3], M. Maasha[3], H. Khiabanian[2], R. Freudenberger[4], J. Feinberg[4], F. Gullo[4], B. Lenes[4]; [1]Root Deep Insight, Inc., Boston, MA, [2]Rutgers Cancer Inst. of New Jersey, New Brunswick, NJ, [3]Root Deep Insight, Boston, MA, [4]Gift of Life, Boca Raton, FL

Disclosure Block: **N.M. Pearson:** None.

Studies of sparsely genotyped people have traced COVID19 susceptibility and severity, in part, to variation in or near human genes encoding cell surface glycoproteins, chemokine and interferon receptors, and other plausibly immune-relevant products. But such common-variant association studies have *not* strongly implicated human leukocyte antigen (*HLA*) genes in SARS-CoV2 response, despite those genes' broad roles in humoral immunity. To better assess how, if at all, diverse and potentially rare *HLA* types may shape COVID19 risks, we invited >200000 largely healthy, well *HLA*-typed bone marrow and stem cell volunteers to answer surveys on exposures, tests, diagnoses, and symptoms during the pandemic. Resulting time-series data, including key covariates on age, sex, locale, background health, and household and kin diagnoses, suggest that variation in or near *HLA* genes may influence COVID19-distinctive symptoms moreso than infection susceptibility per se.

PrgmNr 3169 - Deconvoluting sex-specific effects using GWAS summary statistics and biobank datasets across

View session detail

Author Block: **S. Gao**[1], D. J. Liu[2], C. Khunsriraksakul[3]; [1]Penn State Coll. of Med., Hershey, PA, [2]Penn State Univ., hershey, PA, [3]Hershey, PA
Disclosure Block: **S. Gao:** None.
Many diseases show sex differences, where the disease prevalence and genetic effects of certain causal variants show distinct patterns between sexes. Understanding sex specific genetic architecture is critical for understanding the underlying biology and performing clinical translations. GWAS meta-analyses (GWAMA) aggregate data from multiple studies to enlarge sample size and empower discovery. GWAMA often contain the maximal number of cases and remain the primary source for looking up known associations. In GWAMA, sex is often adjusted as a covariate, but samples of both sexes are often pooled. Very few studies released summary statistics from GWAMA are sex stratified. On the other hand, biobanks, such as UK Biobank, contain a large number of well-genotyped samples, but do not contain enough number of cases for diseases that are not sufficiently common. It is of great interest to jointly analyze these pooled GWAMA summary statistics and biobank datasets to understand sex-specific genetic architecture. To address this, we propose a method MAPBOX (Meta-Analysis Plus Biobanks Or seX-specific analysis) that integrates public GWAMA summary statistics that pool both sexes, with UK Biobank data with sex-stratified results. First, we leverage a subset of variants with clear sex differences to deconvolute the GWAMA summary statistics of pooled sexes and estimate the sex ratio. We then leverage a likelihood framework to jointly model sex-specific effects using both the sex-pooled summary statistics and sex-stratified analysis results from biobanks to estimate sex-specific effects. We conduct extensive simulations and show that MAPBOX is considerably more powerful for identifying sex-specific effects than using sex-stratified biobank alone under a variety of scenarios with different genetic effect distributions, as it combines the sample sizes from GWAMA and biobanks. To apply MAPBOX to real data, we match public GWAMA summary statistics with UK Biobank GWAS results from Neale Lab. For female-specific effects, MAPBOX identifies 382 loci for height, 165 loci for body mass index (BMI) loci and 145 loci for high-density lipoprotein (HDL) loci, while the sex-specific analysis using biobank data only identifies 317 loci for height,144 loci for BMI, 134 loci for HDL. Similar power improvement is also observed for male-specific effects analysis. On average, our method discovers 16% more significant loci in female effect and 19% more in male effect, compared to the method that uses stratified analysis results only. Our method and continued research in this direction will pave the way for more in-depth analysis of sex-specific genetic architectures for complex traits.

PrgmNr 3170 - Developing Trans-ethnic Polygenic Risk Scores Using Empirical Bayes and Super Learning Algorithm

View session detail

Author Block: **H. Zhang**[1], J. Zhan[2], J. Jin[3], J. Zhang[3], T. U. Ahearn[4], Z. Yu[5], J. O. Connell[2], Y. Jiang[2], B. Koelsch[2], 23andMe Research Team, X. Lin[1], M. Garcia-Closas[4], N. Chatterjee[3]; [1]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [2]23andMe Inc., Sunnyvale, CA, [3]Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, [4]Natl. Cancer Inst, Rockville, MD, [5]Broad Inst. of MIT and Harvard, Cambridge, MA
Disclosure Block: **H. Zhang:** None.

Polygenic risk scores (PRS) are useful for predicting various phenotypes/outcomes; however, as most PRS have been developed with data generated in European Ancestry (EA) populations, performances of PRS are often poorer in non-EA populations, reflecting their degree of divergence from EA population.

To improve PRS performance in non-EA populations, we propose a novel method, Two-Dimensional Clumping and thresholding with Super Learning and Empirical Bayes (TDLD-SLEB), which takes advantage of both existing large GWAS from EA populations and smaller GWAS from non-EA populations. TDLD-SLEB uses a two-dimensional thresholding method to incorporate SNPs that have either effects in both the larger (e.g., EA populations) and the smaller (e.g., non-EA populations) target population or specific effects in the smaller population. It estimates effect sizes for SNPs in the target population using an Empirical Bayes method that borrows GWAS information across populations. Finally, it incorporates a super learning algorithm to combine series of PRS generated by various SNP selection thresholds for the target population.

Our simulation analyses mimicked real LD patterns using haplotype data of 1000 Genome Phase 3 for five ancestries. We considered various genetic architectures including different levels of negative selection and genetic correlation across ancestries. We found PRSs generated by TDLD-SLEB had significantly improved predictionary accuracy for non-EA populations in independent validation datasets, compared to single ethnic PRS, EUR derived PRS, or a weighted PRS that combines EUR and single ethnic derived PRS with weights selected to optimize prediction in the target population.

Using 23andMe data, we developed and validated population specific PRS for seven complex traits using GWAS data from Europeans (average N=2,442K), African American (average N=113K), Latino (average N=411K), East Asians (average N=94K), South Asians (average N=25K). We found TDLD-SLEB often led to large improvements in the performance of PRS compared to alternative methods for predicting traits in the African American population (average R^2 increased +277% compared to the weighted PRS method). For other ethnic groups, TDLD-SLEB also led to sometimes notable improvements in the performance of PRS, such as for the cardiovascular disease in the Latino population (AUC = 0.61 for TDLD-SLEB vs. AUC= 0.58 for the weighed PRS method).

In conclusion, we developed a computationally scalable and statistically efficient method for generating predictive PRS in non-European populations using GWAS datasets across diverse populations.

PrgmNr 3171 - Ethnicity-specific high-risk gene variant profiling unmasks diabetes associated genes

View session detail

Author Block: **J. Zhang**; NIH, Bethesda, MD
Disclosure Block: **J. Zhang:** None.
The underlying genetic basis for the significant health disparities among ethnic subpopulations and how such inter-ethnic genetic variance may impact the discovery of disease-associated genes warrant a deeper understanding. Through the whole-genome analysis of the total number of high-risk variants (hrV) of each gene in populations representing 185934 subjects, we identified sets of genes with hrV frequencies (hrVF) either unique to each, or conserved in all, ethnicities and used this to develop a quantitative gene-based high-risk variant index (hrVI) of 20428 genes. Gene-to-gene comparisons of ethnicity-specific hrVFs and hrVIs between the case (20,781 subjects) and control (24440 subjects) populations in the type 2 diabetes mellitus (T2DM) national repository identified 57 T2DM-associated genes, 40 of which were discoverable only by ethnicity-specfic analysis. These results demonstrate the utility of hrV analysis and illustrate how gene-based ethnicity-specific analysis of genetic variations can significantly facilitate the identification of genes associated with polygenic diseases

PrgmNr 3172 - Exact and flexible, conditional and joint analysis of association summary statistics using linkage disequilibrium

Genome-wide association studies (GWAS) have identified thousands of genomic loci associated with hundreds of complex traits and diseases. In order to infer biology from these associations, researchers now seek to identify causal variants within these long lists of significantly associated loci; simply assuming that the lead variant is causal risks overlooking interesting secondary variants, which may still have substantial biological impact. Methods that focus on identifying independent signals within complex loci will be important to elucidating these potentially interesting secondary associations.

Standard conditional analyses to identify these secondary and tertiary associations largely require access to individual-level genotype data. However, the advent of large-scale GWAS from vulnerable or protected populations (for example, 23&Me or MVP analyses), GDPR and other stringent data protection measures, and incomplete sharing of raw data from multi-omic analyses increasingly hamper access to raw data, and standard conditional analyses to refine signals and identify causal variants within genomic loci may not be widely practicable. To address this issue, powerful software exists to perform conditional analyses using summary statistics; most prominently, GCTA-CoJo performs conditional analysis using summary-level statistics and LD estimated from a reference sample. Here, we introduce CoCo, which performs conditional and joint analysis of summary statistics. CoCo offers two important advancements over current software. First, CoCo allows specification of a custom LD Matrix, rather than deriving LD from genotype files. Crucially, this allows the user to derive LD from allelic dosages, rather than hard-called genotypes, which may significantly increase accuracy. Second, the flexible design of our software (ie, the specification of a user-defined LD matrix) and straightforward underlying statistical hypotheses allow this method to be applied beyond GWAS to perform conditional analysis on a wide range of summary statistics, provided that an appropriate correlation matrix is available.

Here, we demonstrate application of our method to perform conditional analyses on eQTL, genetically regulated gene expression (GREX) and phenome-wide association study (PheWAS) data. Application of CoCo therefore allows conditional analyses to be performed using summary statistics from a range of standard genomic and related secondary analyses.

PrgmNr 3173 - Fast and scalable polygenic risk modeling with Variational Inference

View session detail

Author Block: **S. Zabad**[1], S. Gravel[2], Y. Li[1]; [1]McGill Univ., Montreal, QC, Canada, [2]Mc Gill Univ, Montreal, QC, Canada
Disclosure Block: **S. Zabad:** None.
Polygenic risk score (PRS) models are increasingly becoming a valuable diagnostic tool for a variety of complex diseases, providing clinically actionable insights and enabling personalized clinical interventions. Despite their promise, with the exception of a few traits, polygenic scores have not seen wide-scale adoption in clinical practice because their accuracy and robustness remain limited. Many statistical approaches have been developed to extract polygenic scores from biobank-scale datasets. However, statistical challenges abound, illustrated by the limited accuracy of many polygenic scores beyond idealized settings.
A central challenge in this setting is the very high dimensional nature of the data, paired with limited, though rapidly growing, sample sizes. To deal with this challenge, Bayesian approaches, which impose meaningful sparse priors over the effect sizes, have shown great promise. Most of these methods, including SBayesR (Lloyd-Jones et al. 2019) and LDPred (VilhjÃ¡lmsson et al. 2015, Prive et al. 2020), utilize stochastic approximate posterior inference schemes, such as Gibbs sampling. While these methods work well for some polygenic traits, their efficiency and flexibility are hampered by the choice of posterior inference algorithms.
In this work, we present Variational Inference PRS (VIPRS), a Bayesian PRS framework that uses Variational Inference (VI), a deterministic approximate posterior inference scheme. The model is based on the Variational Expectation-Maximization inference algorithm, with closed form updates for the variational parameters as well as hyperparameters, such as the residual variance and the proportion of causal variants. Our model works with individual-level data and summary statistics and can reliably estimate a number of genetic quantities of interest, such as SNP heritability.
We apply VIPRS to simulated and real phenotypes from the White British cohort in the UK Biobank (N = 337195), and demonstrate that it achieves competitive predictive performance with state-of-the-art methods, outperforming SBayesR and LDPred in many settings. We also undertake an ablation study to examine the effects of Linkage Disequilibrium (LD) reference panels and LD estimators on the performance of the method. In our experiments, VIPRS achieves the best predictive performance with non-sparse LD matrices, and our software implementation enables it to run with these large on-disk matrices fairly efficiently and with minimal memory overhead.

PrgmNr 3174 - Fine-mapping robustness in real data

View session detail

Author Block: **R. Cui**[1,2], R. Elzur[1,2], M. Kanai[1,2,3,4], J. C. Ulirsch[1,2,5], B. M. Neale[2,1], M. Daly[1,6], Z. Fan[7], H. K. Finucane[1,2]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA, [3]PhD program in Bioinformatics and Integrative Genomics, Harvard Med. Sch., Boston, MA, [4]Dept. of Statistical Genetics, Osaka Univ. Graduate Sch. of Med., Osaka, Japan, [5]PhD program in Biological and BioMed. Sci., Harvard Med. Sch., Boston, MA, [6]Inst. for Molecular Med. Finland, Univ. of Helsinki, Helsinki, Finland, [7]Dept. of Statistics and Data Sci., Yale Univ., New Haven, CT

Disclosure Block: **R. Cui:** None.

Fine-mapping algorithms have been useful for narrowing down broad GWAS associations to a smaller set of putative causal variants. Popular fine-mapping methods (ABF, SuSiE and FINEMAP) use a Baysian approach to assign each variant a probability of causality (Posterior Inclusion Probability, PIP). Previously, these methods have been shown to be calibrated in simulations. However, simulations usually don't capture the complexities in real data. We aim to evaluate and improve the robustness and calibration of these methods in real data.

To evaluate robustness in real data, we performed fine-mapping of 10 well-powered quantitative phenotypes on a random subset of 100K individuals of white British ancestry from the UK Biobank and compared these results to existing fine-mapping results at a sample size of 360K. We observed inconsistency in the form of non-replication, where high-PIP (>0.9) variants at 100K can drop to low-PIP (Functional enrichment analyses show that 40Â±8% of non-replicating variants are in coding, regulatory or conserved regions. Similar proportion is annotated for low-PIP variants at 360K when matched on PIP with the non-replicating variants. Whereas 91Â±6% of PIP-matched (at 360K) replicated variants are annotated, suggesting non-replicating variants are likely non-causal, thus indicating miscalibration in real data.

We found that the following properties differed non-trivially between replicated and non-replicating variants: PIP, PIP difference between SuSiE and FINEMAP, and whether or not the variant is in a SuSiE 95% credible set. We also examined: MAF, INFO score, LD score, and number of credible sets within 100kb, etc. We did not find any property that, on its own, could accurately classify replication status.

Our realistic simulations show that prior misspecification can lead to miscalibration. When there is a false positive, it is often easier to detect than the true causal variant it's in LD with. We measure detectability of each variant by computing the probability of obtaining high-PIP using single-causal-model fine-mapping given a certain effect size, prior variances and local LD pattern. Our analysis, however, has not concluded that prior misspecification is the major driver of non-replication or miscalibration in real data.

PrgmNr 3175 - Functional Response Regression Model on Correlated Longitudinal Microbiome Sequencing Data

View session detail

Author Block: **B. Chen**, W. Xu; Princess Margaret Cancer Ctr., Toronto, ON, Canada
Disclosure Block: **B. Chen:** None.

Functional regression has been widely used on longitudinal data, but it is not clear how to apply functional regression to microbiome sequencing data. We propose a novel functional response regression model analyzing correlated longitudinal microbiome sequencing data, which extends the classic functional response regression model only working for independent functional responses. We derive the theory of generalized least squares estimators for predictors' effects when functional responses are correlated, and develop a data transformation technique to solve the computational challenge for analyzing correlated functional response data using existing functional regression method. We show by extensive simulations that our proposed method provides unbiased estimations for predictors' effect, and our model has accurate type I error and power performance for correlated functional response data, compared with classic functional response regression model. Finally we implement our method to a real infant gut microbiome study to evaluate the relationship of clinical factors to predominant taxa along time.

PrgmNr 3176 - Genealogical models of LD for Bayesian applications in GWAS

View session detail

Author Block: **P. Salehi Nowbandegani**[1], W. Wohns[2,1], A. Bloemendal[1], B. M. Neale[3], L. O'Connor[1]; [1]Broad Inst., Cambridge, MA, [23]Massachusetts Gen. Hosp., Boston, MA
Disclosure Block: **P. Salehi Nowbandegani:** None.
Pervasive linkage disequilibrium (LD) among nearby common SNPs is a primary challenge in statistical applications of GWAS like heritability estimation, risk prediction and fine mapping. LD is highly structured, reflecting genealogical history. Until recently, this history could not be inferred, but with recent breakthroughs, biobank-scale whole-genome genealogies can be reconstructed and encoded as a sequence of trees along the genome (Kelleher et al. 2019). In the tree sequence, alleles are identified with the mutant ancestral haplotype where they were first observed.
We show that statistical relationships (conditional dependencies) among linked SNPs correspond to genealogical relationships among the mutant ancestral haplotypes. Without recombination, the correspondence is straightforward. If allele b arises on a haplotype carrying allele a, and allele c arises on an ab haplotype, the conditional LD structure is c-b-a: although a and c may be in LD, they are conditionally independent given b. These conditional relationships are encoded in the LD graphical model. We developed a method to compute the LD graphical model from an inferred tree sequence (with recombination), showing that it contains all conditional dependencies as connected sets.
LD graphical models can be applied to GWAS summary statistics, whose sampling distribution is efficiently described by an LD graphical model with edge weights (i.e. a precision matrix). An immediate application is to fixed-effects heritability estimation (Shi et al. 2017). The sparsity of our inferred LD precision matrix is especially useful in Bayesian applications, where conditional independencies enable efficient algorithms. We derive a fast variational algorithm, which can be applied to polygenic risk prediction and fine mapping. This approach extends to association data from multiple traits and multiple ancestry groups.

PrgmNr 3177 - Genetic association analysis of a binary trait detects more than just the genetic effect: implications for pleiotropy and replication studies

View session detail

Author Block: **Z. Zhang**, L. Sun; Univ. of Toronto, Toronto, ON, Canada
Disclosure Block: **Z. Zhang:** None.
Pleiotropy analyses of multiple phenotypes are ubiquitous, and summary statistics such as the effect size estimate, test statistic are the building blocks for such analyses.While it is straightforward to aggregate summary statistics derived from analyzing multiple continuous traits, we show that a critical problem arises when analyzing binary traits. That is, power of testing the association between a genetic variant G and a binary trait Y *also* depends on the effect of other covariates such as age and sex, which may vary between the traits of interests.To demonstrate this, consider a simple logistic regression model, logit(Prob(Y=1))=beta.0+beta.G*G+beta.E*E. We show analytically that power of testing the null hypothesis, H0: beta.G=0, inversely depends on the magnitude of beta.E, in addition to beta.G, sample size and the minor allele frequency (MAF) of the variant of interest. This is not the case when analyzing a continuous trait using a Gaussian linear model.We confirm our theoretical results by simulation. We assume two binary traits measured in the same set of n=1000 individuals, and MAF=0.3 and beta.0=0.5 without loss of generality. We then let beta.G=0.3 for both traits, but beta.E=0.8 for trait Y1 while beta.E=0.3 for trait Y2. The empirical power of testing H0: beta.G=0 is 62% for Y1 while 86% for Y2. In comparison, if the traits are continuous (with an error term of N(0, 3)), the power of testing H0: beta.G=0 is 52% for both traits, not influenced by the differential covariate effect, beta.E.Our findings have important implications for the current pleiotropy studies of binary traits, and planning of a successful replication study, because the presumed genetic association evidence is relative to other covariate effects, which very likely vary between different phenotypes, populations, or samples collected using different ascertainment schemes.

PrgmNr 3178 - GenoToolKit: A convenient and accessible R package for genetic data preparation and analysis

View session detail

Author Block: **D. Loesch**, T. D. O'Connor; Univ. of Maryland Sch. of Med., Baltimore, MD
Disclosure Block: **D. Loesch:** None.

Data preparation is a significant part of statistical genetic workflows in terms of time consumption as well as importance. It is critical to have a unified ecosystem for data preparation, both for reproducibility and for efficiency. Here, we present a convenient and accessible R package, genoToolKit, that can fit into current workflows and stand alone as an analysis toolkit. Functionality of the genoToolKit package is split into three main focus areas: data preparation, statistical genetics, and scans for selection, with the primary emphasis on data preparation. In the case of data preparation, the primary function is alignVCF(). This function aligns a genotype file against a reference for imputation or merging, handling strand flips and allele switches. The package also contains a number of functions for the manipulation of genetic data both within R and via convenient wrapper functions for PLINK and BCFtools. Using these functions, we were able to efficiently and uniformly prepare data for 18,608 subjects for a polygenic risk score (PRS) study as part of the Genetics of Latin American Diversity (GLAD) database project. For the second focus area, the package contains functions for performing an admixture mapping analysis, calculating a PRS, evaluating the PRS using cross-fold validation, and a wrapper function for performing GWAS with PLINK. There are also several related functions for preparing data as input for popular PRS software packages. For the third area of focus, there are functions for performing scans for selection using the population branch statistic and by detecting enrichment of a particular ancestry at a given locus. Overall, this R package can assist with data preparation and perform select analyses in a convenient-to-use manner. To support its usage from the command line, we have created resources for building a Docker image with argument handling (https://github.com/dloesch/genoToolKit-docker). The R package is available at https://github.com/dloesch/genoToolKit.

PrgmNr 3180 - Novel Bayesian TWAS method using eQTL summary statistics

View session detail

Author Block: **Q. Dai**[1], L. Franke[2], U. VÃµsa[3], G. C. Gibson[4], M. P. Epstein[5], J. Yang[5]; [1]Dept. of Biostatistics and Bioinformatics, Emory Univ., Atlanta, GA, [2]Univ. Med. Ctr. Groningen, Groningen, Groningen, Netherlands, [3]Univ. Med. Ctr. Groningen, Groningen, Groningen, Netherlands, [4]Georgia Tech, Atlanta, GA, [5]Emory Univ, Atlanta, GA
Disclosure Block: **Q. Dai:** None.
Transcriptome-wide association studies (TWAS) have been widely used to identify gene-trait associations. Existing TWAS tools like PrediXcan and TIGAR first estimate expression quantitative trait loci (eQTL) effect sizes using a regression model with expression trait as the response variable and cis-SNP genotypes as predictors, and then take these eQTL effect size estimates as SNP weights for a gene-based association test. However, such regression models require access to a reference panel with individual-level genetic and transcriptomic data. Thus, existing methods are unable to utilize public eQTL summary statistics published in recent meta-analyses from large-scale consortiums such as the eQTLGen consortium of blood tissues.

To fill this important gap, we propose a TWAS method that allows for using only eQTL summary statistics as reference. Our method employs a summary-statistics based Bayesian regression method originally proposed for polygenic risk score analyses (PRS-CS), which places a continuous shrinkage prior on cis-eQTL effect sizes to shrink small effect sizes of potentially false eQTL towards zero. Our method can infer posterior effect sizes of cis-eQTLs using only eQTL summary statistics from standard eQTL analyses based on single variant tests and an external linkage disequilibrium (LD) reference panel. These estimated cis-eQTL effect sizes can be used for TWASs using either individual-level or summary-level GWAS data. We develop a novel tool using Python and Bash scripts to implement this Bayesian regression model for TWAS, which is referred to as BS-TWAS. Simulation studies using real genotype data from the Religious Orders Study and Rush Memory Aging Project and simulated expression data illustrated that our BS-TWAS method achieved comparable results with PrediXcan and TIGAR using individual-level reference data, with respect to both gene expression prediction R^2 and TWAS power. We trained gene expression prediction models by BS-TWAS for 1777 genes on chromosomes 2 and 3 with eQTL summary statistics from the eQTLGen consortium (n = 31,684) and the LD reference from GTEx V8 samples, and then tested the prediction accuracy using a non-overlapping set of 315 blood samples from the GTEx V8. We found that 48% of the genes have an imputation R^2 >0.01 with median 0.0335 and range (0.01, 0.36).

These preliminary results showed that BS-TWAS using only eQTL summary statistics obtained comparable results as using individual-level reference data, indicating the effectiveness of using large-scale eQTL summary statistics to unravel gene-trait associations by TWAS.

PrgmNr 3181 - Polygenic risk prediction using gradient boosted trees captures non-linear genetic effects and allele interactions in complex phenotypes

Disclosure Block: **T. Sofer:** None.

Polygenic risk scores (PRSs) are commonly used to quantify the inherited susceptibility for a given trait. However, the scores fail to account for non-linear and interaction effects between single nucleotide polymorphisms (SNPs). Machine learning algorithms can be used to account for such non-linearities and interactions. We trained and validated polygenic prediction models for five complex phenotypes in a multi-ethnic population: total cholesterol, triglycerides, systolic blood pressure, sleep duration, and height. We used an ensemble method of LASSO for feature selection and gradient boosted trees (XGBoost) for non-linearities and interaction effects. In an independent test set, we found that combining a standard PRS within a XGBoost model increases the percentage of variance explained (PVE) of the PRS by: 25% for sleep duration, 26% for height, 44% for systolic blood pressure, 64% for triglycerides, and 85% for total cholesterol. Machine learning models trained in specific racial/ethnic groups performed similarly in multi-ethnic trained models, despite smaller sample sizes. The predictions of the machine learning models were superior to the PRS in each of the racial/ethnic groups in our study. However, among Blacks the PVE was substantially lower than for other groups. For example, the PVE for total cholesterol was 8.1%, 12.9%, and 17.4% for Blacks, Whites, and Hispanics/Latinos, respectively. This work demonstrates an effective method to account for non-linearities and interaction effects in genetics-based prediction models.

PrgmNr 3182 - Polygenic transcriptome risk scores improve cross-ethnic portability for COPD and lung function in the NHLBI Trans-Omics for Precision Medicine (TOPMed) Program

View session detail

Author Block: **X. Hu**[1], M. H. Cho[2], H. Im[3], A. W. Manichaikul[1], TOPMed Lung Working Group; [1]Ctr. for Publ. Hlth.Genomics, Univ. of Virginia, Charlottesville, VA, [2]Channing Div. of Network Med., Dept. of Med., Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, [3]The Univ. of Chicago, Chicago, IL

Disclosure Block: **X. Hu:** None.

Background: Chronic Obstructive Pulmonary Disease (COPD), diagnosed by reduced lung function, is a highly heterogeneous disease. Existing polygenic risk scores (PRS) enable early identification of genetic risk for COPD. However, predictive performance of the PRS is limited when the discovery and target populations are not well matched. **Methods**: To improve cross-ethnic portability of risk prediction, we introduced a PrediXcan-derived polygenic transcriptome risk scores (PTRS), developed under the hypothesis that the biological mechanisms of disease are shared across ancestry groups. We constructed the PTRS using summary statistics from application of PrediXcan on large scale GWAS of lung function (Forced Expiratory Volume in 1 second (FEV1) and its ratio to Forced Vital Capacity (FEV1/FVC)) from the UK Biobank, which representing primarily European ancestry-based cohort. To examine prediction performance and cross-ethnic portability of the proposed PTRS candidates, we performed smoking-stratified analyses on multi-ethnic training data for 29,381 participants from TOPMed population/family-based cohorts (NHW=14,727, AA=7,025, HIS=7,629). The best risk score candidates were then tested for 11,771 multi-ethnic participants from TOPMed COPD-enriched studies (NHW=8,144, AA=3,627). Analyses were carried out for two dichotomous traits of COPD (Moderate-to-Severe and Severe COPD) and two quantitative lung function traits (FEV1 and FEV1/FVC). **Results**: While the novel PTRS had lower prediction accuracy for European ancestry participants than PRS, the PTRS performed slightly better than PRS for predicting COPD in heavy smoking African Americans (OR=1.24 [95%CI: 1.08-1.43] from PTRS and OR=1.10 [95% CI: 0.96-1.26] from PRS for Moderate-to-Severe COPD; for Severe COPD, OR=1.51 [95%CI: 1.04-12.19] from PTRS and OR=1.31 [95% CI: 0.87-1.96] from PRS). In addition, as hypothesized, the cross-ethnic portability was significantly higher for PTRS than for PRS (pConclusions: Our study demonstrates the value of PTRS for improved prediction of COPD risk in African Americans. Future work will strengthen the PTRS framework by leveraging multi-ethnic gene expression reference data of larger sample sizes and from disease relevant tissues.

PrgmNr 3183 - Predicting overweight and obese with genome-wide, epigenome-wide gene-gene and gene-diet interactions using machine learning

Disclosure Block: **Y. Lee:** None.

Obesity is a main risk factor for many chronic diseases and health conditions. Studies have shown that genetic, epigenetic and environmental factors and their complex interactions contribute to obesity. This study aimed to identify genetic, epigenetic and dietary factors, and their interactions that contribute to overweight and obesity in order to develop precise prevention and treatment strategies. We conducted a combined genome-wide and epigenome-wide scan for main effects and up to three-way interactions among 422,793 single nucleotide polymorphisms (SNPs), 415,202 DNA methylation sites and 397 dietary and lifestyle factors using the Generalized Multifactor Dimensionality Reduction (GMDR) method in the training samples (n=1,573) of the Framingham Heart Study Offspring cohort Exam 8. Using identified genetic, epigenetic and dietary factors, we then applied machine learning (ML) algorithms to predict participantsâ obesity status in the testing samples (n=394). The quality of prediction models was evaluated using Area Under the Receiver Operating Characteristic Curve (ROC-AUC). The GMDR method identified 220 SNPs, 536 epigenetic markers and 50 dietary and lifestyle factors that were highly informative predictors predictive for obesity. Comparing several ML algorithms, we found that the stochastic gradient boosting model provided the best prediction accuracy for obesity in the training set, and overall accuracy of 71.8% and ROC-AUC of 0.70 in the test set samples. Top predictors of the best-fit model were 21 SNPs, 230 epigenetic markers in genes of *CPT1A*, *FSD2*, *ABCG1*, *SLC7A11*, *RNF145*, *SREBF1* and others and 26 dietary factors, including processed meat, diet soda, French fries, high fat dairy, calcium, flavonols, sugar, artificial sweeteners, and alcohol intake. In conclusion, our study has demonstrated a novel method by which integrating genomic, epigenomic gene-gene and gene-environment interactions and applying ML supports prediction of obesity status. This genome-wide approach improves our understanding of obesity by identifying dietary and lifestyle factors that interact with genotype and DNA methylation sites. Results such as these can inform personalized nutrition strategies for the prevention and treatment of obesity.

PrgmNr 3184 - Prioritizing disease genes by integrating GWAS and WES with gene-level functional and perturbation data

H. Chan Sch. of Publ. Hlth., Cambridge, MA, [11]Harvard Sch Pub Hlth, Boston, MA

Disclosure Block: **K.K. Kumar Dey:** None.

GWAS have identified thousands of disease-associated variants, but identifying genes and gene programs that impact disease remains challenging. Here, we propose a new method, PolyGene, that assigns a disease association score to each gene using a polygenic ensemble approach that integrates GWAS data for common variants (MAGMA: de Leeuw et al. 2015 PLoS Comp. Biol, PoPS: Weeks et al. 2020 medRxiv), WES data for rare variants when available (SAIGE-GENE: Zhou et al 2020 Nat. Genet), and gene interactions from protein-protein and co-expression networks.

We applied PolyGene to GWAS summary statistics for 28 diseases and traits (average N=270K) for which gold-standard gene sets were available based on approved drug targets, Mendelian genes and CRISPR screen result implicated genes. PolyGene attained higher excess overlap across these gold-standard gene sets than other gene scoring methods: 5.0x (P=8e-32) higher than MAGMA and 1.4x (P=4e-18) higher than PoPS. For a subset of 7 well-powered UK Biobank blood cell traits (average N=443K), incorporating rare-variant driven gene-based association statistics from WES data (PolyGene-S) produced a small but statistically significant further improvement (1.1x, P=1e-05).

We applied PolyGene to score genes in three gene programs (small gene sets defined using functional data). First, we analyzed post-stimulation perturbation programs for 24 genes in dendritic cells, derived from Perturb-seq data (Dixit et al. 2016 Cell). The perturbation programs for known inflammatory genes such as E2f1 and Nfkb1 attained the highest excess overlap with PolyGene scores across 9 autoimmune diseases (1.5x-2.5x, P=1e-04-4e-09). Second, we analyzed perturbation programs for 35 de novo autism risk variant genes in 5 brain cell types, derived from in-vivo Perturb-seq data (Jin et al. 2020 Science). The perturbation programs in astroglia and microglia attained the highest excess overlap with PolyGene scores for autism (mean of 2.4x, vs. mean of 1.2x in other cell types) with perturbation program for Cul3 gene in microglia demonstrating the highest excess overlaps (4.0x, P=3e-13). Third, we defined autism disease progression programs for 16 brain cell types based on genes that were specifically expressed in autism cases vs. controls in post-mortem brain snRNA-seq data (105K nuclei; Velmeshev et al 2019 Science). The disease progression programs in excitatory neurons and microglia attained the highest excess overlap with PolyGene scores for autism, consistent with perturbation program analysis.

In conclusion, PolyGene is a powerful approach for scoring genes and gene programs for association to disease to produce biological insights.

PrgmNr 3185 - Rare variant effect sizes are associated with variant pathogenicity

Efficient assessment of variant pathogenicity, a genetic susceptibility marker, is critical for research and clinical applications. We tested whether associations between rare variants and quantitative endophenotypes for three monogenic cardiometabolic diseases are proxies for variant pathogenicity. In the UK Biobank, we examined associations between rare coding variants in (1) familial hypercholesterolemia (FH) susceptibility genes and low-density lipoprotein cholesterol (LDL-C) levels (n=189,656 individuals), (2) long QT syndrome (LQTS) genes and electrocardiographic QTc intervals (n=33,521 individuals), and (3) maturity-onset diabetes of the young (MODY) genes and hemoglobin A1c (HbA1c) levels (n=189,744 individuals). We observed strong associations between rare variant effect sizes and pathogenicity assertions in ClinVar (p-values

PrgmNr 3186 - Reproducible analyses of petabytes of Heart Lung Blood and Sleep (HLBS) data in the cloud using NHLBI BioData Catalyst, the data analysis ecosystem for HLBS researchers

The rate of population health and biomedical data generation is accelerating rapidly. Cloud computing offers an effective way to store and analyze these data, but substantial investment is necessary to make cloud-based research portals broadly usable by the researcher community. Such systems require substantial infrastructure (scalable and secure environments), analysis resources (analysis environments, harmonized data) and training resources for data sharing, collaboration mechanisms, and new statistical methodologies. The National Heart Lung and Blood Institute (NHLBI) initiated the BioData Catalyst effort with a mission to develop and integrate advanced cyberinfrastructure while championing â□□findable, accessible, interoperable, and reusableâ□□ (FAIR) principles to accelerate HLBS research. Now, NHLBI BioData Catalyst provides access to a highly secure, scalable, reproducible, collaborative, and extensible cloud analysis ecosystem with controlled access to more than 3 Petabytes of HLBS data, including harmonized data from NHLBIâ□□s TOPMed Study, BioLINCC, and several NIH COVID-19 datasets. â□□Bring Your Own Dataâ□□ functionality enables users to securely upload and privately analyze datasets on the platform provided that such usage is allowed by their existing data use agreements and IRB policies. Researchers gain immediate access to interactive analysis environments such as R, Python, and SAS. Additionally, researchers can easily deploy their own docker-based tools or configure hundreds of pre-loaded, cost optimized tools and workflows from Dockstore encoded in Common Workflow Language (CWL) or Workflow Description Language (WDL). An open cohort builder allows researchers to quickly evaluate study feasibility and discover data that can accelerate their research. In this presentation, we will show new examples of research being performed on the NHLBI BioData Catalyst, demonstrate the utility of combining datasets to explore new hypotheses, and illustrate how the NHLBI BioData Catalyst, as a community-driven ecosystem, is democratizing data access and advancing HLBS science.

PrgmNr 3187 - Single-cell allele-specific expression analysis and comparison using mixture models

View session detail

Author Block: **G. Qi**[1], B. Strober[1], A. Battle[2]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Johns Hopkins Univ, Baltimore, MD
Disclosure Block: **G. Qi:** None.
Background. Allele specific expression (ASE), which quantifies the imbalance in gene expression between two parental copies, is a powerful tool to study cis-regulatory effects. In particular, differential ASE across conditions, e.g. experimental interventions, cell types, genotypes, or differentiation trajectories can reflect context-specific cis-regulatory effects. Recently, single-cell RNA sequencing (scRNA-seq) has allowed the measurement of ASE at the resolution of individual cells. However, previous statistical methods for identifying differential ASE were developed for bulk RNA-seq, and cannot be directly applied to scRNA-seq due to considerations including sparsity, repeated measurements from the same individual, and sequencing depth. **Methods.** We develop scASEmix, a mixture beta-binomial random-effects model for conducting differential ASE analysis from scRNA-seq data. The model uses a subject specific random effect to account for the correlation among cells from the same individual. In addition, the model conducts implicit phasing between the heterozygous exonic single-nucleotide polymorphism (SNP) and the causal regulatory SNP using latent variables. We estimate the parameters using Expectation-Maximization (EM) algorithm coupled with numerical integration. **Results.** scASEmix accurately captures differential ASE in a wide range of scenarios. We demonstrate through simulation that it has well-controlled type I error, and leads to large power improvements compared to standard beta-binomial models under weak linkage disequilibrium (LD) between the exonic and regulatory SNPs. We use scASEmix to analyze the single-cell ASE data from an endoderm differentiation experiment by Cuomo et al, which was designed to identify dynamic genetic effects on gene expression. We identify novel genes that show significant differential ASE along the differentiation trajectory. These genes have substantial overlaps with previously reported gene sets related to early differentiation. **Conclusions.** We propose a powerful method for differential ASE analysis using scRNA-seq data. The method can be applied to a wide range of scenarios to study context-specific cis-regulatory effects, ultimately illuminating regulatory effects that may underlie processes including cellular differentiation and disease.

PrgmNr 3188 - Sister haplotype association based on recombination disequilibrium

View session detail

Author Block: **H. Xu**; Augusta Univ., Augusta, GA
Disclosure Block: **H. Xu:** None.
Haplotype-based association analysis has several advantages over single-SNP association analysis. However, to date all associations between haplotypes and diseases have not excluded recombination interference among multiple SNP loci within haplotypes and hence some results might be confounded by recombination interference. We developed a new haplotype association method based on recombination disequilibrium (RD). Applying this method to a SNP haplotype dataset of 210 Alzheimer's disease (AD) cases and 159 nondemented elderly controls, we successfully found that some pairs of sister-haplotypes containing ApoE gene were associated with risk for AD under no RD but all those without ApoE-Îµ3 and ApoE-Îµ4 were not associated with risk for the disease and sister-haplotype pairs within genes IL-13 and COMT were not associated with risk for breast cancer. In addition, none of sister-haplotype pairs in IL-17A gene was detected to be associated with risk for coronary artery disease. All the previously reported associations of haplotypes within these genes with risk for these diseases might be due to strong RD and/or inappropriate haplotype pairs.

PrgmNr 3189 - SUMMIT: An integrative approach for better transcriptomic data imputation improves causal gene identification

View session detail

Author Block: **Z. Zhang**[1], J. R. Bradley[1], L. Wu[2], C. Wu[1]; [1]Dept. of Statistics, Florida State Univ., Tallahassee, FL, [2]Univ. of Hawaii Cancer Ctr., Honolulu, HI
Disclosure Block: **Z. Zhang:** None.
Transcriptome-wide association studies (TWASs), which integrate expression reference panels with genome-wide association study (GWAS) results to discover gene-trait associations, have deepened our understanding of genetic regulation in many complex traits. However, the number of analyzable genes and thus the power of TWAS is largely determined by the size of expression reference panels. One obvious but administratively onerous approach is to combine individual-level data from several consortia to increase the sample size. However, privacy concerns and sample consents often preclude access to individual-level genetic data, making a pooled individual-level expression panel unavailable. In this work, we introduce SUMMIT, a novel method that makes it possible to integrate a summary-level expression reference panel with a much larger sample size into GWAS to identify associated genes. In brief, we build gene expression prediction models in blood based on the summary data released by the eQTLGen consortium, which is to date the largest meta-analysis in 31,684 blood samples from 37 cohorts. Compared with benchmark methods, MR-JTI, TWAS-Fusion, PrediXcan, and UTMOST, SUMMIT built more gene expression prediction models (10,026 with R^2> 0.01) and achieved significantly higher prediction accuracy in different quantiles (p -9 by K-S test). To evaluate the performance of identifying significant associations, we applied SUMMIT to the summary statistics from 25 GWAS. Compared with benchmark methods, SUMMIT identified substantially more associations for each trait analyzed, showing 222% improvement compared with MR-JTI ($p=3.1*10^{-9}$ by the Wilcoxon rank test), 306% improvement compared with TWAS-fusion, 264% improvement compared with PrediXcan, and 211% improvement compared with UTMOST. Next, we compared different methods in terms of identifying the likely causal genes that mediate the associations between GWAS loci and the traits of interest by using a set of 1,424 likely causal gene-trait pairs curated by using the OMIM. We show that the SUMMIT yielded good sensitivity and specificity for identifying the silver standard genes and achieved the highest AUC (0.701) among all the methods compared (MR-JTI 0.6329; PrediXcan 0.6164; TWAS-fusion 0.6041; UTMOST 0.6213). More importantly, SUMMIT was applicable to analyze genes with smaller heritable expressions (0.005 2

PrgmNr 3192 - TIGAR-V2: Efficient TWAS Tool with Nonparametric Bayesian eQTL Weights of 49 Tissue Types from GTEx V8

View session detail

Author Block: **J. Yang**[1], R. Parrish[2], G. Gibson[3], M. P. Epstein[1]; [1]Emory Univ, Atlanta, GA, [2]Emory Univ., Decatur, GA, [3]Georgia Inst. of Technology, Atlanta, GA
Disclosure Block: **J. Yang:** None.
Standard Transcriptome-wide association study (TWAS) methods first train gene expression prediction models using reference transcriptomic data, and then test the association between the predicted genetically regulated gene expression (GReX) and phenotype of interest with these trained models and GWAS data. We previously developed a TWAS tool called **Transcriptome-Integrated Genetic Association Resource (TIGAR)** that can train gene expression imputation models using either nonparametric Bayesian Dirichlet Process Regression (DPR) or Elastic-Net penalized regression (as used by PrediXcan). TIGAR can perform TWAS using either individual-level or summary-level GWAS data. Besides the Burden type TWAS test, the software further implements an additional variance-component test for TWAS that retains power under model misspecification.
Most existing TWAS tools like PrediXcan often require an extra step of preparing genotype input files from the commonly used VCF format, and extra coding to enable parallel computation. To improve the efficiency of TWAS tools to train gene expression prediction models using oneâ□□s own reference transcriptomic data, we develop an improved version of the TIGAR tool (**TIGAR-V2**), which directly reads VCF files, enables parallel computation, and reduces up to 90% computation cost compared to the initial version. Using **TIGAR-V2**, we trained nonparametric Bayesian DPR gene expression prediction models for 49 tissues from the Genotype-Tissue Expression (GTEx) project V8 reference data.
We illustrated the usefulness of these DPR eQTL weights through TWAS of breast and ovarian cancer utilizing public GWAS summary statistics. Using DPR weights, we identified 88 and 37 risk genes respectively for breast and ovarian cancer, most of which are either known or near previously identified GWAS (~95%) or TWAS (~40%) risk genes of the corresponding phenotype. Moreover, three novel independent risk genes of breast cancer were identified with known functions in carcinogenesis, and two of these are shared by ovarian cancer. Using PrediXcan weights estimated by Elastic-Net, we identified only 56 and 4 risk genes respectively for breast and ovarian cancer (37.5% of these breast cancer risk genes and all ovarian risk genes were also identified by using DPR weights) and missed these three novel findings. These findings suggest that using DPR weights can provide additional insight into the transcriptional regulation of complex human traits.
Our **TIGAR-V2** TWAS tool with the trained nonparametric Bayesian DPR eQTL weights of 49 tissues from GTEX V8 will be freely available on Github, providing a useful resource for mapping risk genes of complex diseases.

PrgmNr 3194 - Trans-Ancestry Fine-Mapping using 3.4 Million Individuals from diverse ancestries elucidates the genetic architecture of tobacco and alcohol use and addiction

View session detail

Author Block: **X. Wang**, GWAS & Sequencing Consortium of Alcohol and Nicotine, Trans-Omics for Precision Medicine; Penn State Coll. of Med., Hershey, PA
Disclosure Block: **X. Wang:** None.
Tobacco and alcohol use are heritable traits and leading causes for many diseases. Recently, breakthrough in addiction genetics has been made through GWAS meta-analysis in large samples of European ancestry, yet, the genetic architecture in non-European ancestry remains under-studied. To address this, we have aggregated datasets from 60 cohorts with a total of 3.4 million individuals from diverse ancestries (2,669,029 European, 298,624 East Asian, 285,155 Latinx/Hispanic American, 121,858 African/African American). We fine-mapped 2,543 distinct genomic regions defined by LD structure around conditionally independent variants, the vast majority of which are novel discoveries. This dataset offers an unprecedented opportunity to advance our understanding on the genetic architecture for smoking and drinking behaviors in global populations. We propose an improved meta regression-based model for trans-ancestry genetic effect distributions. Specifically, we use the principal components (PCs) of genome-wide allele frequencies as proxies of continuously varying cohort-level ancestry. We model the genetic effect from each study as a mixture of models with different number of PCs, which can encompass different extent of heterogeneity for each variant. For example, model with 0 PC supports homogenous effects. As the 1st PC separates European and Asian ancestry, model with 1 PC can be interpreted as having heterogenous effects along the European-Asian cline. By imposing a Dirichlet-Multinomial prior, we borrow strength across variants, learn the genetic architecture and fine map causal variants. We perform simulations across different scenarios that assume variants have homogenous effects and/or ancestry-specific effects. We show that our method greatly improves fine mapping resolution and allows us to estimate the fractions of loci that show homogenous effects and ancestry-specific effects. We apply our method to the GSCAN study of 4 smoking phenotypes, i.e., age of initiation of smoking (AgeSmk), cigarettes per day (CigDay), smoking initiation (SmkInit) and smoking cessation (SmkCes), and 1 drinking phenotype, drinks per week (DrkWk). Among 2,543 identified significant loci with a median of 3,274 variants per locus, our proposed method fine-map 34.5% of them to less than 6 variants and 1.51 genes in 90% credible sets, a significant improvement over fine mapping using European ancestry only. Our new results and continued research will elucidate the genetic architecture in global ancestries.

PrgmNr 3195 - Using (Natural) Direct and Indirect Effects of Intermediate Risk Factors between Genotype and Disease to Inform Polygenic Risk Scores

Disclosure Block: **M. Vujkovic:** None.

In human genetics, there is increasing interest into the underlying mechanisms that explain the effect of genotype on outcome. Within the spectrum of cardiometabolic traits such as type 2 diabetes and cardiovascular disease, there are numerous intermediate risk factors between genotype and disease such as body weight, total cholesterol, LDL-C, glucose, HbA1c, blood pressure, smoking, and alcohol use. A substantial number of genetic variants have been found to be associated with multiple traits (e.g. pleiotropy), however it remains unclear whether they exert independent effects on multiple traits (e.g. horizontal pleiotropy) or possibly act in a mediated fashion (e.g. vertical pleiotropy). Our aims are twofold: first, to identify genetic variants exhibiting full or partial vertical pleiotropy through an intermediate risk factor by use of formal mediation analysis and decompose the total effect of genotype on disease into a (natural) direct and indirect effect. Second, to assess whether the replacement of total effect size in the conventional â□□sum-of-weighted-allelesâ□□ PRS model with direct and indirect effect weights ultimately improves disease prediction. As a proof of concept we test a single mediator model, with obesity as the mediator and type 2 diabetes as the outcome. We applied genome-wide mediation analysis by using the â□□product-of-coefficientsâ□□ regression method on summary statistics of BMI from GIANT+UKBB and T2D from DIAMANTE Consortium. In addition, we performed mediation analysis by means of the causal counterfactual framework with individual level data in 69,869 T2D cases and 127,197 controls in the Million Veteran Program restricted to a subset of 1,101 cardiometabolic trait-associated SNPs. As a result, the two methods showed remarkable concordance of quantifying vertical pleiotropy, and identified known loci that have strong mediating effects on type 2 diabetes through BMI, of which FTO, TCF7L2, IRS1, PPARG, JAZF1, and IGF2BP1 have been established previously. In particular, the TCF7L2 locus additionally exhibits interaction, meaning that within strata of BMI the size of the indirect effect on type 2 diabetes varies. Finally, a mediator-adjusted PRS outperformed the conventional PRS (e.g. sum of weighted alleles) method in predicting T2D (AUC 0.69 vs 0.64). To conclude, we show that a risk model that more precisely models the complex relationship between genotype and disease by including preceding risk factors as intermediates more accurately predicts T2D. It is anticipated that this methodology will take us one step closer towards utilizing genetic variants in clinical risk prediction models.

PrgmNr 3196 - Allele-specific expression of SNPs involved in the immune response and gene transcription is associated with BMI

View session detail

Author Block: **A. Keshawarz**[1], T. Huan[2], R. Joehanes[1], C. Yao[3], C-T. Liu[4], C. Demirkale[5], V. Ramachandran[6], L. A. Cupples[7], D. Levy[8]; [1]Natl. Heart, Lung, and Blood Inst., Framingham, MA, [2]Univ. of Massachusetts Med. Sch., Worcester, MA, [3]Framingham Heart Study, Framingham, MA, [4]Boston Univ. Disclosure Block: **A. Keshawarz:** None.
Background. Body mass index (BMI) is an estimate of general adiposity associated with numerous clinical outcomes, including subclinical and clinical cardiovascular and metabolic disease. Growing genome-wide association studies have identified hundreds of BMI-associated loci, but the transcriptomic signature of BMI is incompletely understood. The objective of this study was to quantify the association between allelic imbalance and BMI using allele-specific expression analysis in conjunction with GWAS of BMI. **Methods.** Whole genome sequencing and RNA sequencing data were collected from 720 Framingham Heart Study (FHS) Offspring participants (59% women, mean age 66Â±8 years) and 954 FHS Third Generation participants (52% women, mean age 46Â±9 years) as part of the Trans-Omics for Precision Medicine (TOPMed) program. Heterozygous SNPs (n=780,599) were evaluated for allele-specific expression, and the ratio of reference allele to total allele counts for SNPs was calculated. SNPs with significant allelic imbalance based on a Bonferroni-corrected p-value (0.05/780,599) in a binomial test were subsequently evaluated in multiple linear regression to test the association between the reference allele/total allele count ratio and BMI after adjustment for age, sex, and family structure. SNPs significantly associated with BMI at FDR cis-expression quantitative trait loci (eQTLs) to investigate other known functions and associations. **Results.** After adjustment for age, sex, and family structure, allelic imbalance in 139 SNPs was significantly associated with BMI. SNPs identified were annotated to genes that were enriched for cell activation and immune response pathways, and the top five most significant SNPs identified were annotated to *FLYWCH1, ZDHHC6, MYADM*, and *TCL1A*. Twenty-seven SNPs were in regulatory regions; of these, 18 were in promoter or promoter flanking regions. Seven SNPs identified in these analyses were associated with traits in the GWAS catalog, including BMI. Furthermore, these SNPs overlapped with 181 unique *cis*-eQTLs (pPLGLB2, HLA-J, TRIM31, DHDDS, AL671883.2, DPY19L1P2, AL022345.4). **Conclusion.** SNPs implicated in the immune response pathway and in gene regulation show significant allelic imbalance associated with BMI; thus, allele-specific expression may partially explain population-level variation in BMI.

PrgmNr 3197 - Causal gene-to-trait effect estimation for schizophrenia and bipolar disorder using MRLocus

View session detail

Author Block: **M. Love**, N. Matoba, J. L. Stein; UNC-Chapel Hill, Chapel Hill, NC
Disclosure Block: **M. Love:** None.
A number of integrative statistical methods, including TWAS, allow for gene-level aggregation of association signals from individual genetic variants, leveraging tissue-specific eQTL and GWAS study summary statistics. TWAS has successfully been applied to schizophrenia and bipolar disorder GWAS to identify candidate genes implicated in these disorders. However, genes identified as significant by TWAS may not reflect a causal relationship between gene expression and a downstream trait. We recently published a statistical method, MRLocus, that leverages allelic heterogeneity of eQTL signal for a candidate gene, to prioritize genes causally involved in trait variation. Consistent and proportionate effects across multiple eSNPs provides evidence beyond existing TWAS approaches that gene expression levels in a particular tissue mediate the heritability of the downstream trait, and allows for estimation of the gene-to-trait effect. MRLocus gave more accurate estimates of these effects as compared to other cis-MR approaches.
Here, we apply MRLocus to eQTL data from adult post-mortem brain from PsychENCODE (1,387 brain samples) and GWAS of schizophrenia (PardiÃ±as et al, 2018, PGC, 40,675 cases) and bipolar disorder (Stahl et al, 2019, PGC, 20,352 cases), in order to further prioritize genes implicated in previous TWAS-significant results (Gandal et al, 2018), and to associate those genes with causal effect sizes. We estimate MR slopes from eQTL effect sizes from standardized expression, and GWAS effect sizes from log odds ratios. We find 28 genes with significant gene-to-trait effects for schizophrenia, including large effect sizes (absolute value of MR slope > 0.3) for DCC, DCLK3, DDHD2, EMB, FAM109B, FTSJ2, GLYCTK, PAK6, and TPRKB (by 95% credible interval). An MR slope of 0.3 implies that modifying gene expression by one SD will increase disorder risk by ~1/3, well above the effect size expected of one individual SNP on disorder risk. We find 3 genes with significant and large gene-to-trait effect sizes for bipolar disorder: DCLK3, HAPLN4, and RP11-182J1.16 (95% CI), as well as large and marginal significant effects for SNAP91 and TTC39A (by 90% credible interval).
We find that MRLocusâ□□s estimation of the causal effect of eQTLs on risk for neuropsychiatric disorders provides useful information for prioritizing experiments to understand how perturbation of gene expression may mediate disorder risk. Gene-to-trait effect sizes are much larger than those of individual SNPs on disorder risk, suggesting that manipulation of gene expression may have substantial therapeutic influences despite the fact the individual GWAS variants have low effect sizes.

PrgmNr 3198 - Common and rare genetic risk for autism have opposing effects on cognition at autism-associated genes

View session detail

Author Block: **D. Weiner**[1], J. Grove[2], J. Fu[3], F. Satterstrom[1], H. Brand[3], iPSYCH Consortium, L. O'Connor[1], M. J. Daly[4], A. D. Borglum[5], M. E. Talkowski[4], E. Robinson[6]; [1]Broad Inst., Cambridge, MA, [2]Aarhus Univ., Aarhus C, Denmark, [3]Boston, MA, [4]Massachusetts Gen. Hosp., Boston, MA, [5]Aarhus Univ, Aarhus, Denmark, [6]

Disclosure Block: **D. Weiner:** None.

Multiple classes of genetic variation contribute risk to autism spectrum disorder (ASD), and integrating across these lines of evidence remains an important goal to clarify underlying ASD pathogenesis. Substantial ASD liability originates from common polygenic variation and rare *de novo* coding variation. Paradoxically, these two classes of genetic risk exert opposing effects on cognition in ASD: common polygenic variation is often associated with higher IQ, and rare variation is associated with decreased IQ. While gene set enrichment methods such as MAGMA and stratified LD-Score regression estimate that common variation is concentrated around genes implicated in ASD through rare variation, these approaches do not specify *how* this subset of common variation affects cognition. In other words, it is unclear whether the common variant enrichment at ASD-associated genes is increasing or decreasing IQ, a critical question for understanding the convergence of common and rare genetic risk in ASD.

To answer this question, we adapted a genome-wide common variant association approach, the polygenic Transmission Disequilibrium Test (pTDT), to estimate parent-to-child transmission of polygenic risk scores made from small regions of the genome (Stratified-pTDT, or S-pTDT). By constructing a polygenic score from SNPs within ASD-associated genes, we are able to test whether ASD cases over-inherit IQ-increasing alleles from this small region of the genome. We first identified an updated set of 255 genes implicated in ASD through exome sequencing. We then defined a stratified polygenic score from all SNPs within the boundaries of these genes (+/- 10kb) from a recent GWAS of educational attainment (EA, which we use as a genetic proxy for cognition given their high genetic correlation and the significantly larger sample size of the educational attainment GWAS). We then applied S-pTDT in two independent cohorts of ASD trios: SFARI (Simons Simplex Collection and SPARK, 5,048 trios) and the Psychiatric Genomics Consortium (4,334 trios).

We estimate that ASD cases over-inherit stratified polygenic liability for EA at ASD-associated genes in both cohorts ($P = 0.02$ in SFARI, $P = 0.007$ in PGC). Restated, ASD cases on average inherit IQ increasing alleles at genes associated with ASD through IQ-decreasing loss-of-function variation. This analysis suggests that the convergence of common variation and rare variation at these ASD-associated genes confers ASD liability through at least partially distinct mechanisms. Our analysis also introduces S-pTDT, a novel statistical approach for associating a subset of polygenic risk with any phenotype of interest in family data.

PrgmNr 3199 - Comparing Gene Expression Across Paired Human Airway Models for Cystic Fibrosis Precision Medicine

Disclosure Block: **G. He:** None.
Cystic fibrosis (CF) is caused by loss-of-function variants in the *CF transmembrane conductance regulator (CFTR)*, with modifier genes impacting lung disease severity and therapeutic efficacy. Cultured human nasal epithelia (HNE) are becoming an important surrogate airway model for the gold standard cultured human bronchial epithelia (HBE) to assess the efficacy of CF therapies, because HNE are more easily accessible from patients. However, it remains unknown whether the HNE and HBE genome-wide transcriptome are similar, which we investigate here. RNA-sequencing of paired HNE and HBE samples, cultured and fresh (n=71), that were collected from 21 individuals with CF was carried out. We implemented an equivalence testing procedure based on the two one-sided t-test (TOST) to assess the statistical evidence for similarity in transcriptome between HNE and HBE. A comparison of cultured and fresh airway tissues showed that the culturing process had little impact on the expression level of CF lung disease modifier genes identified in genome-wide association studies (FDR

PrgmNr 3200 - Current methods integrating variant functional annotation scores have limited capacity to improve the power of genome-wide association studies

Disclosure Block: **J. Gao:** None.

Functional annotations have the potential to increase the power of genome-wide association studies (GWAS) by prioritizing variants according to their biological function. Focusing on convenient variant-specific meta-functional scores including CADD (Kircher et al. 2014) and Eigen (Ionita-laza et al., 2016), we broadly examined GWAS summary statistics of 1,132 traits from the UK Biobank (Sudlow et al., 2015) using the weighted p-value approach (Genovese et al., 2006) and stratified false discovery control (sFDR) method (Sun et al., 2006). These 1,132 traits were rated by Benjamin Nealeâ□□s lab from the Broad Institute as having medium to high confidence for their heritability estimates. Averaged across the 1,132 traits, sFDR was more robust to uninformative meta-scores, but the weighted p-value method identified slightly more variants using CADD (or Eigen). We also considered the recent FINDOR method (Kichaev et al., 2019), which leverages a set of 75 individual functional annotations into GWAS. An earlier application of FINDOR to 27 selected traits from the z7 category defined by Nealeâ□□s lab (SNP-heritability testing p-values

PrgmNr 3201 - Determining disease co-occurrence architecture of Hypertensive Heart Disease in Penn Medicine Biobank using longitudinal EHR data linked with PMBB participants

Disclosure Block: **P. Singhal:** None.

An estimated 1.2 billion individuals worldwide suffer from hypertension. Hypertensive heart disease (HHD) refers to structural alterations, such as left ventricular hypertrophy (or left atrial enlargement) in the heart due to prolonged hypertension and can lead to ischemic heart disease, heart failure (HF), and arrhythmias. HHD represents a transitory subclinical condition between the onset of hypertension and overt cardiovascular disease, typically remaining asymptomatic until the time of the adverse cardiac event. This leads to under-diagnosing of HHD and limits the window of clinical intervention to prevent adverse cardiac outcomes. Moreover, the risk of HHD-related diseases, such as HF, is heightened due to hypertension-associated comorbidities such as diabetes, dyslipidemia, and renal failure. The complex etiology underlying HHD phenotypes is poorly understood and thus it is challenging to predict outcomes in patients. The goal of this study is to leverage longitudinal electronic health record (EHR) data to identify the conditions and comorbidities that influence HHD adverse outcomes for prognostication. We defined an HHD patient cohort (n = 4,268) in the Penn Medicine BioBank dataset using diagnoses codes for HHD (ICD-10: I11*). We constructed a disease-disease map of HHD comorbidities using the Ising model, a type of Markov Random Field undirected probabilistic graphical model. We estimated the co-occurrence of disease pairs by calculating pairwise similarities between diseases as relative risk and conducting network analyses. Our results reflect clusters of both known disease-disease connections, including interactions between circulatory, endocrine, and nervous system diseases, as well as novel pairwise disease interactions between genitourinary, digestive, and musculoskeletal diseases. Our findings shed light on the effect of comorbid conditions on the trajectory of HHD adverse outcomes. Using the probabilistic model of disease co-occurrence from these results, we can identify key comorbidities that predict adverse outcomes among HHD patients, allowing for timely clinical intervention. This work lays the foundation to integrate rare and common genetic variants into the Ising model using a gene-based binning approach. Specifically, incorporating rare loss-of-function variants will enable us to evaluate shared genetic connections between HHD comorbidities. In conclusion, we used EHR data to identify the genetic and non-genetic connections between the comorbidities of HHD to develop a predictive metric for the prevention and clinical monitoring of HHD.

PrgmNr 3202 - Genome-wide association study and heritability of Gulf War illness

Hauser[7,2]; [1]Duke Univ., Durham, NC, [2]U.S. Dept. of VA, Durham, NC, [3]Duke Univ, Durham, NC, [4]U.S. Dept. of VA, Little Rock, AR, [5]VA/HMS, Lexington, MA, [6]U.S. Dept. of VA, Boston, MA, [7]Duke Univ Med Ctr, Durham, NC
Disclosure Block: **J. Vahey:** None.
BackgroundThe Gulf War Era Cohort and Biorepository (GWECB) consists of DNA and survey data from individuals who served in the United States Armed Forces in 1990-1991. Many Veterans who were deployed to the Persian Gulf during this era report pervasive chronic symptoms; the constellation of these symptoms has been defined as Gulf War illness (GWI). There are two main research definitions of GWI: the Kansas and CDC definitions, both of which have variants, for a total of four research case definitions. The etiology of GWI is unknown, although there is evidence that some military exposures are risk factors for GWI. There are no biomarkers for GWI and treatments are very limited. Prior genetic studies of GWI have been limited in scope and heritability of GWI is unknown. **Methods**Self-reported symptoms and health conditions captured by the GWECB survey determined GWI case status (CDC, CDC severe, Kansas, Kansas Symptom Criteria, and Kansas exclusionary criteria). Genotyping was performed using the Illumina Omni2.5-8v1.4 microarray. Plink 1.9 was used for genetic quality control and association analysis. Age, sex, and two genetic principal components, accounting for 79% of genetic variability, were used as covariates for the association analysis. Heritability was calculated using GCTA v1.93.2 using the reml command on autosomes only, with covariates age, sex, and genetic principal components 1-10. **Results**The sample size was 1260 after quality control. The four case definitions examined were CDC GWI (82.6% prevalence in GWECB), CDC Severe GWI (21.7%), Kansas GWI (34.6%), and Kansas Symptom Criteria (68.0%). GWAS for all four of these case definitions were completed, with no results that show genome-wide significance. Of these four definitions, CDC Severe GWI was the most heritable, showing 63% heritability in the adjusted model. CDC GWI and Kansas GWI Symptom Criteria showed heritability close to zero, while Kansas GWI was 4%. **Conclusions**We have completed the first genome-wide genetic analysis and heritability calculation for GWI. Estimating heritability demonstrates that while there are several commonly accepted research definitions of GWI, the case definition used has a big impact on estimates of heritability and thus on gene discovery in GWI. The heritability calculations indicate that CDC Severe GWI is heritable and is a good candidate for future genetic work. The GWAS and heritability results indicate a need for a larger sample size for future genetic analyses, which is available through the Million Veteran Program.

PrgmNr 3203 - Genome-wide study on longitudinal MRI outcomes in 3,513 multiple sclerosis cases across six clinical trials highlights a potential role for MS susceptibility loci in progressive biology

View session detail

Author Block: **N. Sadhu**[1], S. J. Loomis[1], E. Fisher[1], A. Gafson[1], E. Hughes[1], A. Herman[2], R. A. Rudick[3], S. John[1], X. Jia[2], T. R. Bhangale[2], P. G. Bronson[1]; [1]Biogen, Cambridge, MA, [2]Genentech, South San Francisco, CA, [3]Optimal Brain Hlth.Consultants, Jupiter, FL
Disclosure Block: **N. Sadhu:** None.
Introduction: Multiple sclerosis (MS) is an immune-mediated disorder of the CNS characterized by relapse biology, insidious progressive injury, and highly variable outcomes. While the genetics of MS risk is well characterized, the genetics of progression is not well understood and could inform patient stratification and drug discovery. Here, we investigate the genetics of quantitative, longitudinal brain MRI outcomes: a) brain volume change (BVC), a measure of progressive tissue loss; and b) T2 lesion volume change (T2LVC), a measure of inflammatory lesion accumulation.
Methods: We performed genome-wide association studies (GWAS) of BVC (N=2,861) and T2LVC (N=3,513) across 6 randomized controlled trials (RCTs) (mean age 40 years; 63% female). Four RCTs included relapsing MS: DECIDE, OPERA I & II, and ADVANCE (T2LVC only). Two RCTs included progressive MS (PMS): ASCEND (secondary PMS), ORATORIO (primary PMS). ASCEND, ADVANCE, DECIDE were genotyped (Thermo Fisher Axiom array) and imputed. ORATORIO, OPERA I & II were whole genome sequenced (Illumina HiSeq). BVC was annualized percent change in whole BV from 6 months to last time point (min 1.4 years). T2LVC was annualized change in total T2LV from first to last time point (min 1.6 years). Mean duration in study was 1.8 years. Analyses were adjusted for age, sex, ancestry, and treatment arms. Summary statistics from each RCT were pooled for meta-analysis, gene-based tests, and comparison with MS risk loci (IMSGC 2019).
Results: Out of 197 MS risk loci, 41 and 54 non-MHC, autosomal, significant SNPs met our inclusion criteria for BVC and T2LVC meta-analyses (4+ RCTs, heterogeneity I^2MERTK (rs57116599, $p=3.6x10^{-3}$), and *TBX6* (rs3809627, $p=3.3x10^{-3}$). Gene-based tests supported association of *TBX6* with BVC ($p=3.1x10^{-4}$) in this region. Genome-wide analysis of T2LVC revealed a novel association in the regulatory region of *NEDD4L* (rs11398377-GC/G, $p=9.3x10^{-8}$), which showed a corresponding gene-based peak ($p=1.5x10^{-5}$).
Discussion: This study represents the largest RCT-based GWAS of longitudinal MS brain MRI outcomes to date. Our results suggest that *MERTK* and *TBX6* may play a role in progressive brain tissue loss. Genome-wide analysis of MS lesion accumulation also identified ubiquitin ligase *NEDD4L*, a regulator of ion channels involved in excitatory synaptic transmission, highlighting a potential link between immune and neurological pathways. Replication in an independent cohort is needed. Nonetheless, these results contribute to a better understanding of genetic factors affecting progression and inflammatory activity in MS.

PrgmNr 3204 - High quality phased whole genome sequence across patient cohorts is achievable and informs genetic understanding of complex traits

Epidemiological studies that rely on genotyping arrays and short read whole genome sequencing fail to capture the complete diploid nature of the human genome as they provide little to no information regarding the phase relationships of heterozygous allele pairs. Disregard for the *cis*/*trans* relationship between heterozygous variants misses key data that informs phenotype-genotype relationships. One of the most well-known examples comes from compound heterozygosity in monogenic disorders such as Cystic Fibrosis (CF).

Modern sequencing approaches enable phasing from a single individual by using reads that simultaneously inform multiple heterozygous sites to establish the phase relationship between alleles. Long-read sequencing technologies such as PacBio SMRT sequencing and Oxford Nanopore produce reads that span multiple heterozygous variants. Technologies such as 10x Genomics linked-read technology (10XG) use a standard short-read sequencing pipeline with an additional experimental step that introduces long-range information into the read data. We used Genome in a Bottle (GIAB) data to benchmark the phasing capabilities of PacBio, Nanopore and 10XG against the NA12878 Platinum Genome phase calls. 10XG demonstrated the lowest error rate (0.037%) and long phase blocks (N50=4.19 Mb) in addition to being cost-effective on the scale of a cohort study. We also generated a high-quality composite phase call set for the public reference individual HG002 by combining six different technologies made available by GIAB; 99.996% of heterozygous variants in the high-confidence GIAB VCF were phased in 81 blocks with a phase block N50 of 90.3 Mb.

We sequenced 358 individuals from the Canadian CF Gene Modifier Study cohort using 10XG and observed an average phase block N50 of 4.5 Mb and >98% of all genes shorter than 100kb were phased in a single block. The 10XG data was used to study a GWAS-suggestive locus within chr7q35 known to influence meconium ileus risk in CF. The ~66kb region is complicated by a common 20kb deletion polymorphism and contains repeated homologous genes: *PRSS1*, *PRSS2* and three pseudogenes. We used the 10XG reads to call and phase variation against alternative contig KI270803.1, which includes the 20kb of sequence that is absent from the HG38 chr7 main chromosome. We found that the deletion polymorphism was significantly associated with meconium ileus risk and that it was also a significant *PRSS2* eQTL. The colocalization of these two signals suggests a link between meconium ileus and expression of *PRSS2*. 10XG data enabled complete characterization of this complex region and was critical in generating novel insights into this locus.

Background: Genome-wide association analyses have identified numerous body mass index (BMI) related loci. However, most underlying mechanisms from SNP to BMI remain unknown. Leveraging OMICs data through integrative analyses could potentially provide more comprehensive views of biological pathways.

Methods: We performed a correlated meta-analysis using BMI data, genotype data and array-based transcript expression level data from fasting peripheral whole blood samples in up to 5,619 samples of Framingham Heart Study (FHS). We started with 3,992 SNPs that are in LD (r^2 >0.8) with 97 previously reported BMI variants (P-8) and focused our analyses on 20,692 transcripts with a start position within 1 Mb. We performed separate association analyses of transcript with BMI and transcript with SNP, yielding respective association p-values P_BMI and P_SNP. Then we aggregated these two association results by conducting a correlated meta-analysis that corrects the traditional meta-analysis for the inflation of type-I error when encountering correlation, leading to a meta-analyzed p-value (P_meta). We screened the results to identify transcripts that meet five criteria: P_meta-6, P_BMI-6, and at least nominal association between BMI and SNP (P_BMI-SNPResults: We found 172 SNP-transcript-BMI associations. Among these 172 associations, we identified four unique genes (*NT5C2*, *YPEL3*, *ZNF646*, and *C9orf5*) that were potentially involved in transcriptional pathways from SNP to BMI, where *YPEL3* and *ZNF646* were in the same region (16p11.2). 115 variants were involved in the SNP-transcript-BMI associations for *NT5C2*, including the reported BMI variant rs11191560. *NT5C2* encodes a hydrolase that participates in cellular purine metabolism. The other 56 SNP-transcript-BMI associations for *YPEL3* or *ZNF646* included two reported BMI variants rs4787491 and rs9925964. Our previous experimental data from Drosophila melanogaster knockdown studies support *YPEL3* as the functional gene influencing BMI. At the *C9orf5* locus, we have pinpointed the SNP-transcript-BMI association to the specific reported BMI variant rs6477694.

Summary: By performing a correlated meta-analysis using BMI, genotype and transcript expression level data from FHS, we found four genes (*NT5C2*, *YPEL3*, *ZNF646*, and *C9orf5*) located in three separate regions that may play important roles in transcriptional pathways from SNP to BMI. Further investigation with colocalization analysis and validation in various tissues (adiposity, liver and brain) are underway to better understand the underlying biological processes.

PrgmNr 3206 - Major sex differences in allele frequency for X-chromosome variants in the 1000 Genomes phase 3 data

View session detail

Author Block: **A. D. Paterson**[1], Z. Wang[2], L. Sun[3]; [1]Hosp for Sick Children, Toronto, ON, Canada, [2]Fudan Univ., Shanghai, China, [3]Univ. of Toronto, Toronto, ON, Canada
Disclosure Block: **A.D. Paterson:** None.
We identified an unexpectedly high proportion of SNPs on the X-chromosome in the 1000 Genomes phase 3 dataset that have significant sex differences in allele frequencies (SDAF). This SDAF persists for some SNPs in the recently released 1000 Genomes high coverage whole genome sequence, and it is consistent between the five superpopulations. Our primary analysis focused on biallelic SNPs in the 1000 Genomes phase 3 dataset that did not overlap with indels and with global MAF â¥5%. We analysed 222,872 SNPs from the non-pseudo-autosomal region (NPR), 13,244 from the pseudo-autosomal region 1 (PAR1), 634 from PAR2, and 9,075 from the controversial PAR3. We obtained p values from testing for SDAF and to be conservative used p

PrgmNr 3207 - Maternal and parent-of-origin gene-environment effects on the etiology of orofacial clefting

View session detail

Author Block: **N. Rasevic**[1], M. Rubini[2], K. Burkett[1], P. A. Mossey[3], B. Peterlin[4], M. F. J. Khan[2], A. Ravaei[2], L. Autelitano[5], M. C. Meazzini[5], J. Little[1], M-H. Roy-Gagnon[1]; [1]Univ. of Ottawa, Ottawa, ON, Canada, [2]Univ. of Ferrara, Ferrara, Italy, [3]Univ. of Dundee, Dundee, United Kingdom, [4]Univ. of Ljubljana, Ljubljana, Slovenia, [5]Univ. of Milan, Milan, Italy
Disclosure Block: **N. Rasevic:** None.
Objective: Our goal was to investigate maternal and parent-of-origin gene-environment interaction effects on the risk of orofacial clefts for candidate SNPs.
Methods: Genome-wide SNP genotypes were obtained for case-parent triads from the EUROCRAN and ITALCLEFT studies. Candidate SNPs were selected from a previous genome-wide association study, along with surrounding SNPs, resulting in a total of 2142 SNPs. Non-genotyped SNPs were imputed. A total of 411 case-parent triads and 25 case-parent dyads were analyzed using log-linear models to test for maternal and parent-of-origin effects, and their interaction with maternal smoking and maternal use of supplements containing folic acid. False discovery rate adjusted q-values were calculated.
Results: An association was detected for a region in the *ATXN3* gene as it pertains to the interaction between maternal periconceptional smoking and maternal genetic effects (minimum q-value in region = 0.025). Some regions displayed nominally significant associations in the interaction between maternal use of folic acid supplements and parent-of-origin genetic effects, specifically those located in the *CSMD1*, *KCNK10* and *SYT17* gene loci.
Conclusion: Investigation of interactions between environmental exposures and maternal genetic and parent-of-origin genetic effects has detected the potential involvement of regions in the *ATXN3*, *CSMD1*, *KCNK10* and *SYT17* genes. A mutation of the *ATXN3* gene has been involved in a neurological disorder, and the latter three genes have high mRNA expression levels in the brain, which suggest that further investigation of the link between orofacial clefts and brain development would be warranted.

PrgmNr 3208 - Mining biopsychosocial attributes in major depressive disorder by a multi-modal latent topic model

View session detail

Author Block: **M. Wang**[1], X. Meng[1,2], Y. Li[1]; [1]McGill Univ., Montreal, QC, Canada, [2]Douglas Res. Ctr., Montreal, QC, Canada
Disclosure Block: **M. Wang:** None.
Aims: Major depressive disorder (MDD) has been widely accepted as a serious public health issue that negatively impacts an individualâ□□s quality of life and significantly contributes to the global burden of disease. The literature has accumulated ample evidence for MDDâ□□s clinical heterogeneity, which limits the ability to accurately diagnose and treat it. Also, the clinical heterogeneity issue is closely related to the complex interactions between genetic and psychosocial environmental factors. Different genetic architectures across different populations increase the difficulty of articulating how genetic and psychosocial factors are combined to predict the risk of MDD. In the present study, we aim to identify meaningful MDD topics fully considering both genetic and psychosocial factors by using a latent topic model. ***Methods***: Data analyzed are from a longitudinal community-based cohort from Southwest Montreal - Zone dâ□□Ã□pidÃ©miologie Psychiatrique du Sud-Ouest de MontrÃ©al (ZEPSOM) study. The sample size included in this present study was 1083 Caucasians. The ZEPSOM study was designed to capture information on mental health outcomes and their relevant psychological and social attributes. We adopted a multi-modal latent topic model (MixEHR) to explore meaningful combinations of psychosocial data across diverse data structures and different data sources. MixEHR is a multi-view Bayesian topic model that projects each individualâ□□s clinical heterogeneity considering his/her high-dimensional psychosocial data. We then used the identified MDD meta-phenotypes to explore potential genetic variants that were statistically associated with MDD meta-phenotypes. ***Results***: We found that MDD meta-phenotypes based on psychosocial attributes demonstrated superior prediction accuracy compared to the raw psychosocial attributes. We discovered new genetic variants that were not able to be identified by the binary clinical MDD diagnosis. The SNP heritability of lifetime MDD meta-phenotypes was 0.167 (SE=0.305), compared to 0.000001 (SE=0.297) for binary lifetime MDD defined by the structured questionnaire. ***Conclusions***: The present study firstly applied the multi-modal topic model (MixEHR) to infer/identify latent clinical subpopulations/clinical heterogeneity of MDD and discover meaningful genetic and psychosocial attributes that are closely related to its clinical manifestations and etiology. The findings of the present study direct the personalized medicine by providing marginal risk for an individual with those identified biopsychosocial attributes of MDD.

PrgmNr 3209 - Patterns of consanguinity and associations between autozygosity and clinical phenotypes in British South Asians

View session detail

Disclosure Block: **D. Malawsky:** None.
Consanguinity results in high levels of autozygosity, which have been shown to associate with clinically-relevant phenotypes (Clark et al., 2019) as well as rare recessive disorders. We investigated consanguinity patterns and associations between autozygosity and common diseases in >30,000 British Pakistani and Bangladeshi people from two cohorts: Born in Bradford and Genes & Health (G&H). We developed an algorithm that infers an individualâ□□s degree of consanguinity based on their distribution of runs of homozygosity (ROHs). 58% of Pakistanis and 18% of Bangladeshis were inferred to be offspring of second cousins or closer. Consanguinity is less common in younger than in older British Bangladeshi people ($p=4x10^{-6}$), but the opposite is true for British Pakistani people ($p=1x10^{-5}$), suggesting changing marriage practices across time. Amongst British Pakistani people in Bradford, we observe that different kinship networks (biraderis) have differential consanguinity practices. In some groups nearly all individuals are inferred to have related parents, while in others it is 67%. Using electronic health records from G&H, we tested associations between ICD-10 codes and the fraction of the genome in ROHs (F_{ROH}), controlling for population structure and social confounders. Importantly, we included parental relatedness inferred by our method (a proxy for consanguinity-related social factors) as a covariate. We permuted individuals with high identity-by-descent values to control for the effects of fine-scale population structure. After multiple testing correction, we find that F_{ROH} is significantly associated with overall health, as measured by the number of subchapters of the ICD-10 tree with at least one code in an individual (relative risk=1.15 for F_{ROH} equivalent to first-cousin offspring; p=0.0002). Higher F_{ROH} also positively correlated with disorders of the respiratory (RR=1.37; p=0.0004), digestive (RR=1.27; p=0.0009), and endocrine (RR=1.20; p=0.0005) systems. These findings were replicated in UK Biobank with p-9) and a ROH at 3p21.31 associated with chronic rheumatic heart disease (OR=1.21; $p=5.37x10^{-8}$). Overall, we demonstrate multiple novel associations between autozygosity and disease phenotypes, while better controlling for social confounders and fine-scale population structure than previous studies.

PrgmNr 3210 - Prioritizing risk factors of heart failure from UK Biobank using explainable artificial intelligence

Understanding and predicting diseases using genetic variation, phenotypic traits, or environmental factors is one of the ultimate goals in human genetic studies. With the recent advancement in machine learning techniques and the availability of large-scale genotype-phenotype databases, sophisticated machine learning methods have become widely adopted by the scientific community for predicting diseases. Many of these techniques offer more flexibility in terms of model assumption compared to traditional statistical methods and the ability to utilize a large amount of data as they have been developed to handle a larger amount of data in other scientific domains. However, the lack of interpretability and explainability of these models faces challenges in detecting errors and building trust.
We demonstrate the use case of explainable artificial intelligence in predicting heart failure, one of the global major causes of death. We experimented with the state-of-art black-box modeling tools such as LightGBM and XGBoost and estimated the contribution of each predictive feature using SHAP. In addition, we also used a recently developed glass-box machine learning model, Explainable Boosting Machine, which directly measures the impact of each predictor and their interactions instead of indirect inference. We found that the ranking of the most contributing risk factors changes with model type, data filtering, and missing value imputation approaches. Nonetheless, at least half of the models reported the higher heart failure rate in males, old age, sedentary lifestyle, and high BMI, which were previously reported in the literature, among the top five risk factors.

PrgmNr 3211 - Stability of polygenic scores across discovery genome-wide association studies

View session detail

Author Block: **L. M. Schultz**[1], A. Merikangas[1,2], K. Ruparel[2], S. Jacquemont[3], D. C. Glahn[4,5], R. E. Gur[2,1], R. Barzilay[2,1], L. Almasy[1,2]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Univ. of Pennsylvania, Philadelphia, PA, [3]CHU Sainte justine Res. Ctr., Montreal, QC, Canada, [4]Boston Children's Hosp., Boston, MA, [5]Harvard Med. Sch., Boston, MA

Disclosure Block: **L.M. Schultz:** None.

Polygenic scores (PGS) are commonly evaluated in terms of their predictive accuracy at the population level by the proportion of phenotypic variance they explain. To be useful for precision medicine applications, they also need to be evaluated at the individual patient level when phenotypes are not necessarily already known. Most genomic research has focused on European ancestry individuals, so it is also important to examine the behavior of PGS in other ancestry groups. Hence, we investigated the stability of PGS by using PRS-CS to compute PGS separately for both European (EUR)- and African (AFR)-ancestry individuals in the Philadelphia Neurodevelopmental Cohort (PNC) and the Adolescent Brain Cognitive Development (ABCD) cohort from multiple EUR- and AFR-ancestry discovery meta-GWAS for post-traumatic stress disorder (PTSD), type-2 diabetes (T2D), and height. We then compared PGS in the same individual from one discovery GWAS to another. For the EUR-ancestry discovery GWAS, all pairs of GWAS for the same trait had genetic correlations > 0.92, and SNP-chip heritability on the observed scale ranged from 0.017 Â± 0.003 (PTSD) to 0.697 Â± 0.067 (height). PGS stability was higher for GWAS that explained more of the trait variance, with height PGS being more stable across discovery GWAS than PTSD or T2D PGS. The correlations between PGS computed from two same-ancestry GWAS were lower than anticipated given the strong genetic correlations, ranging from r = 0.378 for PTSD PGS for the ABCD EUR-ancestry cohort to r = 0.736 for height PGS for the PNC EUR-ancestry cohort. Correlations between PGS computed using two different-ancestry GWAS ranged from r = 0.000867 for PTSD PGS for the EUR-ancestry ABCD cohort to r = 0.404 for height PGS for the EUR-ancestry ABCD cohort. Focusing on the upper end of the PGS distribution, different discovery GWAS did not consistently identify the same individuals in the upper quantiles, with the best case being 60% of individuals above the 80th percentile of PGS overlapping from one EUR height GWAS to another and a worst case of fewer than 5% of the same individuals identified as being above the 95th percentile of PGS calculated using different-ancestry GWAS for T2D or PTSD. The degree of overlap decreases sharply as higher quantiles, less heritable traits, and cross-ancestry GWAS are considered. PGS computed from different discovery GWAS have only modest correlation at the level of the individual patient, underscoring the need to proceed cautiously with integrating PGS into precision medicine applications.

PrgmNr 3212 - Systematic Comparisons for Composition Profiles Taxonomic Levels and Machine Learning Methods for Microbiome based Disease Prediction

View session detail

Author Block: **K. Song**[1], Y-H. Zhou[2], F. A. Wright[3]; [1]North Carolina State Univeristy, Raleigh, NC, [2]Cary, NC, [3]North Carolina State Univ, Raleigh, NC
Disclosure Block: **K. Song:** None.
Microbiome composition profiles generated from 16S rRNA sequencing have been extensively studied for their usefulness in phenotype trait prediction, including for complex diseases such as diabetes and obesity. These microbiome compositions have typically been quantified in the form of Operational Taxonomic Unit (OTU) count matrices. However, alternate approaches such as Amplicon Sequence Variants (ASV) have been used, as well as the direct use of k-mer sequence counts. The overall effect of these different types of predictors when used in concert with various machine learning methods has been difficult to assess, due to varied combinations described in the literature. Here we provide an in-depth investigation of more than 1,000 combinations of these three clustering/counting methods, in combination with varied choices for normalization and filtering, grouping at various taxonomic levels, and the use of more than ten commonly used machine learning methods for phenotype prediction. The use of short k-mers, which have computational advantages and conceptual simplicity, is shown to be effective as a source for microbiome-based prediction. Among machine-learning approaches, tree-based methods show consistent, though modest, advantages in prediction accuracy. We describe the various advantages and disadvantages of combinations in analysis approaches, and provide general observations to serve as a useful guide for future trait-prediction explorations using microbiome data.

PrgmNr 3213 - Two large-scale genome sequencing studies show a consistent association between mitochondrial DNA copy number and personality traits

View session detail

Author Block: **R. Oppong**[1], Y. Qian[1], T. Tanaka[1], A. Z. Moore[1], A. Terracciano[2], F. Cucca[3], M. Picard[4], D. Schlessinger[1], L. Ferrucci[1], J. Ding[1]; [1]Natl. Inst. on Aging, Baltimore, MD, [2]Dept. of Geriatrics, Florida State Univ., Tallahassee, FL, [3]IRGB CNR, monserrato, Italy, [4]Dept. of Neurology, Columbia Univ., New York, NY

Disclosure Block: **R. Oppong:** None.

Levels of mitochondrial DNA copy number (mtDNAcn) in tissues and blood can be altered in conditions of stress and illness such as diabetes, major depression, and peripheral artery disease, suggesting that additional synthesis of mtDNA can occur completely separate from mitochondrial biogenesis. And in the situation of stress, mtDNA can be released from mitochondria into cells and eventually spill into the circulation, indicating that mtDNAcn in the blood may correlate with mtDNA released under stress. Since specific personality traits make individuals more or less susceptible to environmental stress and thus prone to developing pathology and premature death, we hypothesize that mtDNAcn is a biomarker of stress burden and could mediate the association between personality and excess mortality. To test this hypothesis, we studied the relationship between personality (assessed by the *big five* personality domains and facets of the Revised NEO Personality Inventory), levels of mtDNAcn estimated by whole genome sequencing, and mortality in participants of the Baltimore Longitudinal Study of Aging (BLSA; 800 ids with complete data, mean age 75 ranging from 48 to 100, 48% women). Replication of results was sought in the SardiNIA Project (SardiNIA; 600 ids with complete data, mean age 57 ranging from 15 to 96, 62% women). Our results show that mtDNAcn is negatively associated with the Neuroticism domain and positively associated with the Extraversion domain and facets within Agreeableness and Conscientiousness domains. We demonstrate the robustness of these associations by showing that the direction and size of the effects are robust to adjustment for potential confounders such as age, sex, platelet count, and white blood cell parameters. In accordance with results from the literature, we show that participants with depressive symptoms, assessed using the Center for Epidemiologic Studies Depression Scale (CES-D), had lower mtDNAcn than those with no depressive symptoms. Finally, we report an effect of personality on mortality and demonstrate that this effect is fully mediated via mtDNAcn. These results confirm our hypothesis that mtDNAcn is a biomarker in the biological pathway that connects certain personality characteristics with mortality. To our knowledge, this is the first study that shows a clear association between mtDNAcn and personality, and it establishes a new connection between mitochondrial outcomes and psychosocial stressors and emotional states that is highly relevant to human health.

PrgmNr 3214 - Unexpected somatic mosaicism and reduced penetrance: *NF1* pathogenic variants are found in 1 in 850 individuals

View session detail

Author Block: **T. Drivas**[1,2,2], T. Nomakuchi[1], M. Bonanni[3], A. Raper[2], S. M. Kallish[4,2], K. L. Nathanson[5], M. D. Ritchie[3]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]The Univ. of Pennsylvania, Philadelphia, PA, [3]Univ. of Pennsylvania, Philadelphia, PA, [4]Children Hosp Philadelphia, Philadelphia, PA, [5]Univ Pennsylvania SOM, Philadelphia, PA

Disclosure Block: **T. Drivas:** None.

Neurofibromatosis type 1 (NF1), caused by pathogenic variants in the *NF1* gene, is a relatively common autosomal dominant RASopathy thought to affect roughly 1 in 3,000 individuals. Although variable expressivity in NF1 is well-documented, the condition is thought to exhibit near-complete penetrance. We have recently been referred a number of patients with incidentally discovered pathogenic variants in *NF1* with minimal features of the syndrome on exam or history. This led us to hypothesize that the true incidence of pathogenic variants in the *NF1* gene might be higher than reported, with reduced penetrance, a broader phenotypic spectrum, a higher incidence of somatic mosaicism/clonal hematopoiesis of indeterminate potential than has previously been reported, or some combination thereof. We investigated this hypothesis in the Penn Medicine Biobank, which contains electronic health record and exome sequencing data on 43,731 patients of the Penn health system. We identified 51 individuals with clearly pathogenic *NF1* variants, equating to an incidence of 1 in 850, more than 3 times higher than commonly accepted estimates. Only 19 of these 51 individuals had an *NF1* diagnosis in their medical record, suggesting that two thirds of these individuals may be undiagnosed. Comparing variant allele frequencies (VAF) of the *NF1* variants between NF1-diagnosed and undiagnosed patients, we found that patients with a known NF1 diagnosis had an average VAF of 0.47, consistent with germline variation, while the average VAF in the undiagnosed group was only 0.28, implying that in at least some subjects in this group the *NF1* pathogenic variant might exist in a somatic mosaic state. We next conducted a phenome-wide association study (PheWAS) to identify phenotypes more common in the 51 patients with *NF1* pathogenic variants in an unbiased way. Numerous significant associations were identified, but interestingly these associations were entirely driven by the patients with a known NF1 diagnosis, suggesting that the presence of an *NF1* pathogenic variant in blood does not, *per se*, increase risk for disease. This is in line with our clinical experience, where we have seen that patients with incidentally discovered *NF1* pathogenic variants often do not exhibit features consistent with an NF1 diagnosis. In summary, an unbiased investigation of the population-level incidence and penetrance of *NF1* pathogenic variants suggests that these variants are far more common than reported, with a high degree of somatic mosaicism, and significantly reduced penetrance. The further investigation of this finding will be critical for accurate counseling of patients and families.

PrgmNr 3215 - Variants in nicotinic acetylcholine receptor and dopaminergic genes in relation to smoking relapse and proportion of time in relapse throughout adulthood in female nurses

View session detail

Author Block: **S. Jones**[1], B. J. Wolf[1], A. J. Alberg[2]; [1]Med. Univ. of South Carolina, Charleston, SC, [2]Univ. of South Carolina, Columbia, SC
Disclosure Block: **S. Jones:** None.
Background: Smoking cessation and behaviors are heritable. Single nucleotide polymorphisms (SNPs) of nicotinic acetylcholine receptor (nAChR) and dopaminergic genes have been linked to short-term cessation or cross-sectional smoking status, but studies have been limited by short-term follow-up (â¤ 90 days) which cannot account for multiple quit attempts and relapse events over time, a common smoker phenotype. **Methods:** Based on prior short-term studies, ten SNPs in nAChR or dopaminergic genes were selected, six in *CHRNA5-A3-B4*, one in *CHRNB2*, two in *DRD2*, and one in *COMT,* to test associations with odds of smoking relapse and proportion of time in relapse in adulthood in women of European ancestry. The study population was from the Nursesâ Health Study (NHS) and NHS-2, two longitudinal cohorts of female nurses. Participants included 12,060 ever smokers who reported having quit smoking at â¥1 timepoint with existing quality-controlled genotype data. Follow-up time was counted after the first report of smoking cessation with a median follow-up of ~32 years. A zero-inflated beta regression was used to model SNP associations with odds of relapse during follow-up and, conditional on relapse, model SNP associations with proportion of time in relapse. **Results:** Women with AA genotypes compared to those with AG or GG genotypes for *CHRNA5* SNP rs16969968 G>A or *CHRNA3* SNP rs1051730 G>A had 16% increase odds of smoking relapse in adulthood (p = 0.04 for both), but neither SNP was associated with the proportion of time in relapse. Further, among women who relapsed, four other SNPs were associated with the proportion of time in relapse; these included more time in relapse for women with CC genotypes (versus CT or TT genotypes) of *CHRNA5* SNPs rs588765 T>C (p = 0.04) and rs680244 T>C (p = 0.05) and AA genotype (versus AG or GG genotypes) for *DRD2* SNP rs6277 G>A (p = 0.01), whereas time in relapse was less for those with AA or AG genotypes (versus GG genotype) for *COMT* SNP rs4680 G>A (p = 0.03). **Conclusion:** Prior genetic association studies of smoking relapse have been limited by short-term follow-up. This study revealed that some SNPs were associated with relapse over decades of follow-up, whereas other SNPs were not associated with odds of relapse but were associated with the amount of time in smoking relapse during adulthood. The findings emphasize the value of long-term follow-up to characterize smoking relapse phenotypes as this approach can identify smokers with high-risk genotypes for long-term relapse prevention interventions. This may have important translational implications as smoking-related health risk increases with duration of smoking.

PrgmNr 3216 - *NUDT15* Variants Associated with Thiopurine Toxicity in 1,643 Pediatric Leukemia Patients

View session detail

Author Block: **A. M. Muir**[1], Z. E. Fan[1], K. Cao[1], F. Lin[1], M. Luo[1,2], Y. Zhong[1,2], L. F. Surrey[1,2], G. B. Wertheim[1,2], J. Schubert[1], J. Wu[1], E. A. Fanning[1], J. Chen[1], E. H. Denenberg[1], S. R. Rheingold[3,2], S. P. MacFarland[3,2], S. K. Tasian[3,2], S. P. Hunger[3,2], M. M. Li[1,2,3]; [1]Dept. of Pathology and Lab. Med., Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, [3]Div. of Oncology and Ctr. for Childhood Cancer Res., Children□□s Hosp. of Philadelphia, Philadelphia, PA

Disclosure Block: **A.M. Muir:** None.

Thiopurines are commonly used anti-cancer drugs in the treatment of pediatric acute lymphoblastic leukemia (ALL) and lymphoma (LL). Nudix Hydrolase 15 deficiency due to germline genetic polymorphisms in *NUDT15* gene is associated with impaired thiopurine chemotherapy metabolism and potential toxicity. Risk polymorphisms in *NUDT15* occur with a collective minor allele frequency of ~4.5% in the general population and >10% in East Asians. Preemptive screening for known risk alleles allows for genotype-guided dosing of thiopurine chemotherapy, an effective strategy for mitigating severe myelosuppression and hepatotoxicity. In this study, we report *NUDT15* sequencing results in a cohort of 1,643 patients with *de novo* or relapsed hematologic malignancies (HMs) whose specimens underwent targeted *NUDT15* sequencing (n=750) or HM gene panel (n=893) at the Children□□s Hospital at Philadelphia (CHOP). The self-declared racial and ethnic ancestry of our cohort broadly reflects the racial diversity of the United States: 52.8% Caucasian (non-Hispanic), 12.6% Black (non-Hispanic), 13.4% Hispanic/Latino (any race), and 6.1% Asian. Targeted *NUDT15* analysis was performed by Sanger sequencing of all coding exons including intron-exon boundaries. The next-generation sequencing based HM gene panel analyzed 119 HM-associated genes, including *NUDT15*. Known *NUTD15* risk alleles were identified in 8.5% of patients (139/1,643). The higher frequency of our cohort compared to the general population is likely due to â□□detection biasâ□□ amongst non-CHOP specimens, many of which were sent for targeted pharmacogenomic testing given clinical signs of thiopurine intolerance in the patients. The *NUDT15* *2 ([c.50_55dupGAGTCG(;)c.415C>T]; 41.0%) and *3 (c.415C>T, 30.2%) were the most common risk alleles in our cohort with *2 allele highly prevalent in patients of Hispanic ethnicity,*3 and *6(c.50_55dupGAGTCG) alleles in Caucasians, and *2, *3, and *6 in Asians. Ten patients (0.6%) had biallelic variants in *NUDT15*; patients with such genotypes generally manifest with extreme intolerance to thiopurine drugs. In addition, eight rare *NUDT15* missense variants and one in-frame deletion (c.460_468delAACCATCTG) were identified. At least one of these patients required 6-MP dose reduction due to hematologic toxicity. Our results identifying *NUDT15* risk alleles in a large cohort of children with HMs highlight the need for routine *NUDT15* pharmacogenetic testing prior to thiopurine-based chemotherapy administration. Such an approach is essential for optimizing individualized thiopurine dosing to mitigate undesirable hematopoietic and hepatic toxicity during ALL/LL therapy.

PrgmNr 3217 - A case report of rare t(8;22)(p11.2;q13) positive AML

View session detail

Author Block: **N. Owen**[1,2], W. Bi[1,2], J. L. Smith[1,2]; [1]Baylor Coll. of Med., Houston, TX, [2]Baylor Genetics, Houston, TX
Disclosure Block: **N. Owen:** None.
Acute myeloid leukemia (AML) is a genetically heterogeneous form of hematologic cancer with hundreds of known cytogenetic abnormalities driving malignancy. One rearrangement, t(8;22)(p11.2;q13), is a rare finding initially described over 20 years ago. It is a variant of the much more common t(8;16)(p11.2;p13) that creates a fusion protein between KAT6A (MOZ), a histone lysine acetyltransferase and CREBBP, a transcription factor, the effect of which is transcriptional dysregulation. This rearrangement is most common as a therapy-related finding in patients that have been treated with chemotherapy previously for solid tumors or other hematological diseases. The t(8;22) is thought to create a fusion between KAT6A and EP300, a protein with high homology to CREBBP. It is a much rarer phenomenon, so much remains unknown about this abnormality. Interestingly, while the t(8;16) shows a female preponderance (~2/3 of patients), all five cases of t(8;22) to date in the literature have been male. More patients with this translocation are necessary to fully understand the clinical picture and prognosis associated with this translocation, as well as the similarities and differences between it and related variant translocations.
Here we present a case of a 67-year- old male who presented with AML. Initial cytogenetic workup identified t(8;22)(p11.2;q13) as the sole anomaly in 16/20 metaphases analyzed. Five weeks later, a bone marrow sample was clear of cytogenetically abnormal cells. Seven weeks after that, a third sample was once again positive for t(8;22) with significant clonal progression. Four clones were observed, the first containing the t(8;22) and trisomy 8. Trisomy 8 is a common numerical abnormality in myeloid malignancies and is the most common secondary finding in t(8;16) positive AML. The second clone contained the abnormalities in the stemline, and also contained trisomy 5 and an isochromosome of 8p replacing one chromosome 8; this was the most prevalent clone in the sample. The third clone contained only the derivative (22) from the t(8;22), and had structural abnormalities of 8p and 10q. The fourth clone contained all of the abnormalities in clone 3, and had additionally acquired a reciprocal translocation between 2p and 5q. The patient passed away soon after. The prognosis associated with t(8;16) has been described as poor, though newer literature suggests the presence of de novo AML and non-complex karyotypes improve that prognosis. With so few cases described to date, the prognosis associated with t(8;22) has not been clearly established. This case suggests that t(8;22) may share the same prognosis as its counterpart t(8;16).

PrgmNr 3218 - A case study of AML in a patient with an additional *RUNX1T1* signal and a loss of one 3' *CBFB* signal in 88% of the nuclei examined

View session detail

Author Block: **F. Guirales**[1,2], A. Okabe[2,3], B. Hamid[2,3], A. Wang[2,3], J. King[4], M. Guardiola[4], K. Eastwood[4], C. A. Tirado[4,2]; [1]William Paterson Univ., Wayne, NJ, [2]The Intl. Circle of Genetics Studies, Los Angeles, CA, [3]Univ. of California Los Angeles, Los Angeles, CA, [4]Baylor Scott and White Hlth., Dept. of Pathology, Temple, TX

Disclosure Block: **F. Guirales:** None.

Acute myeloid leukemia (AML) is a heterogeneous blood cancer characterized by the proliferation of immature myeloid cells. Herein we present an 18-year old female with marked leukocytosis (WBC of ~300 x 10^9/L), thrombocytopenia with spontaneous intracerebral and cerebellar bleeds and anemia. Mother is noted to have *CHEK 2* mutation. Half sister died of AML S/P stem cell transplant. The bone marrow aspirate smears show numerous blasts, atypical monocytes and rare eosinophilic precursors with large basophilic granules. The blasts display highly irregular nuclei and dispersed chromatin and prominent nucleoli. The bone marrow biopsy is hypercellular (90-100%) and effaced by sheets of immature cells with irregular nuclei and moderate cytoplasm. The flow cytometry reveals the blast population expresses monocytic markers CD14, dim CD4, HLADR, CD13, CD33, CD15, CD36, CD64, CD38, CD11b with a subset co-expressing CD34 and CD117 and aberrantly expressing CD7 and CD5. This population is negative for CD16 and CD56. Chromosome analysis reveals an abnormal karyotype with a derivative trisomy 8 and a derivative chromosome 16 involving an inversion 16q as well as deletion 16q in 21 of the 22 metaphase cells examined. Thus, the karyotype was described as 47,XX,+der(8)add(8)(q24.3),der(16)inv(16)(p13.1q22)del(16)(q22)[21]/ 46,XX[1]. DNA FISH analysis revealed abnormalities for *RUNX1T1* (8q21.3) and *CBFB* (16q22) genes. There was a loss of one 3' *CBFB* signal in 88% of the nuclei examined. There was also an additional *RUNX1T1* signal in 83.5% of the nuclei examined. This was confirmed also in the concurrent chromosome study where there was an extra copy of chromosome 8. These findings correlate with concurrent conventional cytogenetic findings and were described as nuc ish(RUNX1T1x3,RUNX1x2)[167/200],(5'CBFB'x2,3'CBFBx1)(5' con 3'x1)[176/200],(EVI1,TAS2R1,EGR1,DEK,RELN,TES,ABL1,NUP214,KMT2A,PML,RARA,PTPRT,MYBL2,BCR) x2[200]. The National Comprehensive Cancer Network (NCCN) guidelines for AML state that rearrangements of the CBFB gene place the patient in the favorable risk category. An extra copy of chromosome 8 is usually seen in AML with rearrangements of 16q. Clinical correlation was suggested.

PrgmNr 3219 - A rare inv(14)(q11.2q32.3) in Acute Lymphoblastic Leukemia

View session detail

Author Block: **X. Zhao**[1,2], N. Owen[1,2], J. Kubala[2], W. Bi[1,2], J. L. Smith[1,2]; [1]Baylor Coll. of Med., Houston, TX, [2]Baylor Genetics, Houston, TX
Disclosure Block: **X. Zhao:** None.
Introduction: The inv(14)(q11.2q32.3) has been studied extensively in TCRÎ±/Î´-TCL11 fusion positive T-cell Prolymphocytic Leukemia (T-PLL). However, only a few cases have been documented with a cytogenetically identical translocation in patients with Acute Lymphoblastic Leukemia (ALL). These cases are thought to contain a distinct CEBPE-IGH fusion. Due to the scarcity of cases, the disease spectrum and clinical significance of inv(14)(q11.2q32.3) in ALL is still largely unknown. **Methods:** Retrospective review of the cytogenetic and FISH results on a consecutive cohort of 11,120 patients studied at Baylor Genetics from 2010 to 2021 was conducted. The cohort included 5314 females and 5806 males, with a concern for hematologic malignancy. Cytogenetic analysis of bone marrow or leukemic blood samples was performed using standard methods, and nomenclatures of chromosome abnormalities were based on ISCN. The involvement of IGH in the patient identified in this study was confirmed using a commercially available break-apart probe. The probe for CEBPE (RP11-147E17) was grown as a BAC according to standard protocol of the laboratory. **Results:** The patient is a 22-year-old female with a diagnosis of ALL. Her initial cytogenetic workup by FISH and chromosomes was normal. Fifteen months later, a small subclone (8.5%) was identified with an IGH rearrangement detected only by FISH. Five months after that, FISH was 46% positive for an IGH rearrangement and an abnormal clone (11/20 cells) with inv(14)(q11.2q32.3) was identified in the chromosome analysis. A reciprocal translocation between 1p and 6q was also seen. Further FISH studies identified the rearrangement partner for IGH to be CEBPE. One month later the abnormal clone was undetectable after treatment, but the patient relapsed 3 months after that with the same clone; no new clonal abnormalities were observed. **Discussion:** Only a few cases of inv(14) or the analogous t(14;14) have been published. The long term outcomes of patients with this inversion remain to be explored. To our knowledge, this is the first case of a female pediatric ALL driven by an inv(14) with an CEBPE-IGH rearrangement; previously all reported pediatric cases were male. The identification of this one patient in our large cohort has reiterated the rarity of this abnormality and allowed us to track the clinical course of a patient with this inversion over time. In addition, caution should be paid to distinguish these from T-PLL patients when interpreting the results. Further investigation is warranted to understand the disease mechanisms.

PrgmNr 3220 - Does it make sense to report single pathogenic alleles in cancer susceptibility genes for childhood cancer patients? Results from the BASIC3 and Texas KidsCanSeq studies

View session detail

Author Block: **S. E. Plon**[1], L. R. Desrosiers[1], S. Scollon[2], A. K. Petersen[3], H. DAI[4], J. Reuther[5], G. Miles[6], D. M. Muzny[4], A. Roy[5], S. Kulkarni[7], R. A. Gibbs[4], A. L. Disclosure Block: **S.E. Plon:** Non-remunerative positions or influence such as officer, board member, trustee, or public spokesperson; Baylor Genetics.

Background: Multiple studies report that 8-13% of pediatric cancer patients have pathogenic or likely pathogenic variants (PV/LPV) in cancer susceptibility genes, although standards vary for reporting single PV/LPVs in genes associated with autosomal recessive (AR) syndromes. We report here results from two studies of pediatric cancer patients for the frequency of single AR variant results and relationship to the patientâ□□s presentation. **Methods:** The BASIC3 study included clinical germline and tumor exome sequencing in an ethnically diverse cohort of sequentially diagnosed children with CNS and non-CNS solid tumors. The Texas KidsCanSeq study included germline exome and panel sequencing for pediatric solid tumor patients across six sites in Texas. In both studies, other medical problems noted in the medical record were provided to the reporting laboratory. All result categories on the clinical exome and panel (when available) were returned to parents. **Results:** Among 278 enrolled patients in BASIC3 there was one patient with two PVs (a homozygous variant in *TJP2*) and 18 (6.5%) patients had a single PV/LPV in a wide spectrum of AR cancer genes. Only one patient had a tumor type (Wilms tumor) previously associated with the gene (*DIS3L2*). Patent foramen ovale in a patient with *FANCA* allele was the only syndromic feature. In the first 366 patients in KidsCanSeq there were no patients with biallelic PV/LPVs, 15 patients (4.1%) with one PV/LPV in AR genes of which 2 had the associated tumor type (*DIS3L2* with Wilms tumor and *SLC26A4* with thyroid cancer). Not included here are patients with PV/LPV in genes with both AR and dominant cancer phenotypes e.g., *ATM.* Germline results disclosure with parents discussed (1) their oncologist might request further targeted testing for a 2nd variant if there is concern that the patient has this rare disorder, (2) the patient (and often parent) are carriers of this rare disorder, (3) the lack of evidence relating the variant to the childâ□□s cancer diagnosis and (4) lack of any additional surveillance recommendations.**Conclusions:** There is increasing use of exome, genome or large hereditary cancer panels for genomic evaluation of cancer patients. Recessive diagnoses are very uncommon but about 5% of pediatric cancer patients have a single PV/LPV in rare AR cancer genes without other findings. These test results require substantial efforts for disclosure and family understanding. We suggest that limiting reporting to biallelic patients or those with features of the disorder including the specific cancer type would streamline the process at the cost of reproductive information. BASIC3 and Texas KidsCanSeq were supported by 1U01HG006485.

PrgmNr 3221 - Heterogeneity in cytological presentation of gene amplification and concurrent amplification of *MYC* and *PVT1* in therapy related acute myeloid leukemia (AML)

View session detail

Author Block: **R. Koduru**[1], K. Wilson[1], R. Garcia[2], O. Weinberg[1], P. Patel[1], K. Kirthi[3], W. Chen[1]; [1]Univ Texas Southwestern Med Ctr, Dallas, TX, [2]UT Southwestern, Euless, TX, [3]Med. City Hosp., Dallas, TX
Disclosure Block: **R. Koduru:** None.
The chromosomal region at 8q24.1 is a hot spot for somatic alterations in hematological and non-hematological cancers. Amplification of this region has been reported in about 1% of myeloid malignancies including AML and myelodysplastic syndrome (MDS). Here we present a case of therapy related AML in which *MYC* and *PVT1* were concurrently amplified in an amplicon at 8q24.1 which presented as double minute (dmin), ring chromosome or homogeneously staining region (hsr) in leukemia cells in the same bone marrow (BM) specimen. A 70-year female with a history of breast carcinoma, non-small cell lung cancer, and renal carcinoma, developed therapy related AML. Karyotype at the time of diagnosis was abnormal with 45,X,-X,3-12dmin[cp3]. FISH and molecular studies showed loss of *ABL1* in 27.3% cells, but negative for all other FISH probes for AML, and negative for *FLT3*, *IDH1*/*IDH2*, or *KIT* mutations. Repeated karyotype analysis of BM detected four clones: 46,XX,del(9)(q13q34)[5]/47,idem,+1-2r[9]/45,X,-X,dmin[3]/45,X,-X,HSR(8)(q22)[3]. FISH with *MYC* break apart probe detected amplification on the ring chromosome, the hsr and the dmin. Hybridization with *PVT1* probe also detected amplification on all these abnormal chromosomes. Immunohistochemical study on BM core biopsy showed MYC expression in leukemic blasts. Thus, these results together indicate co-amplification of *MYC* and *PVT1* and expression of *MYC* in leukemia cells. Dmin or hsr constitutes amplification of genomic DNA. In myeloid proliferations frequent site of amplification is 8q24.1 containing *MYC* and less frequently 11q23 containing *KMT2A*. *MYC* amplification is frequently reported in non-therapy related AML, and rarely in therapy related AML. Although this region contained 15 other genes, only alterations, a *NSMCE2*/*PVT1* fusion and *PVT1* amplification were reported. This is the second report of amplification of *PVT1* along with *MYC*. Contrary to the previous findings that amplification was mainly in the form of dmin or ring chromosomes, our case showed plasticity in cytological presentation of the amplicon in the form of dmin, ring chromosome, and hsr, and a relatively simple but abnormal karyotype. The presence of independent clones, one with ring chromosomes, the other with hsr, and a third with only dmin in the same specimen suggests independent genetic events that may have occurred simultaneously in leukemia cells. Alternatively, each of these clones may suggest that hematopoietic stem cells were subjected to different genotoxic events when the patient received treatment for prior malignancies. Consistent with previous findings, the patient ultimately had poor clinical outcome.

PrgmNr 3222 - Imputing missing genotypes and examining rare genetic variants in families with high risk of lung cancer

View session detail

Author Block: **Z. Zhang**; Baylor Coll. of Med., Houston, TX
Disclosure Block: **Z. Zhang:** None.
Lung cancer (LC) is the leading cause of cancer death in USA. Although low dose spiral CT screening can detect early-stage LC patients, even early diagnosed patients still have about a 30% cause-specific mortality. Some individuals with genetic susceptibility express a high risk for LC development, particularly if exposed to tobacco smoke or other carcinogens. However, more complete characterization of genetic risk is necessary before it can be used to stratify individuals by the LC risk and diagnose LC at an early stage. Recently, rare variants with large effects on LC risk were identified. However, due to low allele frequency, rare variants are easier to detect in multiplex families than in sporadic samples, because rare variants, especially the causal variants, tend to accumulate in families. Therefore, data from families having multiple relatives affected with LC is a good option for discovery of rare variants. In this study, we investigated the genetic risk of LC by analyzing families from a unique data resource established by Genetic Epidemiology of Lung Cancer Consortium (GELCC). GELCC has been collecting samples and data from individuals with a strong history of LC for the last 20 years. We have cancer phenotypes, detailed smoking exposure data and biological specimens available from 868 probands, as well as next generation whole exome sequencing (WES) of high-risk LC families. Our studies have identified variants associated with familial lung cancer, and further studies to evaluate the quality of the results and validate findings are ongoing. In addition to identifying risk variants, we also developed an efficient pipeline for family-based imputation and association analysis. Missing genotype data is common in genetic studies of lung cancer with short survival time, especially in family-based studies. Genetic imputation is an efficient tool that is widely used to infer the missing data and boost the power of the analysis. Although population-based imputation is very popular and has very high accuracy for variants with high allele frequency, accuracy declines with allele frequency. Family-based imputation may overcome the drawback; however, it is not as mature as population-based imputation. Many problems are unsolved, including software efficiency and quality control of the post-imputed genotypes, etc. We have used the framework of Morgan 2 and GIGI to fill in missing genotypes using array-based analysis on 249 individuals and linkage information from sparser arrays for an additional 2,432 participants. The association analysis is performed by incorporating the metric of the imputation quality as weights to decrease the false discovery rates.

PrgmNr 3223 - Serial cytogenetic studies showing evolution of trisomy 8 positive CMML to AML with a complex karyotype characterized by deletion 7q and a jumping 1q translocation without evidence of trisomy 8

View session detail

Author Block: **J. L. Smith**[1,2], B. Yuan[3,4], L. R. Smith[5], W. Bi[1,2], N. Owen[1,2]; [1]Baylor Coll. of Med., Houston, TX, [2]Baylor Genetics Lab., Houston, TX, [3]Seattle Children's Hosp., Seattle, WA, [4]Univ. of Washington, Seattle, WA, [5]High Mark Genetics, LLC, Los Alamos, NM
Disclosure Block: **J.L. Smith:** None.
Approximately 30% of Chronic Myelomonocytic Leukemia (CMML) patients have one or more clonal cytogenetic abnormalities. Both trisomy 8 and deletion 7q are common findings in CMML, and both have been classified as intermediate to high risk. Jumping translocations are seen on occasion in cytogenetic studies of hematologic samples, most commonly in multiple myeloma and myeloid malignancies. Most reported cases of myeloid malignancies involve an initial diagnosis of MDS with transformation to AML or worsening MDS. We report a rare patient with a jumping 1q translocation that emerges and disappears during a series of studies as the patientâ□□s disease course evolved from CMML to AML.

The first bone marrow sample from a 48-year-old male had an indication of CML. Chromosome analysis was negative for the Philadelphia chromosome but positive for trisomy 8 in 6/20 cells. FISH testing did not include probes to assay for a BCR/ABL1 fusion, so a cryptic rearrangement could not be excluded; however, FISH with a centromeric probe showed 46% of interphase cells with three copies of the centromere 8. A year later, a second bone marrow sample was submitted, this time with an indication of CMML. Again, the sole abnormality was trisomy 8 [8/20 G-banded cells; 84/200 interphase cells by FISH].

Within 5 months, a third sample with an indication of CMML not having achieved remission was submitted. Neither FISH nor chromosome analysis showed any evidence of trisomy 8; however, 16/20 G-banded cells had a deletion of 7q22q36. Four additional bone marrow samples were submitted 3, 4, 5 and 7 months later before the patient succumbed to his illness. At the time of the fourth sample, the diagnosis was classified as CMML-2 with increasing blasts; three different jumping 1q translocations were seen in different clones, all of which contained a deletion 7q. The three recipient chromosome regions were 14p, 21p and 22p; the most common recipients of the 1q are the short arms of the acrocentric chromosomes. The last three samples were submitted with an indication of AML. Two studies showed the deleted 7q as well as the jumping 1q translocations. Finally, while the fifth sample showed no evidence of the 1q translocations, all 20 G-banded cells and 90% of interphase cells were positive for the deletion 7q.

This case report not only highlights a rare case of CMML with a jumping 1q but affords the opportunity to observe the emergence and disappearance of the 1q translocations over time. Jumping 1q chromosomes are thought to be associated with disease progression and are rarely noted to have disappeared, particularly if the patient remains in relapse without normalization of the karyotype.

PrgmNr 3224 - Somatic Mutation Profiling of Basal Cell Carcinoma in a Population Exposed to Arsenic

View session detail

Author Block: **M. G. Kibriya**[1], F. Jasmine[1], T. Islam[2], A. Ahmed[2], M. Rakibuz-Zaman[2], M. Islam[2], M. Kamal[3], C. R. Shea[1], M. Argos[4], H. Ahsan[1]; [1]Univ Chicago, Chicago, IL, [2]Univ Chicago Bangladesh, Dhaka, Bangladesh, [3]Bangabandhu Sheikh Mujib Med. Univ., Dhaka, Bangladesh, [4]Univ. of Illinois Chicago, Chicago, IL

Disclosure Block: **M.G. Kibriya:** None.

Background: Non-melanoma skin cancers (NMSC) are the most prevalent malignancy in the United States, with an estimated 2 million new diagnoses each year. NMSC includes basal cell carcinoma (BCC) and squamous cell carcinoma. While ultraviolet (UV) radiation exposure and skin sensitivity are known risk factors for NMSC in Caucasians, arsenic (As) exposure may be a major risk factor in other populations. **Aim:** To identify cancer-associated somatic mutations in BCC**,** we conducted next-generation sequencing of DNA samples from BCC (n=26), corresponding blood samples (n=26), and the biopsy samples from normal skin tissue (n=16) from sixteen independent subjects. **Material and Methods:** We utilized tissue samples from individuals participating in the **B**angladesh vitamin **E** and **S**elenium **T**rial (BEST). From BEST participants who developed NMSC over the follow-up period of 8 years and had skin biopsy tissue preserved in RNA Later available, we selected the first 26 BCC cases. Healthy skin tissues (surrounding non-cancerous skin lesions) were taken from an independent set of participants (who had arsenical keratosis) for comparison. All participants were exposed to As-through drinking As-contaminated ground water and had visible As-related skin lesions at the time of trial enrollment. Targeted DNA sequencing of a comprehensive cancer panel of 406 cancer related genes was performed on Illumina platform. **Result:** For each sample, ~14 million clusters were sequenced with ~94% reads with quality score >Q30 (average quality score of 35.9) and post-QC average depth of coverage ~240x. To detect somatic mutation in BCC or healthy skin tissues, we excluded the variants found in the corresponding blood DNA. As expected, we detected a number of somatic mutation in healthy skin tissue. Then to detect the BCC associated somatic mutations, we excluded the variants found in healthy skin. Missense somatic mutations (n=214) were detected in 133 genes. On average, each BCC sample revealed 8 missense somatic mutations. The most common missense mutations were seen in *PRKDC, ABL1, TET1 TAF1L, SYNE1, EP400, SETD2, KMT2C, MTOR* etc. Mutations in genes seen in UV-induced BCC (*PTCH1, SMO, NOTCH1, NOTCH2, TP53* etc.) were also found, but were less frequent in this set of As-associated BCC. **Conclusion:** We report the somatic mutational profile using a large comprehensive panel of targeted genes in As-related BCC. The pattern indicates that a different molecular genomic pathway may be involved in the pathogenesis of As-related BCC. Further studies are needed to confirm the findings.

PrgmNr 3225 - The g-quadruplex stabilizing agent GQC-05 inhibits LINE-1 retroelement activity in human bronchial epithelial cells

View session detail

Author Block: **K. Ramos**[1], P. Bojang, Jr.[2], V. Gokhale[3], L. Hurley[3]; [1]TAMHSC-Inst. of BioSci.s and Technology, Houston, TX, [2]Univ. of Kentucky, Lexington, KY, [3]Univ. of Arizona, Tucson, AZ
Disclosure Block: **K. Ramos:** None.
Nearly 100 copies of the Long interspersed element-1 (LINE-1) retrotransposon remain active in the human genome. These elements function as insertion mutagens and epigenetic effectors in various types of cancer. In silico analyses of LINE-1 sequences identified putative guanine-quadruplex (G-quadruplex) structures within the 3â□□ untranslated region (3â□□ UTR). G-quadruplexes are classified into intramolecular and intermolecular structures based on the number of nucleotides involved in forming the G-quadruplex, with both DNA and RNA able to form these structures. G-quadruplexes are secondary structural motifs formed from the stacking of two or more guanine tetrads into square co-planar structures held together by Hoogsteen type hydrogen bonds of guanines that create a central channel where a cation such as K+ resides to stabilize the structure and neutralize the negative central charge. The present studies were conducted to determine if G-quadruplexes within the 3â□□ UTR participate in the regulation of LINE-1 activity. We found that GQC-05 binds to the G-quadruplex sequence in the 3â□□ end of LINE-1, as evidenced by stabilization at one equivalent by 13Â°C. Drug binding reduced LINE-1 mRNA levels in the absence of any appreciable effect on DNA polymerase activity below a concentration of 50Î¼M and inhibited LINE-1 retrotransposition and clonal expansion in soft agar of human bronchial epithelial cells expressing constitutively active LINE-1. The multilevel efficacy of GQC-05 suggests that modulation of G-quadruplexes in the 3â□□ untranslated region of the LINE-1 may be targeted pharmacologically to modulate tumors plagued by aberrant LINE-1 activity.

PrgmNr 3226 - Underutilization of germline testing for prostate cancer patients: Are genetic testing criteria a tool or an obstacle?

Disclosure Block: **S. Nielsen:** Salary/Employment; Invitae.

Background: Pathogenic/likely pathogenic (P/LP) germline variants occur in ~10-15% of all prostate cancer (PCa) patients. However, complicated workflows and restrictive testing criteria lead to underutilization of genetic testing. A multi-center study was conducted to determine the incidence of P/LP variants in PCa patients who met (in criteria, IC) and did not meet (out of criteria, OOC) the NCCN 2019 PCa germline genetic testing criteria. **Methods:** An IRB-approved, multicenter, prospective registry was initiated with 15 community and academic urologists nationwide. Consecutive, unselected PCa patients ages 18-90 were consented and underwent an 84-gene germline panel test, with clinical information collected via clinician-completed case report forms. Statistical significance was determined by chi-square test without Yatesâ correction. **Results**: Of the 764 patients to date, 429 (56%) were IC and 335 (44%) were OOC. Excluding carriers of heterozygous variants in genes associated with autosomal recessive cancer conditions (e.g. *MUYTH* heterozygotes), **7.3**% (56/764) of patients had a P/LP variant on an 84-gene panel: **8.2%** (35/429) of IC patients and **6.3%** (21/335) of OOC patients (p=0.11). For a 12-gene PCa panel, P/LP yield was 5.1% (39/764), with no significant difference between IC and OOC patients (p=0.33). Of 56 pts with P/LP variants, 79% (n = 44) were potentially eligible for precision therapy (e.g. PARP inhibitors), clinical treatment trials, and/or other clinical management interventions, 36% (n = 16) of whom wouldâve been missed by criteria. **Conclusions**: There was no statistically significant difference in the yield of P/LP variants between IC and OOC patients, reinforcing that guidelines miss a significant number of patients with P/LP variants. Current criteria for germline testing of PCa patients are an obstacle to identifying patients with precision therapy-eligible P/LP variants and should be revised.

PrgmNr 3227 - Age-specific transcriptional risk scores (TRS) link GWAS to eQTLs and predict therapeutic response across 8 common cancer types

View session detail

Author Block: **E. Hall**[1], P. Awadalla[2]; [1]Ontario Inst. for Cancer Res., Toronto, ON, Canada, [2]Ontario Inst Cancer Res., Toronto, ON, Canada
Disclosure Block: **E. Hall:** None.
Early-onset cancers (age at pathologic diagnosis â¤ 45) represent a distinct biological age subgroup associated with poor prognosis and recurrence risk. We aimed to identify differences in gene expression and their prognostic significance for early-onset primary tumors across eight common cancer types: breast invasive carcinoma (BRCA), colon adenocarcinoma (COAD), lung adenocarcinoma (LUAD), lung squamous cell carcinoma (LUSC), pancreatic adenocarcinoma (PAAD), prostate adenocarcinoma (PRAD), ovarian serous cystadenocarcinoma (OV), and acute myeloid leukemia (AML). We integrated TCGA and GTEx RNA-seq data to perform differential gene expression (DE) analyses and identify age-related differentially expressed genes (age DE genes) significantly up or down-regulated in early- vs late-onset primary tumors compared to normal tissue for each tumor/tissue type. In parallel, we also identified significant eGenes for each tumor/tissue type by integrating summary-level data from GWAS with data from expression quantitative trait locus (eQTL) studies to identify genes whose expression levels were associated with hereditary cancer risk. We hypothesized that the summation of risk-allele associated gene expression, i.e., a transcriptional risk score (TRS), would provide a superior estimation of cancer risk and prognosis compared to biomarkers identified through differential gene expression analyses. Thus, utilizing either age DE genes or eGenes, we constructed TRS for early-onset cancer risk for each tumor/tissue type. We show that TRS based on eGenes were not only significantly elevated in early- vs late-onset untreated primary tumors, but also served to identify patients who were at high risk of developing disease-specific complications. This relationship between the TRS and risk of disease-specific complications was validated in multiple external cohorts. For example, for BRCA, we identified a 55 gene TRS which was not only significantly elevated in early-onset, early-stage BRCA primary tumors regardless of tumor subtype, but also significantly predicted which patients were at high risk of developing a recurrence following confirmation of disease-free status (p

PrgmNr 3228 - Broadly pleiotropic effects of pathogenic variants in tumor suppressor *CHEK2*

View session detail

Author Block: **L. D. Ward**[1], M. M. Parker[1], A. Deaton[2], H-C. Tu[1], A. Flynn-Carroll[2], R. Hoffing[2], C. Willis[3], G. Hinkle[2], P. Nioi[1]; [1]Alnylam, Cambridge, MA, [2]Alnylam Pharmaceuticals, Cambridge, MA, [3]Alnylam Pharmaceuticals, Boston, MA

Disclosure Block: **L.D. Ward:** Salary/Employment; Alnylam Pharmaceuticals.

Exome sequencing has been performed on most UK Biobank participants, allowing genome-wide and phenome-wide association studies of rare coding variants. In an exome-wide burden test of association between rare predicted damaging variants and menopause timing in the UK Biobank, we found associations with five genes (*CHEK2*, *RAD54L*, *DCLRE1A*, *HROB*, and *TOP3A*), all of which were involved in the DNA-damage repair pathway. Of these genes, the strongest association was between rare predicted damaging variants in *CHEK2* and later menopause (1.46 years; p = 6.2 Ã 10^{-51}). *CHEK2* is a moderate-penetrance breast cancer gene and is known to have pleiotropic associations with other cancers (in the case of Li-Fraumeni syndrome), but the association with later menopause was unexpected. Through causal mediation analysis, we estimate that approximately 8% of the breast cancer risk of *CHEK2* is conferred through delayed menopause. We then performed a phenome-wide association study of rare predicted damaging variants in *CHEK2* to test for additional associated phenotypes in 363,977 men and women in the UK Biobank. We found that in addition to breast cancer (OR = 1.87; p = 6.2 Ã 10^{-51}) and prostate cancer (OR = 1.67; p = 2.8 Ã 10^{-12}), *CHEK2* associates with increased platelet crit (beta = 0.18 SD; p = 5.0 Ã 10^{-39}) and leukocyte count (beta = 0.16 SD; p = 4.6 Ã 10^{-29}), and increased risk of several noncancer diseases: uterine fibroids (OR = 1.49; p = 4.3 Ã 10^{-10}), polycystic ovarian syndrome (OR = 3.05; p = 1.5 Ã 10^{-8}), prostate hyperplasia (OR = 1.40; p = 2.5 Ã 10^{-8}), and seborrheic keratosis (OR = 1.31; p = 6.4 Ã 10^{-7}). While the hematological associations have been described previously, we additionally show in a stratified analysis that they are found in both cancer-free women and men. These results suggest a function for *CHEK2* in protecting against not only cancer, but also other syndromes involving hyperproliferation of tissue, consistent with its role in the cell cycle.

PrgmNr 3229 - Genome-wide interaction analysis identified low-frequency variants with sex disparity in lung cancer risk

View session detail

Author Block: **Y. Li**[1], X. Xiao[1], J. li[1], J. Byun[1], C. Cheng[1], R. Hung[2], C. Amos[1], INTEGRAL-ILCCO consortium; [1]Baylor Coll. of Med., Houston, TX, [2]Lunenfeld-Tanenbaum, Toronto, ON, Canada
Disclosure Block: **Y. Li:** None.
Introduction: Lung cancer is the leading cause of cancer death for both men and women worldwide with a complex genetic and molecular mechanism. Differences by sex in lung cancer incidence and mortality have been reported. There is growing evidence showing that sex disparity in lung cancer risk cannot be fully explained by sex differences in smoking behavior, implying existence of genetic and molecular basis for sex disparity in lung cancer development. However, the information about sex dimorphism in lung cancer risk is quite limited despite the great success in lung cancer association studies.**Methods:** By adopting a stringent two-stage analysis strategy, we performed a genome-wide gene-sex interaction analysis using genotype from a lung cancer cohort including ~ 47,000 individuals with Caucasian ancestry. The significant variants were further submitted to allelic-specific expression using genotype and gene expression data in lung tissue from 244 men and 133 women in GTEx. Two public functional annotation tools, CADD and RegulomeDB were applied for functional inference of the candidate variants.**Results:** Three low-frequency variants (minor allele frequency Conclusions: We conducted a large-scale gene-sex interaction scanning in lung cancer and we identified three significant variants with different risk effects based on sex. Our study is one of the first studies to examine sex disparity in lung cancer development and our results provided insights about the genetic and molecular mechanism underlying the differences in lung cancer susceptibility between men and women. Our findings also suggested quite a few variants still remain undetected in lung cancer, including those with low allele frequency requiring a very large sample size; or the variants affecting disease risk thorough interaction with environmental and biological factors requiring more robust analysis strategy.

PrgmNr 3230 - GWAS of Uveal Melanoma Reveals Novel Genome Wide Significant Locus

View session detail

Author Block: **N. Tsao**[1], H. Thomsen[2], K. G. Ewens[3], S. Coupland[4], K. Hemminki[5], S. M. Damrauer[6], A. GANGULY[7]; [1]Univ. of Pennsylvannia, Philadelphia, PA, [2]Heidelberg Univ., Heidelberg, Germany, [3]Univ Pennsylvania Sch Med, Philadelphia, PA, [4]Univ. of Liverpool, Liverpool, United Kingdom, [5]Univ. of Heidelberg, Heidelberg, Germany, [6]Hosp. of the Univ. of Pennsylvania, Philadelphia, PA, [7]Univ. of Pennsylvania, Philadelphia, PA

Disclosure Block: **N. Tsao:** None.

Background: Uveal melanoma (UM) is a rare intraocular tumor. It is also the most common form of adult-onset primary ocular malignancy with a significantly high degree of mortality associated with distant metastasis. Most cases of UM are sporadic with only a very small fraction presenting with a family history of the disease. The only gene known to be associated with UM is *BAP1*. We performed a genome-wide association study (GWAS) to identify common genetic variants associated with US. **Methods:** We conducted a case control analysis of individuals with tissue confirmed UM and age and sex matched controls that were free of cancer diagnoses based on ICD-9/10 diagnosis codes in their electronic health record, which we identified from the Penn Medicine Biobank. All individuals were genotyped using the Axiom Precision Medicine Research Array (PMRA) and the data imputed to the HRC reference panel using the University of Michigan imputation server. We tested the association of 4,146,536 DNA sequence variants for an association with UVM using logistic regression controlling for age, sex, and population structure using PLINK 2.0. **Results:** There were 399 individuals with UM and 748 without an EHR diagnosis of cancer. Individuals with UM had a mean age of 57.2 and 215 (53.%) were male. The mean age of those without cancer was 54.9, and 48.4(%) were male. We replicated the previous association on chromosome 5p rs421284(OR = 1.39, p = 1.93E-4). Our analysis also identified a single, novel genome wide significant locus on chromosome 5q, rs6862372 (OR = 0.2, p = 7.9 E-11). rs6862372 is a significant cis-eQTL for Pelota MRNA Surveillance And Ribosome Rescue Factor (PELO) (P=1.1E-10) and Integrin Subunit Alpha 1 (IGTA) (P=9.1E-7) based on data from eQTLgen. IGTA1 has previously been shown to be upregulated in metastatic uveal melanoma cells. **Conclusion:** In conclusion, our GWAS identified a novel locus that implicates PELO and IGTA1 could play a role in uveal melanoma oncogenesis. We aim to replicate these findings using local and international cohorts and further these analyses using a time to event frame work to investigate the genetics of uveal melanoma metastasis progression.

PrgmNr 3231 - Predicted gene expression identifies novel genes associated with lung cancer in African Americans

View session detail

Author Block: **M. Betti**[1], J. Jaworski[1], J. S. Rao[2], B. Ryan[3], A. G. Schwartz[4], J. K. Wiencke[5], M. A. Bruce[6], S. Zhao[1], S. J. Chanock[3], M. C. Aldrich[1], J. Hellwege[1]; [1]Vanderbilt Univ. Med. Ctr., Nashville, TN, [2]Univ. of Miami, Miami, FL, [3]Natl. Cancer Inst., Bethesda, MD, [4]4Karmanos Cancer Inst., Wayne State Univ., Detroit, MI, [5]Univ. of California, San Francisco, San Francisco, CA, [6]Univ. of Mississippi Med. Ctr., Jackson, MS

Disclosure Block: **M. Betti:** None.

African Americans have an elevated risk of developing lung cancer compared to Whites, despite lower average cigarette consumption. Recent research has begun to address this paradox with studies attempting to specify genetic mechanisms contributing to this racial disparity with genome-wide association study (GWAS) of lung cancer risk in African Americans. We extended this work with two key innovations, the use of TOPMed imputed single nucleotide polymorphism (SNP) data, as well as the assessment of genetically-predicted gene expression. We performed a GWAS using 1,612 cases and 3,294 controls from the African American Lung Cancer cohort. Genotype data was imputed using the TOPMed Imputation Server, expanding the number of variants from 932,188 to 15,415,642. Associations between SNPs and lung cancer diagnosis were evaluated using a logistic regression model, adjusted for sex, age, smoking status, study site, and proportion of Yoruban ancestry, as determined via ADMIXTURE with 1000 Genomes CEU and YRI reference data. The four SNPs reaching genome-wide significance were near *CHRNA5* within the 15q25.1 locus (lead SNP rs17486278, $p = 4.46 \times 10^{-10}$, odds ratio = 1.30 [95% Confidence Interval: 1.19-1.42]). We observed suggestive (p-6) associations at seven other loci.

We next aimed to link GWAS hits with tissue-specific changes in gene expression using GTEx eQTL data. To boost statistical power, we implemented a joint-tissue imputation (JTI) approach to leverage information across the transcriptomes of different GTEx tissues based on shared chromatin regulatory profiles. Combining GWAS summary results with S-PrediXcan and JTI models resulted in significant gene-tissue pairs (p -7) for 6 genes: *SNRNP200* (significant across 17 tissues), *CEP295* (significant across 6 tissues), *CSKMT* (significant across 4 tissues), *FCSK* (significant across 2 tissues), *CCL28* (significant in tibial artery), and *RPF1* (significant in skeletal muscle). *SNRNP200* was significant in lung tissue ($p = 1.72 \times 10^{-12}$, effect size = 0.703).

We confirmed significant associations between lung cancer risk and GWAS-identified SNPs and discovered tissue-specific predicted gene expression using eQTL data. This work expands our knowledge of the regulatory mechanisms underlying these GWAS signals and contributes to our understanding of the genetic architecture of lung cancer in African Americans. This represents a step forward towards addressing the historic underrepresentation of African ancestry populations in genetics research.

PrgmNr 3232 - SNPs at SMG7 associated with time from biochemical recurrence to prostate cancer death

View session detail

Author Block: **R. J. Klein**[1], X. Song[1], M. Ru[1], Z. Steinsnyder[2], K. Tkachuk[2], Z. GÃ¼mÃ¼Å[1], K. Offit[2], V. Joseph[2]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Mem. Sloan Kettering Cancer Ctr., New York, NY

Disclosure Block: **R.J. Klein:** None.

Previously, in a genome-wide association study we identified several loci with genetic variants associated with prostate cancer survival time. To validate these loci and examine whether they influence the entire course or only a particular stage of the disease, we genotyped two SNPs in de-identified DNA samples of 1298 men who underwent radical prostatectomy at Memorial Sloan Kettering Cancer Center (MSKCC) from January 1990 through January 2006. We tested SNPs rs2702185 and rs73055188 for association with prostate-cancer-specific survival time using a Cox proportional hazard model, adjusted for age, PSA level, Gleason score and stage at surgery and stratified by Ashkenazi Jewish (AJ) or non-Jewish, European ancestry. We further tested the SNP rs2702185 for association with time to biochemical recurrence and biochemical recurrence to death from disease in the non-AJ population. We performed linkage disequilibrium (LD) analysis to identify SNPs in high LD with rs2702185, and examined their functional effects, chromatin accessibilities and gene expressions.

Here, we report an intergenic variant in SMG7, rs2702185, was associated with prostate-cancer-specific survival time in the non-AJ patient population. Decomposing the survival time into two intervals delineated by biochemical recurrence, we identified rs2702185 specifically associated with time from biochemical recurrence to prostate cancer death in the non-AJ patient population. Nine variants were in LD with rs2702185. Of these, rs10737246 was most likely functional, based on differential LD with rs2702185 between AJ and northwest European populations and overlap with open chromatin. Notably, both the tissue distribution of open chromatin around rs10737246 and eQTL analysis using the eQTL Catalogue points to a role for this SNP in immune (primarily T cells) rather than prostate cells. The potential causal effect of rs10737246 is yet to be experimentally validated.

In conclusion, we found that rs2702185 in SMG7 is associated with time from biochemical recurrence to prostate cancer death, and its LD partner rs10737246 is predicted to be functional.

PrgmNr 3233 - Cisplatin induced gene expression across three different cancer cell line types reveal common and distinct molecular regulatory effects

View session detail

Author Block: **M. Luck**[1], C. Del Greco[2], A. L. Stark[3]; [1]Univ. of Notre Dame, Notre Dame, IN, [2]Univ. of Michigan, Ann Arbor, MI, [3]Univ. of Notre Dame, South Bend, IN
Disclosure Block: **M. Luck:** None.
Cisplatin chemotherapy treatment, although a widely utilized and often initially successful anti-cancer treatment, is challenged with immediate or acquired resistance and harmful side effects that can persist once treatment is stopped. This study aims to characterize the molecular effects of cisplatin treatment in breast, lung, and colorectal cancer cell lines and to investigate the induced role of SNAIL regulated genes following cisplatin treatment across different cancer types. Ten genes of interest regulated by SNAIL were selected based on high-fold expression changes following Snail up-regulation, and qPCR was used to assess expression changes 24- and 48- hours following cisplatin exposure in MCF7 (breast), A549 (lung), and HCT116 (colorectal) cancer cell lines. Across the 10 genes (S100P, DECR1, THBS1, TACSTD2, H2AFJ, TMEM47, HOXA9, UPK2, TSPYL5, and AKT3), we observed different patterns of induced expression ranging from consistently induced significant (p

PrgmNr 3234 - Computational evidence of BRCA1-NC3 receptor interaction and druggability analysis in BRCA1-related oncogenesis

View session detail

Author Block: **M. Herceg**[1], M. L. Brown[2], A. Shehu[3]; [1]George Mason Univ. Sch. of Systems Biology, Fairfax, VA, [2]George Mason Univ. Ctr. for Drug Discovery, Fairfax, VA, [3]George Mason Univ. Dept. of Computer Sci., Fairfax, VA
Disclosure Block: **M. Herceg:** None.
Breast cancer susceptibility gene 1 (*BRCA1*) on human chromosome 17q21 was identified in 1994 as the site of breast cancer-causing mutations (Ma *et al*. 2005. Oncogene). The canonical pathway by which mutations in *BRCA1* lead to cancer is through impaired DNA repair (reviewed by Tarsounas and Sung. 2020. Nat. Rev. Mol. Cell Biol.). However, this does not explain the hormone-relatedness of *BRCA1* oncogenesis (Rosen *et al*. 2003. Trends Endocrinol. Metab.). Rosen and colleagues characterized a putative Estrogen Receptor-Î± (ER-Î±; *ESR1*)-BRCA1 binding site (2005. Oncogene.). If the ER-Î±-BRCA1 interaction plays a significant role in breast cancer oncogenesis, it could represent a druggable pathway in a subset of breast cancers. By some estimates, 10-36% of *BRCA1*-related breast cancers retain ER function (ER+) (Tung *et al*. 2010. BCR). ER-Î± is a member of the NC3 Nuclear Receptor family. The members of NC3, including ER-Î² (*ESR2*), the Androgen Receptor (*AR*), and the Progesterone Receptor (*PGR*), are steroid receptors with a characteristic fold. There is evidence that BRCA1/2 interacts with at least some other members of the NC3 family, and with AR in particular (Yeh *et al*. 2000. PNAS.). In addition, Rosen, Brown, and colleagues described the disruption of the ER-Î±-BRCA1 complex by drug A7 and several other drugs (2014. Mol. Endocrinol.). They hypothesized that the disruption was due to a conformational change, since the characterized drugs were not found to bind competitively with estrogen. In this work, using informatics techniques, we present evidence of sequence and structural conservation of binding sites identified by Rosen, Brown, and colleagues as important in drug-ER-Î± and ER-Î±-BRCA1 binding across members of the NC3 nuclear receptor family (2014. Mol. Endocrinol.). In addition, using protein-ligand docking simulations, we present evidence on possible cross-binding of A7 and related drugs to various NC3 receptors. Finally, we validate our simulation results with wet-laboratory measurements. Our work represents a step towards understanding the molecular basis of NC3 receptor family positive *BRCA1*-related cancers by shedding light on the possible hormone-dependence mechanism of these cancers. This work also lays the foundation for drug screening and design for these cancers.

PrgmNr 3235 - Identifying functional melanoma risk variants and susceptibility genes via massively parallel reporter assays and multi-QTL in normal melanocytes and malignant melanomas

Disclosure Block: **E. Long:** None.

Melanoma is a deadly skin cancer that originates from melanocytes. The largest genome-wide association study (GWAS) so far has identified 54 melanoma-associated loci, but molecular mechanisms for most of them have not been characterized. To identify susceptibility genes/variants from 54 melanoma GWAS loci, we integrated massively parallel reporter assays (MPRA) with expression quantitative trait loci (eQTL) and methylation QTL (meQTL) in normal melanocytes and malignant melanomas. For MPRA, we included 2102 variants based on linkage disequilibrium (LD, R^2 > 0.8) or GWAS statistics (log likelihood ratio 0.1) compared to non-significant variants (P = 0.001). A substantial proportion of MPRA-significant variants (121/285, 42.5%) were predicted to have effects on at least one transcription factor binding site and displayed a correlation between transcriptional activity and predicted allelic binding scores (R^2 = 0.05, P = 0.01). Moreover, a majority of the MPRA-significant variants (172/285, 60.4%) overlapped genome-wide significant eQTLs/meQTLs in melanocytes or melanomas, nominating 31 candidate susceptibility genes. In conclusion, MPRA along with multi-QTL analysis in relevant tumor and normal cell types can quickly prioritize plausible functional candidates from thousands of high-LD variants from melanoma GWAS loci.

PrgmNr 3236 - A deep learning approach for efficiently incorporating genomic data into ovarian cancer prognosis prediction

View session detail

Informatics and Genomics, New Orleans, LA, [2]The Univ. of Oklahoma Hlth.Sci. Ctr., Oklahoma City, OK, [3]Tulane Univ. Dept. of BioMed. Engineering, New Orleans, LA, [4]Tulane Univ., New Orleans, LA

Disclosure Block: **L. Jiang:** None.

With high-throughput sequencing technologies, high-dimensional genomic data are becoming more commonly available. Although combining genomic and clinical information can help us develop a better understanding of complex mechanisms behind cancer patientsâ survival, the issue of low sample size with many current datasets can cause overfitting problem in statistical model fitting and machine learning. Moreover, the association between features of interest (e.g., gene expression) and the survival outcome can be nonlinear but the conventional Cox Proportional Hazard model was not designed to handle nonlinearity. Recently, there has been a rapid growth in the application of deep learning techniques in cancer research. These practices deal with nonlinearity intrinsically, and by virtue of the flexibility in building a deep neural network, structures can be incorporated to extract features from high-dimensional data and prevent overfitting. Here, we propose a two-phase deep learning framework composed of a Beta Variational Autoencoder (Beta-VAE) that encodes information underlying the high-dimensional features into lower-dimensioned latent factors, and a Cox layer that outputs the prognosis index for each patient. In the first phase, Beta-VAE is trained for information extraction and dimension reduction. Beta-VAE is an altered form of Variational Autoencoder (VAE) that allows less information to be passed through the bottleneck layer. In the model we expect the network to only encode the most important information for lowering the reconstruction loss, and potentially further prevent overfitting by removing extra noises. With the trained weights retained, in the second phase, the Cox layer is added and the network is trained for prognosis prediction. By implementing this training procedure, we expect the learned latent factors to be more survival-analysis-associated. We collected data for 451 ovarian cancer patients from The Cancer Genome Atlas (TCGA) database, including their clinical data (e.g., age, ethnic group, clinical stage), gene expression, and miRNA data. We applied our method on single-omics data (e.g., gene expression, miRNA, respectively) to assess which single view of the molecular profile grants more improvement to ovarian cancer prognosis prediction when added on top of clinical data. Furthermore, we also assessed the model performance when integrating multi-omics and clinical data. We compared the performance of this proposed model with other approaches (i.e., Cox-EN, PCA, Cox-PASNet) and found that in general our model yielded the best prediction while requiring relatively short running time.

PrgmNr 3237 - An improved approach leveraging MRI and genomic information for classification and segmentation of glioma lesions

View session detail

Author Block: **H. Suryadevara**[1], X. Wang[2]; [1]Univ. of North Texas, Denton, TX, [2]Univ North Texas, Denton, TX

Disclosure Block: **H. Suryadevara:** None.

Gliomas are one of the most common types of primary brain tumors, which can be broken into low- and high-grade. High grade gliomas are more aggressive as compared to low grade. Gliomas are classified according to the type of glial cell involved in the tumor, as well as the tumor's genetic features. Early detection of gliomas can substantially increase the survival rate of a patient. Magnetic resonance imaging (MRI) is widely used for the detection of brain tumors. However, MRI application is an error-prone and exhaustive activity especially in image recognition. In this study, we introduce a Spatial Pyramid Attention Network (SPANet) to investigate the role of attention blocks for medical image analysis. In contrast to other attention-based networks that leverage global average pooling, the SPANet considers both structural regularization and structural information. The SPA block is flexible to be deployed to various convolutional neural network (CNN) architectures in segmentation and classification. Utilizing SPANet, we propose an improved approach for classification, localization, and segmentation of glioma lesions. The proposed approach for tumor detection is validated on glioma genomic data obtained from The Cancer Genome Atlas (TCGA) and corresponding MRI data from The Cancer Imaging Archive (TCIA). The proposed method achieved greater than 0.85 prediction scores in classification, as well as 0.90 Tversky accuracy rate in segmentation when we use the combined data including T1-weighted MRI scans, FLAIR segmentation masks, and patient genomic biomarkers. Moreover, classification and segmentation outcomes are superior as compared to existing methods.

PrgmNr 3238 - Analyses of breast cancer microbiome data

View session detail

Author Block: **S. Sohail**, M. Burns; Loyola Univ. Chicago, Chicago, IL
Disclosure Block: **S. Sohail:** None.
The microbiome has been implicated as a potential driver in a variety of cancers, including breast cancer [3]. There are numerous studies, with associated microbial sequencing data, available on this topic. [1; 2; 3]. However, microbiome analysis is a rapidly developing field and older analytical methods rapidly become deprecated. In the work presented here we have performed a meta-analysis of the raw data from available studies, with the intended goal of assessing (1) the reproducibility of the original findings and (2) assessing breast cancer-specific microbial signatures that occur across study cohorts [1; 2; 3; 4]. Using the DADA2 pipeline, an amplicon sequence variant approach providing high taxonomic resolution, specificity, and lower false positives than the mixture of now-outdated bioinformatic approaches used in the original studies [5], we have identified major improvements in analysis approaches as well as novel findings that were not revealed in the original reports. We anticipate that these new research results arising from a thorough meta-analysis of existing datasets using modern best-practices and up-to-date databases will provide researchers vital information surrounding the relationship between breast cancer and its associated microbial communities.

PrgmNr 3239 - Building multi-omics classifier to improve phenotype prediction in heterogeneous cancer data

View session detail

Author Block: **V. Oza**[1], B. N. Lasseigne[2]; [1]Cell, Dev.al and Integrative Biology, UAB SOM, Birmingham, AL, [2]UAB SOM, Birmingham, AL
Disclosure Block: **V. Oza:** None.
Large scale cancer projects such as The Cancer Genome Atlas (TCGA) have generated multi-dimensional genomic data sets capturing orthogonal as well as complementary information across various cancers. To leverage the advantage of the available data, various integrative analytical approaches have been developed. However, such meta-dimensional analysis is challenging due to high dimensionality, high variability due to noise, and collinearity between different genomic features. Additionally, such analysis is complicated by the need for optimization of different analytical steps for integrating various genomic data. Although previous studies have focused on multi-omics analysis, the methods have not been optimized for individual steps in the multi-omics methods such as data standardization, data selection, feature reduction, machine learning classifier algorithms, and validation methods. Here, we develop an optimal framework for analysis of multi-omics datasets including gene expression, Copy Number Variation (CNV), and microRNA expression in ovarian cancer (as a proof of concept) to predict survival using TCGA data. We look at how the selection of data standardization, feature reduction, machine learning model, and cross-validation methods affect the multi-omics classifier performance in heterogeneous ovarian cancer data.

PrgmNr 3240 - Characterization and prediction of DNA methylation instability across human cancers

View session detail

Author Block: **S. Thalluri**, B. N. Lasseigne; Univ. of Alabama at Birmingham, SOM, Birmingham, AL
Disclosure Block: **S. Thalluri:** None.

DNA methylation instability (DNAmIN) occurs when there are globally altered DNA methylation (DNAm) signatures. While these patterns occur throughout the genome, extensive research to date in the cancer field has implicated that methylation changes occurring at CpG islands may be important biomarkers of disease etiology, progression, or treatment response. While many studies have examined this phenomenon, known as the CpG Island Methylator Phenotype, few have studied the relationship between non-CpG Island methylation, including CpG shores and CpG shelves, within and across cancers and with respect to clinical characteristics. We obtained DNAm array (450k Infinium Chip) data from over 11,000 patients in 33 cancers publicly available from The Cancer Genome Atlas (TCGA) database and compared and contrasted these DNAmIN metrics. In this study, we calculate different DNAmIN metrics and compare them to gain insight into the correlation between these signatures within and across cancer types. Our findings provide insights for generating hypotheses and contributing to the clinical relevance of DNAm as potential targets for future therapeutic intervention.

PrgmNr 3241 - Diagnosing Li-Fraumeni syndrome from the somatic genome

View session detail

Author Block: **B. Laverty**[1], V. Subasri[2], N. Light[1], D. Malkin[3]; [1]Univ. of Toronto, Toronto, ON, Canada, [2]Markham, ON, Canada, [3]Hosp for Sick Children, Toronto, ON, Canada
Disclosure Block: **B. Laverty:** None.
Li-Fraumeni syndrome (LFS) is a hereditary cancer predisposition syndrome caused by germline mutations of the tumour suppressor gene *TP53*. LFS is estimated to occur in 1:500 - 1:5000 people and is associated with an 80% lifetime cancer risk. LFS is diagnosed using personal and family cancer history and germline *TP53* sequencing. Several factors contribute to under-diagnosis, two of which I am going to tackle: germline *TP53* variants of uncertain significance (VUS), and the absence of germline TP53 mutations (30% of â□□classicâ□□ LFS patients).
We hypothesize that LFS cancers evolve uniquely from sporadic cancers, meaning the somatic genomes exhibit distinct characteristics that can diagnose the predisposition syndrome. To investigate this, we interrogated the mutational signatures, *TP53* copy number, *TP53* loss of heterozygosity, ploidy, and the incidence of chromothripsis in individuals with germline *TP53* mutations (n=27), somatic *TP53* mutations (n=17) and wild type for *TP53* (n=158). The proportion of single base substitution signatures 2, 5, 8, 13, 18 were significantly different between the groups as were ploidy, the incidence of chromothripsis and loss of heterozygosity. However, unsupervised hierarchical clustering of patients by these features did not completely separate LFS patients from non-LFS.
Next, we will analyze double base and indel mutational signatures and combine these features to train a logistic regression model with elastic net regularization using 10-fold cross-validation. We believe a machine learning algorithm may recognize patterns with all variants that are unique to LFS. This work will create a tool to diagnose two subsets of LFS patients that are currently hard to recognize. Early diagnosis of LFS facilitates surveillance for early detection of secondary tumours, leading to improved outcomes.

PrgmNr 3242 - Epigenomic landscape and 3D genome structure in pediatric high-grade glioma

View session detail

Author Block: **J. Wang**, T. Huang, Y. Hou, E. T. Bartom, X. Lu, A. Shilatifard, F. Yue, A. Saratsis; Northwestern Univ., Chicago, IL
Disclosure Block: **J. Wang:** None.
Pediatric high-grade gliomas (pHGGs), including glioblastoma multiforme (GBM) and diffuse intrinsic pontine glioma (DIPG), are morbid brain tumors. Even with treatment survival is poor, making pHGG the number one cause of cancer death in children. Up to 80% of DIPGs harbor a somatic missense mutation in genes encoding histone H3. To investigate whether H3K27M is associated with distinct chromatin structure that alters transcription regulation, we generated the first high-resolution Hi-C maps of pHGG cell lines and tumor tissue. By integrating transcriptome (RNA-seq), enhancer landscape (ChIP-seq), genome structure (Hi-C), and chromatin accessibility (ATAC-seq) datasets from H3K27M and wild-type specimens, we identified tumor-specific enhancers and regulatory networks for known oncogenes. We identified genomic structural variations that lead to potential enhancer hijacking and gene coamplification, including A2M, JAG2, and FLRT1. Together, our results imply three-dimensional genome alterations may play a critical role in the pHGG epigenetic landscape and contribute to tumorigenesis.

PrgmNr 3243 - MDC1 restrains ATR-mediated resection of DNA double-strand breaks in human cells

View session detail

Author Block: **S. S. Meyn**[1,2,3], P. S. Bradshaw[2]; [1]Univ. of Wisconsin Sch. of Med. and Publ. Hlth., Madison, WI, [2]Dept. of Molecular Genetics, Univ. of Toronto, Toronto, ON, Canada, [3]Dept. of Pediatrics, Univ. of Wisconsin - Madison, Madison, WI
Disclosure Block: **S.S. Meyn:** Receipt of Intellectual Property Rights/Patent Holder; Gene42.
Double strand DNA breaks (DSBs) are a potentially lethal form of cellular DNA damage that frequently cause genomic instability. Human cells primarily repair induced DSBs via the error prone mechanisms of c-NHEJ (classical-Non-Homologous End Joining), which occurs throughout the cell cycle, and Homologous Recombination (HR) repair, an error free process restricted to S and G2 phases that uses long stretches of homologous sequences. Defects in HR repair genes are responsible for the bone marrow failure syndrome Fanconi anemia, confer high risks for cancer, and can render tumors susceptible to PARP1-based therapies.
Pathway choice exerts a critical effect on the fidelity of DSB repair in human cells with resection determining whether the cell commits to c-NHEJ, or HR. In the G2 phase of the cell cycle, HR-mediated repair of induced DNA damage requires the protein product of the *ATM* gene, whose loss of function can cause the multisystem genetic disorder Ataxia-Telangiectasia.
We verify that, in human cells, ATM plays a major role in CtIP-mediated DSB resection and the creation of 3â□□ single-stranded DNA (ssDNA) ends used for HR. However, we find that DNA end resection in G2 can also be regulated independently of ATM by the cell cycle checkpoint protein MDC1. In human cells, MDC1 loss promotes unrestrained resection of DNA ends, as indicated by increases in the number and intensity of RPA-coated ssDNA foci in a process that is dependent upon ATR and CtIP. Further, optimal loading of the recombination protein Rad51 onto RPA coated ssDNA requires MDC1. While ATM promotes HR repair by initiating CtIP dependent DNA end resection, MDC1 can affect pathway choice through restraining HR repair by preventing ATR- and CtIP-dependent resection. Our work identifies a role for MDC1 in the control of DNA end resection that is independent of ATM and sheds mechanistic insight into the processing of DNA damage that is required for faithful DNA repair, maintenance of genome stability and prevention of tumorigenesis.

PrgmNr 3244 - Single cell transcriptome analysis maps aneuploidy to mesenchymal phenotypes during thyroid cancer progression

View session detail

Author Block: **L. Lu**[1], J. Wang[2], H. Ying[2], S. Bai[3], Y. Yan[4], C-k. Shiau[1], R. Kieser[1], M. Hu[3], X. Zhao[3], J. Wang[2], M. Williams[5], M. Zafereo[2], N. Navin[3], S. Lai[2], R. Gao[1]; [1]The Ctr. for Bioinformatics and Computational Biology, Houston Methodist Res. Inst.s, Houston, TX, [2]Dept. of Head and Neck Surgery, The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX, [3]Dept. of Genetics, The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX, [4]Vivian L. Smith Dept. of Neurosurgery, The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [5]Dept. of Pathology, The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Disclosure Block: **L. Lu:** None.

Anaplastic thyroid cancer (ATC) is arguably the most lethal human malignancy, with a median survival of ~12 weeks.About half ATC tumors have prior differentiated forms of thyroid cancer types, commonly papillary thyroid cancer (PTC), suggesting an evolutionary continuum from PTC to ATC. In comparison to the extreme lethality of ATC, PTC patients are typically indolent with long life-histories. The molecular mechanisms driving ATC progression have been challenging to resolve, mostly due to the heterogenous cellular systems that are undergoing dynamic changes and the rarity of human ATC tissue samples. In this study, we applied high throughput 3â□□ scRNAseq to unbiasedly analyze the cell populations in thyroid tumors. In total, we analyzed 79,747 single cell transcriptomes from 11 ATC tumors, 7 PTC tumors and 7 normal thyroids. To make the precise inference of tumor cell lineages, we stratified the epithelial cells into 5 categories by calculating genotypes from 3â□□ sc-RNAseq data that include normal epithelial cells, two subtypes of PTC cancer cells and two subtypes pf ATC cancer cells (i.e. inflammatory ATC and mesenchymal ATC). Our data showed that aneuploidy is strongly associated with mesenchymal phenotypes in ATC cancer cells, whereas inflammatory ATC cancer cells often only have 2N copy numbers. Mesenchymal ATCs are characterized with co-expression of epithelial and mesenchymal phenotypes and loss of thyroid differentiation programs. Several abnormal mitotic checkpoint pathways associated with survival of aneuploids are enriched in mesenchymal ATC cells. We further analyzed the transcriptional programs of immune] and stromal cell types. Our results showed that T cells in ATC are more exhausted while macrophages undergo M2 polarization and mesenchymal transition. In addition, we found that ATC tumors are enriched towards inflammatory cancer associated fibroblasts (CAFs) that also have strong mesenchymal features. A significantly tight relationship between these mesenchymal cell types (i.e. cancer cells, myeloid cells and CAFs) are defined through intercellular network reconstruction. Collectively, our results suggest that ATC progression is driven by aneuploidy associated mesenchymal transitions in both cancer and non-cancer cell types, providing novel insights into targeting this extremely lethal disease.

PrgmNr 3245 - Statistical analysis of breast cancer co-methylation patterns

View session detail

Author Block: **S. Sun**[1], J. Dammann[2], P. Lai[3], C. Tian[4]; [1]Texas State Univ., San Marcos, TX, [2]St. Stephenâ□□s Episcopal Sch., Austin, TX, [3]Massachusetts Inst. of Technology, Cambridge, MA, [4]Liberal Arts and Sci. Academy, Austin, TX
Disclosure Block: **S. Sun:** None.
Breast cancer is one of the most commonly diagnosed cancers. It is associated with DNA methylation, which is an epigenetic event. In an adult human genome, methylation occurs when a methyl group is covalently added to a cytosine base that is paired with a guanine, i.e., a CG site. DNA methylation can have different effects on gene functions. The methylation patterns of different genes or sites in a genome may be correlated in certain ways. This correlation pattern is known as co-methylation. It is still not clear how different genes co-methylate with each other in the whole genome of breast cancer samples. Two previous studies are conducted based on relatively small datasets, Illumina methylation 27K data with only 27,000 CG sites per sample. In this study, we analyze much larger publicly available datasets, Illumina methylation 450K (i.e., 450,000 sites) data of 53 breast cancer patients including their matched normal data. Our key findings are summarized below. First, normal samples have 1.7 times more highly correlated or co-methylated CG pairs than tumor samples. Both tumor and normal have more than 93% of positive co-methylation, but normal samples have significantly more negatively correlated CG sites than tumor samples (6.6% vs 2.8%). Second, both tumor and normal samples have about 94% of co-methylated CG pairs on different chromosomes, but normal samples have 470 million more CG pairs. For the highly co-methylated pairs on the same chromosome, they tend to be located close to each other. Third, a small proportion of CG sitesâ□□ co-methylation patterns change dramatically from normal to tumor. The percentage of differential methylation (DM) sites among them is larger than the DM rate in the whole genome (10.53% vs 8.56%). Fourth, certain CG sites are highly co-methylated with other CG sites; the top 100 of such CG sites in tumor and normal samples have no overlaps. Fifth, chromosome X co-methylation patterns are very different from other chromosomes. Finally, the network analyses of genes associated with several sets of co-methylated CG sites mentioned above show that tumor and normal samples have different patterns as well. Our findings will provide researchers with a new and improved understanding of co-methylation patterns in breast cancer. Our ability to thoroughly analyze co-methylation of large datasets will allow researchers to study relationships and associations between different genes in breast cancer.

PrgmNr 3246 - Subtype-associated epigenomic landscape and 3D genome structure in bladder cancer

View session detail

Zhang[2], L. Wang[1], J. Warrick[2], J. Raman[2], J. Meeks[1], D. DeGraff[2], F. Yue[1]; [1]Northwestern Univ., Chicago, IL, [2]The Pennsylvania State Univ., Hershey, PA, [3]Univ. of Illinois, Chicago, IL

Disclosure Block: **Q. Wang:** None.

Muscle-invasive bladder cancers are characterized by their distinct expression of luminal and basal genes, which could be used to predict key clinical features such as disease progression and overall survival. Transcriptionally, FOXA1, GATA3, and PPARG are shown to be essential for luminal subtype-specific gene regulation and subtype switching, while TP63, STAT3, and TFAP2 family members are critical for regulation of basal subtype-specific genes. Despite these advances, the underlying epigenetic mechanisms and 3D chromatin architecture responsible for subtype-specific regulation in bladder cancer remain unknown. We determine the genome-wide transcriptome, enhancer landscape, and transcription factor binding profiles of FOXA1 and GATA3 in luminal and basal subtypes of bladder cancer. Furthermore, we report the first-ever mapping of genome-wide chromatin interactions by Hi-C in both bladder cancer cell lines and primary patient tumors. We show that subtype-specific transcription is accompanied by specific open chromatin and epigenomic marks, at least partially driven by distinct transcription factor binding at distal enhancers of luminal and basal bladder cancers. Finally, we identify a novel clinically relevant transcription factor, Neuronal PAS Domain Protein 2 (NPAS2), in luminal bladder cancers that regulates other subtype-specific genes and influences cancer cell proliferation and migration.In summary, our work identifies unique epigenomic signatures and 3D genome structures in luminal and basal urinary bladder cancers and suggests a novel link between the circadian transcription factor NPAS2 and a clinical bladder cancer subtype.

PrgmNr 3247 - Survival analysis and evaluation of germline genomic patterns across multiple cancers using boosted trees and model interpretability

View session detail

Author Block: **L. Chapman**[1,2], Z. Boukouvalas[2]; [1]NIH, Rockville, MD, [2]American Univ., Washington, DC

Disclosure Block: **L. Chapman:** None.

Approximately 5-10% of all cancers can be linked to heritable genetic variants. Evaluation of germline genetic variants in cancer has largely been limited to variants within a certain set of genes known to be associated with cancer. Previous studies have shown that approximately 8% of the 10389 patients from The Cancer Genome Atlas (TCGA) carried pathogenic germline variants. Common variants have smaller effect sizes; however, many select variants could collectively contribute to cancer development. In the proposed study, we evaluate germline variants that are associated with survival across multiple cancer types in TCGA. We apply a boosted tree method - XGBoost - to select a feature set consisting of non-linear SNP interactions within each cancer type, and classify patients based on survival using SVM. Over 1 million germline substitutions from TCGA representing multiple cancer types will be evaluated. To identify sets of germline SNPs that are significantly associated with cancer survival predictions, model interpretation is conducted using a local surrogate model: local interpretable model-agnostic explanations (LIME). Spearman correlation is used to identify associations between SNP burdens and COSMIC somatic signatures to evaluate the possible impact of germline SNP networks on oncogenic pathways. Our approach will enable us to identify putative therapeutic targets as well as possible markers for survival will be identified, and could also possibly discover clinically actionable non-coding genetic variants within the networks.

PrgmNr 3248 - The clinical impact of somatic variants in *AGT*, *MGMT* and *TP53* in Mexican patients with astrocytoma

View session detail

Author Block: **J. Carlos-Escalante**[1], T. Wegman-Ostrosky[2]; [1]Inst. Natl. de CancerologÃa, Jesus Maria, Mexico, [2]NCI, Rockville, MD
Disclosure Block: **J. Carlos-Escalante:** None.
Introduction: Astrocytomas are the most common primary malignant brain tumor in adults. They are highly disabling, and the prognosis of patients is dismal, particularly for grade IV astrocytomas. Clinical prognostic factors for astrocytomas include sex, age, performance status, extent of resection, and adjuvant chemoradiotherapy. Molecular prognostic factors have been described, being the presence of somatic mutations in *IDH1* or *IDH2* the best characterized. Somatic mutations in other genes could serve as molecular prognostic factors as well. *AGT* encodes for angiotensin, which is a central piece of the renin-angiotensin system (RAS). Somatic mutations in *AGT* could be related to astrocytoma prognosis as most components of the RAS are expressed in human astrocytomas. *MGMT* promoter methylation is an already established predictive marker for astrocytoma therapy, however, the role of somatic mutations in this gene in prognosis is unknown. *TP53* is commonly mutated in astrocytomas, nonetheless, the prognostic value of these mutations is still debated.
Objective: The aim of this work was to evaluate the association of variants in *AGT*, *MGMT*, and *TP53* with astrocytoma prognosis.
Materials and Methods: Tumor tissue and peripheral blood samples from 48 patients with astrocytoma from the Instituto Nacional de NeurologÃa y NeurocirugÃa (INNN) were analyzed through targeted panel sequencing for *AGT*, *MGMT*, and *TP53.* Somatic mutations called were filtered and annotated. The data from 503 individuals with astrocytoma from TCGA were analyzed as validation cohort.
Results: 61 mutations were detected in the samples from Mexican patients. *TP53* mutations associated to loss of function were associated with higher 2-year survival in our cohort (OR 4.14, 95% CI: 1.02-16.8, p=0.039). *TP53* mutations in general were associated with longer overall survival after adjustment in the TCGA cohort (HR: 0.71, 95% CI: 0.5-0.99, p=0.049). Women in our cohort tended to have more mutations than men, without reaching statistical significance, however, mutations in *AGT* and *MGMT* were found only in females. *AGT* mutations were present only in females of TCGA cohort.
Conclusions: In this study we found that the presence of *TP53* somatic mutations may be a prognostic factor for patients with astrocytoma. In addition, we observed a sex-differentiated mutation distribution for *AGT*.

PrgmNr 3249 - Tumor spectrum of *FLCN* gene mutation carriers in an unselected pan-cancer patient population

View session detail

Author Block: **S. Kane**[1], Y. Kemel[2], A. Maio[1], N. Mehta[3], D. Mandelker[3], Z. Stadler[1], M. I. Carlo[1]; [1]Clinical Genetics, Med., Mem. Sloan Kettering Cancer Ctr., New York, NY, [2]Sloan Kettering Inst., Mem. Sloan Kettering Cancer Ctr., New York, NY, [3]Pathology, Mem. Sloan Kettering Cancer Ctr., New York, NY

Disclosure Block: **S. Kane:** None.

Background: Birt-Hogg-DubÃ© syndrome (BHD) is a genetic syndrome caused by deleterious germline mutations in the *FLCN* gene. BHD is characterized by benign skin lesions, pulmonary cysts and pneumothorax, and increased risk of renal tumors. Whether the phenotype extends beyond these features is unknown, as most patients with BHD are identified when they present with classic features. We describe the phenotypes of patients with BHD from an unselected, pan-cancer population.

Methods: 22,440 patients with cancer were tested via MSK-IMPACT, a matched tumor-normal next generation sequencing platform. Germline testing included >70 genes associated with cancer risk. Patients with deleterious *FLCN* germline mutations were identified. Clinical features were obtained from medical records and clinical notes. Tumor sequencing was analyzed for loss of heterozygosity (LOH) using the Fraction and Allele-Specific Copy Number Estimates from Tumor Sequencing (FACETS) algorithm.

Results: 12 patients (0.05%) had deleterious germline mutations *FLCN*. Median age at cancer diagnosis was 59 (range 22-73). Cancers included RCC (n=2), colorectal (n=2), prostate (n=2), and 1 each with breast, thyroid, pancreas, uterus, undifferentiated pleomorphic sarcoma, squamous cell carcinoma (skin) and non-small cell lung cancer. One patient had 3 cancers: synchronous colon and rectal, and prostate cancers. Of the 2 patients with RCC, pathology was â□□unclassifiedâ□□ RCC. Of 6 patients with available colonoscopy records, 5 (83%) had colon polyps. 9 patients (75%) had emphysematous changes on imaging. 6 patients (50%) had no personal or family history of BHD features noted prior to genetic testing. At least 3/12 tumors (breast, kidney, and sarcoma; 25%) were found to have *FLCN* LOH.

Conclusions: BHD is a rare genetic syndrome and the spectrum of associated tumors is broad. The phenotypic spectrum of patients with *FLCN* gene mutations from this pan-cancer population differ from patients described in the literature, many of which were tested due to features consistent with BHD. Most patients in this study were found on imaging to have emphysematous lung changes, which may correspond to the cystic lung findings seen in BHD. Identification of *FLCN* mutations can direct cancer screening, lifestyle modification and cascade testing in at-risk relatives. Of interest, several non-canonical cancers were found to have LOH, suggesting a possible role for *FLCN* in the pathogenesis of the tumor. Our study suggests that criteria for BHD evaluation could be broadened due to the clinical variability of patients identified in this study. The role of *FLCN* in the development of other cancers can be further explored.

PrgmNr 3250 - Up-regulation of chromatin remodeling genes contributes to chemoresistance and tumorigenesis in PDAC

View session detail

Author Block: **C. Wright**[1,2], E. R. Gordon[1], R. M. Myers[1], S. J. Cooper[1]; [1]HudsonAlpha Inst. for Biotechnology, Huntsville, AL, [2]The Univ. of Alabama in Huntsville, Huntsville, AL
Disclosure Block: **C. Wright:** None.
Pancreatic ductal adenocarcinoma (PDAC) is the most common form of pancreatic cancer and one of the most lethal forms of cancer with a five-year survival rate of 10%. Existing therapies are not sufficient and the few recurrent mutations found in PDAC tumors have failed to yield effective targeted therapies. The combination of late-stage diagnosis, lack of targeted therapies and resistance to existing therapies contribute to poor outcomes. We used genome wide CRISPR screens to show that activation of chromatin remodeling genes including *HDAC1* appears to contribute to multi-drug resistance. HDAC1 overexpression is also correlated with poor patient outcome. Transcriptomic analysis shows that HDAC1 overexpression may lead to drug resistance by inducing cell state transition. We generated PDAC cell lines that we endogenously activated HDAC1 expression using the dCas9-VP64 epigenome editing system. ChIP-sequencing and RNA-sequencing were performed on HDAC1 activated cell lines, control cell lines, and a normal pancreas cell line to find novel HDAC1 binding sites and altered chromatin accessibility, measured by H3K27ac ChIP-seq, that are associated with gene expression changes previously linked to chemoresistance. We compared the presence of H3K27ac between the cell lines to identify active promoters and enhancers that are regulated by HDAC1 and contribute to drug resistance. Combining DNA binding site data with gene expression data following HDAC1 overexpression showed how new binding sites alter gene expression programs that result in a more stem-like state and contribute to chemoresistance in pancreatic cancer. An improved understanding of the regulatory elements that are relevant for resistance might help us understand how mutations contribute to drug resistance in pancreatic cancer. Our work provides an improved understanding of the regulatory landscape in PDAC, and will particularly resolve the genomic changes most relevant to drug resistance with the goal of inspiring new treatment options.

PrgmNr 3251 - Assessment of population-appropriate polygenic risk scores for lipid traits in African Americans

View session detail

Author Block: **D. Drouet**, S. Liu, D. C. Crawford; Case Western Reserve Univ., Cleveland, OH
Disclosure Block: **D. Drouet:** None.
Polygenic risk score (PRS) studies for cardiovascular disease (CVD), while promising, are based on genome-wide association studies in European-descent populations. Here we calculate population-appropriate PRS in an African American (AA) patient population from a biobank linked to electronic health records (EHRs) for risk factors of CVD: high density lipoprotein cholesterol (HDL-C), low density lipoprotein cholesterol (LDL-C), triglycerides (TG) and total cholesterol (TC). We limited analyses to individuals (n=1,898; 1,898; 1,978; and 2,106) with Illumina Metabochip genotypes available for 44, 36, 51, and 48 previously associated HDL-C, LDL-C, TG, and TC single nucleotide variants, respectively, reported by the Population Architecture using Genomics and Epidemiology (PAGE) Study. Using PAGE Study risk allele and effect estimates, we calculated an unweighted and weighted PRS for each individual and tested each for an association with each lipid trait using linear regressions unadjusted and adjusted for age, sex, and body mass index. The majority of patients (63.4%) are female and are on average (46.20) middle age. Almost one-third had mention of heart attack keywords in their EHR problems list; 1% and 1.5% had current procedural terminology (CPT) codes for coronary artery bypass graft and angioplasty and/or coronary stents, respectively, and 1.7% had three mentions of International Classification of Diseases (ICD)-9 codes for myocardial infarction. Mean weighted PRS was 3.44, 2.2, 5.96, and 3.69 for HDL-C-, LDL-C, TG, and TC, respectively, in this AA patient population. Despite previous reports of strong associations between each lipid trait and genetic load, weighted PRS (adjusted betas = -0.65, -1.52, -6.72, and -0.86, respectively) was not associated with HDL-C, LDL-C, TG, or TC levels in this AA patient population (p-values>0.05). None of the PRS was associated with CVD; however, AA patients in the 90th percentile of genetic load trended towards higher number of CVD cases compared with those with less genetic load. These data suggest this population appropriate PRS for these lipid traits cannot predict risk for CVD in AA, likely due to the small sample sizes, small individual genetic effect sizes, and/or the need for additional variants to be included in the PRS.

PrgmNr 3252 - Bivariate genome-wide association study of circulating fibrinogen and C-reactive protein (CRP) levels

Introduction: Previous genome-wide association studies (GWAS) have identified 41 loci associated with circulating fibrinogen and 58 loci with C-reactive protein (CRP) levels. Both proteins play an important role in inflammatory pathways, and several of the previously described loci overlap between fibrinogen and CRP, suggesting that they share a common genetic background. Hence, by integrating these phenotypes in a bivariate GWAS, we aimed to identify novel genetic variants that are pleiotropic and associated with both fibrinogen and CRP. **Methods**: We performed a bivariate GWAS by combining summary statistics of previously published GWAS on fibrinogen (n=120,246) from the CHARGE Consortium and CRP (n= 363,228) from UK Biobank, both comprised of European individuals, using metaUSAT, a unified score-based association test. Loci were considered to be pleiotropic when: 1) the bivariate p-values were 5Results: We identified 81 pleiotropic loci, of which 51 were novel for fibrinogen, and 14 were novel for CRP. Of these, 11 loci were novel for both fibrinogen and CRP. Out of the 14 novel pleiotropic loci for CRP, using Bonferroni correction of 3.57E-3 (0.05/14), 7 genetic variants were replicated. They were located in or near genes *CCT3*, *MICU1*, *ARL14EP*, *GSDMA*, *NPEPL1*, *NR1I2*, and *RNA5SP158*. **Conclusion**: Bivariate GWAS was an efficient method to identify numerous pleiotropic loci for fibrinogen and CRP. Our study identified 81 pleiotropic loci associated with both fibrinogen and CRP. From these, we discovered and replicated 7 new loci for CRP. This shows that fibrinogen and CRP indeed share a common genetic architecture with many pleiotropic loci.

PrgmNr 3253 - Blood Pressure Polygenic Score Associations in a Pediatric Cohort Requiring Surgery for Congenital Heart Defects

View session detail

Author Block: **J. Breeyear**[1], J. M. Keaton[2], A. H. Smith[3], D. Klarin[4], S. M. Damrauer[5], P. Natarajan[4], S. L. Van Driest[6], J. G. Weiner[6], P. J. Kannankeril[6], T. L. Edwards[6]; [1]Vanderbilt Univ., Nashville, TN, [2]NIH/NHGRI, Clarksburg, MD, [3]Johns Hopkins All Children's Hosp., St. Petersburg, FL, [4]Massachusetts Gen. Hosp., Boston, MA, [5]Hosp. of the Univ. of Pennsylvania, Philadelphia, PA, [6]Vanderbilt Univ. Med. Ctr., Nashville, TN

Disclosure Block: **J. Breeyear:** None.

Congenital malformations are the leading cause of infant mortality in the United States. Congenital heart defects (CHD) are the most prominent congenital malformation, affecting 40,000 US births per year: with most children requiring surgical intervention(s). Better understanding of the basis for clinical variability in morbidity and mortality has the potential to improve clinical management and outcomes. To date, few studies have evaluated blood pressure polygenic risk scores (PRS) associations with post-operative outcomes. We used imputed genotypes from pediatric participants requiring surgery for CHD (median age = 201 days, nmax = 2,498). Base data for systolic (SBP) and diastolic (DBP) blood pressure PRSs used published GWAS data (nmax = 760,226). The PRSs were validated in BioVU (nmax = 37,132) with genetic data pruned for linkage disequilibrium at an r2 threshold of 0.1 at a maximum distance of 250 kilobases from associated SNPs in the BP summary statistics. PRSs associations with in-hospital mortality (HM), intensive care unit length of stay (ICU-LOS), length of hospital stay (LOS), and vasoactive-inotropic scores (VIS) were modeled using logistic or linear regression in STATA, adjusted for age, sex, BMI, Society for Thoracic Surgeons-European Association for Cardio-Thoracic Surgery category, and the top ten principal components of ancestry. The DBP PRS was associated with decreased HM risk (0.64 (0.46 - 0.89), p = 0.0085), decreased ICU-LOS (-1.79 Â± 0.66 days, p = 0.0071), decreased LOS (-2.16 Â± 0.91, p = 0.018), and decreased VIS (-0.52 Â± 0.23, p = 0.022) The SBP PRS was not significantly associated with any outcomes. A combined model of the DBP and SBP PRSs was associated with decreased HM risk (0.48 (0.29 - 0.78), p = 0.0033), decreased ICU-LOS (-2.36 Â± 0.61 days, p = 0.000096), and decreased LOS (-3.74 Â± 1.46, p = 0.011). Our findings present evidence that pediatric patients with a genetic predisposition to high blood pressure have a reduced risk of in-hospital mortality and a protective effect in pediatric post-surgical recovery following congenital heart surgery. The observed associations of blood pressure PRSs with post-operative outcomes provides insight into the use of adult-derived cardiovascular PRSs as tools to anticipate negative outcomes and understand inter-individual variability of response to CHD repair in children.

PrgmNr 3254 - Detecting blood-pressure regulatory mechanisms with tissue specific CRE maps and biobank scale datasets

View session detail

Author Block: **O. Yaacov**[1], D. Lee[2,1], P. Mathiyalagan[1], X. Zhu[3], S. Ganesh[4], A. C. Morrison[5], N. J. Risch[6], A. Chakravarti[1]; [1]Ctr. for Human Genetics and Genomics, NYU Grossman Sch. of Med., New York, NY, [2]Boston Children's Hosp., Boston, MA, [3]Case Western Reserve Univ, Cleveland, OH, [4]Univ. of Michigan, Ann Arbor, MI, [5]Univ. of Texas at Houston, Houston, TX, [6]Univ. of California San Francisco, San Francisco, CA

Disclosure Block: **O. Yaacov:** None.

Blood pressure (BP) is a common quantitative trait with ~30% heritability. Numerous genetic studies have clearly demonstrated that the majority of this heritability is explained by ~900 genetic associations of small effect (median effect size ~0.25â□□mm Hg per allele) distributed across the genome. In this study, we demonstrate how genome-wide epigenomic maps can be used to identify the contributions of specific genes and variants in the kidney, heart, artery and adrenal gland, to BP regulation. We collected tissue samples from human kidneys, hearts, arteries and adrenal glands and performed both ATAC- and RNA- sequencing. Combined with H3K27ac and ATAC-seq data from the ENCODE project we created tissue-restricted open chromatin maps, using our prior published methods. We used these maps to train machine learning models, delta-SVM, an established method to predict tissue-specific CRE variants. We scored all common (minor allele frequency>1%) single nucleotide variants (SNVs) from the 1000G project in each of the tissue -restricted accessible chromatin peaks. We then performed a custom SKAT gene-wise analysis, using the delta-SVM scores as weights and limiting analysis to SNVs within chromatin peaks. For phenotypes, we used systolic (SBP) and diastolic (DBP) BP measurements (corrected for age, BMI, sex and anti-hypertensive medication use) and imputed genotypes of 77,823 individuals from the RPGEH biobank (Research Program on Genes, Environment, and Health, Kaiser Permanente North California). We Identified 309, 259, 331 and 367 statistically significant genes (Î±=0.05 BH corrected) for DBP in the tibial artery, kidney, heart left ventricle (LV) and adrenal gland, respectively. Similarly, we detected 191, 184, 204 and 204 genes for SBP. 50-70% of these genes were replicated using an independent dataset of 315,270 unrelated individuals from the UK Biobank. This is highly significant because permutation analysis of these data replicated

PrgmNr 3255 - Epigenetic age acceleration predicts subclinical atherosclerosis among participants of the Bogalusa Heart Study

View session detail

Author Block: **X. Sun**, W. Chen, A. C. Razavi, M. Shi, E. Harville, J. He, L. A. Bazzano, T. N. Kelly; Tulane Univ., New Orleans, LA
Disclosure Block: **X. Sun:** None.
Background: Epigenetic age acceleration (EAA), or increased DNA methylation (DNAm)-based age relative to chronological age, has been associated with cardiovascular disease (CVD) risk factors. However, the relationship between EAA and subclinical atherosclerosis is unclear. We examined associations of EAA with carotid intima-media thickness (cIMT) and carotid plaque in the Bogalusa Heart Study (BHS).
Methods: We included 1,487 BHS participants with simultaneous measures of whole-blood DNAm and cIMT. DNAm data generated using the Illumina HumanMethylation450 BeadChip was used to estimate extrinsic EAA (EEAA) and intrinsic EAA (IEAA), based on Hannumâ□□s and Horvathâ□□s epigenetic clocks, respectively. cIMT was measured using carotid ultrasound, with carotid plaque defined as a distinct focal wall thickening of >1.5 mm. Cross-sectional associations of EAA with cIMT and carotid plaque were tested using multiple linear and logistic regression models, respectively. Three multivariable models were employed, adjusting for: age, sex, and race (model 1); model 1 covariables plus education, smoking, and drinking (model 2); and model 2 covariables plus blood pressure, lipids, and glucose (model 3). Among 321 BHS participants with an additional prospective measure of cIMT, we used logistic regression to test whether baseline EAA predicted incident carotid plaque over an average of 6.0 years follow-up. The same multivariable models were employed, additionally adjusting for baseline cIMT and follow-up time in all models.
Results: Individuals were on average 47 years old, 56% were women, and 33% were African American. Each standard deviation increase in EEAA was cross-sectionally associated with a 0.037 mm increase in cIMT in model 1 ($P=3.09Ã□10^{-6}$), a 0.031 mm increase in model 2 ($P=8.35Ã□10^{-5}$), and a 0.021 mm increase in model 3 ($P=5.97Ã□10^{-3}$). Similarly, each standard deviation increase in EEAA was cross-sectionally associated with a 1.29-fold higher odds of carotid plaque in model 1 ($P=6.66Ã□10^{-5}$), a 1.23-fold higher odds in model 2 ($P=1.24Ã□10^{-3}$), and a 1.17-fold higher odds in model 3 ($P=2.3Ã□10^{-2}$). In prospective analyses, EEAA significantly predicted development of carotid plaque in model 1, with similar but marginally significant trends observed in models 2 and 3. EEAA was associated with a 1.32-fold higher odds of incident carotid plaque in model 1 ($P=3.01Ã□10^{-2}$), 1.28-fold higher odds in model 2 ($P=6.12Ã□10^{-2}$), and 1.24-fold higher odds in model 3 ($P=7.76Ã□10^{-2}$). IEAA was not associated with cIMT or carotid plaque.
Conclusions: We identified significant associations of EEAA with subclinical atherosclerosis, which were independent of known CVD risk factors.

PrgmNr 3257 - Identification of genetic variants that confer susceptibility to familial combined hyperlipidemia

Disclosure Block: **H. Ata Ul Mustafa:** None.

Familial combined hyperlipidemia (FCHL) is a common genetic disorder that is characterized by elevated cholesterol and triglycerides. The disorder exhibits diverse clinical manifestations with complex etiology. Our goal is to detect single nucleotide variants (SNVs) associated with FCHL within regions with evidence of linkage to the disease. We hypothesize that variants associated with FCHL may affect gene function or lipid metabolism and contribute to its etiology. FCHL families were ascertained by: (1) identifying probands with fasting plasma total cholesterol â□¥95th percentile and triglycerides â□¥90th percentile for age, sex, and race and (2) having at least 2 participants with FCHL and 1 unaffected relative. We had a total of 638 individuals (315 males, 304 females, 19 unknown) in 41 extended families (size: 4-46 individuals) from 3 centers in WV and KY. We excluded families who only had singletons, without DNA or only have 2-3 individuals with DNA. For families included in the analysis, we trimmed individuals to focus on pedigree branches having affected individuals who are closely related. After trimming, we have a total of 446 individuals (211 males, 218 females, 17 unknown) in 23 families (size=4-41) with ages ranging from 2 to 95 years old (Î¼= 40.51Â± 21.63years old). As for phenotype data, fasting plasma total cholesterol ranged from 94-490 mg/dL (Î¼= 226.14Â±64.47 mg/dL) and triglycerides ranged from 37-3021 mg/dL (Î¼=220.11Â±273.25 mg/dL). A total of 180 individuals were genotyped using ~654K SNP panel. Of these, we conducted whole exome sequencing (WES) in 119 individuals that were selected using GIGI-Pick to capture segregation of founder alleles. We use the pedigree-based analysis pipeline (PBAP) to: (1) perform file manipulations, (2) validate pedigree structures, (3) sub-select linkage disequilibrium (LD)-reduced panel of markers from the dense SNP array, and (4) access gl_auto of the MORGAN package to sample inheritance vectors (IVs), which specify the flow of founder alleles in the pedigree. Using sampled IVs, we perform linkage analyses using PBAP to identify genomic region(s) of interest (ROI) that have evidence of linkage to FCHL. Within ROI(s), we perform family-based genotype imputation in individuals without WES data that enables us to obtain genotypes at a much lower cost. We perform family-based association analysis to determine variants associated with FCHL using both observed and imputed genotypes.

PrgmNr 3258 - Phenotypic features of TGFB3 disease-causing variants in a group of North Americans

View session detail

Author Block: **N. Garg**[1], J. R. Schweber[2], J. Fleischer[1]; [1]Southern Illinois Univ. Sch. of Med., Springfield, IL, [2]Washington Univ. Sch. of Med., St Louis, MO
Disclosure Block: **N. Garg:** None.
TGFB3 gene mutations, newly described as a cause of Loeys-Dietz Syndrome type IV (LDS4) in 2015, have been reported in around 80 patients to date, with the largest cohorts being described by Marsili et al, 2020 and Schepers et al, 2018. To further delineate the phenotype associated with TGFB3 mutations, we present 7 new cases of LDS4 with two novel TGFB3 mutations with comparison to the previously reported cohorts. We also describe a patient with an FBN1 variant in combination with a TGFB3 variant and the possible effect of this variant combination on the phenotype.
In our cohort, we found joint hyperlaxity and pectus deformity were the most common features and were present in 71% of the cases. Scoliosis was the second most common finding present in 57% of the cases. Twenty-Eight percent were found to have arterial tortuosity. Aortic root aneurysm, ascending aortic aneurysm and mitral valve prolapse represented the most common cardiovascular findings, and each was present in 14% of the cases. Other prominent features included myopia in 28%, bifid uvula in 42%, flat feet in 42%, and stria in 28% of these individuals. In familial cases, incomplete penetrance and variable clinical expressivity were noted. In summary, TGFB3 variants had multisystemic involvement and were associated with a significant aortic disease as well as arterial tortuosity, highlighting the importance of early diagnosis of TGFB3 mutations to provide focused screening to prevent morbidity and mortality in such individuals.

PrgmNr 3259 - Polygenic risk for atrial fibrillation across ancestry: the Electronic Medical Records and Genomics (eMERGE) Network

View session detail

Author Block: **M. J. Puckelwartz**[1], K. T. Sawicki[1], L. L. Pesce[1], S. D. Kearns[1], E. R. Duvall[1], J. A. Pacheco[1], C. Liu[2], M. S. V. Elkind[2], N. Vaitinadin[3], G. E. Davogustto[3], M. B. Shoemaker[3], J. D. Mosley[3], L. J. Rasmussen-Torvik[1], R. L. Chisholm[1], D. M. Roden[3], E. M. McNally[1]; [1]Northwestern Univ., Chicago, IL, [2]Columbia Univ., New York, NY, [3]Vanderbilt Univ. Med. Ctr., Nashville, TN
Disclosure Block: **M.J. Puckelwartz:** None.
Rationale: Atrial fibrillation (AF) is the most common cardiac arrhythmia, affecting over 30 million people worldwide. In the US, lifetime risk for AF differs across groups with Whites having the highest risk, followed by Blacks, and with Hispanic and Asians having the lowest incidence of AF. These lower risks occur in spite of higher occurrence of comorbidities that increase risk of AF in some non-White groups. The role of inherited susceptibility to AF is well established, from rare monogenic disorders to polygenic traits. Polygenic risk scores (PRS) utilize risk allele information to generate a single measure of inherited susceptibility. Genome-wide association studies (GWAS) have identified independent risk variants for AF, but these are derived largely from European ancestry cohorts and may not be applicable to non-European ancestries.
Objective: Determine if polygenic risk scores (PRS) derived from the AF risk variants have similar discrimination in non-European ancestries in the diverse Electronic Medical Records and Genomics (eMERGE) Network cohort.
Methods: The AF PRS was applied to a diverse cohort of 39,908 participants (self-reported: 89.3% European, 6.9% African and 2.7% Hispanic and 1.1% Asian) in eMERGE I-III with and without AF and genotype data. Diagnosis of AF was based on electronic health record (EHR) information including inpatient International Classification of Disease (ICD-9, ICD-10) diagnosis codes. The PRS was generated using 163 SNPs derived from two published GWAS studies with ~1.65 million subjects (97% European, 0.55% African, 2.27% Asian, and 0.20% Hispanic).
Results: Among the 39,908 participants, there were 9,128 AF cases. After adjustment for age, sex, and four principal components of ancestry, the PRS discriminated similarly across groups (area under curve [AUC] 0.65 in African, 0.68 in Asian, 0.66 in European and 0.67 in Hispanic). The odds ratio of the top 3% of polygenic scores compared to the bottom 97% was also similar across all groups with the largest associations in Europeans with an OR per SD (95% CIs) of 2.5 (2.2-2.8, p=1.3E-47). In African ancestry subjects the OR per SD was 1.7 (1.0-3.0, p=0.04), in Hispanic subjects the OR per was 2.9 (1.2-7.2, p=0.02) and 4.6 (1.3-16.7, p=0.02) in Asians.
Conclusions: Common genetic variation as defined by PRS is significantly associated with AF across multiple ancestries in the eMERGE Network. These findings suggest that despite the differing risk across ancestries, there are likely common genetic pathways that contribute to AF across ancestries. Future work will include evaluating integrative risk models for AF across diverse cohorts.

PrgmNr 3260 - Polygenic risk score for coronary artery disease worsens disparity by HIV status in clinical prediction of coronary artery calcium

Disclosure Block: **G.L. Wojcik:** None.
The development and application of polygenic risk scores (PRS) for cardiovascular disease have moved us closer to the promise of precision medicine. However, the performance of such scores depends on the original study population used for their development being representative of patients with respect to both genetic and non-genetic factors. Their application can be problematic for subpopulations of patients not represented in the original study population, such as people living with human immunodeficiency virus (HIV) who have an increased risk for coronary artery disease (CAD) compared to those without HIV. To address this question, we assessed the predictive performance for coronary artery calcium (CAC) of a genome-wide PRS for CAD of 6.6 million variants (Khera 2018) in 731 HIV-infected and -uninfected men of European ancestry in the Multicenter AIDS Cohort Study (MACS), independently and in combination with the ACC/AHA Pooled Cohort Equation (PCE). CAC scores were calculated by the Agatston method from cardiac CT scans. Regression models were stratified by HIV serostatus and adjusted for the top 10 principal components to account for residual population substructure, age, CT scanning center, and cohort enrollment date (before or after 2001). The overall median age was 57 (interquartile range (IQR): 52-62) years, 66% with CAC > 0, median CAC 24 (IQR: 0-186), and 58% living with HIV (HIV+) of whom 89% were virologically suppressed (plasma HIV RNA 2 of 0.19 for HIV+ and 0.29 for HIV-) and for the dichotomous absence or presence of CAC (area-under-the-curve (AUC) of 0.75 for HIV+ and 0.81 for HIV-). This trend was consistent with the differential performance of the non-genetic PCE (adjusted R^2: 0.19 for HIV+ vs 0.23 for HIV-). When we added the PRS to the PCE estimates, the adjusted R^2 increased to 0.22 for HIV+ men and 0.28 for HIV- men, widening the performance gap between the two with the adjusted R^2 for HIV+ men being only 78% of that for HIV- men, compared with 82% for PCE alone. These results suggest that PRS for CAD may not adequately capture the gene x environment interactions which may differ between HIV+ and HIV- men when predicting CAC, resulting in reduced accuracy for HIV+ men relative to HIV- men when used alone or in conjunction with existing clinical risk scores. Future research must extend these questions to assessing risk performance for clinical CAD in people living with HIV in order to develop more accurate risk prediction models and ensure that PRS have clinical utility in all patient populations.

PrgmNr 3261 - The genetic determinants of body mass index & fasting glucose are mediators of grade 1 diastolic dysfunction development

View session detail

Author Block: **N. Vaitinadin**[1], M. Shi[1], C. M. Shaffer[1], E. Farber-Eger[2], B. D. Lowery[1], V. Agrawal[1], Q. S. Wells[2,1], J. D. Mosley[1]; [1]Vanderbilt Univ. Med. Ctr., Nashville, TN, [2]Vanderbilt Univ., Nashville, TN

Background Early (grade 1) cardiac diastolic dysfunction (G1DD) is a common functional change in the heart that increases the risk for heart failure (HF) with preserved ejection fraction and is treatable with aggressive risk factor modification. Type 2 diabetes (T2D), obesity, hypertension, and coronary heart disease are associated with increased incidence of diastolic dysfunction. The predisposing genetic drivers of G1DD are not defined. **Methods** We curated genotyped European Ancestry cases (n=668) and controls (n=1772) for G1DD from Vanderbiltâ□□s biobank, BioVU. GWAS, employing an additive genetic model was used to identify common variants associated with G1DD status. Common variant polygenic risk scores (PRS) for coronary heart disease, systolic blood pressure, T2D, and body mass index (BMI) were developed using data from prior GWAS for use in association studies and Mendelian randomization (MR) analyses. Logistic regression was used to test the associations between G1DD status and risk scores for each risk factor. Predictors with significant associations were further evaluated using 2-sample Mendelian randomization methods (the inverse-variance weighted [IVW], MR-Egger and median). Candidate mediator exposures were further characterized using multivariable mendelian randomization. **Results** There were no common SNPs associated with G1DD status at genome-wide significance by GWAS. A PRS for BMI was significantly associated with increased G1DD risk (OR = 1.20 for 1 SD increase in BMI, 95% CI = 1.08,1.32, p = 0.0003). The association was confirmed by IVW [OR=1.89 (95% CI=1.37, 2.61). Among the candidate mediators for BMI - HDL cholesterol, LDL cholesterol, triglycerides, fasting glucose (FG), and HbA1C - only FG was significantly associated with G1DD status by IVW (OR = 4.14 for 1 SD increase in FG, 95% CI = 1.55,11.02, p = 0.005). Multivariable mendelian randomization showed a modest attenuation of the BMI association [OR=1.84 (1.32, 2.57)] when adjusting for FG. **Conclusions** In sum, these data suggest that a genetic predisposition to elevated BMI increases the risk of G1DD. Part of this effect may be mediated through altered glucose homeostasis. BMI is an important modifiable risk factor for G1DD.

PrgmNr 3262 - The genetics of coronary artery calcification in individuals with type 2 diabetes

View session detail

Author Block: **N. R. Hasbani**[1], J. B. Meigs[2], S. Kwak[3], P. S. de Vries[4]; [1]Epidemiology, Human Genetics, and Environmental Sci.,The Univ. of Texas Hlth.Sci. Disclosure Block: **N.R. Hasbani:** None.

Coronary artery calcification (CAC) is a marker of atherosclerosis and is associated with increased risk of coronary heart disease (CHD) mortality, especially in individuals with type 2 diabetes (T2D). While numerous studies have identified genetic loci involved in CAC, CHD, and T2D, the shared genetic architecture between these highly associated traits is still being understood. We compared the effects of 207 genetic variants that were previously identified as associated with CHD and/or CAC in 2,971 individuals with T2D and 13,022 non-diabetic controls utilizing whole genome sequencing generated by the National Heart, Lung, and Blood Instituteâ□□s Trans-Omics for Precision Medicine (TOPMed) program. Participants were from four race/ethnic groups, including European American, African American, Hispanic/Latinx, and East Asian. CAC was first log transformed, then further transformed through inverse rank-based normalization of the residuals accounting for age and sex. Linear mixed models accounting for relatedness, implemented in GENESIS, were used to test for interaction between each variant and T2D status. Analyses were adjusted for age, sex, study and the first eleven principal components. The genetic main and interaction effects were assessed in a joint test using a two degree of freedom model to determine if a CHD variant was associated with CAC, then further evaluated to determine if these variants had a significantly different effect in T2D cases versus controls. Using Bonferroni corrected significance threshold of *P*-4 (0.05/207), we identified eighteen CHD variants associated with CAC according to the joint test, of which six had a statistically significant different effect in T2D cases and controls (rs6494488 near *RBPMS2,* rs7212798 in *BCAS3,* rs1321309 near *CDKN1A,* rs668948 near *APOB,* rs840616 near *CALCRL,* rs12897 near *FNDC3B*). The association of five of these variants was stronger in T2D cases than in controls, while for rs7212798 it was stronger in controls. While rs668948 has not previously been implicated in previous CAC GWAS, it lies nearest to *APOB,* which is a known driver of plaque development and subsequent atherosclerosis. Similarly, rs840616 lies near *CALCRL*, which is a part of a group of calcitonin receptors involved in the maintenance of calcium homeostasis. Overall, 85 of the CHD variants were nominally significant (*P*

PrgmNr 3263 - An exposome-wide association study (ExWAS) and comparison of clinical, environmental and polygenic risk scores for Type 2 Diabetes

Author Block: **F. Akhtari**[1], D. T. Lloyd[1], J. S. House[1], D. C. Fargo[1], S. Schurman[2], C. S. Schmitt[1], J. E. Hall[1], A. A. Motsinger-Reif[1]; [1]NIEHS, Durham, NC, [2]Natl. Inst on Aging, NIH, Baltimore, MD
Disclosure Block: **F. Akhtari:** None.
Type 2 diabetes (T2D) is a complex disease influenced by genetic and environmental factors. Few studies have examined the effects of environmental exposures on T2D, especially in the context of genetic risk. We investigate the individual and cumulative effects of environmental and genetic factors on T2D, and report novel exposures associated with the disease. Analogous to a genome-wide association study, we conducted an exposome-wide association analysis (ExWAS) to assess the influence of diet, lifestyle, and environmental factors on T2D risk. We collected environmental and genetic data from the Personalized Environment and Genes Study (PEGS), a diverse North Carolina-based cohort, using three survey instruments: the Health and Exposure Survey (N = 9,414) for demographics, family medical history, lifestyle factors, and occupational exposures; the Internal Exposome Survey (N = 2,962) for exposures such as medications, physical activity, stress, sleep, and diet; and the External Exposome Survey (N = 3,519) for exposures such as chemical and environmental exposures at work and home. We performed single-exposure association analysis for 680 environmental factors with self-reported T2D status using logistic regression models with appropriate covariate adjustment. After multiple testing correction, we identified 27 significant associations. Notably, we identified novel associations of exposure to asbestos (OR = 1.44, CI = 1.10-1.88), textiles (OR = 1.39, CI = 1.05-1.83), and coal dust (OR = 1.60, CI = 1.05-2.43) with T2D. To compare cumulative risk due to genetic and non-genetic factors, we computed clinical risk scores (CRS), environmental risk scores (ERS), and polygenic risk scores (PRS) for a subset of participants (N = 3,236) for whom exposure data and whole genome sequencing was available. We calculated CRS using self-reported BMI, pre-diabetes, hypertension, and high cholesterol. We computed ERS using 16 variables selected by LASSO from the significant ExWAS results. We developed a trans-ethnic PRS for T2D with LDPred2 using UK Biobank data (N = 440,757; 122,359 SNPs) and then calculated the PRS for PEGS participants. Using logistic regression models adjusted for age, gender, and the first ten principal components, we found that all three risk scores were significantly associated with T2D, with odds ratios for CRS (3.85, CI = 3.38-4.42), ERS (2.90, CI = 2.49-3.40) and PRS (1.29, CI = 1.11-1.52). Notably, ERS had a stronger association and higher correlation with T2D compared to the more frequently reported PRS. Future work should replicate this finding and assess the predictive performance of PRS. In ongoing work, we are evaluating PRSxE interactions.

PrgmNr 3264 - Assessment of Polygenic Risk Score for Predicting Type 2 Diabetes Risk in Asian Indians: Results of the Asian Indian Diabetic Heart Study/Sikh Diabetes Study

View session detail

Author Block: **D. K. Sanghera**[1], S. Goyal[1], J. R. Singh[2], N. K. Mehra[3], G. S. Wander[4], S. Ralhan[4]; [1]Univ Oklahoma HSC, Oklahoma City, OK, [2]Central Univ. of Punjab, Bathinda, India, [3]All India Inst. of Med. Sci. and Res., New Delhi, India, [4]Hero DMC Heart Inst., Ludhiana, India
Disclosure Block: **D.K. Sanghera:** None.
Genome-wide polygenic risk score (PRS) is considered a good predictor of disease risk, however, its utility as an independent risk predictor in complex diseases such as type 2 diabetes (T2D) remains inconclusive. Epidemiological studies reported that people from the Indian subcontinent suffer from a greater risk of cardiovascular disease-associated mortality than other global populations. Overwhelming data support a strong influence of genetic factors and their interaction with lifestyle and environmental factors. Populations from the Indian subcontinent are underrepresented in genetic studies despite Asian Indians contribute more than 25% of the world population and have up to 6 times more risk for T2D compared to European whites. Here we have evaluated the additive value of multilocus PRS in T2D risk-prediction in comparison to the Clinical Risk Score (CRS, modified from the Joint British Society (JBS) risk score) using 4,588 individuals (2,566 cases and 2,022 controls) from the Asian Indian Diabetes Heart Study/Sikh Diabetes Study (AIDHS/SDS). The PRS for T2D was constructed using 63 genetic variants associated with T2D in 1,613 individuals in the training set and validated in 2,975 individuals in the test set. Logistic regression analyses were performed using age, gender, BMI, and five principal components as covariates to determine the risk prediction for T2D using PRS and CRS. Prediction accuracy of PRS and CRS was assessed by measuring the area under the receiver operating characteristic (ROC) curve (AUC). PRS for T2D yielded an adjusted odds ratio (OR)1.86 95% CI (1.73-2.00), $p=2.39x10^{-62}$ with AUC of 0.78 (95% CI 0.75-0.80) in the training set, and OR1.51 95% CI (1.43-1.59), $p=5.64x10^{-55}$ with AUC of 0.76; 95% CI (0.75-0.78) for the test set. In comparison to the PRS, the composite analysis of CRS revealed a higher OR and increased AUC in both training and the test sets, respectively [OR 2.63 95%CI (2.36-2.92), $p=1.58x10^{-69}$ and AUC of 0.80 (95% CI 0.78-0.82)] and [OR 2.7195% CI (2.50-2.95), $p=1.66x10^{-123}$, and an AUC of 0.84; 95% CI (0.83-0.85)]. In summary, though the PRS was an independent predictor of the T2D risk in this study, the CRS has still outperformed the PRS. Nevertheless, as more risk loci with population-specific effects are being identified by sequencing, combining the PRS approach with clinical/traditional risk factors would enhance predictive value to CRS to identify and stratify individuals at higher risk of developing T2D.

PrgmNr 3265 - Do methods of inclusion and presentation of non-European ancestry data in GWAS allow for novel discoveries?

View session detail

Author Block: **A. R. Bentley**[1], C. N. Rotimi[2]; [1]Natl Human Genome Res. Inst., Bethesda, MD, [2]NIH, Bethesda, MD
Disclosure Block: **A.R. Bentley:** None.
As is well appreciated, studies of European ancestry populations (EUR) dominate the GWAS literature. The call for greater inclusion of non-EUR studies has been partly motivated by the potential for novel discoveries. As more non-EUR populations are being included in GWAS publications, it is worth evaluating how these data are being incorporated, and if the study designs and presentation allow for the scientific advances that motivate their inclusion. We investigated GWAS studies published from 2015-2021 of type 2 diabetes (T2D) and related traits (retrieved from the GWAS catalog 5/13/2021) and sought to characterize them in terms of whether the study design and presentation allow for the discovery of novel associations in the non-EUR data.
Of the 102 publications that met our study criteria, 44% focused exclusively on EUR, both in discovery and replication, and are not discussed further. Of the 57 publications that included non-EUR studies in some way, the degree to which the inclusion facilitated novel findings varied. Three studies only included non-EUR studies to evaluate generalizability of EUR GWAS findings, thus limiting non-EUR associations to those already discoverable in EUR. Publications focused on non-EUR populations (n=35) were dominated by those of East Asian ancestry (n=23), but also included studies of Hispanics (n=4), Native Americans (n=2), Arabic individuals (n=2), Africans (n=2), African Americans (n=1), and Aboriginal Australians (n=1). There were 19 publications that conducted discovery GWAS in multiple ancestry groups. Eight of these only presented trans-ancestry meta-analyses, which do not allow for future ancestry-specific meta-analyses and may not adequately capture novel discoveries in each ancestry in the presence of heterogeneity of effects or linkage disequilibrium differences. In total, 19% of the studies including non-EUR populations were not optimized in design and/or presentation for facilitating genomic discoveries in these populations.
While studies have characterized the number and sample sizes of included studies of diverse ancestries, it is not only inclusion of non-EUR ancestry studies that matters. To maximize the potential for novel findings, it is also important how these cohortsâ data are analyzed and interpreted. To take advantage of the genetic diversity in non-EUR populations, it is key to conduct and present discovery studies in these populations separately. It is preferable to accompany trans-ancestry meta-analyses with ancestry-specific analyses and presentations.

PrgmNr 3266 - Expanded Genetic Clustering of Type 2 Diabetes Loci Using a High-throughput Pipeline Reveals Mechanistic Pathways of Metabolic Diseases

Disclosure Block: **H. Kim:** None.
Complex diseases such as type 2 diabetes (T2D) are highly polygenic and influenced by multiple biological pathways. Rapid expansion in the number of T2D loci can be leveraged to identify such pathways, which may facilitate improved patient management.
We developed a high-throughput pipeline to enable clustering of T2D loci based on variant-trait associations. Our pipeline extracted summary statistics from genome-wide association studies (GWAS) for T2D and related trait to generate a matrix of 336 variants x 64 trait associations and applied Bayesian Non-negative Factorization (bNMF) to identify genetic components of T2D.
We identified ten genetic clusters of T2D, which included five from our published prior analysis of 94 T2D loci. Four of the ten clusters related to mechanisms of insulin deficiency, five to insulin resistance, and one had an unclear mechanism. Novel clusters identified in this analysis related to beta-cell dysfunction, pronounced insulin secretion, and circulating levels of alkaline phosphatase, lipoprotein A, and sex hormone binding globulin.
The T2D genetic clusters displayed tissue-specific epigenomic enrichment, particularly in pancreatic islets, liver, and adipose tissue. Two of the clusters relating to insulin deficiency were differentially enriched in functional and stressed pancreatic beta-cell states. Additionally, cluster-specific polygenic scores were associated with distinct clinical outcomes across GWAS and confirmed in participants in the Mass General Brigham Biobank. Multiple observed T2D genetic pathways were shared across genetic clusters of coronary artery disease and chronic kidney disease.
Our approach stratifies T2D loci into physiologically meaningful clusters with distinct tissue specificity and association with metabolic conditions. The pipeline allows for efficient updating and refining of clusters as additional GWAS datasets become available, and can be readily applied to other conditions. This method supports translation of GWAS findings into a more granular understanding of disease mechanisms, with a view toward precision medicine.

PrgmNr 3267 - Genetic Regulation of Obesity Explains Cardiovascular Sex Differences in Polycystic Ovary Syndrome for Predisposed Individuals

View session detail

Author Block: **K. Actkins**[1], L. K. Davis[2]; [1]Meharry Med. Coll., Nashville, TN, [2]Vanderbilt Univ Med Ctr., Nashville, TN
Disclosure Block: **K. Actkins:** None.
Introduction: Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in reproductive age women with a complex polygenic architecture largely defined by metabolic dysregulation. Despite only being diagnosable in females, males with a family history of PCOS can also exhibit a poorer cardiometabolic profile that can be detected as early as infancy. In our previous phenome-wide association study (PheWAS), we found that males with a higher polygenic risk score (PRS) for PCOS ($PCOS_{PRS}$) were more likely to develop cardiovascular diseases like hypertension compared to females who had higher odds of developing type 2 diabetes (T2D). Therefore, in this study, we aimed to further elucidate the role of sex in the relationship between PCOS and its comorbidities by evaluating bidirectional genetic pathways. **Methods:** To do this, we first calculated PRS for BMI, T2D, systolic and diastolic blood pressure, and coronary artery disease (CAD) (i.e., the phenome-wide significant phenotypes identified in the prior PheWAS). Each PRS was then fitted against PCOS diagnosis in a logistic regression model adjusted for median age, genetic ancestry, and clinically measured body mass index (which captured both genetic and environmental BMI variance). Next, to examine the independent effects of environmental BMI, genetically regulated BMI variance was regressed out of clinical BMI measurements. Mediation analyses were then conducted in which BMI or residual BMI (i.e., with genetic variance removed) were coded as the mediator, $PCOS_{PRS}$ was coded as the exposure variable, and the above dichotomized clinical diagnoses as outcomes. **Results:** Only $T2D_{PRS}$ was significantly associated with PCOS in females (OR = 1.16[1.05-1.28], p=3.69e-03). This association was attenuated when including BMI as a covariate (OR = 1.07[0.97-1.19], p=0.20). However, the association reappeared when residual BMI was covaried (OR = 1.18[1.06-1.30], p=2.07e-03). Unsurprisingly, clinically measured BMI variance significantly mediated the effect of $PCOS_{PRS}$ on cardiometabolic outcomes in both sexes, but residual BMI alone did not mediate the effect of $PCOS_{PRS}$ on T2D (p=0.78) nor $PCOS_{PRS}$ on hypertension (p=0.82) in males. **Conclusions:** Our findings show that genetically predicted BMI has a greater relative impact than residual BMI on PCOS and its cardiometabolic comorbidities. Moreover, the genetic architecture of PCOS results in distinct metabolic sex differences. It is possible that comorbid conditions (e.g., T2D, CAD) may increase risk for PCOS through shared metabolic genetic pathways.

PrgmNr 3268 - Genotype-Phenotype Analysis in African Americans with Inflammatory Bowel Disease

View session detail

Author Block: **A. Stiemke**[1], L. W. Datta[2], M. G. Lazarev[2], Inflammatory Bowel Disease Genetics Consortium, D. P. B. McGovern[3], S. R. Brant[4,2], C. L. Simpson[1]; [1]Genetics, Genomics and Informatics, Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN, [2]Meyerhoff Inflammatory Bowel Disease Ctr., Dept. of Med., Sch. of Med. and Dept. of Epidemiology, Sch. of Publ. Hlth., Johns Hopkins Univ., Baltimore, MD, [3]F. Widjaja Fndn. Inflammatory Bowel and Immunobiology Res. Inst., Cedars Sinai Med. Ctr., Los Angeles, CA, [4]Rutgers Robert Wood Johnson Med. Sch., New Brunswick, NJ
Disclosure Block: **A. Stiemke:** None.
Inflammatory bowel disease (IBD) is an immune-mediated chronic intestinal disorder that is typically divided into two distinct types; ulcerative colitis (UC) and Crohn's disease (CD). Although each respective disease is classified based on clinical presentation, each diseaseâ□□s presentation is highly heterogenous. Here we aimed to better discern the heterogeneity within disease types by characterizing the many endophenotypes within UC and CD rather than their initial classification. A total of 1135 African American patients, 772 with CD, 323 with UC, and 41 with inflammatory bowel disease unclassified (IBDU), were included in this study. Genomic DNA data on the HumanOmni2.5 microarray was obtained from all patients and mapped to GRCh37/hg19. Extensive phenotyping was conducted on all patients, which allowed for the creation of 14 direct and derived endophenotypes, including perianal disease, smoking status, and age of onset. Analysis was restricted to the area Â±500kb around 15 previously identified candidate single nucleotide polymorphisms previously documented in IBD GWAS. Statistically significant results have been found for a number of stratified endophenotype analyses including disease severity and disease behavior. One such result for this stratification (*P*-value 2.64e-6, OR 0.21) is approximately 380kb proximal to NOD2 in ADCY7. Additional analyses are ongoing. Utilizing endophenotypes to differentiate various disease presentations will allow for additional genetic markers to be discovered. As additional genetic risk loci are identified, more robust screening will improve patient outcomes and overall quality-of-life. If the disease can be caught in its early stages, treatment options can be taken to ensure the best patient outcome.

PrgmNr 3269 - Identification of hepatocellular gene expression phenotypes influencing fatty liver disease in Hispanics

View session detail

Author Block: **S. Kumar**[1], J. E. Curran[2], E. De Leon[1], J. C. Granados[1], A. C. Leandro[2], M. Leandro[2], J. M. Peralta[2], S. Williams-Blangero[2,1], J. Blangero[2]; [1]Dept. of Human Genetics and South Texas Diabetes and Obesity Inst., Univ. of Texas Rio Grande Valley Sch. of Med., McAllen, TX, [2]Dept. of Human Genetics and South Texas Diabetes and Obesity Inst., Univ. of Texas Rio Grande Valley Sch. of Med., Brownsville, TX

Disclosure Block: **S. Kumar:** None.

Fatty liver disease (FLD) encompasses conditions that are associated with excess fat deposits in the liver (hepatic steatosis) and is the common cause of chronic liver disease worldwide. Non-alcoholic FLD (NAFLD) has been associated with a wide range of risk factors including diabetes, obesity, dyslipidemia, and metabolic syndrome and disproportionately affects the medically underserved Hispanic minority in the United States. NAFLD risk is likely due to a complex interaction of genetic and environmental factors that are still largely unidentified. We used an induced pluripotent stem cell (iPSC) based disease modeling approach to identify novel gene expression phenotypes influencing the disease to better understand disease genetics and develop targeted treatments. Well characterized, iPSC differentiated functional hepatocytes (HEPs) generated from six participants of our San Antonio Mexican American family study (SAMAFS) were analyzed for cellular lipid accumulation in *in-vitro* culture and by genome wide mRNA sequencing. The quantitative measures of cellular lipids, obtained by staining neutral lipids with BODIPY lipid probe and high content screening analysis of the iPSC generated HEPs, showed a high correlation (r^2 = 70%) with individualâ□□s *in-vivo* liver fat measures obtained by magnetic resonance imaging (MRI). Genome wide differential gene expression analysis between HEPs generated from individuals with high liver fat (MRI liver fat â□¥ 8%; n = 4) and normal/low liver fat (MRI liver fat â□¤ 6%; n = 2) identified 104 genes that were significantly differentially expressed (moderated t statistics p-value â□¤ 0.05, fold change (FC) absolute â□¥ 2.0). Functional annotation and gene network analyses performed using Ingenuity Pathway Analysis platform showed significant enrichment of differentially expressed genes in lipid metabolism (p- value range $9.11x10^{-5}$ to $7.84x10^{-3}$), small molecule biochemistry (p- value range $9.11x10^{-5}$ to $7.89x10^{-3}$) and cell-to-cell signaling (p- value range $2.43x10^{-4}$ to $1.17x10^{-2}$) cellular and molecular functions. Expression of several genes involved in lipid oxidation (*HAO2*, *RGS16* and *MB*), and lipid and sphingolipid homeostasis (*ORM1, ORM2, PON3,* and *ABCG1*) were found significantly altered in HEPs of high liver fat individuals. The expression of *ABCG1* which plays an important role in deposition and mobilization of cholesterol and overall lipid homeostasis in the liver was found to be significantly downregulated. An *in-vitro* fatty acid challenge performed on HEPs showed significant (FC â□¥ 2.0) upregulation of *ABCG1* in normal individuals, however nominal upregulation was observed in high liver fat individuals.

Multiple observational studies have reported an inverse relationship between 25-hydroxyvitamin D concentrations (25(OH)D) and type 2 diabetes (T2D). However, the results of short- and long-term interventional trials concerning the relationship between 25(OH)D and T2D risk have been inconsistent. To evaluate the causal role of reduced blood 25(OH)D in T2D, here we have performed a bidirectional Mendelian randomization study using 59,890 individuals (5,862 T2D cases and 54,028 controls) from European and Asian Indian ancestries. We used six known SNPs including 3 T2D SNPs and 3 vitamin D pathway SNPs as a genetic instrument to evaluate causality and direction of the association between T2D and circulating 25(OH)D concentration. Results of the combined meta-analysis of eight participating studies showed that a composite score of three T2D SNPs would significantly increase T2D risk by odds ratio of 1.24, $p=1.82x10^{-32}$; Z score 11.86 which however had no significant association with 25(OH)D status (Beta -0.02nmol/L Â± SE 0.01nmol/L; p=0.83; Z score -0.21). Likewise, the genetically instrumented composite score of 25(OH)D lowering alleles significantly decreased 25(OH)D concentrations (-2.1nmol/L Â± SE 0.1nmol/L, $p=7.92x10^{-78}$; Z score -18.68) but was not associated with increased risk for T2D (odds ratio 1.002, p=0.12; Z score 1.54). However, using 25(OH)D synthesis SNP (DHCR7; rs12785878) as an individual genetic instrument, a per allele reduction of 25(OH)D concentration (-4.2nmol/L Â± SE 0.3nmol/L) was predicted to increase T2D risk by 5%, p= 0.004; Z score 2.84. This effect, however, was not seen in other 25(OH)D SNPs (GC rs2282679, CYP2R1 rs12794714) when used as an individual instrument. Our new data on this bidirectional Mendelian randomization study suggests that genetically instrumented T2D risk does not cause changes in 25(OH)D levels. However, genetically regulated 25(OH)D deficiency due to vitamin D synthesis gene (DHCR7) may influence the risk of T2D.

PrgmNr 3271 - Pediatrics and proteins: Molecular discovery in the Hearts & Parks study of children with obesity

Obesity is occurring at earlier ages in contemporary society. Mirroring adults, one third of US children are overweight or obese. This portends a worsening epidemic of the downstream consequences of obesity including cardiovascular disease. Unfortunately, similar to studies in adults, there is heterogeneity with regards to weight and metabolic response to obesity interventions in children which is poorly characterized with clinical factors. Thus, we sought to use proteomic profiling to elucidate biology underlying this heterogeneity and identify biomarkers with potential use for personalized weight loss interventions. Proteomic profiling of 768 proteins using the Olink proximal extension platform was performed in frozen baseline serum samples from two behavioral weight loss intervention cohorts: (1) Hearts & Parks (H&P; N=116), a lifestyle-based weight loss study of children (5-12 yo); (2) Pediatric Obesity Microbiome & Metabolism Study (POMMS; N=184) of adolescents (10-18 yo). Outcomes included: baseline and percent change in Homeostatic Model Assessment of Insulin Resistance (%â□□HOMA-IR); and obese/lean status and change in BMI P95. Linear/logistic models were used to associate proteins to outcomes. The mean baseline HOMA-IR was: H&P = 3.2Â±3.3; POMMS = 3.8Â±4.5; and the mean %â□□HOMA-IR was: H&P = 0.2Â±0.7; POMMS = 0.7Â±1.1. The mean change BMI P95 was H&P = -1.0Â±6.7; POMMS = 1.0Â±7.0. Proteomic profiling identified 328 proteins associated with obese vs lean, two with â□□BMI P95, 66 with baseline HOMA-IR, and none with %â□□HOMA-IR, all after FDR correction for multiple testing. IGFBP-1 and IGFBP-2 (both correlated with r2=0.64) were the most significantly associated with obese/lean status (FDR p

PrgmNr 3272 - Phenome-wide investigation of health outcomes associated with the genetic correlates of 25 hydroxyvitamin D concentration

Vitamin D deficiency, a prevalent condition that is commonly associated with poor general health, may place individuals at increased risk for subsequent disorders. Previous research demonstrated links between genetic correlates of vitamin D concentration and dyslipidemia, coronary artery disease, and type 2 diabetes. This study aims to explore associations between common genetic variants associated with 25 hydroxyvitamin D (25OHD) concentration and a comprehensive range of general clinical phenotypes and laboratory tests.

25OHD-related polygenic risk scores (PRS_25OHD) were generated for Vanderbilt University Medical Center Biobank (BioVU) participants of European ancestry (EA, n=72,741) and African ancestry (AA, n=15,283). 25OHD_PRS were used to perform a phenome-wide association study (PheWAS) and laboratory test-wide association study (LabWAS).

In EA PheWAS models, PRS_25OHD was negatively associated with clinical vitamin D deficiency (OR=0.84, 95% CI=0.81-0.87, p=2E-32), hypercholesterolemia (OR=0.91, 95% CI=0.88-0.94, p=3E-11), disorders of lipid metabolism (OR=0.94, 95% CI=0.92-0.96, p=2E-10), hyperlipidemia (OR=0.94, 95% CI=0.92-0.96, p=2E-10), hyperglyceridemia (OR=0.79, 95% CI=0.70-0.88, p=3E-07), type 2 diabetes (OR=0.94, 95% CI=0.92-0.96, p=3E-08), and obesity (OR=0.95, 95% CI=0.92-0.98, p=1E-06). In AA PheWAS models, PRS_25OHD was not associated with any phenotypes. In EA LabWAS models, PRS_25OHD was positively associated with observed concentrations of 25OHD ($\hat{I}^2$=0.18, SE=0.01, p=4E-82) and 1,25 hydroxyvitamin D, the hormonally active form of vitamin D ($\hat{I}^2$=0.15, SE=0.01, p=2E-120). PRS_25OHD was negatively associated with levels of triglycerides ($\hat{I}^2$=-0.06, SE=0.01, p=9E-27), cholesterol ($\hat{I}^2$=-0.04, SE=0.01, p=5E-16), and cholesterol in low density lipoproteins ($\hat{I}^2$=-0.03, SE=0.01, p=1E-06). In AA LabWAS models, PRS_25OHD was positively associated with observed concentrations of 1,25 hydroxyvitamin D ($\hat{I}^2$=0.07, SE=0.02, p=2E-5).

This study confirms that genetic instruments related to vitamin D status can predict a range of medical conditions and laboratory measures within electronic health records. PRS_25OHD was significantly associated with clinically defined vitamin D deficiency and laboratory measures of both 25OHD and the hormonally active form of vitamin D. Furthermore, lower genetically predicted vitamin D levels were associated with increased risk of lipid-related phenotypes, obesity, and diabetes. Future work is needed to elucidate mechanisms underlying associations reported in this study to understand how vitamin D deficiency may contribute to subsequent clinical manifestations.

PrgmNr 3274 - Rare variants associated with serum creatinine in 350k UK Biobank whole exome sequences

View session detail

Author Block: **M. M. Parker**[1], A. Deaton[2], L. D. Ward[1], R. Hoffing[2], C. Willis[1], M. Plekan[2], A. Flynn-Carroll[2], G. Hinkle[2], P. Nioi[1]; [1]Alnylam, Cambridge, MA, [2]Alnylam Pharmaceuticals, Cambridge, MA
Disclosure Block: **M.M. Parker:** Salary/Employment; Alnylam Pharmaceuticals.
Background High serum creatinine is an indicator of poor kidney function and is strongly negatively correlated with estimated glomerular filtration rate (eGFR). **Methods** We aggregated variants by gene and tested if rare (MAF P of $3.4x10^{-6}$ was considered statistically significant. Genes associated with creatinine were tested for association with a diagnosis of chronic kidney disease (CKD), with a *P* Results We find 11 significant associations between aggregated pLOF variants and serum creatinine. The strongest associations of pLOF variants with serum creatinine were in *PKD1* (OR CKD = 6.1) and *PKD2* (OR CKD =2.3), which are known causes of polycystic kidney disease. Of 638 carriers of pLOF variants in *PKD1*, 102 (16%) were in were diagnosed with CKD and of 125 carriers of pLOF variants in *PKD2*, 31 (30%) were diagnosed with CKD. Other genes associated with both lower creatinine and increased risk of CKD included *SLC22A2* (P creatinine = $1.7x10^{-38}$, P CKD = $1.0x10^{-7}$, OR CKD=1.7), *SLC34A3* (P creatinine = $4.0x10^{-14}$, P CKD = $1.9x10^{-3}$, OR CKD=1.7) and *OBSCN* (P creatinine = $2.3x10^{-9}$, P CKD = $4.1x10^{-3}$, OR CKD=1.2). Genetic variants in or around *SLC22A2* and *OBSCN* have been previously associated with eGFR in GWAS. Our rare variant associations suggest that loss of function in these genes increases risk of CKD, providing a potential mechanism to explain the GWAS associations. Similarly, genetic variants in *SLC34A3* have been previously associated with kidney stones and nephrocalcinosis, which our data suggests may be explained by loss of function of *SLC34A3*. **Conclusions** Tests between rare pLOF variants in 14,863 genes and serum creatinine revealed 11 significant associations, 5 of which also showed an association with increased risk of CKD diagnosis. Our results help explain previously identified GWAS associations and will aid the advancement of precision medicines like RNAi therapeutics.

PrgmNr 3275 - The effect of obesity-related traits on COVID-19 severe respiratory symptoms and hospitalization and its mediation by socioeconomic status: a multivariable Mendelian randomization study

View session detail

Author Block: **B. Cabrera Mendoza**[1,2], F. Wendt[1,2], G. Pathak[2,1], F. de Angelis[1,2], A. De Lillo[1], D. Koller[1,2], R. Polimanti[1,2]; [1]Yale Univ., New Haven, CT, [2]VA CT Hlth.Care System, West Haven, CT
Disclosure Block: **B. Cabrera Mendoza:** None.
Obesity has been associated with a higher susceptibility to coronavirus disease 2019 (COVID-19), particularly with its more severe clinical manifestations. However, this association can be affected by many correlates of these traits. Due to its large impact on human health, socioeconomic status (SES) could influence at least partially the association between obesity and COVID-19 severity. To estimate the independent effect of traits related to body size and SES on the clinical manifestations of COVID-19, we conducted a Mendelian randomization (MR) study analyzing the effect of obesity-related anthropometric traits on COVID-19 outcomes. We evaluated the effects of body mass index (BMI), waist circumference (WC), hip circumference, (HIP) and waist-hip ratio (WHR) studied in up to 234,069 participants from the Genetic Investigation of ANthropometric Traits (GIANT) consortium with respect to three COVID-19 outcomes: severe respiratory COVID-19 (5,101 cases vs. 1,383,241 controls), hospitalized COVID-19 (9,986 cases vs. 1,877,672 controls), and COVID-19 infection (38,984 cases vs. 1,644,784 controls) obtained from the COVID-19 Host Genetics Initiative (HGI). Finally, to investigate the effect of SES, we analyzed genetic data related to self-reported household income (HI) information from 286,301 UK Biobank (UKB) participants. We found that BMI and WC were associated with severe respiratory COVID-19 (BMI: ORâ□□=â□□1.68 pâ□□=â□□0.0004; WC: ORâ□□=â□□1.72, pâ□□=â□□0.0072) and hospitalized COVID-19 (BMI: OR =â□□1.62, pâ□□=â□□1.35e-06; WC: ORâ□□=â□□1.62, pâ□□=â□□0.0001). Also, HIP showed to influence hospitalized COVID-19 (ORâ□□=â□□1.31, pâ□□=â□□0.012) and COVID-19 infection (ORâ□□=â□□1.18, pâ□□=â□□0.0016). Conversely, HI was associated with reduced severe respiratory COVID-19 (ORâ□□=â□□0.57, pâ□□=â□□0.011) and hospitalized COVID-19 (ORâ□□=â□□0.71, pâ□□=â□□0.045). Testing these effects in multivariable MR models, we observed that the effect of obesity-related anthropometric traits on COVID-19 outcomes is not independent of the SES effect assessed as HI.. In summary, our findings indicate that low SES is a contributor to the observed association between body size and COVID-19 outcomes. Thus, the association of obesity with COVID-19 outcomes may be due to the conditions related to low SES rather than pathogenic mechanisms linked to obesity. This result has major public health implications because it supports that preventive strategies targeting body size and composition to reduce COVID-19 morbidity and mortality may not be effective if they are not considered in the context of SES.

PrgmNr 3276 - Whole exome sequencing analyses of BMI and obesity in a multi-ancestry cohort of > 300,000 individuals

Disclosure Block: **N. Chami:** None.

Background: Obesity is a major risk factor for T2D and CVD. GWA studies identified hundreds of common variants associated with BMI and obesity. In contrast, exome-chip analyses by the GIANT consortium in 718,734 individuals suggest that large-scale sequencing data is required to identify truly rare variants. Here, we aimed to identify rare (MAF Methods: We performed ancestry-specific single variant (SV) association analysis of BMI and obesity within Europeans (N=234,719), Africans (N=31,452), Hispanics (n=21,687), Asians (n=8,437), and other ancestry groups (N=3,375). We restricted analyses to protein truncating & missense variants with MAF10. We analyzed 1.2 million variants and used a Bonferroni-corrected P-value threshold of $4x10^{-8}$ for significance. Analyses were performed using GENESIS and regenie. Summary statistics were meta-analyzed across datasets using fixed effects. Gene-based analyses is underway.**Results:** None of the variants reached the Bonferroni-corrected threshold for our SV analysis. However, among our most significant results, we identify rare variants in thirteen biologically relevant genes. For example, p.Arg35Gln in *WDTC1* (MAF_{AFR}=0.5%) is associated with obesity (OR=2.4, $P=4x10^{-7}$) in the African-ancestry population, whereas this variant was much rarer in other ancestries and monomorphic in Europeans. As WDTC1 plays a role in adipogenesis and lipid accumulation in mouse models, the gene may present as a new candidate for human obesity. Also p.Gly85Glu in *MMP20* (MAF_{EUR}: 0.08%) was associated with obesity (OR=1.5, $P=6x10^{-7}$). MMP20 belongs to the matrix metalloproteinase family, which includes several other proteins implicated in obesity. Additionally, we observe many novel rare variants (P-6) in genes (*TNRC18, ZNF687, PARG1, USH2A and GEM*) in which common variants have been associated with BMI, extreme obesity or height. We note that the well-known monogenic obesity mutation, p.Tyr35Ter in *MC4R* (MAF=0.01%, $P=8.5x10^{-6}$; $Beta_{BMI}$=0.74) and the previously reported p.Gly245Arg in *SPARC* (MAF 0.04%; $P=4.9x10^{-6}$; $Beta_{BMI}$=0.07) did not reach our corrected P-value threshold.**Conclusions:** We observed thirteen rare variant associations that failed to reach the exome-wide Bonferroni-corrected P-value but that lie in genes that have a functional evidence for a role in obesity/adipogenesis or in which common variants are associated with BMI or a related trait and therefore warrant further consideration in follow-up analyses.

PrgmNr 3277 - Whole Genome Sequence Analysis of Dyspnea in Current and Former Smokers in COPDGene

View session detail

Author Block: **J. Chiles**[1], H. K. Tiwari[2], M-L. N. McDonald[1]; [1]Univ. of Alabama at Birmingham, Birmingham, AL, [2]Univ Alabama at Birmingham, Birmingham, AL
Disclosure Block: **J. Chiles:** Major Stockholder/Ownership Interest; Amgen.
INTRODUCTION: The development of dyspnea, both in patients with and without COPD, is known to have significant effects on quality of life for those who suffer from it. Various risk factors for the development of clinically-significant dyspnea have been identified and the development of dyspnea itself is a predictor of five-year mortality. Identification of genomic regions associated with dyspnea could provide mechanistic insight as to why only some patients develop dyspnea. **METHODS:** Dyspnea was dichotomized based on whether a participant reported a modified Medical Research Council (mMRC) dyspnea score greater or equal to 2. Trans-Omics for Precision Medicine (TOPMed) Freeze 8 whole-genome sequencing (WGS) data from 8390 current and former smokers from COPDGene were analyzed. Single nucleotide variants (SNVs) with minor allele frequency > 0.1% were analyzed in 5594 Non-Hispanic White (NHW) and 2796 African American (AA) participants, separately. SNVs were tested for association with dyspnea using SAIGE adjusting for age, sex, pack-years of smoking, and the presence or absence of COPD (defined as a Z-score of less than -1.64), along with 4 principal components of ancestry for the NHW and 6 principal components of ancestry for the AA. Analyses were performed using the NHLBIâ□□s BioData Catalyst cloud-based environment. Physical positions for SNVs are reported using the Human Genome Reference 38. **RESULTS:** No SNV was associated with dyspnea at a level reaching genome-wide significance (P-8) in either the NHW or AA. In the NHW, the most statistically significant finding was for the 21: 19705527 SNV (Beta(95% confidence interval) = 5.71(4.66 - 6.75), P = $5.2x10^{-8}$). The 21: 19705527 SNV was intergenic with the nearest gene (1.3Mb) being Neural Cell Adhesion Molecule 2 (NCAM2). Multiple other loci in this region on chromosome 21 had p-values in the range of 10^{-6} to 10^{-7}. Additionally, several other SNVs in the chromosome 21 region as well as multiple regions on chromosomes 1, 5, 8, 12, and 13 enriched with suggestive p-values. In the AA, the most statistically significant finding was for the 3: 172861520 SNV (Beta(95% confidence interval) = -0.45(-0.36 - -0.54), P = 1.8×10^{-7}). **CONCLUSION:** Though no SNV achieved genome-wide significance in our analyses, there are multiple suggestive association signals meriting further follow-up in a larger sample size available in other studies included in the TOPMed consortium. Also, we will perform additional analyses on specific subset of the population of interest and further characterization of the full cohort with rare variant testing.

PrgmNr 3278 - Association of *CXCR6* with COVID-19 severity: host genetic factors underlying transcriptomic regulation in *3p21.31* locus

Disclosure Block: **Y. dai:** None.

Background: The coronavirus disease 2019 (COVID-19) is an infectious disease that mainly affects the host respiratory system with ~80% asymptomatic or mild cases and ~5% severe cases. Recent genome-wide association studies (GWAS) have identified several genetic loci associated with severe COVID-19 symptoms, such as *3p21.31* locus. There is a cluster of 6 genes (*SLC6A20*, *LZTFL1*, *CCR9*, *FYCO1*, *CXCR6*, and *XCR1*) nearby the lead SNP rs35081325, which makes the â□□causalâ□□ gene and functional implication of this locus remain elusive. **Methods**: We implemented integrative approaches, including transcriptome-wide association studies (TWAS), colocalization and functional element prediction analyses, to interpret the genetic risks in lung, whole blood, and immune cells using two independent GWAS datasets from Host Genetics Initiative round 4 A2 (2,972 severe respiratory confirmed COVID-19 cases and 284,472 controls with unknown SARS-CoV-2 infection status) and Severe COVID-19 GWAS Group (1,980 COVID-19 confirmed cases with severe status and 2,205 control participants). To understand the context-specific molecular alteration, we further performed deep learning-based single cell transcriptomic analyses on a bronchoalveolar lavage fluid (BALF) dataset from moderate and severe COVID-19 patients. **Results**: In TWAS analysis, we discovered and replicated the genetically regulated expression of *CXCR6* and *CCR9* genes. These two genes have a protective effect on lung and a risk effect on whole blood, respectively. The colocalization analysis of GWAS and *cis*-expression quantitative trait loci highlighted the regulatory effect on *CXCR6* expression in lung and immune cells. The Hi-C cell line data from lung also showed significant interactions between lead SNPs and promoter regions of both *CXCR6* and *CCR9*. In lung resident memory $CD8^+$ T (T_{RM}) cells, we found a 2.24-fold decrease of cell proportion and lower expression of *CXCR6* (fold change = 0.56, two-sided Wilcoxon p = 1.8 Ã□ 10^{-18}) in severe patients than moderate patients. Pro-inflammatory transcriptional programs, apoptosis, and hypoxia pathways were highlighted in T_{RM} cells transition from moderate to severe groups. **Conclusion**: *CXCR6* tends to have a lower expression in severe patients than in moderate patients, which aligns with the protective effect of *CXCR6* from TWAS analysis. We illustrated one potential mechanism of host genetic variants or other unknown risks that might impact the severity of COVID-19 through altering the expression of *CXCR6* and lung T_{RM} cell proportion and stability, therefore, impairing the first-line defense in lung. Our results shed light on potential therapeutic targets for severe COVID-19.

PrgmNr 3279 - Asthma-associated genetic variants induce *IL33* differential expression through a novel regulatory region

View session detail

Author Block: **I. Aneas-Swanson**[1], D. C. Decker[2], D. R. Sobreira[1], N. Sakabe[1], K. M. Blaine[2], K. M. Magnaye[1], S. Clay[1], C. Ober[1], A. I. Sperling[2], M. A. Nobrega[1]; [1]Univ. of Chicago, Human Genetics, Chicago, IL, [2]Univ. of Chicago, Med., Section of Pulmonary and Critical Care Med., Chicago, IL
Disclosure Block: **I. Aneas-Swanson:** None.
Genome-wide association studies (GWAS) have implicated the *IL33* locus in asthma, but the underlying mechanisms remain unclear. We used the LD structure at this locus across populations of different ethnicities combined with a Bayesian fine-mapping tool to define a critical 20 kb genomic interval containing candidate causal SNPs for the asthma association. Epigenetic signatures further reduced this region to 5 kb, which we demonstrated to have enhancer blocking activity *in vivo* and *in vitro*. Chromatin conformation showed a crucial role in looping formation between *IL33* promoters and the regulatory elements within the critical interval. Humanized mouse BAC transgenics further confirmed the necessity of the 5 kb region for proper IL33 regulation. To identify nuclear proteins that can differentially bind to the risk and non-risk alleles and potentially alter *IL33* expression, we performed an electrophoretic mobility shift assay (EMSA) followed by mass spectrometry and selected OCT-1 (POU2F1) as a candidate differentially bound to the risk allele of rs1888909. RNA-seq data obtained from asthmatic and non- asthmatic subjects showed that carriers of one or two copies of the rs1888909 (T) risk allele had significantly higher *IL33* transcript levels in airway epithelial cells and IL-33 protein in the plasma compared to non- carriers of this allele. Our data demonstrate that asthma-associated variants at the *IL33* locus mediate allele-specific regulatory activity and *IL33* expression, through differential binding of OCT-1 to the asthma-risk allele. Altogether, these data provide a novel mechanism through which a regulatory SNP contributes to genetic risk of asthma.

PrgmNr 3280 - Complex Architecture of COVID-19 Host Genetics from Whole Genome Sequencing of a Multi-Ethnic Hospitalized Cohort

View session detail

Author Block: **D. M. Jordan**[1], L. G. Sloofman[1], R. C. Thompson[1], D. M. Del Valle[1], H. Shah[1], N. W. Simons[1], S. Gnjatic[1], M. Merad[1], E. Cheng[1], B. Losic[1], R. Sebra[2], N. D. Beckmann[1], A. W. Charney[1], E. Schadt[1], The Mount Sinai COVID-19 Biobank; [1]Icahn Sch. of Med. at Mt Sinai, New York, NY, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY

Disclosure Block: **D.M. Jordan:** None.

Several large studies have been performed on COVID-19 host genetics, and multiple relevant loci have been found. However, very few of these studies have examined features other than binary indicators of infection and severe disease. Additionally, these studies have been conducted primarily in subjects of European ancestry. We analyzed 12 traits measuring different features of COVID-19 disease progression and severity in a multi-ethnic cohort of 486 patients hospitalized for severe COVID-19 in the Mount Sinai Health System in New York, NY. These traits consisted of 4 quantitative measures of disease severity within the hospitalized cohort, 4 indicators of improvement or decline after hospitalization, 2 measures of intensity and effectiveness of immune response, and 2 measures of timing of disease progression. We collected whole genome sequences and performed multi-ethnic GWAS on common variants using the GENESIS package, which has been shown to be robust to heterogeneous ancestry and admixture. Despite the small sample size, we detected a locus at 9q33.2 associated with decline and end organ damage; three loci at 6p12.1, 9q33.1, and 21q21.2 associated with clearance of virus after hospitalization; a locus at 13q12.3 associated with improvement after hospitalization; and a locus at 10p15.1 associated with time between onset of symptoms and hospitalization. Many of the specific variants identified are not present on any standard genotyping array and could only be detected by whole genome sequencing. We also performed a SMMAT association test aggregating predicted loss of function variants by gene, also using GENESIS, and found two genes nominally associated with time between hospitalization and discharge or death: *MNDA* (FDR = 0.085), previously identified as a component of the interferon response; and *NPNT* (FDR = 0.059), previously implicated in lung disease including COPD and silicosis. Except for 9q33.1-2, which may be near the well-known *ABO* locus, none of these loci has been previously reported to be involved in COVID-19 host genetics. Additionally, again except for 9q33.1-2, each locus is unique to only one of the measured traits. Taken together, these results suggest that the host biology of COVID-19 infection is complex and multifactorial and is controlled by different factors at different stages, and binary indicators of infection and severity capture only a small fraction of host biology. These results also illustrate the enormous improvement in power that can be achieved using multi-ethnic cohorts, whole-genome sequencing rather than genotyping arrays, and granular, biologically meaningful phenotypes.

PrgmNr 3281 - Fine-mapping studies distinguish genetic risks for childhood- and adult-onset asthma in the HLA Region

View session detail

Author Block: **S. Clay**[1], N. Schoettler[1], A. Goldstein[1], P. Carbonetto[1], M. Dapas[1], M. C. Altman[2], M. G. Rosasco[2], J. E. Gern[3], D. J. Jackson[3], H. Im[1], M. Stephens[1], D. L. Nicolae[1], C. Ober[1]; [1]Univ. of Chicago, Chicago, IL, [2]Benaroya Res. Inst., Seattle, WA, [3]Univ. of Wisconsin, Madison, WI
Disclosure Block: **S. Clay:** None.
Genome-wide association studies (GWAS) of asthma have described robust associations with variation across the human leukocyte antigen (HLA) complex, including significant associations with both childhood-onset asthma (COA) and adult-onset asthma (AOA). This includes independent associations centered on the HLA class I (*HLA-C/B*) and class II (*HLA-DR/DQ*) regions for both COA and AOA in individuals from the UK Biobank (UKB). However, the specific HLA region variants and genes contributing to risk are unknown. In this study, we examined SNPs, HLA alleles, and HLA amino acid polymorphisms in British white individuals from the UKB. We used SuSiE to fine map both the COA and AOA risk loci and expression quantitative trait loci (eQTLs) in three asthma-relevant cell types, and examined putatively causal protein coding variation. In the class I region, our studies revealed a credible set (CS) containing a single, shared variant (rs2428494) for both COA (Posterior Inclusion Probability (PIP)=0.97) and AOA (PIP=0.999), and a COA-specific CS with two highly correlated variants: rs28481932 (PIP=0.43) and HLA-C Ala11Ser (PIP=0.57). In the class II region, however, there were no shared variants. Of the two COA CSs, one included one SNP (rs28407950, PIP=0.997) and one contained 5 non-coding SNPs spanning 152kb (median r^2=0.99). Two CSs were also identified for AOA. CS1 contained 60 variants (median r^2=0.99) and CS2 contained 33 variants (median r^2=0.96), with a mix of SNPs and HLA amino acid polymorphisms in both. eQTL fine mapping with SuSiE revealed that the same four putatively causal SNPs for AOA in CS1 (rs9272346, rs9274660, rs1063355, rs3828789) were also putatively causal for expression of the nonclassical class II genes, *HLA-DQA2* (P-9) and *HLA-DQB2* (P-10) in LCLs, PBMCs, and nasal epithelial cells and overlapped with strong enhancer annotations (H3K27ac) in LCLs from ENCODE. No variants in the class I or COA class II CSs were eQTLs. However, protein coding variation in HLA-C (Ala11Ser) for COA and the *HLA-DQA1**03 alleles in CS2 for AOA are plausible causal candidates. Overall, we highlight roles for both expression and protein coding variation in the HLA genes in asthma risk with both shared and distinct risk factors for COA and AOA, and provide a framework for how to conduct fine-mapping studies of variants in the HLA region. This research was conducted using the UK Biobank Resource under application number 44300.

PrgmNr 3282 - Infinity Biologix - A Biorepository Answers the Call and Becomes a Leading COVID-19 Assay Development and Testing Center

View session detail

Author Block: **M. H. Sheldon**[1], C. J. Bixby[1], C. P. Goswami[1], J. A. McDevitt[1], J. LaPorta[1], E. Kwon[1], P. Shah[1], J. Moore[2], C. Hevi[1], A. K. Bogdanowicz[1], R. H. Siegel[1], K. M. RUCDR Infinite Biologics was established in 1998 and grew to become a world leader in providing the scientific community with comprehensive solutions in sample collection, processing, quality control, technical consultation, complex assays, storage and biosample distribution. On August 17, 2020, RUCDR Infinite Biologics became Infinity BiologiX (IBX, https://ibx.bio/). As IBX, we maintain the same core mission, to provide customers in the commercial and academic sectors the highest quality service and support in advancing their research. As a research organization and biorepository with a proven track record of innovation in developing and offering diagnostic assays, IBX was approached by local, state and federal entities to support the global community in expanding COVID testing by offering rapid testing to enable clinicians and patients to make critical decisions. In April 2020, IBX received the first FDA Emergency Use Authorization (EUA) enabling the use of saliva tests to detect the presence of the SARS-CoV-2 coronavirus, paving the way to the later approval of an EUA for its use in an at-home saliva sample collection kit. The IBX response to the pandemic was swift and decisive. Within a matter of months, significant investments were made in infrastructure and labor as well as collaborations established with two companies, Spectrum Solutions and Accurate Diagnostics Labs, to oversee the manufacturing and distribution of kits. As a result of these efforts, IBX established a COVID-19 PCR diagnostic lab with the capability of testing as many as 100,000 samples per day. Using the IBX TaqPath SARS-CoV-2 Assay (EUA200090), IBX has tested 7.5 million samples as of this writing, with 4.1% of those detected as positive and 95.2% coming in Spectrum saliva collection kits as opposed to nasopharyngeal swabs. Additional data will be presented that explores the global implications of our testing experience, including rates of positivity over time and detection of variants of concern in the US and internationally.

PrgmNr 3283 - Integrative analysis of DNase-I footprinting and genome-wide association data uncovers transcription factors involved in nine autoimmune diseases

Autoimmune and Inflammatory diseases (AIDs) are a group of > 80 complex diseases caused by loss of tolerance of the immune system for self-antigens. The biological mechanisms of AIDs are largely unknown, preventing the development of effective treatment options. Integrative analysis of genome-wide association studies and epigenetic data has shown that AID risk variants are enriched in epigenetic regions of immune cells, supporting their role in gene regulation. However, we still lack a systematic and unbiased identification of transcription factors (TF) involved in disease gene regulation.

We hypothesized that for some of the disease-relevant TFs, their binding to DNA is affected at multiple genomic sites rather than a single site, and these effects are cell-type specific. In this study, we developed a statistical approach to assess enrichment of TFs in being affected by disease risk variants at multiple sites. We used Immunochip data from nine AIDs and identified 99% credible interval (CI) SNPs for each trait. We then integrated CI SNPs and DNase-I footprinting data of 376 samples comprising 35 unique cell types, and used a probabilistic model (by Moyerbrailean et. al.) to identify the CI SNPs that are likely to change binding probability of certain TFs at specific cell types. Finally, for each TF (out of 1,372 TFs), we used Fisher's Exact test to assess whether CI SNPs are enriched in changing the binding probability of that TF at multiple sites (FDR Our analysis resulted in identification of significantly enriched TFs and their relevant cell types for each trait. The number of prioritized TFs in immune cell types varied between 1 and 14 for 7/9 AIDs. For the two other traits with smaller sample sizes, we did not find any significant TFs, likely due to a lack of statistical power. Our analysis identified some TFs previously known to be relevant to AIDs (e.g. Ahr:Arnt for rheumatoid arthritis and SPI-B for multiple sclerosis), and some other less studied new TFs. The enriched cell types also varied across the traits (e.g. CD8 and Mobilized CD4 T cells for rheumatoid arthritis, and CD56 and Mobilized CD4 T cells for multiple sclerosis). Our ChromHMM analysis proved that our predicted DNase-I footprinting sites are active enhancers or promoters in the relevant cell types. Additionally, our Great pathway analysis showed that the majority of the significant biological pathways are immune-related, an example of which is B cell adhesion pathway in multiple sclerosis. Our study provides a general framework for the identification of disease-relevant TFs and their relevant cell types, and facilitates discovering specific gene regulatory mechanisms of complex diseases.

PrgmNr 3284 - MHC class II alleles are associated with rare dermatologic autoimmune diseases in an analysis of over 200,000 participants of the UK Biobank

View session detail

Author Block: **D. T. Truong**[1], J. Molineros[1], Y. Chen[2], D. M. Waterworth[1], S. Li[3], M. Black[1]; [1]Janssen Res. & Dev., Spring House, PA, [2]Janssen Res. & Dev., San Diego, CA, [3]Janssen Res. & Dev., Spring house, PA
Disclosure Block: **D.T. Truong:** Salary/Employment; Janssen R&D.
Purpose: Dermatologic diseases are the fourth leading cause of disability worldwide and contribute to chronic pain, disfigurement, and poor mental health. Yet knowledge of disease pathogenesis remains unclear and treatment options are limited, especially for rare dermatologic autoimmune diseases (AuD) such as lichen planus (LP) and alopecia areata (AA). Variation in the major histocompatibility complex (MHC/HLA) accounts for nearly half of the explained genetic variation in AuD, highlighting its critical role in disease etiology. However, the role of HLA in rare dermatologic AuD is poorly understood, with genetic analyses to date limited to family-based or small-scale clinical studies. **Methods:** We curated 37 AuD phenotypes in the UK Biobank, a population-based cohort of ~500,000 individuals, using diagnostic codes (ICD9 and ICD10), primary care and self-reported data. We identified 3,610 and 886 cases of LP and AA, respectively. A common control set was defined as individuals with no self-reported or clinical diagnosis of any AuD (n=208,974). HLA imputation was previously conducted using HLA*IMP:02 in the UK Biobank, but recent comparison of different HLA imputation methods revealed suboptimal performance. We re-imputed HLA-A, -B, -C, -DPB1, -DQA1, -DQB1, and -DRB1 alleles from genotyping data to four-digit resolution using HLA Genotype Imputation with Attribute Bagging v4.1. Analyses were restricted to individuals of white British ancestry. Experimental models to evaluate the additive effect of HLA alleles on each AuD were fit using a Firth logistic regression to account for case-control imbalance. The reduced model did not include HLA. All models were adjusted for age, age^2, sex, age*sex, and the first 10 genetic principal components. We assessed HLA association using an omnibus test. **Results:** Novel associations were identified across several class II alleles for LP, including DQB1*5:01 and DQA1*1.01 (OR = 1.83, p = 5.98E-77 and OR = 1.76, p = 4.09E-61, respectively), as well as previously reported associations with DRB1*1:01 (OR = 1.83, p = 3.19E-53). For AA, a significant novel association was observed for class II allele DQB1*3:01 (OR = 1.36, p = 3.39E-7) and associations with DRB1*4:01 (OR = 1.49, p = 5.26E-6) were replicated. Residue and haplotype analyses and evaluation of utility for patient stratification are underway. **Conclusions:** MHC class II alleles are associated with increased risk of LP and AA, suggesting that genes in this region play a critical etiological role and provide a starting point to investigate promising biological mechanisms that could be targeted for future therapeutic development and improved treatment options.

PrgmNr 3285 - mRNA expression analysis reveals degenerative phenotype and immune cell infiltration in spleen, thymus and pancreas of *Clec16a* knockout (KO) mice

View session detail

Author Block: **M. A. Bakay**[1], B. P. Strenkowski[1], R. Pandey[1], H. Hakonarson[1,2]; [1]The Ctr. for Applied Genomics, The Childrenâ□□s Hosp. of Philadelphia, Philadelphia, PA, [2]Dept. of Pediatrics, the Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA
Disclosure Block: **M.A. Bakay:** None.
Multiple GWAS and functional studies prove *CLEC16A* as an important autoimmunity gene and suggest CLEC16A could be a critical regulator of aberrant autoimmune responses; however, the exact mechanism of its action is still largely unknown. To investigate the role of CLEC16A in autoimmunity we generated an inducible ubiquitous *Clec16a* KO mouse. The global *Clec16a* KO (*Clec16a*$^{\hat{I}\square UBC}$) exhibit a complex phenotype with marked immune dysfunction. We demonstrated loss of CLEC16A in immune cells leads to an abnormal mitophagy, cell death and immune dysfunction. Recently we reported dramatic pathological differences in spleen, thymus and pancreas of Clec16a$^{\hat{I}\square UBC}$ mice not observed in controls. We performed a longitudinal mRNA expression analysis using TaqMan RT-PCR expression assays. Considering the fast-evolving symptoms after knockout induction, we performed a time course expression study of the 16 immune markers in spleen, thymus and pancreas and observed a wide dysregulation of the expression in *Clec16a*$^{\hat{I}\square UBC}$ mice in comparison to controls. To exclude effect of tamoxifen (Tam) on the expression profile we have had two control groups (Oil and Tam) and observed no differences in them. The most significant findings were the following: CD163 expression was increased in all studied organs, suggesting macrophage infiltration. CD3, CD4 and CD8 markers were dysregulated in spleen and thymus. Adhesion proteins were dysregulated in spleen and thymus: Vcam1 up, Icam1 down. Bcl2, apoptosis regulator, was upregulated. FoxP3 and GzmB were upregulated in thymus only. While these finding require further in-depth investigation, they are in concordance with *CLEC16A* being a well-documented type 1 diabetes susceptibility gene and provide additional support for the direct involvement of CLEC16A in regulation pancreas, spleen and thymus functions. To determine predominant types of pancreas infiltrating immune cells and state of their activation we will perform high-resolution immunophenotyping. Identification of these cell subpopulations will inform on our choose of drugs aimed at reversing the abnormal processes in *Clec16a*$^{\hat{I}\square UBC}$ mice, that may be effective in treating and preventing symptoms of autoimmune disorders, such as T1D, in individuals with risk associated *CLEC16A* variants.

PrgmNr 3286 - Role of theFYVE and Coiled-Coil Domain Autophagy Adaptor 1 in severity of COVID-19 infection

View session detail

Author Block: **J. Shinn**[1,1], S. P. Smieszek[1,1], B. P. Przychodzen[2,1], M. H. Polymeropoulos[2,1]; [1]Vanda Pharmaceuticals, Inc., Washington, DC, [2]Vanda Pharmaceuticals, Washington, DC
Disclosure Block: **J. Shinn:** Salary/Employment; Vanda Pharmaceuticals, Inc.
Coronaviruses remodel the intracellular membranes to form specialized viral replication compartments, such as double-membrane vesicles where viral RNA genome replication takes place. Understanding the factors affecting host response is instrumental to the design of therapeutics to prevent or ameliorate the course of infection.
We obtained samples for whole genome and viral genome sequencing analysis from hospitalized patients with confirmed COVID-19 infection participating in VANDA COVID-19 studies, the strongest severity region thus far reported in association with severe COVID-19: is 3p21.31 with lead variant rs73064425 (rs73064425, OR=2.14, discovery p=4.77 Ã 10^{-30}) reported by Pairo-Castineira et al., 2020. We were able to replicate this association in our cohort of severe hospitalized patients with confirmed COVID-19 infection. We focused on the coding variants that are in LD with the tagging variant. Based on LD analysis, we report three coding mutations within one gene in the region of FYVE and Coiled-Coil Domain Autophagy Adaptor 1 (*FYCO1*). We specifically focus on the functional role of *FYCO1* nonsynonymous variants (rs33910087, rs13079478, rs13059238). Functionally, *FYCO1* encodes a protein involved in vesicle transport and autophagy. It has been suggested as a key mediator linking ER-derived double membrane vesicles, the primary replication site for coronaviruses, with the microtubule network. Interestingly, rs33910087 is an eQTL for CXCR6 (GTEX) and based on GeneATLAS, the genotyped variant is highly significant modifier of monocyte percentage ($p=3.8479e^{-46}$). We report the associations between the region and clinical characteristics in this set of hospitalized COVID-19 patients with severe course of infection.
To discover potential, pharmaceutical agents capable of affecting transcriptional expression levels of *FYCO1* implicated in SARS-CoV and SARS-CoV-2 pathophysiology, we have screened 466 compounds belonging to 14 different therapeutic classes. We focused only on compounds that significantly downregulate the expression of *FYCO1*. The most significant candidate was indomethacin - an anti-inflammatory drug that could potentially downregulate *FYCO1* already shown in a clinical trial to be efficacious in treatment of COVID-19. We hypothesize that via its direct effects on efficiency of viral egress, it may serve as a potent therapeutic decreasing the replication and infectivity of the virus. Further clinical studies will be necessary to examine the therapeutic utility of indomethacin and other compounds, downregulating *FYCO1* in COVID-19 infection and other strains of betacoronaviruses.

PrgmNr 3287 - The long-term effect of SARS-CoV-2 infection on host genetic regulation

Ctr., Nashville, TN, [2]The Univ. of Texas Hlth.Sci. Ctr. at Houston, Brownsville, TX, [3]Univ North Carolina, Chapel Hill, NC

Disclosure Block: **H. Chen:** None.

Since the COVID-19 pandemic, over 173 million individuals have been reported as confirmed infected cases globally. Although most of them successfully recover from the illness, some post-acute complications have been observed frequently, including fatigue, dyspnea, palpitations, and loss of smell and taste, and it may suggest COVID-19 is not only an acute infection but a chronic health condition. Therefore, the further and continued effect of SARS-CoV-2 infection is an urgent topic after the pandemic. In this study, we comprehensively investigated the transcriptome of post-infection subjects and aimed to study the long-term effect of COVID-19 on gene expression. We RNA-sequenced both prior and post COVID-19 whole blood samples of 81 antibody-confirmed cases from an established cohort, Cameron County Hispanic Cohort, and blood samples of two-time points from 88 age-, sex-, and interval-matched healthy controls. A mixed-effects model was applied to identify the genes with different changes in expression over time from prior to post-infection as compared to changes in expression over time in controls with no evidence of COVID-19 infection. Our preliminary analysis included complete two timepoints data from 27 cases and 48 controls, and five genes show a significantly different trend with p-value -4, including *LSM6* (p-value=$1.9x10^{-5}$), *GPR4* ($2.5x10^{-5}$), *RELN* ($2.9x10^{-5}$), *C8orf86* ($3.8x10^{-5}$), and *FUNDC2P2* ($9.5x10^{-5}$). *GPR4* encodes a G protein-coupled receptor that is highly expressed in the lung, heart, and kidney. Functionally, *GPR4* has been reported to regulate the inflammatory response and leukocyte infiltration and demonstrates an up-regulated trend in our post-COVID-19 samples which may suggest an important role for host immune response post-infection. Also, we used the 145 genes with p-value -3 for the phenome-wide enrichment test, and the secondary malignancy of respiratory organs is the most significant trait associated with our identified genes (p-value-5). The full analysis will include data from 338 RNA sequencing samples from two-time points in 81 cases and 88 controls and identified genesâ phenome-wide effects would be explored in Vanderbiltâs electronic health record-linked biobank.

PrgmNr 3288 - Trans-ethnic association analysis of HIV viral load and Chromosome X markers in individuals living with HIV

View session detail

Author Block: **C. I. Vergara**[1], P. McLaren[2], J. Tuff[3], The International Collaboration for the Genomics of HIV (ICGH), P. Duggal[4], E. Scully[1]; [1]Johns Hopkins Univ, Baltimore, MD, [2]Univ. of Manitoba, Winnipeg, MD, Canada, [3]Natl. Microbiol. Lab., Winnipeg, MB, Canada, [4]Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD

Disclosure Block: **C.I. Vergara:** None.

Host genetic factors contribute to outcomes of HIV-1 infection. The robust phenotype of HIV-1 set point viral load (spVL), defined as $\log_{10}$ HIV-1 copies/mL blood of individuals during chronic, untreated infection, is a strong correlate of rate of disease progression and transmission potential and has been used to identify genetic determinants relevant to disease. Prior genome wide association studies (GWAS) identified genomic regions in the HLA class I region on chromosome 6 and the chemokine (C-C motif) receptor gene cluster on chromosome 3 that associate with disease phenotype. There are significant HIV-1 phenotype differences between men and women; women have ~0.4 $\log_{10}$ lower spVL as compared to men, and are more frequently spontaneous viral controllers. The genetic mechanisms for the observed sex differences are unknown. There is a paucity of data on sex-specific autosomal genetic architecture and on sex chromosome polymorphisms in HIV. We investigated the association of HIV spVL with markers on chromosome X in 10 879 individuals of European (N=7159, 6341 males/ 818 females) and African ancestry (N =3720, 2484 males/1235 females) enrolled as participants in the ICGH. 340,489 high quality genotyped and imputed variants on chromosome X from 17 genotype groups were tested for their association with HIV spVL. Linear regression models, with sex as a covariate and males coded as 0/2 copies of the minor allele (assuming X inactivation in females) were built for each group, and the results were combined using an inverse-variance weighted meta-analysis. Similar analyses were performed only in males. In the complete group, we found suggestive associations with the SNP rs6629425 (C>G, P $value_{Meta}=1.3x10^{-5}$) located ~3kb upstream of the Membrane Bound Transcription Factor Peptidase, Site 2 (*MSTP2*) gene. Each copy of the G allele has a decreasing effect in spVL consistent across most ancestry groups (effect sizes= -0.17 to -0.03). Male specific analysis showed similar, stronger results (rs6629425 P $value_{Meta}=1.8x10^{-6}$) with decreasing effect of G allele in spVL. *MBTPS2* is a membrane-embedded zinc metalloprotease that linked to sterol transcriptional control and endoplasmic reticulum stress response. Other suggestive associations were observed in the gene Neuroligin 4 X-linked (*NLGN4X*, rs5916333, P $value_{Meta}=2.8x10^{-5}$) and in an intergenic region (rs5986678, P $value=1.0x10^{-4}$). This analysis of X chromosome variation highlights potential genes and regions with effect on the variance of HIV spVL. Our findings are the first step towards a wider analysis evaluating the sex-specific genetic architecture of HIV related phenotypes in individuals of different ancestries.

Trajectories of lung function in early life predict the subsequent development of both asthma and COPD. Numerous genetic associations have been discovered for measures of lung function in genome-wide association studies, but these studies have mostly been limited to adults of European descent. Identifying genetic variants associated with lung function in a multi-ethnic pediatric population may highlight ethnic-specific risk loci or yield more generalizable insights into the development of chronic lung disorders. In this study, we analyzed measures of lung function from the Asthma Phenotypes in the Inner City (APIC) and Urban Environment and Childhood Asthma (URECA) cohorts, which consist of children living in low-income neighborhoods in 10 U.S. cities. We performed whole-genome sequencing on 897 individuals (ages 5-17 yrs; 67% Black, 25% Hispanic; 66% with MD-diagnosed asthma) and tested for associations with covariate-adjusted, normalized residuals for percent predicted forced expiratory volume in 1 sec (FEV1) and the ratio of FEV1 to forced vital capacity (FEV1/FVC). Sequence read processing, quality control, and variant calling were performed using the Genome Analysis Toolkit suite. Genetic associations were evaluated using linear mixed models accounting for asthma, age, sex, body mass index, ancestry, and relatedness, including 14.1M variants with MAF â¥1%. No associations with FEV1/FVC were genome-wide significant, but FEV1 was significantly associated with SNPs in a large LD block across the *TDRD9* gene on chromosome 14 (lead SNP rs10220464, $p=1.19x10^{-9}$). Because altered DNA methylation in the *TDRD9* gene in newborns was previously associated with maternal smoking, we analyzed DNA methylation (EPIC array) in nasal epithelial cells from 246 URECA children (age 11) and tested for correlations with FEV1-associated variants. rs10220464 was an meQTL for cg03306306, a CpG site located 65kb from the lead SNP, also in *TDRD9* ($p=1.54x10^{-4}$, FDR-2). Together, these results highlight a novel methylation-mediated genetic association with lung function, potentially linking environmental exposure to genetic risk on pulmonary health in urban youth.

Preeclampsia is a pregnancy related condition that affects 4% of pregnancies in the United States of America (USA) and has a higher morbidity and mortality in many low- and middle-income countries (LMICs). As a multi-systemic syndrome, it affects the kidneys and many other organs. Variants in Apolipoprotein L1 (APOL1) gene, which confer resistance to Human Acquired Trypanosomiasis (HAT), have been implicated in kidney disease and more recently, preeclampsia. APOL1 variants are specific to people of African descent and are being extensively investigated as key predictors of preeclampsia. High prevalence of these variants in sub-Saharan African populations demands further investigation, and numerous studies are ongoing in Africa to explore the effects of APOL1 variants. SPOT-BIO is part of the Severe Preeclampsia Adverse Outcome Triage (SPOT) study, an ongoing international research collaboration with multiple sites in Ghana. We collect biological samples from mother/baby dyads to determine effects of APOL1 genotypes on risk of developing preeclampsia. With only limited research infrastructure existing in LMICs, we will describe challenges in setting up biobanks geared towards improving the quality of maternal and child health in Africa. We will delve into the feasibility of implementing biobanks in a West African country and explore what LMICs in the subregion need to focus on to build robust, sustainable biobanks to develop capacity for cutting-edge genetics research. We will also show that despite these challenges, we have already recruited over 450 women, making it the largest cohort of African women with early preeclampsia in the world.

Myasthenia Gravis (MG) is a rare autoimmune disorder affecting the neuromuscular junction (NMJ). Here, we investigate the genetic architecture of MG via a genome-wide association study (GWAS) of the largest MG dataset analyzed to date. We performed GWAS meta-analysis integrating three different datasets (total of 1,401 cases and 3,508 controls). We carried out HLA fine-mapping, gene-based and tissue enrichment analyses and investigated genetic correlation to 13 other autoimmune disorders as well as pleiotropy across MG and correlated disorders. We observed the strongest MG association to *TNFRSF11A* (rs4369774, p=1.09Ã10 -13 ; OR=1.4). Gene-based analysis revealed *AGRN* as a novel MG susceptibility gene. HLA fine-mapping pointed to two independent MG loci: *HLA-DRB1* and *HLA-B*. MG onset-specific analysis reveals differences in the genetic architecture of Early-Onset (EOMG) versus Late-Onset MG (LOMG). Furthermore, we find MG to be genetically correlated with Type 1 Diabetes (T1D), Rheumatoid Arthritis (RA), late-onset Vitiligo and Autoimmune thyroid disease (ATD). Cross-disorder meta- analysis reveals multiple risk loci that appear pleiotropic across MG and correlated disorders. Our gene-based analysis identifies *AGRN* as a novel MG susceptibility gene, implicating for the first time a locus encoding a protein (agrin) that is directly relevant to NMJ activation. Mutations in *AGRN* have been found to underlie congenital myasthenic syndrome. Our results are also consistent with previous studies highlighting the role of the HLA and *TNFRSF11A* in MG etiology and different risk genes in EOMG versus LOMG. Finally, we uncover genetic correlation of MG to T1D, RA, ATD, and late-onset Vitiligo, pointing to shared underlying genetic mechanisms.

PrgmNr 3292 - Cognitive trajectories diverge by genetic risk in the Wisconsin Registry for Alzheimerâ□□s Prevention

Background: *APOE* Îµ4 allele status predicts both age of late-onset Alzheimerâ□□s disease (LOAD) onset and rate of cognitive decline leading up to LOAD. However, most of those studies have been done in older samples and with LOAD diagnosis. There is less known about when *APOE* related differences in cognition emerge. Moreover, traditional modeling of *APOE* risk using Îµ4 allele carrier status does not account for non-linear risk between combinations of Îµ2, Îµ3, and Îµ4 alleles. Our objective was to identify if the rate of cognitive decline differs by the *APOE* score, a composite score of the six *APOE* allele combinations weighted by the log odds of their association with LOAD.

Methods: We analyzed cognitive trajectories (n=1074) across *APOE* scores of participants in the Wisconsin Registry for Alzheimerâ□□s Prevention (WRAP). WRAP is a longitudinal study of adults age 40-70 and non-demented at baseline who were followed for up to 16 years with assessments every 2 years. We compared the rates of decline across the *APOE* score for four neuropsychological composite scores using a mixed effects regression model for longitudinal change with age.

Results: We found a significant age by *APOE* score interaction in predicting cognitive decline such that the rate of cognitive decline for all four composite scores was greatest for people with the highest *APOE* score. The effect of age was non-linear on all outcomes. Age was modeled as a cubic polynomial for immediate learning, delayed recall, and PACC3 and a quadratic polynomial for executive function. For immediate learning and delayed recall, the age of detectable cognitive function difference by *APOE* score is between 60 and 65 years. The initial statistically significant (Îœ = 0.05) difference in predicted cognitive function between the lowest and highest risk *APOE* score is about 0.15 standard deviation (SD) for immediate learning and 0.24 SD for delayed recall. For executive function and PACC3, the age of detectable cognitive function difference by *APOE* score is between 55 and 60 years. The initial difference in predicted cognitive function between the lowest and highest risk *APOE* score is about 0.3 SD for executive function and 0.34 SD for PACC3.

Conclusions: These results indicate that the rate of cognitive decline is greatest for people with highest *APOE* risk. Mean cognitive function and decline divergence by *APOE* risk happens between the age of 55 and 65 in the WRAP sample.

PrgmNr 3293 - Concordance of genetic variation that affects neuroinflammatory biomarkers for Alzheimerâ□□s disease and that influences brain volumes

The increased number of Alzheimer's disease (AD) is one of the most daunting and potentially costly implications of ever-longer life expectancies. Currently, treatments targeting amyloid-beta or tau-protein pathology all failed at their late stage of clinical trials. Neuroinflammation has been accepted widely as the third core pathology of AD over the years, which provides a new perspective to understand AD and develop new drugs or treatments. Neuroinflammation can also be a bridge to link amyloid-beta and tau protein pathologies of AD. However, the mechanisms of how neuroinflammatory biomarkers influence specific brain regions are still largely unknown. This work aims to apply imaging genetics technique to investigate the overlap of genetic influence on both neuroinflammatory biomarkers and volume of each brain region for AD.We performed genome-wide association study (GWAS) of neuroinflammatory biomarkers (87 AD, 277 mild cognitive impairment, 46 controls) and brain volume (153 AD, 256 mild cognitive impairment, 108 controls) changes at baseline and 12 months using the Alzheimer's Disease Neuroimaging Initiative (ADNI) database. To examine genetic pleiotropy and concordance single nucelotide polymorphism (SNP) effect directions, GWAS summary statistics of three neuroinflammatory biomarkers, CD40 Ligand (CD40L), Epidermal Growth Factor (EGF) and Neutrophil Gelatinase-Associated Lipocal with significant SNP (p

PrgmNr 3294 - Creating sex-specific phenome risk classifiers to identify under-documented cases of developmental stuttering in electronic health records

View session detail

Author Block: **D. G. Pruett**[1], D. M. Shaw[1], H-H. Chen[2], L. E. Petty[3], H. Polikowsky[1], S. Kraft[4], R. M. Jones[1], J. E. Below[3]; [1]Vanderbilt Univ., Nashville, TN, [2]Nashville, TN, [3]Vanderbilt Univ Med Ctr., Nashville, TN, [4]Wayne State Univ., Detroit, MI

Introduction: Developmental stuttering is a speech disorder that typically begins around age 3 and is characterized by syllable/word repetitions and prolongations. Despite population prevalence of 1%, no population-based genetic studies of stuttering have been conducted and few, if any, studies utilizing electronic health records (EHRs). Given that communication disorders like stuttering are diagnosed by speech pathologists, not physicians, information regarding diagnosis of these disorders is not consistently noted in EHRs. Rather than relying on ICD 9/10 codes, medication lists, or other typical approaches to defining phenotypes in EHRs, keyword searches and text-mining algorithms followed by manual review have proved helpful in identifying stuttering. However, despite extensive manual review, many stuttering cases likely go undetected in EHRs. **Purpose:** The purpose of this project is to develop sex-specific phenome risk classifiers to identify high-likelihood cases of developmental stuttering in EHRs; this will enable use of large-scale DNA biobank resources for well-powered, sex-stratified GWAS of developmental stuttering, a highly-sex skewed disorder. **Method and Results:** A keyword text search for stuttering and related terms within the Synthetic Derivative, a de-identified EHR database at Vanderbilt University Medical Center (VUMC), identified ~18,000 individuals with at least one keyword mention in their records. From these records, 50 confirmed cases of males who stutter and 50 confirmed cases of females who stutter will be used to create a text-mining algorithm to identify high-likelihood cases and reduce manual review to ~1,500 files. Confirmed cases will be stratified by sex and matched to controls in a permutation-based, sex-stratified comorbidity analysis of phecodes. Significantly enriched phecodes will be used to create sex-specific phenome risk classifier prediction models to identify additional high-likelihood stuttering cases that lack clinical documentation and were not otherwise identifiable using the multi-step identification process described above. A previous study created and tested a non-sex specific phenome risk classifier with a positive predictive value of 83%, validating this approach for acquiring developmental stuttering cases (Pruett et al., 2021). Ultimately, the creation of the sex-specific phenome risk classifiers will increase the number of high-likelihood stuttering cases identified within BioVU, VUMCâ□□s biorepository, to conduct well-powered sex-specific genome-wide association studies to investigate the genetic etiology of this highly heritable and sex-skewed disorder.

Approximately 30% of elderly adults are cognitively normal at time of death despite presence of Alzheimer's disease (AD) neuropathology at autopsy. Studying these â□□resilientâ□□ individuals provides a unique approach to studying AD. It is well-established that sex differences are present in AD, with growing evidence suggesting genetic factors contribute to such differences. To this end, we sought to elucidate the sex-specific genetic etiology of resilience to AD. We leveraged our groupâ□□s published latent variable model of resilience representing better-than-predicted cognitive performance given an individualâ□□s age, sex, and amyloid burden and performed sex-stratified meta-analyses across four cohorts of cognitive aging. Then we performed a series of genetic correlation analyses (GNOVA) between the sex-stratified resilience meta-analyses and sex-stratified UK Biobank (UKBB) GWAS, adjusting for multiple comparisons. We evaluated 3,592 traits tested in females and 3,448 traits tested in males. Regardless of sex, resilience was genetically correlated with

education and neuropsychiatric traits. Among males, we observed 37 statistically significant correlations, whereby 24 appeared to be male-specific with non-overlapping confidence intervals with females. For example, among males, we observed a positive correlation with pulse rate (Rho=0.095, CI=[0.052,0.138], P.Bonferroni=0.048), representing unhealthy heart-rate variability, but we did not observe this correlation in females (Rho:-0.034, CI:[-0.067,-0.003], P.Bonferroni=1.000). Among females, we observed statistically significant correlations with 31 traits, whereby 10 appeared to be female-specific with non-overlapping confidence intervals with males. For example, among females, we observed a negative correlation with taking sotalol, an arrhythmia medication, representing unhealthy heart-rate variability (Rho=-0.041, CI=[-0.058,-0.025], P.Bonferroni=0.003), but we did not observe this correlation in males (Rho=0.018, CI=[-0.002,0.039], P.Bonferroni=1.000). Although genetic predictors of healthy heart-rate variability were associated with higher resilience in females, such measures were associated with lower resilience in males. Together, these results highlight that biological pathways, such as cardiovascular pathways, may relate to resilience against the downstream consequences of amyloidosis in a sex-specific manner, and re-emphasize the importance of considering biological sex in genetic explorations of AD.

Studies of cognitive impairment (CI) in the Amish identified sibships containing multiple CI and cognitively normal (CN; unaffected after age 75) siblings. We hypothesize that CN people carry alleles delaying age at onset (AAO) of CI, preserving cognition in older age despite increased genetic risk. We conducted a genome-wide study (GWAS) to identify loci associated with AAO of CI.1,522 Amish aged 43-99 (mean age 73.1, 42% men) screened at least once for CI using the modified mini-mental status exam (3MS) were genotyped using Illumina chipsets. Genotypes were imputed for 7,815,951 single nucleotide variants (SNV) with minor allele frequency (MAF)>1%. Disease-free time, defined as 1) age at first 3MS result indicating impairment (AAO; 3MS 86, 1,160 CN individuals) was the outcome. Cox mixed-effects models examined association between age and each SNV, adjusting for sex, population structure, and kinship. Analysis stratified by *APOE* genotype evaluated effect modification by APOE-4. To replicate genome-wide significant findings, SNVs 500 kb on either side of the peak SNV were examined for association with age in the NIA-LOAD family dataset (1,785 Alzheimer disease, 1,565 unaffected, mean age 73.5). Three SNVs were significantly associated (p-8) with AAO in the Amish, on chromosomes 6 (rs146729640; Hazard Ratio (HR)=6.38), 9 (rs534551495; HR=2.82), and 17 (rs14538074; HR=3.35). Each region found the common allele associated with later AAO. Replication analysis detected association at rs146729640 on chromosome 17, with nominal statistical significance (HR=1.49, p=0.02). The effect at rs146729640 was stronger in the APOE-4 negative subsets in both the Amish (HR=8.96) and NIA-LOAD (HR=1.82) samples. The replicated genome-wide significant association with AAO on chromosome 17 implicates the *SHISA6* gene, which is involved in post-synaptic transmission in the hippocampus. The analysis stratified by APOE-4 carrier status suggests that this effect is stronger in people without an APOE-4 allele. GWAS studies have not reported association in this region with AD risk or AOO, suggesting this might be a novel locus influencing onset of cognitive impairment, and highlights the power of using unique populations.

PrgmNr 3297 - Genomic and Transcriptomic-wide Analysis Identifies Novel Genetic Risk Loci and Prioritization of Therapies for Myasthenia Gravis

Disclosure Block: **R. Chia:** None.

Myasthenia gravis is a chronic autoimmune disorder caused by antibody-mediated destruction of receptors at the neuromuscular junction (NMJ) resulting in loss of communication between motor neuron and skeletal muscle. Genetics are likely to play a role as myasthenic patients have a higher risk of developing other autoimmune diseases. We performed a genome-wide association study (GWAS) and a transcriptome-wide association study (TWAS) to identify the genetic risks and candidate genes involved in disease etiology. The discovery cohort consists of 1,873 myasthenic patients with acetylcholine receptor antibodies and 36,370 healthy individuals, whereas 354 cases and 7,058 healthy individuals from the UK Biobank were included in the replication cohort. In addition to previous signals in *PTPN22*, *HLA-DQA1/HLA-B*, and *TNFRSF11A*, two novel signals in the acetylcholine receptor subunits genes, which are common antigenic target of the autoantibodies, were identified. From GWAS, the risk variant located in a promoter region of the cholinergic receptor nicotinic alpha 1 subunit (*CHRNA1*) gene on the forward strand increased risk by 1.57 ($p=3Â·07Ã10^{-8}$). TWAS identified two genes of which lower expression in skeletal muscle was predicted to increase disease risk: cholinergic receptor nicotinic beta 1 subunit (*CHRNB1,* $p=3Â·01x10^{-6}$, Z=-4Â·67*)* and epidermal growth factor receptor family of receptor tyrosine kinases (*ERBB2*, $p=5Â·63x10^{-7}$, Z=-5Â·00). Both *CHRNB1* and *ERBB2* are highly expressed at the NMJ and involved in the formation of functional acetylcholine complex. Thus, it is reasonable that lower expression of these proteins could impair neurotransmission. Onset-stratified analysis demonstrate that the genetic architecture is different between patients with early (CHRNA1, *CHRNB1* and *ERBB2* genes. In an unbiased approach, we identified several immunotherapies that may modify the disease progression based on their genetic profile. Our results demonstrate the power of genomics as a viable strategy for drug repurposing across diseases.

PrgmNr 3298 - Identification of novel genetic associations of epilepsy with functional validation in a zebrafish model

View session detail

Author Block: **T. Nagai**[1], E. Knapik[2], E. Gamazon[3,4,5]; [1]Human Genetics Graduate Program, Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Univ. Med. Ctr., Nashville, TN, [3]Genetic Med., Vanderbilt Univ. Med. Ctr., Nashville, TN, [4]MRC Epidemiology Unit, Univ. of Cambridge, Cambridge, United Kingdom, [5]Clare Hall, Univ. of Cambridge, Cambridge, United Kingdom
Disclosure Block: **T. Nagai:** None.
Epilepsy is a neurological disease that affects millions of people around the world, and is defined by the occurrence of repeated, unprovoked seizures. While several different anti-epileptic drugs (AED) are approved to prevent or reduce the occurrence of these seizures, there is still a large proportion of epilepsy cases that are currently considered drug-resistant, limiting the treatment options available for those patients. Genomic analysis has been instrumental in identifying novel drug targets, which could potentially lead to an increased repertoire of AEDs for previously unknown genes and mechanisms of epilepsy and reduce the number of drug-resistant epilepsy cases. Genome-wide association studies (GWAS) of epilepsy were performed, but only few of the novel findings have been functionally validated. In our study we utilize the PrediXcan method, which combines the imputation of genetically regulated expression (GReX) and transcriptome-wide association studies (TWAS), and has shown to be effective at identifying novel disease-gene associations. However, rather than use single-tissue models of gene expression, we will apply joint-tissue imputation (JTI) models that leverage multi-tissue expression quantitative trait loci (eQTL) data from the Genotype-Tissue Expression study (GTEx) combined with epigenetic data from the ENCODE project and Roadmap Epigenomics. This allows the JTI models to incorporate tissue similarity into GReX imputation, producing better predictive performance. By using these JTI models with S-PrediXcan to analyze summary statistics of previous epilepsy GWAS data, our study has the potential to identify novel functional genes and mechanisms of epilepsy that have an increased likelihood of being causal. Once identified, these genes can then be validated in a high-throughput manner using a functional zebrafish seizure model. Zebrafish have proven to be a robust model capable of complex seizure phenotypes using pentylenetetrazol (PTZ), a seizure-inducing drug. Zebrafish can be easily genetically edited using CRISPR and their expression can be altered using morpholinos to generate models of newly identified genes. We will use these models to screen for genes that increase seizure susceptibility and perform molecular analysis to understand underlying mechanisms. By combining these computational and functional approaches, we can identify new causal genes associated with epilepsy.

PrgmNr 3299 - Linkage and association of cognitive resilience to chromosomes 4 and 18 in Midwestern Amish

Disclosure Block: **D. Dorfsman:** None.

Inherited risk of Alzheimerâ□□s disease (AD) can be estimated by aggregating the effects of genome-wide risk loci into a genetic risk score (GRS). Individuals that are cognitively resilient (CR) are disease-free despite being at elevated risk of AD due to higher GRS and advanced age; studies of these individuals might identify genetic variants that protect against AD. The Midwestern Amish population is genetically and culturally homogenous, making it suitable for such studies. By integrating genetic risk of AD into a genetic linkage framework, we may better illuminate evidence of linkage and association in high-risk families exhibiting CR.

Subjects were classified as cognitively impaired (CI) or CR using the modified mini-mental status exam (3MS). Genotypes (Illumina platform) for 1,061 Midwestern Amish adults were imputed using the HRC reference panel, generating doses at ~ 7 million SNPs. Nonparametric linkage analysis was performed on sibships (n=120) with â□¥ 2 CR members using a panel of 2,167 SNPs (MAF â□¥ 0.3). Ordered-subsets analysis (OSA) can increase evidence of linkage in the presence of trait heterogeneity by arranging families in order of a trait-related covariate. Families were ranked from high-to-low genetic risk of AD using the mean GRS of CR sibship members. Effect sizes of 24 genome-wide late-onset AD loci were used to calculate GRS (Kunkle et al, 2019). Regions with significantly increased LOD* in the OSA-subset were examined by mixed model association testing in the overall sample. SNPs (MAF > 0.01) within 5 Mb of observed LOD* peaks were retained.

Mean family GRS=2.97 Â± 0.54. After OSA, significant LOD* increases were found on chromosome (chr) 4 (21 families with highest mean GRS, peak LOD*= 3.07, p=0.017, 67.55 Mb) and chr 18 (22 families with highest mean GRS, peak LOD*=2.65, p=0.021, 48.68 Mb). These regions do not contain known AD risk loci. 55,535 SNPs (MAF â□¥ 0.01) in the linked regions were analyzed. SimpleM was used to estimate the number of independent tests performed across both regions, resulting in a Bonferroni-corrected significance threshold of Î±=5.2 x 10-5. The strongest evidence of association was observed at rs28646178 (p=2.56 x 10-5, OR = 0.85, chr 18: 46.4 Mb), The strongest association on chr 4 was at rs72636894 (p=9.25 x 10-4, OR = 0.75).

These results suggest that novel genetic loci may promote CR, and that accounting for known AD genetic risk factors in linkage and association studies is an effective approach toward identifying novel protective alleles underlying CR.

PrgmNr 3300 - Measuring similarities and differences between EOAD and LOAD trough genome-wide association study, colocalization and heritability analysis

Introduction: Alzheimer disease (AD) is a degenerative brain disease, the most common cause of progressive dementia and the sixth leading cause of mortality in the United States. While early onset AD (EOAD, age at onset [AAO] 65), it is still unclear how much the two forms overlap, particularly with respect to their etiology.

Methods: Genetic data on 21,622 individuals from the Alzheimer Disease Genetics Consortium (ADGC) were used: (1,476 EOAD and 9,695 LOAD cases, and 10,451 controls). Single-variant association analyses were performed using logistic regression: full model (ancestry, sex, APOE-É□4 dosage, and SNP) and reduced model (ancestry and SNP). Evidence for colocalization was assessed to test if there is an association for both EOAD and LOAD, and if it is driven by the same causal variants. Locus zoom analysis was performed for significant index EOAD SNPs. The SNP heritability (h^2) and genetic correlation (rg) were estimated through LD score regression, considering the additional models: reduced + sex (ancestry, sex, and SNP) and reduced + APOE-É□4 (ancestry, APOE-É□4 dosage and SNP).

Results: Under full model, we identified three novel biologically plausible loci associated with EOAD: Chromosome 5 (*RP11-6N13.1*, rs15620839, $P=4.15x10^{-09}$); Chromosome 6 (*BACH2*, rs62408171, $P=3.67x10^{-08}$); and Chromosome 14 (*PRKCH*, rs186388694, $P=6.65x10^{-09}$). At each locus, the signal was supported by multiple associated SNPs. These genes are associated to chronic myeloid leukemia and immunodeficiency, cerebral hemorrhage, stroke, bipolar disorders, and hyperactivity. *BIN1* and *APOE* loci have posterior probabilities greater than 0.8, indicating that these two loci highly likely colocalized between EOAD and LOAD. The other three loci, *RP11-6N13.1*, *BACH2*, and *PRKCH*, failed colocalizing. Heritability analyses showed higher h^2 values for EOAD (h^2=0.30, 0.32, 0.34 and 0.33) than LOAD (h^2= 0.14, 0.18, 0.18, and 0.14), for full, reduced, reduced + sex and reduced + APOE-É□4 models respectively. Genetic correlation showed moderate genetic overlap between EOAD and LOAD only for full (rg=0.35, p=0.0283) and reduced + APOE-É□4 (rg=0.34, p=0.0261) models.

Conclusion: There is still a gap in our understanding of the similarities and differences between EOAD and LOAD forms. This study begins to address this by quantifying the amount of genetic overlap, identifying novel loci associated with EOAD, and confirming multiple other LOAD loci. We also identified three novel loci that are biologically highly plausible for EOAD, supported by a larger

heritability and suggesting a stronger polygenic effect in EOAD than LOAD.

PrgmNr 3301 - APOE gene associated with dementia related disorders and neuropsychiatric diseases in the Hispanic population

View session detail

Author Block: **C. Xu**[1,2], V. Padilla[1], K. Wang[3]; [1]UTRGV, Brownville, TX, [2]Univ. of Texas Rio Grande Valley, Brownville, TX, [3]West Virginia Univ., Virginia, WV
Disclosure Block: **C. Xu:** None.
Alzheimer's disease (AD), a common form of dementia, is commonly seen in the aging populations and is known to have a strong genetic component to its development. AD is one of the most common neurodegenerative disorders; it is a genetically and clinically heterogeneous disease. Specific demographic factors and genetic variants have been identified in non-Hispanic populations; however, a limited study was conducted in the Hispanic population. Therefore, we focused on investigating known gene, APOE, and demographic factors associated with the development of AD-related phenotypes and two psychiatric diseases (depression and anxiety) within the U.S. Hispanic population in our current study. A total of 1,382 subjects were collected from the Texas Alzheimer's Research and Care Consortium (TARCC, N=1,320) and the Initial Study of Longevity and Dementia from the Rio Grande Valley (ISLD-RGV, N=62). Questionnaires for demographics, medical history, and blood/saliva samples were collected. We genotyped the APOE gene. From the three APOE alleles, Îµ3 (90%), Îµ4 (21%), and Îµ2 (6%), the APOE Îµ4 allele showed association with AD (p=8.45E-7) in the Hispanic population. In addition, APOE Îµ4 allele was also associated with anxiety (p=4.84E-26), while the APOE Îµ3 allele showed an association with depression (p=0.002). We provide additional evidence in which APOE Îµ4 increased the risk for AD in Hispanics. For the first time, APOE Îµ4 and Îµ3 alleles show increased risks for anxiety and depression in Hispanics, respectively. Further research is warranted to confirm the current findings.

PrgmNr 3302 - Association between polygenic risk for substance use and music engagement across multiple cohorts

View session detail

Author Block: **P. Coleman**, R. L. Gordon, D. E. Gustavson; Vanderbilt Univ. Med. Ctr., Nashville, TN
Disclosure Block: **P. Coleman:** None.
Substance use (SU) is highly prevalent, particularly the use of nicotine and alcohol. Music engagement is often utilized as an independent coping strategy and clinical treatment for SU. Recent phenome-wide association findings from our group show decreased risk of tobacco use disorder in female musicians. Whether there is a genetic relationship between SU and music engagement is unknown, though recent findings from our group show genetic correlations between rhythmic ability and increased tobacco use, contrary to the negative phenotypic association. This study aims to (a) explore the phenotypic and genetic associations between music engagement and SU, and (b) create a model of the interaction between music engagement, genetic risk, and SU behaviors. Preliminary phenotypic analyses show that music engagement is generally correlated with reduced SU, though some music behaviors (e.g., going to many concerts) are associated with increased SU. Using summary statistics from the GWAS and Sequencing Consortium of Alcohol and Nicotine use (GSCAN) and UK Biobank, we constructed polygenic risk scores (PRS) for alcohol and nicotine use in the research database BioVU. PRS for smoking initiation, cigarettes per day, age of smoking initiation, and alcohol frequency were compared with musicianship status, which had been defined in a prior study via algorithmic categorization through text-mining of electronic medical records (e.g., 'guitarist' or 'musician') and validated through manual chart review. Here we found those with higher genetic risk for smoking initiation (UK Biobank) and higher number of drinks per week (GSCAN) were more likely to be musicians. To further explore the relationship between music engagement and SU, we plan to replicate these findings in two additional cohorts: the Adolescent Brain and Cognitive Development (ABCD) cohort, and the Vanderbilt University Online Musicality (OM) cohort, both of which include more detailed music engagement questionnaires and genotyping. Analyzing this relationship in ABCD will be particularly interesting, as it contains many nicotine and alcohol-related measures, and SU behaviors usually begin in adolescence. The present study uses cross-trait PRS analysis to test a recent framework by our group, which posits that musicians may be at a higher genetic risk for SU, but music engagement may actually reduce SU behaviors. This research may be evidence for the use of music interventions to reduce SU behaviors for people at high genetic risk, and showcases a cross-trait method to examine the genetic relationship between cognitive traits.

PrgmNr 3303 - Dimensional traits in genetic research of autism show greater heritability and generalization than case-control traits

View session detail

Author Block: **T. Thomas**, T. Koomar, J. J. Michaelson; Univ. of Iowa, Iowa City, IA
Disclosure Block: **T. Thomas:** None.

The complexity of the autismâ□□s phenotypic spectra is well-known, yet most genetic research in this area uses a binary case/control status as the target trait. Numerous instruments exist to measure the core features of autism, including social and communication difficulties (measured by SCQ), restricted and repetitive behaviors (measured by RBSR), and motor coordination problems (measured by DCDQ). Here, we employed the SPARK autism cohort to illuminate the genetic etiology of 15 scales of autism symptomatology (N = 6,904 to 7,961 participants with autism) by calculating SNP heritability, performing genome-wide association studies (GWAS), identifying pleiotropy with polygenic risk scores (PRS), and lastly replicating the genetic signal in the typically-developing ABCD cohort (N = 6,659). Surprisingly, the PRS derived from previous autism GWAS had no association with symptomatology. Likewise, despite previous reports of autism and educational attainment being positively genetically correlated, higher educational attainment PRS was significantly associated with less autism symptomatology in all three core domains. Other significant PRS associations include bipolar disorder and openness PRS positively correlated with higher DCDQ, while ADHD, major depression, and neuroticism PRS positively correlated with both higher DCDQ and higher RBSR. In addition, modeling the PRS-by-sex interaction revealed the autism PRS (PGC) having slightly positive or no effect in males, while in females the autism PRS was negatively correlated with the RBSR. Significant PRS-by-sex interactions were also found for bipolar disorder, anorexia, major depression, and several personality PRS, underscoring the central role of sex in mediating genetic risk. Significant SNP heritabilities were observed across many of the subscales, with RBSR subscales having the highest heritabilities, ranging from 0.11 to 0.25, followed by the DCDQ (0.07-0.14), and the lastly the SCQ (0.01-0.1). Finally, we tested the generalization of the genetic associations to ABCD traits by calculating PRS from the 15 subscale GWAS, which were then tested for association with behavioral and emotional problems measured by the Child Behavior Checklist (CBCL). Notably, PRS from our subscale GWAS outperformed the PGCâ□□s autism PRS in predicting all 8 CBCL subscales as well as total problems, despite our GWAS having much lower sample sizes than the PGC autism study. Overall, these analyses suggest that more meaningful phenotyping is at least as important as the pursuit of ever-larger sample sizes in the ultimate success of genetic research in neuropsychiatric conditions like autism.

PrgmNr 3304 - Identify high risk individuals for Alcohol use disorder using polygenic risk scores

View session detail

Author Block: **D. Lai**, COGA Investigators; Indiana Univ Sch. of Med., Indianapolis, IN
Disclosure Block: **D. Lai:** None.
Alcohol use disorder (AUD) is one of the most common and preventable health problems. The estimated heritability of AUD is ~50% and identification of high risk individuals for AUD based on their genetic constitution will help us develop novel and targeted prevention and therapeutic strategies. Polygenic risk scores (PRS) are sum of risk alleles across the entire genome and have shown promises in identification of high risk individuals for diseases such as cardiovascular disease, cancer, etc. However, current PRS of AUD can only explain up to 2.5% of the variation and cannot be used to evaluate disease risk. In this study, we aimed to develop new PRS of AUD that can be used to identify high risk individuals. We first meta-analyzed two large-scale genome-wide association studies (GWAS) of AUD and related problems: AUD identified using the ICD codes from the Million Veteran Program and Alcohol Use Disorder Identification Test (AUDIT) problems scores (items 4-10) from the UK Biobank. Both GWAS used European ancestry samples only (N_{total}=323,608). Due to the different phenotypes and cohorts studied, study-specific findings were excluded and 2,757,681 variants were used. Using the meta-analysis results as the discovery dataset, we calculated PRS in three target datasets: the Collaborative Study on the Genetics of Alcoholism (COGA, N_{case}=3,453, N_{contol}=1,616), Study of Addiction: Genetics and Environment (SAGE, N_{case}=630, N_{contol}=337), The Australian twin-family study of alcohol use disorder (OZALC, N_{case}=1,650, N_{contol}=527). All three target datasets were European ancestry only to match the discovery dataset. PRS-CS was used to calculate the posterior effect sizes and European ancestry samples from the 1000 Genomes Project was used as the linkage disequilibrium reference panel. Then PRS were calculated using PLINK. For COGA and OZALC, GEE framework was used with a random effect to adjust the family relationships. For SAGE, logistic regression was used. Sex and Birth-cohorts were used as covariates for COGA and SAGE while sex and age were used for OZALC. Since COGA samples were genotyped on different arrays, an array indicator was also included as a covariate. Compare to the remaining samples, those samples with the 10% highest PRS have Odds Ratio of 2.22 (95%CI: 1.73-2.84, P-value

PrgmNr 3305 - Identifying potential environmental influences on clinical comorbidities of schizophrenia through integration of electronic health data and genetics

View session detail

Author Block: **T. Vessels**[1], N. Strayer[1], K. Choi[2], T. J. Morley[3], H. Lee[2], J. W. Smoller[4], Y. Xu[1], D. M. Ruderfer[3]; [1]Vanderbilt Univ., Nashville, TN, [2]Massachusetts Gen. Hosp., Boston, MA, [3]Vanderbilt Univ. Med. Ctr., Nashville, TN, [4]Massachusetts Gen Hosp, Boston, MA
Disclosure Block: **T. Vessels:** None.
Background: Clinical comorbidities affect 68% of patients with psychiatric disorders and contribute to 60% of premature mortalities. Patients with schizophrenia (SCZ) have a reduced life expectancy of 10-20 years that is often a byproduct of associated comorbidities. We hypothesize that comparing clinical comorbidities from electronic health record (EHR) data to genetic associations will provide insights into which comorbidities are effects of the SCZ genetic etiology vs consequences of treatment, behavior or other environmental factors. **Methods:** We defined clinical comorbidities from a logistic regression of pairwise comparisons of diagnostic billing codes (PheCodes), adjusting for demographic and other covariates from two health care systems (Vanderbilt University Medical Center, VUMC; Mass General Brigham, MGB). Comorbidities were calculated on 250,000 randomly selected patients from each site individually and then averaged together. SCZ polygenic risk scores (PRS) in 64,190 genotyped patients of European ancestries were generated and compared in a logistic regression to each PheCode. After comparing the overall clinical and PRS associations, a TOST test of equivalence was used to further evaluate top SCZ comorbidities on whether they showed a well-powered absence of association with the SCZ PRS. **Results:** Clinical comorbidities were highly consistent across both institutions overall (r=0.79) and for SCZ specifically (r=0.85). We show significant replication of comorbidities previously identified in the literature including epilepsy, diabetes, and atrial fibrillation (9/15 with p-118) and cross institution (r =0.49, p =$8.4x10^{-81}$). After multiple test correction, there were 59 significant comorbid associations with SCZ. Interestingly, 11 of the 59 comorbidities had significant equivalence of SCZ PRS between cases and controls indicating an absence of contribution to phenotypic comorbidity from common variant SCZ genetics. **Discussion:** These 11 comorbid phenotypes may represent examples caused by other risk factors including rare variation, disease or treatment consequences or medical practice. Our results also identify several positive control examples with expected temporal patterns including movement disorders that are a known byproduct of antipsychotics and hepatitis as an outcome of behavior such as substance use. We further identify other comorbid phenotypes that could be modifiable environmental risk factors and point to strategies to improve health outcomes for SCZ patients.

PrgmNr 3306 - Investigating shared genetic liability between recurrent major depression and cardiometabolic traits in East Asian populations

View session detail

Author Block: **E. Lancaster**[1], T. B. Bigdeli[2], K. S. Kendler[3], B. T. Webb[3], R. E. Peterson[3]; [1]Virginia Commonwealth Univ., Richmond, VA, [2]SUNY Downstate Hlth.Sci. Univ., Brooklyn, NY, [3]Virginia Commonwealth Univ, Richmond, VA
Disclosure Block: **E. Lancaster:** None.
Introduction: Major depression (MD) is a common yet potentially debilitating disorder that is often comorbid with other diseases, such as hypertension, coronary artery disease, and diabetes, further contributing to the overall impairment associated with MD. Given the high global burden and increasing rates of both cardiometabolic disorders and MD, investigating the origins of these disease relationships remains pertinent. While causal mechanisms linking these phenotypes are unknown, the moderate heritability reported for MD and several common cardiometabolic conditions suggests that shared genetic factors may be influencing these observed disease associations. This study utilized results from a genome-wide association study conducted in the CONVERGE (China, Oxford and Virginia Commonwealth University Experimental Research on Genetic Epidemiology) cohort alongside summary statistics from Biobank Japan to estimate the genetic correlation between recurrent MD and 14 cardiometabolic traits. Given the sex-specific differences in the prevalence and presentation of these traits, sex-stratified genetic correlations will also be examined. **Methods**: CONVERGE recruited 11,670 Han Chinese women with the primary goal of investigating etiological factors related to recurrent MD. Recurrent MD cases (n= 5,303) had experienced 2 or more episodes of MD defined by the Composite International Diagnostic Interview (CIDI). Healthy controls (n= 5,337) had no history of psychiatric illnesses. LD score regression (LDSC) was used to estimate genetic correlations between MD and 14 cardiometabolic traits selected from Biobank Japan, including both disease outcomes (e.g., type 2 diabetes) and related quantitative traits (e.g., hemoglobin A1c levels). To investigate whether sex-specific shared genetic influences may exist, additional genetic correlations were performed using the female-only subset of Biobank Japan for those phenotypes with sex-stratified summary statistics available (n= 7). **Results**: Significant negative genetic correlations were identified between MD and systolic blood pressure (rg= -0.22, p= 0.011), BMI (rg= -0.18 p= 0.001), and type 2 diabetes (rg= -0.15, p= 0.010). Analyses using female-only summary statistics showed a significant relationship between BMI (rg= -0.25, p= 3 x 10â»â´) and type 2 diabetes (rg= -0.18, p= 0.009). **Conclusions**: Results from this study suggest that MD may only partially share common genetic risk factors with some cardiometabolic traits. Further research is needed to determine whether observed correlations between these phenotypes result from common environmental factors or shared rare genetic variation.

PrgmNr 3307 - Pilot targeted gene analysis of resting heart rate variability in individuals with anxiety disorders and healthy controls

View session detail

Author Block: **J. Tomasi**, A. J. Lisoway, C. C. Zai, G. Zai, J. L. Kennedy, A. K. Tiwari; Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada
Disclosure Block: **J. Tomasi:** None.
Background: Heart rate variability (HRV) is a heritable measure of the variation in milliseconds between consecutive heart beats, and reflects the ability of the parasympathetic nervous system (PNS) to deactivate the sympathetic nervous system. Low HRV has been linked to poor cardiac health in addition to reduced psychological health. Anxiety disorder, which is related to deficient PNS activity, is associated with low resting HRV, and HRV is decreased during anxiety states. HRV may thus indicate the bodyâ□□s reactivity to anxiety and ability to recover. Therefore, genetic variants related to HRV may provide insight on the underlying biology of anxiety.
Methods: Our pilot sample consists of 47 individuals (15 patients with anxiety disorder and 32 controls, age 21-38, 33 female, predominantly European ancestry). Resting HRV was recorded via photoplethysmography for 5 minutes using a wearable Empatica wristband. Blood volume pulse data was processed via Kubios HRV software, and HRV was calculated using the root mean square of successive beat-to-beat interval differences. Global Screening Arrays were used to capture genome-wide SNP data. We performed a targeted analysis of SNPs in 17 genes involved in autonomic nervous system regulation (e.g. HPA-axis, serotonin, renin-angiotensin, norepinephrine, acetylcholine) using linear regression with an additive genetic model. Hypothesis-free GWAS was performed on HRV as well. Covariates included age, sex, diagnostic status, and the first two principal components of ancestry.
Results: The average HRV was 50.89msÂ±27.35ms (22.03ms-135.86ms). In our targeted gene analysis, rs4570625 from *TPH2* (Î²=16.59, p(unadj)=0.02), and rs878886 and rs110402 from *CRHR1* (Î²=26.30, 11.76; p(unadj)=0.004, 0.05) were nominally associated with HRV. In the hypothesis-free analysis, three SNPs passed Bonferroni correction: rs76239887, rs118065261 (*AKAP6*), and rs34434064 (Î²=56.12, 70.49, 77.83; p(unadj)= 4.7e-08, 8.5e-08, 1.1e-07; p(adj)=0.02, 0.04, 0.05).
Conclusion: This preliminary study identified several SNPs of interest for HRV through both hypothesis-free and hypothesis-driven approaches. In previous studies, *TPH2* rs4570625 and *CRHR1* rs878886 and rs110402 have been associated with anxiety-related phenotypes, and *AKAP6* has been associated with general cognitive ability as well as cardiac function. Our study is limited by the very small sample size, which will be increased as recruitment continues. Given the potential utility of HRV as a physiological marker of anxiety disorder, the SNPs of interest identified here, if replicated, may aid the identification of pathological anxiety risk and novel treatment targets.

PrgmNr 3308 - Targeted sequencing of genes most likely to harbor rare causal variants in schizophrenia

View session detail

Author Block: **D. Liu**, Psychiatric Genomics Consortium, Schizophrenia Exome Meta-analysis Consortium, A. Charney; Icahn Sch. of Med. at Mount Sinai, New York, NY
Disclosure Block: **D. Liu:** None.
The Schizophrenia Exome Sequencing Meta-Analysis (SCHEMA) Consortium conducted the largest-so-far whole exome sequencing (WES) study in 24,248 schizophrenia (SCZ) cases and 97,322 controls. Their results implicated an excess burden of ultra-rare coding variants in cases and identified genes conferring substantial risk at exome-wide significance. Based on these results, the Psychiatric Genomics Consortium (PGC) has conducted targeted sequencing of the top SCHEMA risk genes in a multi-ethnic cohort of 12,196 schizophrenia cases and 11,053 controls. The aims are (1) to replicate the findings from SCHEMA in a large independent cohort; (2) to meta-analyze with SCHEMA to increase the power for risk gene discovery.
The targeted panel comprised 161 genes with a high prior probability of harboring excess rare disruptive variants in SCZ. Targeted sequencing was performed on the Ion Torrent platform, and variants were called and filtered using an in-house pipeline optimized specifically for Ion Torrent data. Variant annotation was performed using The Ensembl Variant Effect Predictor, and missense variants were further prioritized using MPC pathogenicity score. The composition of the final callset was comparable to several other sequencing datasets including SCHEMA. SCHEMA demonstrated that rare protein-truncating variants (PTVs) are concentrated in constrained genes in SCZ cases compared to controls (OR=1.26), and we replicated this enrichment across the 80 constrained genes included in the sequencing panel, while carefully controlling for population stratification and technical confounding (P = 0.0016; OR = 1.29, 95% CI = 1.10 - 1.53). Conversely, damaging missense variants did not show a higher burden in cases compared to controls in this cohort (MPC > 3, OR = 1.00, P = 0.99; MPC 2~3, OR = 1.03, P = 0.66). When restricting to the 40 panel genes that ranked among the top 200 in SCHEMA, PTVs were more strongly enriched (P = 0.0004; OR = 1.44, 95% CI = 1.18 - 1.78), and damaging missense variants also showed extra burden in cases (MPC > 3, P = 0.43, OR = 1.43; MPC 2~3, P = 0.02, OR = 1.28). We also demonstrated a contribution of complete knockout (homozygous or compound heterozygous damaging variants) to SCZ risk (OR=2.26, P = 0.002). A meta-analysis with SCHEMA using Stoufferâ□□s method implicated two additional genes in which rare disruptive variants confer significant risk for SCZ: AKAP11 with P = 8.9 Ã□10-7, and SRRM2 with P =7.1 Ã□10-7. The integration of the genome-wide common SNP data is underway, which will enable a comprehensive assessment of the relationship between rare variant burden, copy number variation and polygenic risk from common SNPs.

PrgmNr 3309 - *MS4A* gene cluster variant modifies CSF sTREM2 associations with AD biomarkers of pathology

View session detail

Author Block: **R. Weiner**[1,2], L. Dumitrescu[2,3], K. Blennow[4], H. Zetterberg[5,6,7,8], K. A. Gifford[2], K. R. Pechman[2], A. L. Jefferson[2,3], T. J. Hohman[2,3], and for the Alzheimer's Disease Neuroimaging Initiative; [1]Dept. of Pharmacology, Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Memory and Alzheimer's Ctr., Vanderbilt Univ. Med. Ctr., Nashville, TN, [3]Vanderbilt Genetics Inst., Vanderbilt Med. Ctr., Nashville, TN, [4]Dept. of Psychiatry and Neurochemistry, Sahlgrenska Academy, Univ. of Gothenburg, MÃ¶lndal, Sweden, [5]Dept. of Psychiatry and Neurochemistry, Inst. of NeuroSci. and Physiology, Sahlgrenska Academy, Univ. of Gothenburg, MÃ¶lndal, Sweden, [6]Clinical Neurochemistry Lab., Sahlgrenska Univ. Disclosure Block: **R. Weiner:** None.
Background: Soluble Triggering Receptor Expressed on Myeloid Cells-2 (sTREM2) and its transmembrane parent (TREM2) are microglial signaling machinery, both of which have been implicated in the modification of Alzheimerâ□□s disease (AD) pathology. Higher CSF sTREM2 levels at baseline are thought to be associated with protection in AD, whereas membrane-spanning 4-domains subfamily A (*MS4A*) gene cluster variants modify both AD risk and levels of CSF sTREM2 protein. We previously found high baseline CSF sTREM2 relates to increases in CSF amyloid-Î² (AÎ²) species as well as blood-brain barrier (BBB) marker, CSF/plasma albumin ratio, leveraging Vanderbilt Memory and Aging Project (VMAP) participants. It is unknown whether *MS4A* variants interact with sTREM2 to modify levels of AD pathology. **Methods:** Baseline CSF sTREM2 measurement in 155 VMAP participants (meanÂ±standard deviation age=72Â±6.33, male=67%, mild cognitive impairment=47%), was assessed using linear regression models adjusted for age, sex, education, and cognitive diagnosis. Models examined whether sTREM2 levels interacted with *MS4A*-associated SNPs on the following biomarkers of AD pathology: $AÎ²_{x-42}$, $AÎ²_{1-42}$, $AÎ²_{x-40}$, total tau, phosphorylated tau, and the CSF/plasma albumin ratio. Alzheimerâ□□s Disease Neuroimaging Initiative (ADNI) data was used to replicate interaction results with AÎ² species measured by mass spectrometry (N=399). **Results**: CSF sTREM2 protein levels were significantly higher in minor allele carriers of rs1582763 than non-carriers (p=0.004). Previously defined associations of sTREM2 and CSF/plasma albumin ratio, $AÎ²_{x-40}$, as well as $AÎ²_{x-42}$, by our group were modified by the presence of rs1582763_A minor allele (Î²=7.087e-4, p.FDR=0.026; Î²=-0.439, p.FDR=0.033; Î²=-0.093, p.FDR=0.026, respectively) whereby higher sTREM2 was most strongly associated with higher AÎ² species among non-carriers. There were no significant interactions of rs1582763 on tau outcomes. Replication of AÎ² species results in ADNI approached but fell short of statistical significance ($AÎ²_{1-40}$ p=0.159, $AÎ²_{1-38}$ p=0.334 and $AÎ²_{1-42}$ p=0.689). **Conclusion:** AD-protective *MS4A*-associated rs1582763_A is associated with increased levels of CSF sTREM2 in VMAP, and the presence of this allele interacts with sTREM2 levels selectively on AD biomarkers. This includes shorter AÎ² peptides and a BBB marker, and excludes the well-established association between sTREM2 and tau. This suggests genetic regulation by *MS4A* of AD pathophysiology may be closer linked to amyloid rather than tau associations. Larger sample sizes are needed to clarify the modifying role of *MS4A* variants on sTREM2 associations with AD pathology.

PrgmNr 3310 - Analysis of genome-wide associations, exposome and lifestyle factors of skin-aging using medical proxies in the UK BioBank

Skin, the largest organ of the human body, plays a first-line role in protection against environmental and physical harm. Skin changes represent human health and aging, but a system to comprehensively analyze the etiopathogenesis of skin aging remains elusive and must assess many variables. Extrinsic damage due to ultraviolet radiation or pollution exposure causes skin health deterioration and visible skin aging, and heritability analysis from twin studies have shown that additive genetics may account for 60% of the variation in skin aging. Lifestyle factors such as smoking, poor sleep or diet have also been shown to influence skin aging. In this study, the UK Biobank (UKB), a large well-phenotyped population database, was utilized to assess the association of environmental, genetic, and lifestyles factors with skin-aging related traits. We integrated self-reported data and curated primary care data from the UKB to conduct a well-powered analysis of skin-aging related phenotypes. A combination of medical codes was utilized as proxy information for skin aging-related phenotypes - sunspots (N = 31,211), and broken capillaries (N = 1,111). To investigate genetic factors, a genome-wide association study (GWAS) was run in a European-ancestry subset of the imputed UKB genotypes for each of those traits and 12 significant loci were found to be associated with a proxy of sunspots. We replicated 2 loci containing genes, *MC1R* and *IRF4*, which were previously reported, for more precise skin-quality scores such as Beagley and Gibson six-point rating system. Co-dependent environmental or lifestyle factors that may affect skin aging were also assessed. Preliminary analysis demonstrated a strong positive correlation between time spent outdoors and poor sleep with sunspots. The research presented here provides a system to assess the environment, lifestyle and genetic factors of skin aging research in one sample population. Our findings highlight the value of using proxy phenotypes in biobank to define and elucidate the etiopathogenesis of skin quality and skin aging. Ongoing work will explore additional skin aging-related phenotypes and Mendelian randomization to explore the effect of exposure on the skin. Future work aims to replicate and validate these medical proxies in additional population cohorts.

PrgmNr 3311 - Associated phenotypic and genotypic characteristics in a cohort of patients with infantile hemangiomas: a case series

View session detail

Author Block: **M. Frigeni**, D. F. Rodriguez-Buritica; Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX
Disclosure Block: **M. Frigeni:** None.
Infantile hemangiomas are the most common benign tumors of infancy, being present in approximately 2% to 3% of neonates and in 10% of all infants by 12 months of age. The majority of infantile hemangiomas are present as an isolated finding; however, in a small subset of patients they can be associated with other anomalies, such as in case of PHACE and LUMBAR associations. To date, there is a lack of studies analyzing the spectrum of phenotypic features that can be found in patients with non-isolated infantile hemangiomas. Here, 39,017 subjects from the DECIPHER database were screened for the presence of an infantile hemangioma. A total of 85 subjects were identified, and their phenotypic features analyzed. In 75% of the subjects, a congenital anomaly was present in association with the infantile hemangioma. About 60% of the anomalies identified involved the musculoskeletal system, followed by the genitourinary (35%), nervous (28%), and cardiovascular (20%) systems. It was also noted that 87% of the subject had at least one comorbidity reported, with most of them being neuro-developmental problems. Lastly, facial dysmorphism was observed in 76% of the subjects. Only 5% of the subjects had no additional finding other than the infantile hemangioma. As a next step, genotypic analysis of the 85 subjects was performed and uncovered a high prevalence of copy number variations on Chromosomes 9 and 4. Interestingly, there are at least 11 genes with crucial dose effect for vasculogenesis located on Chromosome 9. This finding warrants further investigation of these genomic regions, and could shed new light on the mechanisms responsible for infantile hemangiomas, whose genetic bases remain unknown.

PrgmNr 3312 - Association of whole-person polygenic component scores with Alzheimer's disease pathology

View session detail

Common neurodegenerative disorders, such as Alzheimerâ□□s Disease (AD), are highly heterogeneous and genetically correlated with many other age-related traits. Growing online compendia of GWAS summary statistics now enable phenome-wide assessments of SNP-based polygenic scores (PRS). We harnessed such summary statistics to describe the â□□whole personâ□□ genetic risk landscape in an elderly population, and test if meta-PRS scores derived from over 2,000 traits can improve risk prediction of AD and AD-related phenotypes. The Religious Order Study and Memory Ageing Project (ROS/MAP) are two ongoing longitudinal studies of ageing, involving annual cognitive testing and post-mortem neuropathological assessment. We imputed genotypes for 2,052 unrelated ROS/MAP participants of European ancestry using the TopMed Imputation panel and calculated PRSs for up to 2,312 heritable ($h^2 > 0.05$) and sex non-specific phenotypes, selected from the Pan-UKBB consortium, at 15 different P-value thresholds using PRSice v2.3.3. PRSs were corrected for fine population structure and omitted if they were constructed from fewer than five SNPs. At each P-value threshold, principal component analysis was applied to PRSs for all traits, with the resulting latent components representing â□□meta-PRSâ□□. We observed that the top meta-PRSs explained up to 5.7% of the variability in all PRSs at lower p-value thresholds (e.g. $5x10^{-8}$) and loaded most strongly onto cardiovascular and metabolic phenotypes. At higher P-value thresholds, prescriptions for pain killers were the major loadings of top meta-PRSs. In direct phenotypic association analyses, meta-PRSs representing all-cause dementia, ocular health, and cardiovascular disease were most strongly associated with rates of cognitive decline and levels of amyloid and tau neuropathology. The clustering of â□□whole personâ□□ genetic risk in this population offers a map of heterogeneity in genetic risk profiles for AD-related traits and reveals methodological influences on broad-scope polygenic correlation in the elderly population.

PrgmNr 3313 - Candidate causal variants affecting tissue-specific regulatory mechanisms in the GWAS catalog

View session detail

Author Block: **D. Hemerich**[1], Z. Wang[1], R. Loos[2,3]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]The Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]The Novo Nordisk Ctr. for Basic Metabolic Res., Univ. of Copenhagen, Copenhagen, Denmark
Disclosure Block: **D. Hemerich:** None.
Genome-wide association studies (GWAS) have revealed thousands of variants associated with a multitude of diseases and traits, the vast majority located in the non-coding region of the genome. These variants likely affect disease risk by acting on regulatory elements in tissues critical for the disease or trait of interest. While most regulatory elements, such as enhancers, are shared across tissues, some are tissue-specific and regulate genes that are essential for the function of that tissue. Identifying genetic variants acting in enhancers that are unique to tissues implicated in the disease can be a first step towards prioritizing candidate causal variants and identifying regulatory mechanisms. Here, we created a data resource of high confidence enhancers that are specific to one of 33 cell-types. We intersected these tissue-specific enhancers with independent variants from the GWAS catalog and their proxies at high linkage disequilibrium. We identified 20,405 independent loci associated with 3,149 diseases and traits that affect tissue-specific enhancers. We also retrieved the nearest gene to each associated variant as well as the gene predicted by the Epimap project, as candidate target genes that can be affected by the associated variant potentially disrupting the tissue-specific enhancers. In addition, we included the probability of causality of variants overlapping tissue-specific enhancers generated using PICS.Every tissue-specific set of enhancers showed enrichment for variants associated with diseases that implicate these tissues. For example, variants associated to pulse pressure are enriched in artery-specific enhancers (p=1.2E-10), those associated with intelligence are enriched in brain-specific enhancers (p=8.7E-06) and those associated with electrocardiogram morphology are enriched in heart-specific enhancers (p=2.2E-08). We observed well-known genes such as *PCSK9* implicated in liver-specific enhancers by variants associated to cholesterol levels, as well as *TTN* implicated in heart-specific enhancers by variants associated to atrial fibrillation. Taken together, we created a data resource that can help with prioritizing genetic variants acting in tissue-specific enhancers for functional studies. We plan to make this resource available as an online portal, to aid researchers in elucidating the biological mechanisms of diseases.

PrgmNr 3314 - Curated catalog of 309 functional GWAS non-coding variants across 125 diseases: a systematic review

View session detail

Author Block: **A. J. Alsheikh**[1], S. Wollenhaupt[2], E. A. King[1], J. Reeb[2], S. Ghosh[1], L. R. Stolzenburg[1], S. Tamim[1], J. Lazar[1]; [1]Genomics Res. Ctr., AbbVie, North Chicago, IL, [2]Information Res., AbbVie, Ludwigshafen, Germany
Disclosure Block: **A.J. Alsheikh:** Salary/Employment; AbbVie.
Genome-wide association studies (GWAS) have revolutionized our understanding of genetic susceptibility to complex human diseases. With more than 90% of GWAS associated variants being non-coding, the most challenging aspect remains the functional validation of these variants and deciphering the biological processes that underlie the genetic associations. The extent of experimental wet lab validation studies of GWAS non-coding variants conducted across all human disease traits remains largely unknown and no curated resource is published. To address this gap, a systematic literature review of experimental validation studies published in Medline from 2007 to 2020 was conducted in accordance with the 2020 PRISMA guidelines. We used an initial set of manually identified index studies to build a broad systematic search identifying 36,676 articles. Using natural language processing and ontology-based text-mining of abstracts and metadata, we built filters for 7 eligibility criteria 1) primary research articles, and mention of 2) GWAS, or association, 3) any human disease, 4) any human gene, 5) non-coding context, 6) functional, causal, or regulatory variant or specific rsID, and 7) wet-lab experimental validation techniques reducing the search results to 1,454 articles that met all the 7 criteria. These were manually reviewed for the same eligibility criteria. For 875 eligible articles, we manually curated the validated variant rsID, variant class, target gene symbol, and associated disease per article. This data was cross validated using the GWAS catalog resulting in a final set of 286 articles. These articles report 309 experimentally validated functional non-coding variants regulating 255 genes across 125 human disease traits. The variants cover a variety of classes and regulatory mechanisms and primarily act through gene promoters, enhancers, silencers, insulators, microRNAs, and long non-coding RNAs. Our analysis quantifies progress that has been made in the last decade and identifies the beginning of validation of distal regulatory element variants. Although extensive research is needed until we understand the biological mechanisms of all GWAS loci, we believe that this curated resource will provide tremendous value for a broad base of scientists who pursue validation studies by providing concrete prior exemplars of validations studies for wide variety of non-coding variant types in all disease areas. Additionally, for computational biologists interested in developing tools for functional non-coding variant prediction that has been previously hindered by lack of a truth set of experimentally validated variants.

PrgmNr 3315 - Determining the Genetic risk of Complex Disorders in Global populations

View session detail

Author Block: **P. JAIN**, M. Martinez, P. Drineas, P. Paschou; Purdue Univ., West Lafayette, IN
Disclosure Block: **P. Jain:** None.
Complex disorders are caused by a combination of genetic, environmental and lifestyle factors, and their prevalence can vary greatly across different populations. This difference could be due to genetic or environmental influences and understanding its basis could help us identify which groups of people might have a higher risk of developing certain disorders. Here, we undertake a systematic evaluation of genetic risk across worldwide populations for 20 different disorders and explore how it relates to disease prevalence. GWAS summary statistics of 20 different disorders (cardiovascular, neurological, metabolic, autoimmune and psychiatric disorders) were used to estimate Polygenic Risk Scores (PRS) in 9 European and 24 worldwide reference populations. We then estimate the correlations between average genetic risk for each of the 20 disorders and their prevalence around the world. We find significant correlations between prevalence and PRS for 13 of the studied disorders with Obesity having the highest correlation (R2=0.73, corrected P-value=0.001). A clear variation in genetic risk is observed based on ancestry and we identify populations that have a higher genetic liability for developing certain disorders both within European and global regions. Compared to other populations, Africans have a higher genetic risk for Obesity, East Asians have a higher genetic risk for Type 2 Diabetes and Coronary disease, and Europeans have a higher genetic risk for Alzheimerâ□□s and moderate risk for psychiatric and Autoimmune conditions. These results can help shed light on the genetic architecture of complex disease around the world and could inform early intervention strategies for populations at higher risk for certain disorders, promoting equity in medical treatment.

PrgmNr 3316 - DNA-methylation quantitative trait loci in Asian populations

DNA methylation (DNAm) is a key regulator of transcriptional regulation and is increasingly recognized as a contributor to health and disease. Population-level variation in DNAm is under strong genetic influence, according to twin and family studies. Several studies in a variety of tissues, including the brain and whole blood, have found widespread associations between common DNA sequence variants and DNAm. These DNAm quantitative trait loci (mQTL) are enriched in regulatory chromatin domains and transcription-factor binding sites, providing critical insights into the connection between the noncoding genome and human health and disease phenotypes. However, most QTL studies to date were conducted in the European populations, leaving the noncoding genome of non-European individuals unexplored and exacerbating the healthcare disparity.To alleviate this critical knowledge gap, we performed the largest mQTL analysis to date in the Asian populations. DNAm was profiled in 2,039 subjects of Han Chinese ancestry from the Taiwan Biobank using the Illumina EPIC array. All subjects were also genotyped using the Taiwan Biobank array, with 8,033,242 genomic variants available after quality control and imputation. We tested the association between genetic variants and variations in 7,115,522 DNAm sites using principal components as covariates to control the population structure, PEER factors to control unknown variables. We removed batched effect and position effect by ComBat. We used sex, age, smoke experience, and cell proportion as covariates. Using a stringent significance threshold controlling multiple testing (p

PrgmNr 3317 - Fibromyalgia as a Nexus of Multiple Liability Distributions

View session detail

Author Block: **A. B. Faucon**[1], A. Moscati[2], C. Arnaiz-YÃ©pez[1], K. Sundquist[3], G. M. Belbin[2], J. H. Cho[2], R. Loos[4], K. S. Kendler[5], L. K. Davis[6]; [1]Vanderbilt, Nashville, TN, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]Lund Univ., Lund, Sweden, [4]The Icahn Sch. of Med. at Mount Sinai, New York, NY, [5]Virginia Commonwealth Univ, Richmond, VA, [6]Vanderbilt Univ Med Ctr., Nashville, TN
Disclosure Block: **A.B. Faucon:** None.
Introduction: Epidemiological estimates indicate fibromyalgia affects up to 8% of the population[1], is underdiagnosed[2], and frequently lasts a lifetime. The heritability of chronic pain conditions is estimated at 50%[3]. Small sample sizes have precluded finding significant genetic loci to date, despite investigations using methods including linkage[4] and candidate gene studies[5,6], genome-wide association methods[7], and exome sequencing approaches[8]. Thus, to more fully elucidate the genetic architecture of fibromyalgia, we examine sex differences and provide estimates of prevalence, comorbidities across the phenome, polygenic overlap between fibromyalgia and other traits, and perform a genome-wide association study (GWAS) of fibromyalgia from the largest sample to date.
Methods: Fibromyalgia cases were identified by the ICD10 code M79.7. Controls were identified by presence of any ICD10 code, together with the absence of ICD9 code 729.1 and ICD10 code M79.7. Ancestry classification was based on principal component clustering. We calculated polygenic risk scores (PRSs) for eight comorbid phenotypes with PRSice2[9] in BioVU (Vanderbilt biobank) and BioMe (Mount Sinai biobank). We fitted multivariable logistic regression models to test the association between fibromyalgia diagnosis and each component PRS while controlling for median age and genetic PCs 1-10. We perform GWAS using Saige v0.42.1[10]with PCs1-10, age, BMI, and sex, as covariates and meta-analyze using METAL.
Results: Swedish register data indicate enrichment among fibromyalgia cases of comorbidities including major depression, anxiety, back pain, inflammatory bowel disease, asthma, rheumatoid arthritis, osteoarthritis, and decreased subjective well-being. In our analyses, fibromyalgia case status was significantly associated with PRSs for back pain, inflammatory bowel disease, major depression, neuroticism, rheumatoid arthritis, and subjective well-being. The PRS for rheumatoid arthritis demonstrated the strongest positive association with fibromyalgia (OR per standard deviation of risk: 1.9-2.2) while subjective well-being yielded the strongest negative association (OR: 0.84-0.91). The first genome-wide significant locus is identified by two separate SNPs and will also be reported.
Discussion: In this work, we improve the fieldâ□□s understanding of fibromyalgia, a pain condition linked with anxiety, depression, and subjective well-being, among other commonly comorbid traits and we make advances towards understanding shared genetic architecture of these related traits.

PrgmNr 3318 - Genetic architecture of risky sexual behavior: Correlational structure and causal effects

View session detail

Author Block: **N. Berley**[1], B. M. Huibregtse[2], L. M. Evans[2], M. C. Stallings[2]; [1]Virginia Commonwealth Univ., Richmond, VA, [2]Univ. of Colorado Boulder, Boulder, CO
Disclosure Block: **N. Berley:** None.
An ambiguous measure of risky sexual behavior (RSB), number of lifetime sexual partners, has been hypothesized to reflect either of two competing domains. The first is that it is related to reproductive fitness specifically success in the sexual selection of mates in males and the second is that it is a risk-taking behavior akin to speeding in an automobile or using alcohol and drugs. Using structural equation modelling to jointly estimate the genetic architecture of selected risk and fitness phenotypes, demonstrates that number of lifetime sexual partners is more closely related, genetically, to a latent risk factor as opposed to a fitness factor. Follow up results, from univariate and multivariate Mendelian randomization to assess casual effects using Egger regression were inconclusive. A two factor model indicates that number of sexual partners is best explained as a risk-related trait.

PrgmNr 3319 - Genome-wide association study of anthropometric traits in a health-disparate Hispanic population

Below[5]; [1]Vanderbilt Univ., Nashville, TN, [2]Univ North Carolina at Chapel Hill, Chapel Hill, NC, [3]Univ. of Texas, Houston, TX, [4]Univ North Carolina, Chapel Hill, NC, [5]Vanderbilt Univ Med Ctr., Nashville, TN

Disclosure Block: **W. Zhu:** None.

Obesity is a common metabolic disorder associated with many chronic diseases, including type 2 diabetes, coronary heart disease, and certain types of cancer. The prevalence of obesity in the US adult population is ~42% and the prevalence is even higher, ~44.8%, among Mexican Americans. Low socioeconomic status is also often linked to obesity rates. Cameron County Hispanic Cohort (CCHC) is a population-based cohort established 17 years ago. It includes almost 5,000 individuals from low-income border communities, over 90% of whom are Mexican American. Hispanic/Latino populations are known to have higher rates of metabolic disease compared to non-Hispanic whites, and prior epidemiologic studies in CCHC have shown the obesity (51%) and diabetes (28%) rates are significantly higher than national estimates. This disproportionate burden of disease may make CCHC well-suited to study of obesity-related metabolic traits.

We performed a GWAS of waist-to-hip ratio in CCHC participants to identify for genetic factors associated with obesity. We removed pediatric measurements (age EX array and imputed to TOPMed phase 8 reference data following standard protocols. 2,946 individuals passed quality control and were included in our GWAS. Covariates including age, age squared, three principal components, and body mass index (BMI) were modeled using a generalized linear model to calculate residuals. Residuals were rank-based inverse normal transformed prior to analysis using EPACTS. Initial results identified five variants, chr8:6551122 and chr21:19511384 without BMI adjustment, and chr5:173508154, chr21:19511384, hr11:17563655 and chr21:20190723 without BMI adjustment. Additional GWAS on waist-to-height and height were also reported following the same analysis procedure.

PrgmNr 3320 - Genomic approaches to identify shared genetic architecture among comorbid phenomes of eye disease

View session detail

Author Block: **A. Scalici**[1,2], T. W. Miller-Fleming[1,2], D. Zhou[1,2], E. W. Knapik[1,2], N. J. Cox[1,2]; [1]Div. of Genetic Med., Vanderbilt Univ. Med. Ctr., Nashville, TN, [2]Vanderbilt Genetics Inst., Vanderbilt Univ. Med. Ctr., Nashville, TN

Disclosure Block: **A. Scalici:** None.

Genome-wide association studies have identified a significant number of SNPs associated with human disease. However, many of these associations provide little insight into the underlying biological mechanisms or pathways involved in disease pathogenesis. Examining genetic pleiotropy is one means by which we can identify shared disease mechanism. Previous studies suggest that there is potential shared genetic architecture among different eye diseases. To better understand the potential shared underlying mechanisms of eye disease, we used both a gene-based approach to assess shared genetic architecture and a phenome-based approach to identify comorbidities and expand the nascent pathways associated with eye diseases. To assess shared genetic architecture among eye diseases, we used transcriptome-wide association study (TWAS) to test if imputed genetically regulated expression (GReX) in genotyped individuals of European ancestry (N=70,493) within BioVU is associated with eye disease status (Zhou et al., 2020). We identified two genes (*GPX7* & *AC016590.3*) that had significant associations to eye disease status. To identify the comorbid phenomes of eye disease, we conducted a phenome-wide association study (PheWAS) within non-genotyped subjects with at least three visits to VUMC in five years (N=685,820). Using phenomes significantly associated with eye disease case status, we calculated a phenotypic risk score (PheRS) by calculating a weighted sum of phenotypic effects, and applied this score to an independent population - genotyped subjects in BioVU (Bastarache et al., 2018). This PheRS based only on non-eye disease comorbid phenome is predictive of eye disease status. The PheRS was significantly associated with the predicted expression of six genes (*BBS5*, *NEU2*, *C4B*, *PAK1*, *RPL41*, *AC091100.1*), previously characterized as being involved in eye diseases. Functional analysis of these genes using zebrafish as a model system has the potential to shed light upon some of the common pathways and mechanisms of eye disease.

PrgmNr 3321 - Individual Imputation of Genetically Regulated Gene Expression in the Million Veteran Program

View session detail

Author Block: **S. Venkatesh**, W. Zhang, G. E. Hoffman, G. Voloudakis, P. Roussos; Icahn Sch. of Med. at Mount Sinai, New York, NY
Disclosure Block: **S. Venkatesh:** None.
Most neuropsychiatric disorders are moderately heritable but characterized by many genetic risk variants with weak effects. As such, it is difficult to point to direct causes or elucidate mechanisms of action. Despite the ease in gathering genetic data from humans, genetic data does not easily explain mechanistic effects. Gene expression on the other hand, can more easily explain mechanistic effects, but is harder to gather, especially in brain regions which are critical to the understanding of neuropsychiatric disease. To address this, we developed methods to impute genetically regulated gene expression (GREx) from genotypes and imputed GREx in over four hundred thirty thousand European individuals in the Million Veteran Program (MVP) for a wide variety of tissues and cell types. We use EpiXcan (based on PrediXcan) to develop machine learning models from training genotype, expression, and epigenetic data. We use custom scripts to impute individual GREx and perform a variety of downstream association analyses, including Principal Component Analysis (PCA), GREx Phenome Wide Association Studies (PheWAS), and Transcriptome Wide Association Studies (TWAS). Results show an overlap in Schizophrenia genes identified by individual level TWAS and those identified by summary level TWAS informed by GWAS. Inverse-variance meta-analyzed single gene imputation efforts across ancestries confirm clinical results obtained from COVID-19 positive individuals in both *IL10RB* and *IFNAR2*. GREx PheWAS for these particular genes using a novel negative binomial distribution for phecodes confirm COVID-19 related phenotypes. GREx presents a unique solution to integrate effects across the genome and increase sample size in gene expression analyses. We are pursuing the creation of additional EpiXcan models, improved statistical methods for downstream association analyses, and replication efforts across biobanks. We plan to perform these analyses in all ancestries, available EpiXcan and PrediXcan models, and phenotypes.

PrgmNr 3322 - Investigation of a complex phenotype involving craniosynostosis and cataracts leads to identification of a novel mutation related to Galactosemia type II

View session detail

Author Block: **R. H. Finnell**[1], B. Oliveira[2], T. Silva[2], y. lei[1], C. Souza[2], J. Filho[3], I. Schwartz[2]; [1]Baylor Coll. Med., Houston, TX, [2]Med. Genetics Service, Hosp. de ClÃnicas de Porto Alegre, Porto Alegre, Brazil, [3]Projeto Genomas Raros, Albert Einstein Hosp., SÃ£o Paulo, Spain
Disclosure Block: **R.H. Finnell:** None.
Introduction,Galactosemia is an inborn error of metabolism resulting in an accumulation of galactose metabolites, which can lead to cataracts and hepatic complications. Treatment consists of maintaining a lactose-restricted diet preferably initiated early in life. During a genetic investigation of a patient with a complex phenotype involving cataracts and craniosynostosis, a novel variant in the *GALK1* gene was identified. **Case report**, A 2yo male patient was referred for genetic evaluation due to bilateral dense cataracts. He is the fourth child of a non-consanguineous couple; his 18yo sister has a history of congenital cataract. Clinical examination revealed a metopic crest and trigonocephaly, with tomographic confirmation of craniosynostosis. Karyotype was normal and oligosaccharide chromatography suggested galactosemia but was excluded upon finding normal Galactose-1-phosphate-uridyltransferase activity. Initial dried-blood-spot galactose levels were 10 times above normal upper limits, which normalized after starting dietary treatment. His sibling with congenital cataracts had no clinical or biochemical evidence of galactosemia. He underwent lensectomy and surgical correction of craniosynostosis. WGS led to identification of a large novel homozygous truncating duplication in *GALK1* gene affecting splice site c.166-16_227dup (NM_000154.2). **Discussion**:There are previous reports of the association between craniosynostosis and classic galactosemia in rare cases of homozygous contiguous deletion affecting *GALT* and *IL11RA* genes (9p13.3); however, there exists no data on craniosynostosis with other forms of galactosemia. The identified novel likely pathogenic variant explains both galactosemia and cataract phenotypes. No pathogenic variants related to craniosynostosis phenotype were identified. **Conclusion**, This case report describes a novel variant related to galactosemia type II. Future investigations involve analyses at the transcriptional level.

PrgmNr 3323 - Modeling the longitudinal changes of ancestry diversity in the MVP cohort: systematic comparison of methods

Background/Aims: The birth years of MVP participants span nearly 100 years, but it remains unclear (i) if longitudinal changes in ancestry are present and (ii) how these changes can be accounted for in the MVP cohort to conduct reliable gene-phenotype association analyses.

Methods: We divided MVP participants into five birth cohorts (BCs) of approximately 125,000 individuals each and compared ancestry classifications using HARE (harmonized ancestry and self-reported race/ethnicity) and a random-forest genetic principal component clustering using the 1KGP and the HGDP reference panels. We used these ancestry classifications in genome-wide association studies (GWAS) of height, a highly polygenic trait with strong potential for population-stratification bias. GWAS were conducted in each BC stratified by ancestry, including age, sex, and ten within-ancestry principal components. Linkage Disequilibrium Score Regression (LDSC) was used to calculate the intercepts and attenuation ratios to assess residual population stratification in the GWAS statistics. These metrics were then compared with two-sided Z-tests.

Results: Relative to the oldest BC, more contemporary HARE Europeans (EUR; ~0.2% reduction in EUR), Africans (AFR; ~2% reduction in EUR), and Hispanics (HIS; ~3% reduction in EUR) had a significant reduction in EUR ancestry proportion. Conversely, HARE East Asians (EAS) showed an increase in EUR ancestry proportions over time. The most contemporary EAS BC had three times greater EUR ancestry than the oldest BC (pConclusions: We provide the first characterization of MVP cohort ancestry diversity over time, highlight potential biases in gene discovery, and show how the methods available can perform differently in accounting adequately for human genetic variation.

Disclosure Block: **M.N. McDonald:** None.

Osteoarthritis (OA) is a progressive, degenerative joint disease with a poorly understood etiology primarily limited in clinical care to symptom management related to pain and inflammation. The prevalence of OA is high at 40% and associated with great disability. To date there have been no large multi ancestry genetic studies of OA. We leveraged the unique resources of 473,388 participants in the combined Million Veteran Program (MVP) and UK Biobank to address this gap including participants of European, African, Asian and Hispanic descent. In doing so, we discovered OA associated genetic variants in or near 71 genes and replicated findings from 52 previously identified OA variants or genes. We also discovered evidence some OA associated regions may be robust to population ancestry. Our novel findings provide insight to how strategies for managing metabolic syndrome may be used to help prevent and manage OA.

PrgmNr 3325 - Novel phenotyping approaches: Empirical Bayes methods improve heritability of dietary phenotypes from repeat diet questionnaire data

View session detail

Author Block: **J. B. Cole**[1], J. C. Florez[2], J. N. Hirschhorn[3]; [1]The Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Massachusetts Gen Hosp, Boston, MA, [3]Boston Children's Hosp., Boston, MA
Disclosure Block: **J.B. Cole:** None.
Unhealthful dietary intake is a leading risk factor for metabolic disease and mortality, yet the precise aspects of diet which influence health are largely unknown. Recent advent of large biobanks has enabled genomic discovery for modestly heritable traits, such as dietary intake. However, diet represents a complex set of multifactorial, dynamic, and highly correlated variables, and therefore studies on the genetics of diet would greatly benefit from novel phenotyping approaches. Previously we identified loci unique to either univariate or multivariate diet traits derived from the same food frequency data in UK Biobank (UKB).

Here, we aim to extract meaningful biological traits from 24-hour diet recalls, consisting of hundreds of questions about the specific foods/drinks and quantities consumed in the prior 24 hours. While an individualâ□□s diet on any given day is highly variable, many individuals in UKB took this questionnaire multiple times, providing an opportunity to apply methods to incorporate certainty from repeated measures. In a population of 176K individuals of European ancestry in UKB, for which 47K individuals took the questionnaire >2 times and 2K individuals took it all 5 times, we applied empirical Bayes methods to weight an individualâ□□s food values by the number of times they took the questionnaire. Specifically, we applied this to how often an individual ate a specific food as a proportion of the number of questionnaires completed and to how much an individual ate using weighted averages. We used LD score regression heritability analysis to benchmark Empirical Bayes to their non-Bayes counterparts: an ever/never eaten phenotype and a simple average for continuous variables, respectively.

The heritability estimates for 139/158 (89%) Empirical Bayes food proportions were larger than their ever/never counter-part phenotypes, with the largest difference in fruit intake (heritability from 2 to 5%) and the heritability estimates for 206/242 (85%) Empirical Bayes weighted averages were larger than simple averages, particularly for less commonly eaten foods where one data point is not an accurate reflection of eating habits. Interestingly, when we weight averages for derived nutrients, we find no evidence for improvement. This is in line with epidemiological work demonstrating there is larger day-to-day variation in food consumption vs. nutrients.

We demonstrate that novel phenotyping approaches, and in particular Empirical Bayes methods for repeated data, can improve genomic discovery. These methods can be extended to many other complex traits with repeated measures, with particular utility for traits with high intra-individual variation.

PrgmNr 3327 - Programming biobank-scale relatedness analysis improvements

View session detail

Author Block: **G. Evans**[1], H-H. Chen[2], C. D. Huff[3], R. J. Bohlender[4], J. E. Below[2]; [1]Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Univ Med Ctr., Nashville, TN, [3]U.T. MD Anderson Cancer Ctr, Houston, TX, [4]Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

The program PRIMUS (Pedigree Reconstruction & Identification of the Maximum Unrelated Set) was developed to facilitate rapid pedigree reconstruction using genome-wide estimates of identity-by-descent (IBD). However, PRIMUS is sensitive to IBD estimation bias and fails to assess relationship complexity prior to attempting reconstruction, both of which can cause execution errors. We are in the process of completing a total overhaul of the original PRIMUS codebase to upgrade it both computationally and analytically as well as integrate it with relatedness estimation software ERSA (Estimation of Recent Shared Ancestry) and PADRE (Pedigree-Aware Distant Relatedness Estimation) to form COMPADRE (Combined PADRE) to streamline the relationship detection and pedigree construction pipeline.

We have accomplished several upgrades thus far in the COMPADRE development undertaking. First, we implemented a quality control framework that ingests family network data (non-directional relatedness graphs) at scale to evaluate the likelihood of successful downstream pedigree reconstruction given network size and sparsity. This framework improved the proportion of completed pedigree reconstructions by ~25% in a large data setting (n~100,000 from Vanderbilt University Medical Centerâ□□s biobank, BioVU). We also successfully introduced a series of multithreading-based computational improvements to the overall PRIMUS infrastructure, which improved overall runtime by ~35% and lowered computational footprint by ~20% particularly during execution of pedigree reconstruction. Finally, we are currently improving PRIMUSâ□□s relationship likelihood assessment by harnessing ERSA output data to introduce a composite probability vector that increases pedigree confidence and reduces runtime errors by clarifying ambiguous second- and third-degree relationship estimation. This, and other analytically novel components of the PRIMUS rewrite are being tested using an augmented data simulation pipeline adapted from past collaborators that is being directly incorporated for enhanced user experience.

Our findings thus far demonstrate that targeted computational and analytical updates can successfully reduce bias and improve pedigree reconstruction in PRIMUS. Future work will continue to introduce and refine novel methods to proactively assess COMPADREâ□□s ability to dynamically analyze biobank-scale data. COMPADRE development is also happening alongside that of a shared segments repository, specifically engineered to maximize relatedness analysis through intimate connections to both large DNA biobanks and the tools needed (such as PRIMUS) for analysis.

PrgmNr 3328 - Reanalysis of exome data via Diagnosticator identifies significant variant reclassification with updated ClinGen SVI-WG recommendations

View session detail

Author Block: **E. Cocchi**[1], M. Elliott[2], N. Vena[3], A. G. Gharavi[4]; [1]Columbia Univ., New York, NY, [2]Columbia Univ. Irving Med. Ctr., Calgary, AB, Canada, [3]Hammer Hlth.Sci. Building, New York, NY, [4]Columbia Univ, New York, NY

Disclosure Block: **E. Cocchi:** Grant/Contracted Research Support (External); American Society of Nephrology.

The current standard in sequence variant interpretation is the 2015 ACMG guidelines, which have improved reproducibility and provided a common nomenclature. To further improve consistency of reported results, ClinGenâ□□s Sequence Variant Interpretation Working Group (SVI WG) has developed recommendations that clarify specific ACMG criteria, however the impact of the revised criteria on variant reclassification is unknown.

We previously evaluated 2144 Columbia patients with kidney disease who underwent exome sequencing (ES) using the ACMG 2015 guideline. We identified 193 pathogenic or likely-pathogenic kidney-related variants, with a diagnostic yield of 9%. We used the *Diagnosticator* clinical annotation tool to reanalyze these cases incorporating both newly published genetic information and the SVI WG criteria recommendations. *Diagnosticator* is a flexible annotation tool which can rapidly implements the SVI WG recommendations and is faster and more accurate than manual curation.

Reanalysis of the entire cohort, incorporating newly available genetic data and the recent SVI WG recommendations, led to a change in the ACMG classification in 79 (40.9%) of the variants. 53 (27.4%) variants downgraded their overall classification: 18 (9.3%) variants changed from P to LP, 33 (17.0%) variants changed from LP to VUS, and 2 (2.5%) variants changed from P to VUS. 26 (13.5%) variants were upgraded from LP to P. These changes are driven by criteria with SVI WG recommendations (PVS1, PM2, PM3, PP5) and with new information available (PS1, PS4, PM3, PM5, PP1, PP3).

We demonstrate the utility of *Diagnosticator* as a tool for rapid reanalysis of ES data, and show that incorporating the ClinGen SVI WG recommendations and newly available genetic data lead to reclassification for a significant number of variants. These data motivate reanalysis of ES data at standardized intervals to assess impact on clinical care.

PrgmNr 3329 - Study of over one million people finds that novel and previously reported familial genetic effects impact stuttering risk at a population-level

View session detail

Author Block: **H. Polikowsky**[1], D. M. Shaw[2], L. E. Petty[2], H-H. Chen[1], Y. Yu[3], 23andMe Research Team, C. D. Huff[3], N. J. Cox[2], S. J. Kraft[4], J. E. Below[2]; [1]Vanderbilt Genetics Inst., Vanderbilt Univ Med Ctr., Nashville, TN, [2]Vanderbilt Univ Med Ctr., Nashville, TN, [3]U.T. MD Anderson Cancer Ctr., Houston, TX, [4]Behavioral Speech & Genetics Lab, Wayne State Univ., Detroit, MI
Disclosure Block: **H. Polikowsky:** None.
Despite an ~1% prevalence of persistent stuttering in the general adult population, developmental stuttering, characterized by prolongation of sounds and interruptions in speech, remains a largely idiopathic disfluency disorder. Its complex mode of inheritance combined with thus-far underpowered genetic studies contribute to the challenge of identifying and reproducing genes implicated in developmental stuttering susceptibility. Here, we report the results of a genome-wide association study of stuttering for >1 million individuals. We conducted a GWAS in individuals genotyped by 23andMe, Inc. who consented to participation. Cases were defined as those who self-reported ever having a stammer or a stutter (N=99,776), with all other individuals considered controls, comprising a total of 1,023,243 multi-ethnic participants. We performed ancestry and sex-specific logistic regression models assuming an additive model for allelic effects and including age, five principal components, and genotype platforms as covariates: 18 genome-wide significant hits were identified. The most significant risk variant (p = 5.8 x 10-16) was identified in the European-female (rs13107325, RAF= 8.16%, OR = 1.117) GWAS for a missense variant in *SLC39A8*, a gene encoding solute-carrier proteins critical for cellular transport in mitochondria. The European-male GWAS also found a strong signal at this locus. Interestingly, in the European-male GWAS we identified a near-significant (p = 9.8 x 10-7) risk variant (rs111790048, RAF= 0.005%, OR = 10.854) in the intronic region of *GNPTG*, a gene previously implicated in a linkage study of developmental stuttering by Kang et. al. (NEJM, 2010). To evaluate our hypothesize that developmental stuttering represents a complex polygenic trait akin to neurogenic traits, we developed a preliminary polygenic-risk model using variants from the European male-specific GWAS. We tested this PRS model within an independent European-male clinically-ascertained developmental stuttering GWAS and achieved moderate model performance (AUC= 0.6134), suggesting that our self-report stuttering phenotype is capturing genetic effects for clinically-confirmed cases. Independent replication analysis in this clinically-ascertained GWAS is ongoing. These exciting preliminary results represent the first report of genetic contributions to developmental stuttering at a population-level. Our results highlight the polygenicity of the trait and suggest that variation at both novel and previously reported loci identified via family-based analyses impact population-level stuttering risk.

PrgmNr 3330 - The contribution of common versus low-frequency variation to hearing loss heritability

INTRODUCTION: Age-related hearing loss is prevalent and heritable with an established common variant component to its genetic architecture. Genome-wide association studies (GWAS) have identified over 40 associated common variant loci and shown significant SNP heritability with estimates ranging from ~0.08 to ~0.19. We previously conducted a combined GWAS+ExWAS of hearing loss in 115,675 and 344,085 European-ancestry cases and controls across four cohorts (Geisinger DiscovEHR, UK Biobank, Mount Sinai *BioMe* Biobank, and the MalmÃ¶ Diet and Cancer Study), resulting in 53 common and 41 rare variant associations. Our analysis not only confirmed this common variant component but also implicated rare variation in the etiology of age-related hearing loss. To quantify the heritability due to variants of lower frequencies and to characterize the relative contributions from rare and common variation, we conducted heritability analyses using an approach (Gazal et. al. 2018) that extends stratified LD score regression (S-LDSC) to low-frequency variation. METHODS: Through multivariate regression of association statistics on LD scores from our hearing loss meta-analysis, we estimated heritability for 14 functional categories. To capture both common and rare variation in our LD scores, we generated scores using a reference panel created by merging imputed and exome data for 6,189 European-ancestry samples from the UK Biobank. We calculated LD for seven functional categories (coding-synonymous, coding-nonsynonymous, 5-prime-UTR, 3-prime-UTR, splice site, intronic, and intergenic) each split into a common (MAF>=0.05) and low-frequency (MAF0.001, and variants identified by machine learning as false-positives on the basis of sequence QC metrics were excluded. Association statistics were filtered at MAF>0.001 and INFO>0.9. RESULTS: Total liability-scale heritability (h^2_{total}) was estimated to be 0.076, with a common variant heritability (h^2_{CV}) of 0.071 and a low-frequency variant heritability (h^2_{LFV}) of 0.005. Common intronic variants were significantly (Bonferroni P2, and low-frequency intronic and intergenic variants were depleted for h^2. Categories with the largest enrichments were common coding-synonymous, 5-prime-UTR, and coding-nonsynonymous (enrichments of 52.5x, 39.6x, and 18.4x, respectively), and low-frequency 5-prime-UTR and coding-nonsynonymous (enrichments of 16.9x and 11.7x). Our results show that despite having a small absolute contribution, low-frequency variation is significantly enriched in hearing loss heritability.

PrgmNr 3331 - Transcriptome-wide association study and eQTL colocalization identify potentially causal genes responsible for bone mineral density GWAS associations

Genome-wide association studies (GWASs) for bone mineral density (BMD) have identified over 1,100 associations to date. However, identifying causal genes implicated by such studies has been challenging. Recent advances in the development of transcriptome reference datasets and computational approaches such as transcriptome-wide association studies (TWASs) and expression quantitative trait loci (eQTL) colocalization have proven to be informative in identifying putatively causal genes underlying GWAS associations. Here, we used TWAS/eQTL colocalization in conjunction with transcriptomic data from the Genotype-Tissue Expression (GTEx) project to identify potentially causal genes for the largest BMD GWAS performed to date. Using this approach, we identified 512 genes as significant (Bonferroni PPP6R3, the gene with the strongest support from our analysis which was not previously implicated in the regulation of BMD, for further investigation. We observed that *Ppp6r3* deletion in mice decreased BMD. In this work, we provide an updated resource of putatively causal BMD genes and demonstrate that *PPP6R3* is a putatively causal BMD GWAS gene. These data increase our understanding of the genetics of BMD and provide further evidence for the utility of combined TWAS/colocalization approaches in untangling the genetics of complex traits.

PrgmNr 3332 - Whole-exome sequencing of a family with specific language impairment suggests *BUD13* as a novel SLI candidate gene

View session detail

Author Block: **E. M. Andres**, K. K. Earnest, C. Zhong, M. L. Rice, M. H. Raza; Univ. of Kansas, Lawrence, KS
Disclosure Block: **E.M. Andres:** None.
Specific language impairment (SLI) is characterized by a delay in the mastery of language and family studies have shown aggregation of cases in medium, large and extended families. Genetic investigation of SLI is complicated by behavioral heterogeneity of the disorder. Several candidate genes have been suggested but the biological mechanisms underlying the transmission and expression of SLI are still not well understood. The current study utilized a family-based approach, reducing behavioral trait and genotypic variance, with the aim of identifying co-segregating rare exonic variants. Whole-exome sequencing was performed in six individuals of a family with SLI (*N*=11). Three co-segregating rare non-synonymous variants (MAF â¤ 0.005) were identified in three genes: *BUD13*, *APLP2* and *NDRG2*, suggesting oligogenic inheritance of SLI in this family. Then, we Sanger sequenced all coding exons (including flanking intronic regions) of the identified genes in additional unrelated individuals with SLI (*N*=175). We observed variants in both BUD13 and APLP2 (in the 3â□□UTRs) in a second family, indicating further evidence of an oligogenic basis of SLI. In total, 13 additional rare non-synonymous or 3â□□UTR point mutations were observed across the three identified genes in 18 unrelated individuals with SLI. Nine of the variants were observed in *BUD13*, a rate that reached genome-wide significance according to comparison with the rate of similar variants in the global population within the 1000 Genomes database. Of the rare variants identified in *BUD13*, three were observed in more than one unrelated individual with SLI. Bud13 is a component of the retention and splicing (RES) complex with an important role in controlling gene expression during cellular differentiation. Moreover, a previous animal model has shown Bud13 has a role in neural phenotypes. The evidence together suggests *BUD13* is a novel candidate for SLI.

PrgmNr 3333 - Year of birth and polygenic scores in the Electronic Health Records

View session detail

Author Block: **M. Niarchou**[1], D. Zhou[1], R. Kember[2], R. Karlsson LinnÃ©r[3], G. Voloudakis[4], L. Yengo[5,6], G. Chen[7], C. Chabris[8], L. K. Davis[9]; [1]Vanderbilt Univ., Nashville, TN, [2]Univ. of Pennsylvania, Philadelphia, PA, [3]Vrije Univeristeit Amsterdam, Amsterdam, Netherlands, [4]Icahn Sch. of Med., New York, NY, [5]Brisbane, Australia, [6]Inst. for Molecular BioSci., University of Queensland, Australia, [7]Univ. of Wisconsin-Madison, Wisconsin, WI, [8]Geisinger Hlth.System, Lewisburg, PA, [9]Vanderbilt Univ Med Ctr., Nashville, TN

Disclosure Block: **M. Niarchou:** None.

Polygenic scores (PGS) are already been used in the clinical context and they may eventually be implemented in routine clinical practice as clinical biomarkers. It is important to have a better understanding of how factors not directly related to disease biology may affect the value of the PGS before applying them in clinical settings. For example, we and others have observed a correlation between Year of Birth (YoB) and PGS for different health conditions and quantitative traits. We further investigated this phenomenon in the Vanderbilt Biobank (BioVU) and replicated the finding in biobanks in the PsycheMERGE network. We first generated PGS trained on summary statistics from the latest genome-wide association studies of a variety of health conditions (i.e., ADHD, coronary artery disease (CAD), major depressive disorder (MDD), insomnia, Alzheimerâ□□s disease (AD)), quantitative traits (BMI, height, educational attainment), and blood traits (i.e., white blood cell count (WBC), red blood cell count (RBC), red blood cell count distribution width (RDW)), and applied them to genome-wide data from 66,904 unrelated individuals of European Ancestry. We then fitted separate linear regression models to test whether each PGS (predictor variable) was associated with YoB (outcome variable) after adjusting for sex and 10 principal components of ancestry. All PGS, except for scores trained on blood cell traits, were significant predictors of YoB. Next, we performed ten different sets of analyses to test four possible hypotheses for the observed correlation. We hypothesized that the correlations may be induced by 1) the effects of age in the discovery GWAS; 2) differences in population structure by birth cohort; 3) increase in relatedness across birth cohorts; or 4) changing ascertainment bias within the medical system over time. There was no single factor that stood out as accounting for the trends, and the observed relationship between YoB and PGS was robust to most adjustments. Overall, our findings indicate that the correlation between birth year and PGS is likely due to a combination of factors and the extent to which they are implicated in the associations vary depending on the trait.

PrgmNr 3334 - A global transcriptomic approach reveals sex-specific differences in a middle-aged frailty cohort

View session detail

Author Block: **N. L. Pacheco**, N. Noren Hooten, Y. Zhang, C. S. Prince, N. A. Mode, N. Ezike, K. G. Becker, A. B. Zonderman, M. K. Evans; Natl. Inst. on Aging, NIH, Baltimore, MD
Disclosure Block: **N.L. Pacheco:** None.
Frailty is a clinical syndrome described as reduced physiological reserve and increased stress or vulnerability. Usually studied in older groups, recent work shows frailty occurs in middle-aged individuals and is associated with increased mortality. Identifying biologic pathways underlying frailty development in middle-aged adults is crucial to detect and prevent frailty as well as reduce premature mortality. Previous examination of global gene expression changes in a middle-aged cohort of African Americans and whites from the Healthy Aging in Neighborhoods of Diversity across the Life Span (HANDLS) study demonstrated that activation of inflammatory genes and pathways was significantly altered by frailty status and race. As there are well-established sex differences in frailty burden and mortality, it is important to decipher transcriptome-wide differences in frailty-associated genes by sex. In this study, we sought to identify novel genes and pathways associated with sex and frailty in a diverse middle-aged cohort using RNA-Sequencing. Differential gene expression and pathway analyses were performed for 4 comparison groups: 1) frail females (FRAF, n = 4) vs non-frail females (NORF, n = 4); 2) frail males (FRAM, n = 4) vs non-frail males (NORM, n = 4); 3) FRAM vs FRAF; and 4) NORM vs NORF as a control. We evaluated exclusive significant genes and pathways, as well as overlaps, between the 4 comparison groups. Over 80% of the significant genes exclusive to FRAF vs NORF, FRAM vs NORM, and FRAM vs FRAF, respectively, were novel and associated with inflammatory and metabolic pathways. Pathways exclusive to FRAF vs NORF were associated with inhibition of inflammatory pathways. FRAM vs NORM exclusive pathways were associated with decreased musculoskeletal protein turnover. Pathways exclusive to FRAM vs FRAF were associated with activated metabolite degradation. Notably, genes with key inflammasome and apoptotic roles in the Coronavirus Pathogenesis Pathway were activated in FRAM vs FRAF. We also confirmed frailty-associated changes in gene expression from other previous studies for *OTUD1* (FRAF vs NORF), *LRG1* (FRAM vs NORM), and *TNF* (FRAM vs FRAF), as well as pathways like IL-1 signaling (FRAF vs NORF), B cell development (FRAM vs NORM), and Salvage Pathways of Pyrimidine Deoxyribonucleotides (FRAM vs FRAF). Our results indicate sex-specific transcriptional changes occur in middle-aged frailty, advancing knowledge on frailty progression and identification of potential therapeutic targets to prevent frailty.

PrgmNr 3335 - A single cell chromatin accessible and transcriptome atlas of the human heart facilitates identification of risk variants and genes of Atrial Fibrillation

View session detail

Author Block: **S. Pott**[1], A. Selewa[2,1], M. Wasney[1], L. Smith[1], H. Eckart[1], I. Moskowitz[1], A. Basu[1], X. He[3]; [1]Univ. of Chicago, Chicago, IL, [2]Chicago, IL, [3]Univ Chicago, Chicago, IL
Disclosure Block: **S. Pott:** None.
Genome-wide association studies (GWAS) have identified thousands of loci for hundreds of diseases. However, most trait-associated variants are located in noncoding regions with no clear functions, making it difficult to identify causal variants, their targeted genes, and the specific cell type(s) affected. Single-cell genomics promises to close these gaps, by de-convoluting complex cellular mixtures into constituent cell types, and annotating functional elements in each cell type. In this work, we combined single cell RNA-seq and ATAC-seq to profile the human heart. We detected 8 major cell types across both modalities and identified 349,000 open chromatin regions (OCRs), half of which are cell-type-specific. Leveraging this dataset, we identified lineage-specific transcription factors (TFs), and assigned putative target genes to 39% of distal OCRs.
We used this dataset to study the genetics of heart-related traits. Risk variants of Atrial Fibrillation (AF) are >10-fold enriched in cardiomyocytes (CMs) but not other cell types. Taking advantage of this enrichment pattern, we used a Bayesian statistical framework to fine-map causal variants of AF, favoring variants in CM-OCRs. This leads to 54 variants at posterior inclusion probability (PIP) > 0.5 - suggesting >50% probability of being causal variants, nearly doubling the number of variants under fine-mapping without functional information. This list of SNPs show a high proportion of overlapping heart H3K27ac regions, and TF targets from ChIP-seq. Furthermore, we developed a novel computational procedure that aggregates all putative causal variants and combines multiple sources of information linking SNPs to genes, to identify putative causal genes. This procedure identified 53 genes at 'gene-level PIP' > 0.5. A large fraction of these genes are TFs, ion channels, and cardiac signaling proteins with known roles in heart development and/or AF. Our results support a model where a gene regulatory network centered on TFs, including TBX5, GATA4, NKX2-5, and PITX2, underlies the AF genetic risk. Together, our study provides a comprehensive map of AF risk variants and genes, and demonstrates the power of combining single-cell genomics and advanced fine-mapping to reveal the genetic basis of complex traits.

PrgmNr 3336 - Blood-based differential DNA methylation and gene expression at the *TREM* locus in mild traumatic brain injury and Alzheimerâ□□s disease

View session detail

Author Block: **L. M. Bekris**[1], G. E. Weber[1], E. D. Tuason[1], M. Khrestian[1], S. Formica[1], Y. Shao[1], S. Rao[2], J. Pillai[2], J. B. Leverenz[2]; [1]Cleveland Clinic Lerner Res. Inst., Cleveland, OH, [2]Cleveland Clinic Lou Ruvo Ctr. for Brain Hlth., Cleveland, OH
Disclosure Block: **L.M. Bekris:** None.
Alzheimerâ□□s disease is a devastating neurodegenerative disorder and the most prevalent form of dementia worldwide. Alzheimerâ□□s disease (AD) has long been characterized by the presence of amyloid beta (AÎ²) plaques and tau neurofibrillary tangles in the brain, which makes prediction difficult and diagnosis definitive only at postmortem analysis. Triggering receptor expressed on myeloid cells 2 (TREM2) regulates inflammation in the periphery and brain. TREM2 has been implicated in AD due to its affinity for AD-related apolipoprotein E and binding of AÎ² to increase its uptake; mutations in *TREM2* have been shown to increase risk for AD and other neurodegenerative disorders. *TREM2* is part of a complex DNA locus that also includes other TREM and TREM-like (TREML) proteins. Inflammation can affect the epigenetic profile of circulating cells such as DNA methylation changes, resulting in altered expression of proteins. RNA sequencing of TREM and TREML transcripts provides insight into the molecular effects of DNA methylation. One such inducer of systemic acute and chronic inflammation that has been linked to AD is traumatic brain injury. To our knowledge this is the first study to compare methylation levels of the entire *TREML1-TREM1* locus in peripheral blood leukocytes in people with a history of TBI compared to AD, and correlate those findings to levels of RNA transcripts. It is unknown whether other regulatory region CpG sites in the *TREM* locus are differentially methylated in AD, and how this relates to levels of sTREM2 and AD biomarkers. Our previous findings indicate that plasma sTREM2 and cytokines are elevated in the mild cognitive impairment stage of AD, compared to later stage AD, suggesting an initial alteration of the immune system that is dampened in the later stages of AD. Therefore, we set out to determine whether *TREM* locus DNA methylation underlies this alteration in sTREM2 level. We hypothesized that the *TREM* locus would be differentially methylated in our cohort of people with TBI and AD compared to age- matched, cognitively normal controls, and correlate with known AD biomarkers. We found that genomic regions across the *TREM* locus exhibited differential methylation where in general promoters are hypomethylated while non-promoter regions are hypermethylated. Our preliminary findings also show *TREM*-locus methylation and transcriptome profiles differ between active and retired professional fighters and older adults with AD compared to age-matched cognitively normal controls. We anticipate that future studies will contribute to a better understanding of how *TREM2* is regulated during disease progression and whether it is a feasible therapeutic target.

PrgmNr 3337 - Comparing gene expression imputation resources in a diverse Latin American Parkinsonâ□□s disease cohort

View session detail

Author Block: **J. French-Kwawu**[1], V. Borda[2], D. Loesch[3], T. A. Thornton[4], I. Mata[5], T. D. O'Connor[1], on behalf of LARGE-PD; [1]Inst. of Genome Sci., Univ. of Maryland Baltimore, Baltimore, MD, [2]Univ. of Maryland Sch. of Med., Petropolis, Brazil, [3]Univ. of Maryland Baltimore, Baltimore, MD, [4]Univ of Washington, Seattle, WA, [5]Lerner Res. Inst., Genomic Med., Cleveland Clinic Fndn.,, Cleveland, OH
Disclosure Block: **J. French-Kwawu:** None.
Background: Genome wide association studies (GWAS) have proven to be a useful tool to identify variants associated with disease but interpreting results can be challenging. Imputing gene expression for GWAS results can identify genes involved in disease and highlight pathways involved in disease progression. However, many prediction models for gene expression are based on individuals of European ancestry. We compare imputed gene expression in the Latin American Research Consortium on the Genetics of Parkinsonâ□□s Disease (LARGE-PD) using prediction models from two cohorts - one of Latin American individuals and one of predominantly European ancestry individuals with a diversity of tissues (GTEx). Methods: We imputed gene expression for 1504 individuals from LARGE-PD using PrediXcan with four elastic net prediction models: three tissues from GTEx (whole blood, basal ganglia, and substantia nigra) and whole blood from Latin American individuals within the Multi-Ethnic Study of Atherosclerosis (MESA) cohort. We estimated the correlations of gene-level expression imputation for each pair of the four models. Results: The correlation of gene expression levels in GTEx basal ganglia and substantia nigra is 0.678 (pFunding: R01 NS112499 and T32 AG00262

PrgmNr 3338 - Cross-omics analysis of DNA methylation and gene expression in post-mortem 41 brain tissues of opioid use disorder patients and controls

View session detail

Author Block: **A. Liu**[1], Y. Dai[2], E. Mendez[3], R. Hu[4], G. Fries[5,3], K. Najera[3], S. Jiang[6], T. Meyer[3], L. Stertz[3], P. Jia[4], C. Walss-Bass[7], Z. Zhao[2,3]; [1]Dept. of Epidemiology, Human Genetics and Environmental Sci., Sch. of Publ. Hlth., The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [2]The Univ. of Texas Hlth.Sci. Disclosure Block: **A. Liu:** None.

Background: Opioid use disorder (OUD) affects millions of people, causing nearly fifty thousand deaths annually in the United States. While opioid exposure and OUD are known to cause widespread transcriptomic and epigenetic changes, few studies have been conducted in human brain samples. Moreover, understanding how OUD affects the brain at multi-omics scale could help to decipher disease pathogenesis and shed light on OUD treatment. **Methods:** To fill in the gap, we generated genome-wide transcriptomic and DNA methylation profiles from post-mortem brain samples of 22 OUD subjects and 19 non-psychiatric controls. After performing quality control and normalization, we applied weighted gene co-expression network analysis (WGCNA) to identify network modules and genetic markers consistently associated with OUD at transcriptomic and methylomic levels. We further employed cross-omics analyses at the network module and gene levels to uncover OUD-specific regulatory networks. We performed hypergeometric tests at the network module level to assess overrepresented genes in OUD-associated co-methylation and co-expression modules. Functional enrichment analyses were performed on identified genes for biological interpretation. At the gene level, we examined global correlations between DNA methylation and gene expression changes. IngenuityÂ® Pathway Analysis (IPA) was used to identify canonical pathways and gene regulatory relationships underlying OUD pathogenesis for the genes with high methylation and gene expression variations. **Results:** In WGCNA, we found six OUD-associated co-expression gene modules and six co-methylation modules (p_{FDR} FDR = 1.16Ã□10^{-8}), gliogenesis (GO:0042063, p_{FDR} = 1.86Ã□10^{-8}), and astrocyte differentiation (GO:0048708, p_{FDR} = 2.26Ã□10^{-8}). At the gene level cross-omics analysis, we found a large proportion of the genes followed standard DNA methylation-gene expression regulatory patterns. Among the few exceptions, we identified their upstream transcription regulators that might bypass the regulations. **Conclusion:** Our integrative analysis of multi-omics data in OUD post-mortem brain samples suggested complex gene regulatory mechanisms involved in gene expression, transcription regulators, and epigenetic modification. Taken together, the current findings suggested that regulation of astrocyte and glial cells involved molecular mechanisms might constitute promising targets for OUD treatment.

PrgmNr 3339 - Identifying and characterizing superhypomethylation in head and neck cancer: drivers and transcriptional effects

View session detail

Author Block: **O. Dancu**[1], X. Chen[2], A. Djedid[3], C. Lu[2], J. Majewski[1]; [1]McGill Univ., Montreal, QC, Canada, [2]Columbia Univ., New York City, NY, [3]St-Justine Hosp., Montreal, QC, Canada

Epigenetic dysregulation driving transcriptional changes is a phenomenon occurring in many cancers. The effects of dramatic DNA hypomethylation are poorly understood and remain an active area of research. Of particular interest are the aberrant transcription events that are thought to be associated with a hypomethylated DNA methylation landscape. Indeed, these aberrant transcripts are thought to play a role both in carcinogenesis and in immune response. In the Head & Neck Cancer data from the TCGA, we have discovered a severely hypomethylated sample subset that we have termed as â□□superhypomethylatedâ□□. In this work, through analyzing mutational, transcriptional and DNA methylation data, I identified 1) promising candidate drivers of the superhypomethylation, and 2) the transcriptional aberrations that result from this dramatic loss of DNA methylation.This sample subgroup represents an ideal dataset in which to explore the transcriptional aberrations that occur in severely hypomethylated cancer landscapes.In expanding my investigationâ□□s scope to look for other superhypomethylated cancers, I identified superhypomethylated samples in other cancer types and potential superhypomethylation drivers in those cancers as well. Given that this superhypomethylation phenomenon was more widespread than just occurring in HNSC, this indicates wider clinical relevance than we initially anticipated.

PrgmNr 3340 - Integrative meta-analysis of blood and brain epigenome-wide association studies of Alzheimerâ□□s disease

View session detail

Author Block: **L. Wang**[1], T. Silva[1], J. Young[2], L. Zhang[1], M. A. Schmidt[3], L. Gomez[4], A. Varma[4], E. R. Martin[1]; [1]Univ. of Miami Miller Sch. of Med., Miami, FL, [2]Univ Miami, Miami, FL, [3]Univ Miami Miller Sch Med., Miami, FL, [4]Univ. of Miami, Miami, FL

Disclosure Block: **L. Wang:** None.

Alzheimerâ□□s disease (AD) is the most common cause of dementia and affects about 11% of people 65 years and older in the U.S. With the rising elderly population, AD has become a major public health concern. Currently, there is a severe lack of objective, inexpensive, and minimally invasive biomarkers for AD. Methylated DNA is more stable than mRNA and might provide an excellent source of biomarkers. We performed a meta-analysis of 1620 blood samples from two large blood-based epigenome-wide association studies in AD, generated by the ADNI and AIBL consortiums recently. We found DNA methylation levels at 5 CpGs, mapped to the *SPIDR*, *CDH6* genes, and intergenic regions were significantly associated with AD diagnosis. In addition, to prioritize significant methylation differences associated with AD in both brain and blood, we also performed a cross-tissue meta-analysis by combining these methylation datasets measured in blood with four additional DNA methylation datasets, which included 1030 samples generated from the brain prefrontal cortex, to prioritize 97 CpGs and 10 differentially methylated regions that are significantly associated with both AD neuropathology and AD diagnosis. Integrative analysis with AD GWAS loci, nearby gene expression, TF binding sites, and protein biomarkers suggested these DNA methylation differences play important functional roles in AD. In particular, our analysis revealed that DNA methylation at cg05157625, located in the gene body of the *RIN3* gene, is significantly associated with both AD diagnosis and AD neuropathology as well as expressions of the target gene *RIN3*. *RIN3* is involved in endosomal transport and signaling and has previously been linked to AD in GWA studies. Importantly, DNA methylation at cg05157625 also showed considerable agreement in matched brain and blood samples, indicating it could be a candidate biomarker for AD.

PrgmNr 3341 - Methylation Profiling using Reduced Representation Bisulfite Sequencing for Basal Cell Carcinoma in a Population Exposed to Arsenic

View session detail

Hlth.Sci., Univ. of Chicago, Chicago, IL, [2]Univ. of Illinois at Chicago, Chicago, IL, [3]Univ. of Chicago, Bangladesh, Dhaka, Bangladesh
Disclosure Block: **G. Da Silva:** None.
Background: Non-melanoma skin cancers (NMSC) are the most prevalent malignancy in the United States, with an estimated 2 million new diagnoses each year. NMSC includes basal cell carcinoma (BCC) and squamous cell carcinoma. While ultraviolet (UV) radiation exposure and skin sensitivity are known risk factors for NMSC, in Caucasians, arsenic (As) exposure may be a major risk factor in other populations. **Aim**: To identify differential DNA methylation in As-related BCC lesions, we compared DNA from BCC tissue (n=7) and normal skin tissue (n=3). **Material and Methods**: We utilized tissue samples from participants in the **B**angladesh vitamin **E** and **S**elenium **T**rial (BEST). From BEST participants who developed NMSC over the follow-up period of 8 years and had skin biopsy tissue preserved in RNA Later available, we selected the first seven male BCC cases. Healthy skin tissues (surrounding non-cancerous skin lesions) were taken from an independent set of participants (who had arsenical keratosis) for comparison. All of the participants were exposed to As through drinking As-contaminated groundwater and had visible As-related skin lesions at the enrollment of the trial. Over 3.6 million CpG sites were sequenced using Reduced Representation Bisulfite Sequencing Library Kit on the Illumina platform. The Bismark was used for the alignment of the reads and the methylation extraction. SeqMonk was used for the differential DNA methylation analysis. **Results**: From the sequence data, we created a total of 130,040 probes with a window size of 60 CpGs, and the bisulphite pipeline was used. Chi-Square test (q-value Conclusion: We present one of the very first genome-wide DNA bisulfite sequencing studies in BCC in Arsenic exposed males to identify several differentially methylated genes that may be relevant in understanding the pathogenesis of BCC. Further studies are needed to confirm the findings.

PrgmNr 3342 - Methylome-Wide Association Study Identifies Candidate DMRs for Carotid Bifurcation Intima-Media Thickness in Dominican Republic Families

View session detail

Author Block: **N. Dueker**[1], H. Zhao[2], C. Dong[3], D. Cabral[4], R. L. Sacco[4], S. H. Blanton[3], L. Wang[5], T. Rundek[4]; [1]1.John P. Hussman Inst. for Human Genomics, Univ. of Miami, Miami, FL, [2]Yale Univ. Sch. of Publ. Hlth., New Haven, CT, [3]Univ Miami, Miami, FL, [4]Dept. of Neurology, Miller Sch. of Med., Univ. of Miami, Miami, FL, [5]Univ. of Miami, Miami, FL
Disclosure Block: **N. Dueker:** None.
Stroke is a complex disorder influenced by genetic, epigenetic and environmental factors. One strategy to identify stroke risk factors is to study intermediate phenotypes which may be less complex than the clinical outcome. We have previously assembled a large collection of extended families from the Dominican Republic to characterize the genetic determinants of subclinical phenotypes for stroke, including carotid intima-media thickness (IMT). Using this sample, we have shown evidence for linkage and association of genetic variants with carotid bifurcation IMT (BIF), although identified variants only account for a portion of variation in BIF. To identify the â□□missing heritabilityâ□□, we performed a methylome-wide association study to identify methylation sites associated with BIF in 61 extended Dominican families with 799 individuals. CpG methylation in blood-derived DNA was assayed using the Illumina Infinium Human MethylationEPIC BeadChip. Using these data, linear mixed model analyses were performed regressing BIF on beta values for individual CpG sites, adjusting for age, sex, the first ancestry principal component (PC), two methylation PCs and cell composition proportions as fixed effects. Family and batch effects were included as random effects. Region-based analyses were performed using Comb-p to identify differentially methylated regions (DMRs). From this analysis, we identified 15 individual CpGs suggestively associated with BIF (p-5). These included cg04950204, located on chromosome 2 near the hippocalcin like 1 (*HPCAL1*) gene ($p=6.5x10^{-6}$). Notably, methylation within *HPCAL1* was previously implicated in incident myocardial infarction. Region-based analyses identified 24 DMRs significantly associated with BIF, with an average of 4.9 Â± 2.2 CpGs per DMR. Our most strongly associated DMR, chr1: 205819178- 205819610, was located on the peptidase M20 domain containing 1 (*PM20D1*) gene (N CpGs=10; Sidak p-value=$1.8x10^{-11}$). Methylation and genetic variants within *PM20D1* have been previously implicated in obesity and diabetes. Additional DMRs implicated genes involved in processes and phenotypes related to atherosclerosis including adaptive immunity (*PRR5*), chronic kidney disease (*PTPRN2*), Type I and Type II diabetes mellitus (*PTPRN2*, *MAEA*). Together, these results provide suggestive evidence for a role of DNA methylation in subclinical atherosclerosis in Dominicans. Additional analyses exploring the genetic and environmental factors influencing these associations are in progress.

PrgmNr 3344 - PTSD, major depression, and advanced transcriptomic age in neural tissue

Psychiatric stress has been associated with advanced epigenetic age in DNA methylation in blood and brain tissue, yet no study to date has examined this relationship in the transcriptome. The recent development of a multi-tissue RNA age algorithm (RNAAgeCalc) permits the evaluation of factors that accelerate cellular aging in gene expression. We examined age-adjusted RNA age (AgeAccelRNA) and its association with posttraumatic stress disorder (PTSD), major depressive disorder (MDD), and alcohol use disorder (AUD) using RNA sequence data from three postmortem cortical tissues--dorsolateral prefrontal cortex (dlPFC), ventromedial prefrontal cortex (vmPFC), and motor cortex. Tissue was from the VA National PTSD Brain Bank (n = 55 men, n = 39 women; 74% PTSD and/or MDD; PTSD and MDD cases were grouped due to considerable comorbidity). RNA age was calculated from gene expression values in each brain region and AgeAccelRNA was defined as the residuals from a regression of age at death predicting RNA age. Psychiatric disorders were examined in linear models predicting AgeAccelRNA. In the region(s) that achieved corrected significance, we identified the genes in the RNAAgeCalc that were differentially expressed as a function of the same psychiatric variable(s). We also tested the association between AgeAccelRNA and the neural cell type balance estimated by BrainInABlender. RNA age was highly correlated with age at death across the three regions (rs=.69-.76, ps<.001 ptsd was significantly associated with ageaccelrna in the vmpfc p=".004," padj=".012)" after adjustment for three regions. genes were correction rnaagecalc:>KCNJ16 (log2foldchange [l2fc] = -.84, padj=6.45E-05), *HYAL1* (l2fc = .61, padi=.02), and *CEBPB* (l2fc = .59, padi=.02). Inflammatory and immune-related pathways were enriched among the 43 RNAAgeCalc genes that were at least nominally associated (p

PrgmNr 3345 - Role of differential DNA methylation in Mexican Americans & their risk for Alzheimerâ□□s disease & type 2 diabetes

View session detail

Author Block: **A. Abraham Daniel**[1], T. Silzer[2], J. Sun[1], C. Hall[1], Z. Zhou[3], N. R. Phillips[1], R. C. Barber[1]; [1]UNT Hlth.Sci. Ctr., Fort Worth, TX, [2]Hosp. for Sick Children, Toronto, ON, Canada, [3]Sch. of Publ. Hlth., UNT Hlth.Sci. Ctr., Fort Worth, TX

Disclosure Block: **A. Abraham Daniel:** None.

DNA methylation is an epigenetic mechanism that influences gene expression and has been associated with age related diseases such as metabolic disorders and cognitive decline in several cohorts. Mexican Americans are the largest ethnic minority group in the US and are consequently predicted to have the largest elderly ethnic population within a few decades. Susceptibility to age-related phenotypes such as Alzheimerâ□□s disease (AD), mild cognitive impairment (MCI) and prevalence of type 2 diabetes (T2D), are unique in this cohort. Mexican Americans have an earlier age of onset for cognitive decline (AD/MCI) and have a higher prevalence rate of T2D in comparison to non-Hispanic whites. Mexican Americans also have a metabolic heavy predisposition for AD, compared to non-Hispanic whites who develop inflammation-based AD. The risk for these phenotypes is multifactorial involving epigenetic factors, such as differential DNA methylation, which is the addition of a methyl group to certain cytosine bases of DNA in the genome. Studies have shown the presence of T2D almost doubles the risk of developing AD/MCI, however an epigenetic link between these phenotypes in the Mexican American cohort remains to be established. We aim to elucidate an epigenetic association between cognitive decline and T2D, specific to the Mexican American population, through analysis of methylation profiles from participants selected from the Texas Alzheimer's Research and Care Consortium (TARCC). The TARCC participants consist of Mexican Americans diagnosed with either cognitive impairment alone (either AD/MCI), T2D alone or both cognitive impairment and T2D together and matched for gender and age with a non-Hispanic white counterpart. Peripheral blood samples were drawn from participants and run on the Illumina Infinium MethylationEPIC chip array assessing >850,000 CpG sites to obtain individual methylation profiles. The Chip Analysis Methylation Pipeline (ChAMP) package within R software will be used to assess differential methylation profiles from all 566 TARCC participants. The results obtained will be analyzed using pathway and gene set enrichment analysis tools. Potential identification of differential methylation specific to the Mexican American population could help provide ethnic specific risk information for T2D and cognitive decline together. This could contribute towards developing ethnic-specific biomarkers, treatments or therapies in the near future.

PrgmNr 3346 - Single-cell coexpression analysis of schizophrenia genes refines the dopamine hypothesis and implicates novel treatments

View session detail

Author Block: **K. Pang**[1,2], Z. Liu[1,2]; [1]Baylor Coll. of Med., Houston, TX, [2]Jan and Dan Duncan Neurological Res. Inst., Houston, TX
Disclosure Block: **K. Pang:** None.
A significant number of genes have been implicated in schizophrenia, but their contributions to schizophrenia pathology and treatment development are difficult to decipher without understanding their functions in specific brain cell types. Here, we integrated schizophrenia genetics with single-cell RNA sequencing data of dopamine receptors-expressing neurons in the striatum to assess coexpression patterns of different types of schizophrenia genes. We discovered significant negative correlation of schizophrenia genes with the *DRD2* gene which encodes dopamine D2 receptor and the genes whose expression represents the expression state of dopamine D2 receptor-expressing neurons (D2 neurons), indicating high functional convergence of schizophrenia genes in D2 neurons and suggesting convergent dysregulation of D2 neuron function beyond D2 receptor expression in the presence of schizophrenia gene mutations. Further integration with drug-target gene interaction data elucidated mechanisms of action of the approved antipsychotic drugs and prioritized novel high-confidence drug targets and drugs that can potentially modulate the expression state of D2 neurons. The most promising drugs either convergently target D2 receptor, its interacting pathways, and its downstream signaling cascades or hit other individual components crucial for the function of D2 neurons, providing a rich resource to achieve shared and/or personalized therapies tailored to the genetic variants of individual schizophrenia patients. This approach provides a general framework for dissecting the cell-type-specific pathophysiology of complex genetic diseases and identifying genetics-based drugs to target disease mechanisms.

PrgmNr 3348 - Transcriptomic and epigenomic signatures associated with autoimmunity in Parkinson's Disease

View session detail

Author Block: **L. Andriamboavonjy**[1,2], C. Michaud[1,2], A. Lannuzel[3], M. Panisset[1,2], D. Matheoud[1,2], M. TÃ©treault[1,2]; [1]Univ. of Montreal, Montreal, QC, Canada, [2]CRCHUM, MontrÃ©al, QC, Canada, [3]Inst. du cerveau et de la moelle Ã©piniÃ¨re, Paris, France
Disclosure Block: **L. Andriamboavonjy:** None.
I- Objectives: 1- To characterize the transciptomic and/or epigenomic modulation of autoimmunity associated genes in parkinson's disease 2- To identify the potential omics signature involved in parkinsonism clinical expression (Parkinson's Disease vs. other parkinsonism)
II- Background: The correlation between autoimmunity and Parkinson's disease pathogenesis tend to be confirmed. In the familial form of PD, genetics analysis has confirmed the association between PD linked genes and autoimmune diseases. Furthermore, PINK1 and PARKIN proteins involved in PD are essential in immune response via the mitochondrial antigen presentation pathway. The autoimmune basis in PD has led us to the hypothesis of a peri-genetic modification in autoimmunity associated genes for sporadic PD. Besides, transcriptomic and epigenomic alteration can occur after a viral infection or downstream to the activation of immune cells. In Guadeloupe, where flaviviruses infections are endemic, the prevalence of atypical parkinsonism is much higher compared to North America and Europe. We suspect a link between the flaviviruses infection and atypical parkinsonism due to a peri-genetic alteration.
III- Methods: Six specific groups will constitute our research population:- From Montreal: PD patients, atypical parkinsonism patients, control patients
- From Guadeloupe: PD patients, atypical parkinsonism patients, control patients
1- Establishing a transcriptomic signature: Peripheral blood mononuclear cells' (PBMC) RNA will be extracted and subject to a bulk RNA-seq. A bioinformatic pipeline will align the transcripts and identify: variants, alternative splicing, differential expression, specific isoforms and differential polyadenylation.
2- Establishing an epigenomic signature: PBMC's DNA will be extracted and subjected to a methyl-ATAC-sequencing, which will allow to determine the opened chromatin regions and the methylation profile.
IV- Results: Research on process.
V- Conclusion: Presently, our understanding of the neuropathogenesis of PD is not well-rounded. The path of autoimmunity has to be deepened. Exploring the genetic and peri-genetic differences between PD and other parkinsonism can lead us to a more accurate diagnosis and a better care for patients with this neurodegenerative disease.

PrgmNr 3349 - A cryptic splice acceptor as a cause of X-linked heterotaxy

View session detail

Author Block: **J. Wells**[1], M. B. Padua[2], S. M. Ware[1,2]; [1]Dept. of Med. and Molecular Genetics, Indiana Univ. Sch. of Med., Indianapolis, IN, [2]Dept. of Pediatrics, Indiana Univ. Sch. of Med., Indianapolis, IN
Disclosure Block: **J. Wells:** None.
Heterotaxy syndrome is typically characterized by severe congenital heart defects (CHDs) and abnormal arrangement of thoracic and abdominal organs due to perturbed left-right (LR) asymmetry. The genes currently known to cause heterotaxy explain only 15-20% of cases and are largely biologically related to the structure or function of the embryonic node, a ciliated LR organizer. Mutations in Zinc finger of the Cerebellum 3 (*ZIC3*) are the only known cause of X-linked heterotaxy, accounting for 75% of X-linked cases. We identified an X-linked heterotaxy pedigree with four affected males and performed exome sequencing. Although we did not identify a coding variant in *ZIC3*, a rare predicted damaging hemizygous variant in G-protein coupled receptor 101 (*GPR101* c.1225G>A;p.V409M), a gene tightly linked to *ZIC3*, segregated with disease in the pedigree. *GPR101* is a compelling candidate based on the known cilia function of its closely related family member *GPR161*. Morpholino-induced knockdown of *gpr101* in Xenopus laevis resulted in a heterotaxy phenotype. However, our *Gpr101* global knock-in mouse line with an inserted LacZ reporter (*Gpr101*$^{tm1b(KOMP)Mbp}$) did not display a heterotaxy phenotype and expression analysis showed that *Gpr101* is not expressed at the embryonic node. In the same X-linked heterotaxy pedigree, we conducted whole genome sequencing and identified a novel, intronic variant in *ZIC3* also segregating with disease phenotype. This new *ZIC3* c.1224+3286A>G variant was predicted to result in a cryptic splice acceptor that would lead to novel exon inclusion after exon 2. Structurally, this novel isoform is predicted to share 408 amino acids with known *ZIC3* isoforms followed by cryptic exon inclusion encoding 80 novel amino acids and several predicted polyadenylation sites. This novel isoform is predicted to lack a critical portion of the fifth zinc finger DNA binding domain previously demonstrated to be required for DNA binding and nuclear localization. A minigene splicing assay was performed in HEK293 cells to determine if cryptic exon inclusion occurs. This assay confirmed that the *ZIC3* c.1224+3286A>G variant results in altered splicing between exon 2 and the predicted cryptic exon. Experiments are in progress to further functionally validate this novel isoform. These results demonstrate the second reported instance of a noncoding *ZIC3* variant associated with heterotaxy and the first due to cryptic exon inclusion.

PrgmNr 3350 - Adipose eQTL meta-analysis of 2,256 samples identifies 517 conditionally distinct signals colocalized with 426 cardiometabolic trait GWAS loci

View session detail

Inst., NIH, Bethesda, MD, [6]Dept. of Human Genetics and Inst. for Precision Hlth., David Geffen Sch. of Med. at UCLA, Los Angeles, CA, [7]Inst. of Clinical Med., Kuopio Univ. Hosp., Univ. of Eastern Finland, Kuopio, Finland
Disclosure Block: **S.M. Brotman:** None.
At many GWAS loci, the genes underlying disease risk remain unknown. Candidate genes can be detected through colocalization of GWAS loci with expression quantitative trait loci (eQTL) in trait-relevant tissues, and colocalized loci may be more readily identified by analyzing conditionally distinct GWAS and eQTL signals. We performed an RNA-seq-based local (Â± 1 Mb) eQTL meta-analysis of 2,256 subcutaneous adipose tissue samples from 5 studies, and performed conditional analysis to detect distinct signals using APEX. Of 28,346 genes tested in â¥2 studies, 19,286 (68.0%) had â¥1 significant eQTL, which is more than the 13,115-17,582 genes with eQTL in the individual studies. Of these 19,286 genes, 10,244 (53.1%) genes had â¥2 eQTL signals and 4,562 (23.7%) genes had â¥3 eQTL signals. Among genes with â¥2 eQTL signals, we find a median distance of 28 kb from the lead variant to the transcription start site (TSS) for primary signals, 41 kb for secondary signals, and 59 kb for 3rd to 10th signals. As the number of signals increased, the median eQTL effect size generally decreased: 0.26 for primary signals, 0.17 for secondary signals, and 0.17 for 3rd to 10th signals. Compared to the 10-fold larger eQTLGen blood eQTL meta-analysis (n > 30,000 samples), more than half of adipose eQTL signals (20,372; 54.0%) were not significant (FDR coloc2 (PP4 > 0.8) to perform colocalization of adipose eQTL with GWAS loci from six cardiometabolic traits. In total, 426 GWAS loci (132 waist-to-hip ratio adjusted for BMI, 115 body mass index, 110 waist-to-hip ratio, 61 type 2 diabetes, 4 coronary artery disease, 4 fasting glucose) were colocalized with eQTL signals from 517 genes. Secondary eQTL signals have not been analyzed in most prior studies, but here we observed that more secondary eQTL signals colocalized with GWAS loci. Among the genes with â¥2 eQTL, 171 primary eQTL were colocalized with 159 GWAS loci, while 221 eQTL with â¥2 signals were colocalized with 193 GWAS loci. One example of an eQTL detected in the meta-analysis but not the individual studies is for *EXOC3L1* (eQTL *p*-value = 8.1 x 10^{-8}), which is colocalized with a waist-to-hip ratio adjusted for BMI GWAS signal. *EXOC3L1* encodes a protein of the exocyst complex that functions as a tether of secretory vesicles to the plasma membrane to facilitate molecular trafficking. Using our five-study adipose eQTL meta-analysis, we find 53.1% of genes have conditionally distinct eQTL signals that would have been missed if we only detected primary signals, and we identify biologically plausible genes that may influence variation of cardiometabolic traits.

PrgmNr 3351 - Characterization of neonatal epigenetic markers associated with elevated stress from the COVID-19 pandemic

View session detail

Author Block: **K. Kocher**[1,2], S. Bhattacharya[1], J. Quistorff[3], C. Lopez[3], M. Almalvez[1], N. Niforatos-Andescavage[3], E. J. Vilain[1,2], C. Limperopoulos[3], E. Delot[1,2]; [1]Ctr. for Genetic Med. Res., Children's Natl. Med. Disclosure Block: **K. Kocher:** None.
With the sudden outbreak of COVID-19 in early 2020 came a prolonged period of quarantine and shutdown of society. Job insecurity, economic instability, isolation, and fear of exposure to COVID-19 led to widespread psychological distress for many. During gestation, stressors to the fetus, including maternal stress, anxiety, and depression, can lead to impaired fetal brain development, which may result in long-term reduced quality of life and cognitive impairment. However, the mechanisms by which these prenatal stressors disrupt fetal brain development remain unclear, and outcomes vary even for similar stressors, suggesting the existence of factors providing resilience or susceptibility to stress. We have previously identified DNA methylation patterns in newborn issued from stressed pregnancies of other causes (e.g. heart or placental defect, premature birth). In this study we aim to determine whether there are unique epigenetic signatures in newborns associated with stress during pregnancy due to the COVID-19 pandemic that may accompany modified fetal brain development. We investigated DNA methylation differences in newborns who experienced otherwise healthy pregnancies that occurred during the COVID-19 pandemic (RESCUE cohort). Biospecimens were collected at birth as part of a comprehensive, longitudinal study. Maternal mental health metrics as well as fetal brain MRI imaging were recorded throughout pregnancy and at birth. We designed and validated a bioinformatic pipeline to filter and normalize output data from Illumina Infinium MethylationEPIC BeadChip for this application. Unsupervised clustering showed appropriate clustering by tissue type, no gender bias, and gross appropriate clustering of cohort samples. Exceptions to this clustering are being further studied to uncover phenotypic associations using clinical, demographic, and MRI data. Widespread differential methylation was found between RESCUE (n=33) newborns and age- and sex-matched healthy controls (CTL, n=13), recruited before the start of the pandemic. In contrast, there were no apparent epigenetic differences associated with COVID-19 infection during pregnancy. While we found specific DNA methylation signatures that are unique to this cohort, we also identified signatures that overlap between other stressful pregnancy cohorts, suggesting that there may be common epigenetic markers to all types of prenatal stress.

PrgmNr 3352 - Defining the effects of noncoding genetic variation on human regulatory element activity

View session detail

Disclosure Block: **K. Strouse:** None.
Millions of noncoding genetic variants are associated with common human traits and disease. As a step towards understanding how noncoding variants contribute to disease, we are generating a population-scale atlas of the effects of 40 million genetic variants on gene regulatory element activity. To do so, we are assaying regulatory activity genome-wide across 300 individuals from diverse populations using the high-throughput reporter assay STARR-seq. We have developed a pooling approach to whole-genome STARR-seq that allows for comprehensively assaying regulatory variation across five individuals at once; and a Bayesian model of allele-specific STARR-seq signal to estimate allele-specific regulatory activity from that data. To maximize the number of genetic variants we assay, we have prioritized the genomes of individuals with African ancestry, but still include representation from diverse ancestries. In total, we will assay all common noncoding variants and over 20 million rare variants (MAF

PrgmNr 3353 - DNA-binding consequences of human homeodomain missense variants

View session detail

Author Block: **K. Kock**[1], P. K. Kimes[2], S. Inukai[1], S. K. Phanor[1], S. S. Gisselbrecht[1], C. H. Lipper[3], G. Ramakrishnan[1], J. T. Anderson[1], J. V. Kurland[1], J. M. Rogers[1], S. C. Blacklow[3], R. A. Irizarry[2], M. L. Bulyk[1]; [1]Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, [2]Dana-Farber Cancer Inst. and Harvard T.H. Chan Sch. of Publ. Disclosure Block: **K. Kock:** None.

Homeodomains are transcription factors with important roles in development, patterning, and cellular differentiation. Numerous homeodomain coding mutations, particularly within the DNA-binding domain (DBD), have been associated with an array of human Mendelian diseases. While a select number of these mutations have been studied in detail, the broader biochemical consequences of missense variation across the span of the homeodomain DBD remain understudied. Since every single position within the homeodomain DBD has been reported in ClinVar to have pathogenic variants and variants of uncertain significance (VUS), a more comprehensive understanding of the effects of these variants is important for variant interpretation and insights into disease mechanisms.

We sought to elucidate the consequences of such missense variation on DNA binding by studying disease-associated and naturally-occurring variants, alongside variants designed to test for tolerance of mutations at particular residues. We profiled >90 DBD missense variants across 30 human homeodomains using protein-binding microarrays to evaluate DNA binding to all possible 8 base pair sites (8-mer). We utilised a parametric model framework to make inferences about differential binding affinity and altered binding specificity by homeodomain missense variants to sets of 8-mers.

More than 75% of disease-associated variants we examined resulted in diminished binding affinity, particularly to 8-mers bound by the wild-type homeodomain with high affinity. Several variants showed stark changes in DNA-binding specificity, with recognition of novel sets of 8-mers. More surprisingly, we identified variants that altered binding affinity specifically for sets of 8-mers that were recognised by the wild-type homeodomain at moderate affinity, which we interpreted as a subtler change in DNA-binding specificity. We identified 9 novel DNA-binding specificity-determining positions across our dataset, with several distal from homeodomain-DNA interfaces. We performed structural modelling to suggest mechanisms for alterations in DNA-binding specificity, such as changes in intra-homeodomain side-chain interactions, or introduction of contacts with DNA target sites.

Our results suggest pathogenic mechanisms for several VUS and disease-associated variants and genes, and contribute towards clarification of VUS; ~5% of homeodomain DBD VUS in ClinVar affect novel specificity-determining positions identified in our study. We envision our findings contributing towards a deeper understanding of homeodomain-DNA recognition rules, and improved variant interpretation and target gene prediction.

PrgmNr 3354 - Genome-wide association studies identify novel genetic loci for epigenetic age acceleration among survivors of childhood cancer

View session detail

Author Block: **Q. Dong**[1], N. Song[2,3], N. Qin[4,5], Z. Li[1], X. Sun[1], J. Easton[2], H. Mulder[1], G. Neale[1], E. Walker[1], X. Ma[1], I-C. Huang[1], J. Zhang[6], K. K. Ness[1], M. M. Hudson[1], L. L. Robison[1], Z. Wang[6]; [1]St. Jude Children's Res. Hosp., MEMPHIS, TN, [2]St. Jude Children's Res. Hosp., Memphis, TN, [3]Chungbuk Natl. Univ., Cheongju, Korea, Republic of, [4]Nanjing Med. Univ., Nanjing, China, [5]St. Jude Childrenâ□□s Res. Hosp., Memphis, TN, [6]St Jude Children's Res. Hosp., Memphis, TN

Disclosure Block: **Q. Dong:** None.

Background: We have shown that epigenetic age acceleration (EAA), based on Levineâ□□s clock (i.e., PhenoAge), is significantly higher in survivors of childhood cancer and is associated with specific treatment exposures, unfavorable health behaviors, and presence of specific chronic health conditions. To better understand inter-individual variability, we aimed to investigate the genetic basis of EAA among survivors of childhood cancer.

Methods: Genome-wide association studies of EAA based on four different epigenetic clocks (Hannum, Horvath, PhenoAge, and GrimAge) were performed with DNA methylation EPIC array and whole-genome sequencing data generated from blood-derived DNA from 2138 survivors (discovery), an additional set of 504 survivors (replication), and 282 community controls for comparison (exploration). Both sets of survivors as well as community controls are of European ancestry from the St. Jude Lifetime Cohort Study. Linear regression models were fit for each epigenetic age against the additive dose of each genetic variant across the genome, adjusting for age at DNA sampling, sex, and cancer treatment exposures. Fixed-effects meta-analysis was used to combine summary statistics for discovery and replication sets. LD score regression was used to estimate SNP-based heritability.

Results: For EAA-Horvath, a genome-wide significant association peak was mapped to *SELP* gene with the strongest SNP rs732314 (combined: Beta=-0.56, P=3.91Ã□10^{-11}, I^2=50.48%; discovery: Beta=-0.50, P=1.55Ã□10^{-7}; replication: Beta=-0.81, P=2.69Ã□10^{-5}). rs732314 is a meQTL for cg01459453 (a CpG in Horvathâ□□s clock). For EAA-Hannum, an association peak was mapped to *HLA* locus with the strongest SNP rs28366133 (combined: Beta=-0.78, P=3.74Ã□10^{-11}, I^2=0; discovery: Beta=-0.76, P=5.30Ã□10^{-8}; replication: Beta=-0.84, P=2.02Ã□10^{-4}). There was no genome-wide significant SNP for EAA-PhenoAge or EAA-GrimAge. Interestingly, among community controls, rs732314 was significantly associated with EAA-Horvath (Beta=-1.09, P=5.43Ã□10^{-5}) but rs28366133 was not associated with EAA-Hannum (Beta=-0.21, P=0.48). The estimated heritability was 0.33 (SE=0.20) for EAA-Horvath and 0.17 (SE=0.23) for EAA-Hannum. In contrast, the estimated heritability was close to zero for EAA-PhenoAge and EAA-GrimAge.

Conclusions: We identified novel genetic variants in *SELP* and *HLA* gene loci associated with EAA-Horvath and EAA-Hannum, respectively, among survivors of childhood cancer. Heritability estimates showed measurable genetic components of EAA based on the first generation of epigenetic clocks (Horvath and Hannum) but not the second generation (PhenoAge and GrimAge).

PrgmNr 3355 - Genome-wide detection of enhancer-hijacking and reconstructing complex SVs in cancer genome

View session detail

Author Block: **F. Yue**, X. Wang, J. Xu, B. Zhang, Y. Hou, F. Song, H. Lyu; Northwestern Univ., Chicago, IL
Disclosure Block: **F. Yue:** Major Stockholder/Ownership Interest; Sariant therapeutics. Receipt of Intellectual Property Rights/Patent Holder; Feng Yue and Xiaotao Wang.
Recent efforts have shown that structural variations (SVs) can disrupt three-dimensional genome organization and induce enhancer hijacking, yet no computational tools exist to identify such events from chromatin interaction data. Here, we develop NeoLoopFinder, a computational framework to identify the chromatin interactions induced by SVs, including interchromosomal translocations, large deletions and inversions. Our framework can automatically resolve complex SVs, reconstruct local Hi-C maps surrounding the breakpoints, normalize copy number variation and allele effects and predict chromatin loops induced by SVs. We applied NeoLoopFinder in Hi-C data from 50 cancer cell lines and primary tumors and identified tens of recurrent genes associated with enhancer hijacking. To experimentally validate NeoLoopFinder, we deleted the hijacked enhancers in prostate adenocarcinoma cells using CRISPR-Cas9, which significantly reduced expression of the target oncogene. In summary, NeoLoopFinder enables identification of critical oncogenic regulatory elements that can potentially reveal therapeutic targets.

PrgmNr 3356 - Automated localization and quantification of RNA transcripts from RNA-fluorescent in situ hybridization imaging data

View session detail

The regulation of gene expression is a major factor in cells' ability to respond to environmental stimuli and differentiate during the development of multi-cellular organisms. However, a transcriptional program is not only defined by which genes are upregulated and downregulated. Understanding the finer kinetics of transcriptional tuning is important for fully understanding transcription as a process and how its regulation impacts cellular phenotype. Because variability increases with length of time and the number of cells measured in a population, high resolution spatiotemporal localization of individual RNA molecules in single cells is important for studying these dynamics at high precision. RNA fluorescent in situ hybridization (RNA-FISH) is a frequently used technique for visualizing RNA in fixed cells using fluorescent probes. Automated processing of the resulting images is essential for large datasets that may include many different transcripts and time points. Here we demonstrate that our MATLAB based RNA-FISH image processing pipeline is a useful tool for automatically detecting the 3D locations of cell boundaries and RNA transcripts at single molecule resolution in an RNA-FISH image stack. In particular, this tool is effective for facilitating quantitative analyses of FISH data such as determining the colocalization of multiple transcripts or the relative amount of RNA in various subcellular compartments. We aim to develop a tool capable of performing analysis for a variety of imaging-based approaches to studying RNA dynamics. Our hope is to use this tool to advance understanding of eukaryotic transcription regulation mechanisms by studying the quantities and behaviors of transcripts and regulatory RNA at discrete time points.

PrgmNr 3357 - Deep Learning Study to Predict Ribosome Binding from RNA-seq Data

View session detail

Author Block: **H. Kumar**[1], T. Yang[1], P. Kim[2]; [1]Sch. of BioMed. Informatics, The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [2]The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX
Disclosure Block: **H. Kumar:** None.
It is critical to have a ribosome footprint for identifying the actively translated mRNAs and peptide folding and measuring the protein synthesis. Ribo-seq provides the global snapshot of the translation efficiency. However, there are not many publicly available Ribo-seq data compared to the huge amount of RNA-seq data. Mathematical modeling of translation process uses such information as production of mRNA, initiation of translation, assembly of ribosome, elongation, termination, degradation of mRNA and proteins. Based on this context, there were several trials to model the translation process from the molecular unit in the view of biochemistry for the prokaryotes. To date, there were no studies to infer the translation status from the RNA-seq data in humans, which is resulted in the relatively low number of studies of translatome compared to the transcriptome. To fill this gap, we will build a deep learning model to infer the active ORFs from RNA-seq data, named virtual Ribo-seq, by utilization of diverse translation-related information from the transcript level such as expression, splicing, and RNA degradation events. We trained our model using publicly available 11 human cell lines that have matched data of RNA-seq and Ribo-seq, incorporating three RNA process information (expression, splicing, and degradation of RNA) and other basic information (conservation and number of evidences of Ribo-seq peak). Virtual Ribo-seq is a convolutional neural network model. We tested our model on one of the most studied human cancer cell-line, K562. This study is mainly aimed to better understand the translation process through inferencing the translation state of individual genes from the active RNA processing status in the new cell.

PrgmNr 3358 - Interpreting Epigenetic Aging with Deep Neural Networks Using High Dimensional DNA Methylation Data

View session detail

Author Block: **H. Guan**; Basis San Antonio Shavano, San Antonio, TX
Disclosure Block: **H. Guan:** None.
Aging is a normal process linked to specific patterns and changes in the epigenome, e.g., DNA methylation. Multiple epigenetic aging clocks have been developed, but little research have focused on interpretation of these aging equations. Deep neural networks (DNN) are powerful prediction models which can model higher-order of interaction between biomarkers. We have previously developed a DNN-based prediction model for aging prediction. In this study, we use three model-agnostic interpretability methods to interpret how trained DNN predict human biological age by high-dimensional DNA methylation data. Specifically, we compare the Local Interpretable Model-agnostic Explanations, Shapley Values, and MMD-Critic by using the maximum mean discrepancy and large-scale submodular optimization. We discover that, for a large number of candidate features, such as genome-wide DNA methylation data, a key factor in improving prediction accuracy is to appropriately weight features that are highly correlated with the outcome of interest. We also show that explanations can mitigate the impact of misclassified features from the perspective of the end-user. We conclude that explanations are valuable for improving our understanding of epigenetics and what it means for aging.

PrgmNr 3359 - Investigating the utility of sex-informed PrediXcan models in whole blood

View session detail

Author Block: **V. A. Janve**, L. Dumitrescu, K. A. Gifford, K. R. Pechman, A. L. Jefferson, T. J. Hohman; Vanderbilt Univ. Med. Ctr., Nashville, TN
Disclosure Block: **V.A. Janve:** None.
Introduction: Based on Oliva et al. (Oliva et al. Science 2020), there are known sex differences in tissue-specific gene expression and in the genetic architecture of gene expression, but such differences have not been incorporated into predicted gene expression models to date. Gene based methods such as PrediXcan use expression quantitative trait loci (eQTLs) to build gene expression models. Compared to traditional GWAS methods these have higher power, reduced multiple testing burden and potential to identify causal pathways. Sex and tissue specific predicted expression can be imputed for investigating the genetic architecture of gene expression, when only genetic data is available. However, careful evaluation is needed before such methods are applied with confidence. **Methods:** We built sex-stratified models using whole blood RNA sequencing in GTEx(v8) and evaluated their performance in an independent dataset. Specifically, prediXcan models were built following the method described in Gamazon et al. (Gamazon et al. Nature Genetics 2015), but we included joint and sex-specific models. Validation was evaluated leveraging RNA sequencing data from Non-hispanic white, cognitively normal partcipants in the Vanderbilt Memory & Aging Project (Jefferson et al. J Neurology 2017, n=170; 99 males, age=72.1Â±6.44; 71 females, age=73Â±8.17). The associations were evaluated with observed expression in all the predicted genes (n=16,592) and sex-biased genes identified in Oliva et al. (n=353 of 500, 189 females and 164 males specific, respectively) in a joint and sex-stratified manner. **Results:** Sex-stratified models perform well, comparable to joint models with more heritable genes showing stronger observed R^2 in validation analyses. Several of PrediXcan gene models are observed in sex-stratified models that are not observed in joint models, however, these sex-specific predicted models inclined not reproduce in a robust manner (only 63/189 reproduced in females and 63/164 in males). When comparing joint models restrictively applied in one sex to sex-stratified models applied in one sex, the joint models tended to perform better, even when restricting to genes that show pronounced sex differences across sex. **Conclusion:** While we do see evidence of sex-specificity in the genetic architecture of gene expression, we do not provide evidence supporting the application of sex-stratified PrediXcan builds across the autosomes in this small study. Future work will integrate the X-chromosome, test models in larger brain eQTL databases that may have increased power for sex-stratified PrediXcan model evaluation.

PrgmNr 3360 - A site-specific mutation rate model uncovers signatures of localized hypermutability

View session detail

Author Block: **V. Seplyarskiy**[1], E. Koch[1], J. S. Lichtman[2], H. H. Luan[2], D. Lee[1], S. Sunyaev[3]; [1]Harvard Med. Sch. Div. of Genetics, Boston, MA, [2]NGM biopharmaceuticals, South San Francisco, CA, [3]Harvard Med. Sch. and Brigham & Women's Hosp., Boston, MA
Disclosure Block: **V. Seplyarskiy:** Consultant/Consulting Fees/Other Remuneration; NGM biopharmaceuticals.
Mutation rate is inhomogeneous along the human genome. The precise knowledge of mutation rate in each position of the genome would highlight relevant mutagenic forces, it would generate a proper baseline for estimation of selective constraint and will equip statistical methods for identifying genes causing human Mendelian diseases. Capitalizing on large-scale population sequencing datasets, we developed a statistical model of mutation rate at the base pair resolution. Our model was trained on the filtered and recurrence corrected rare SNV data from the GNOMAD v.3.1 resource. Validation of the model on *de novo* mutation data obtained in parent-child trio sequencing studies demonstrated high accuracy exceeding that of the existing models. The mutation rate model relies on known genomic factors influencing mutagenesis. It includes extended nucleotide sequence context, enumerating mutagenic properties of each pentanucleotide and using a sparse regression model to incorporate the influence of eight additional nucleotide positions. The model also takes into account DNA methylation, directions of transcription and replication, and mutation rate variation at the 50kb scale for all tri-nucleotide mutation types. We found that mutation rate varies within each pentamer at least 2.5-fold, and up to 100-fold. This implies, that incorporation of the effect of immediately adjacent nucleotides is insufficient to estimate position-specific mutation rate. We detected a number of 100-nucleotide long elements with greatly elevated mutation rate compared to the model. These elements include all tRNA, small nuclear RNA and a subset of ribosomal RNA genes. At the same time, pseudogenes from the same families show no signs of hypermutability. We validated hypermutability of these RNA genes using *de novo* mutations and confirmed the 32-fold increase (18-48, 95% confidence interval) of mutation rate for small nuclear RNAs. A tempting interpretation is that the hypermutability is associated with transcription by polymerase III. For most functional annotations (transcription factor binding sites and ENCODE regulatory elements) the observed mutation rate is in line with our predictions. However, mutation rate in CTCF binding sites in promoters is deviated from our estimates and displays an excess of T>G and T>A mutations. Mutational footprint of CTCF binding in promoters is greatly distinct from both CTCF binding sites outside of promotors and from non-CTCF bound promoters. This enables accurate prediction of CTCF bound promotors solely from mutational data AUC (0.87).

PrgmNr 3361 - Assessment of the rates of pathogenic variants across the All of Us Research Program cohort

Radhakrishnan[7], A. Haddad[2], M. M. Wheeler[4], Q. Wang[8], D. A. Nickerson[9], D. M. Toledo[10], A. Musick[11], R. A. Gibbs[12]; [1]HGSC - Baylor Coll. of Med., Houston, TX, [2]Univ. of Pittsburgh, Pittsburgh, PA, [3]Univ Arizona, Tucson, AZ, [4]Univ of Washington, Seattle, WA, [5]Univ. of Washington Genome Sci., Seattle, WA, [6]Columbia Univ. Med. Ctr., New York, NY, [7]Univ. of Washington, Seattle, TX, [8]Baylor Coll. of Med., Houston, TX, [9]Univ Washington Sch Med, Seattle, WA, [10]Dartmouth-Hitchcock Med. Ctr., Lebanon, NH, [11]NIH, Bethesda, MD, [12]Baylor Coll. Med., Houston, TX
Disclosure Block: **E. Venner:** Major Stockholder/Ownership Interest; Codified Genomics.
The All of Us Research Program (AoURP) has a more diverse cohort of participants than within previously studied large cohorts. It is currently unknown, however, whether the rate of positive health-related genetic findings in the AoURP cohort will differ from those in the other healthy populations that have been ascertained. Identification of such differences will be a powerful reinforcement of the importance of the AoURPâ□□s mode of recruitment and engagement.
Using the AoU Research Hub, we have begun a â□□demonstration projectâ□□ that will assess health-related genetic findings within AoURP whole genome sequence (WGS) data, and provide feedback on the Research Hub itself. After automated filtering, we have begun manual assessment of putative pathogenic variants on aggregated data from 9,151 AoURP participants. Preliminary results show a 0.5% positive rate for cancer or tumor diseases (not counting recessive conditions MYH-associated polyposis and Wilson disease, which have not been fully assessed during the aggregate review phase), 0.7% for cardiac disease-related findings, and 0.3% for hypercholesterolemia. As these data mature they can be compared to other cohorts and broken down into subgroups by ancestry backgrounds. As a preliminary comparison, in the eMERGE III program, in patients not ascertained for a specific indication, 2% of patients had a finding related to cancer risk, 1.7% had a finding related to cardiac disease, and 1.1% had a finding related to familial hypercholesterolemia. These rates are generally higher than within the AoURP data, but this may reflect that although the eMERGE III participants were not ascertained with a specific indication, they were enrolled as part of clinical visits. These ratios will also change as we continue to review variants of unknown significance.
More studies of specific loci and comparison with other cohorts will determine whether there are exceptional features within the AoURP cohort. This will test the hypothesis that the increased diversity of the AoURP cohort will lead to a higher positive rate of health related results, across the program, than one would expect from a less-diverse population of healthy individuals.

PrgmNr 3362 - Cataloging human *PRDM9* allelic variation using long-read sequencing reveals *PRDM9* population-specificity and two distinct groupings of related alleles

View session detail

Author Block: **B. Alleva**[1], K. M. Brick[2], F. Pratto[3], M. Huang[3], R. D. Camerini-Otero[4]; [1]NIDDK, Bethesda, MD, [2]NIDDK, NIH, Bethesda, MD, [3]NIH, Bethesda, MD, [4]Natl. Inst.s Hlth, Bethesda, MD
Disclosure Block: **B. Alleva:** None.
In humans, localization of DNA double strand breaks (DSBs) during meiosis is dependent upon the DNA-binding protein PRDM9. DSB targeting specificity is encoded by a hypervariable array of C2H2 zinc fingers, resulting in potentially countless alleles with different DNA recognition sites. Since *PRDM9* alleles have gross differences in recombination hotspot localization, systematic assessment of *PRDM9* diversity is important for understanding the complexity of population genetics and inheritance linkage patterns. However, due to the repetitive nature of *PRDM9*, large-scale genotyping is difficult. In addition, previous studies of *PRDM9* diversity disproportionately surveyed individuals of European descent and therefore a comprehensive survey of *PRDM9* across human populations has never been performed. To address these issues, we developed a high throughput long-read sequencing strategy to genotype *PRDM9* from 722 individuals across 7 populations composed of individuals from Asia, Africa, South America, and Europe. We detected 70 alleles including 34 novel alleles and 11 alleles previously identified in sperm suggestive of greater undiscovered *PRDM9* diversity. To assess potential relatedness between human *PRDM9* alleles, we developed an algorithm to infer sequence similarity between different alleles based on template switching as the mechanism for new *PRDM9* allele formation. Our relatedness analysis revealed that these alleles group into two major clusters around the most prevalent alleles, *PRDM9-A* and *PRDM9-C*. Importantly, by mapping DSBs in human testis we also found that individuals harboring small variations in PRDM9 can substantially alter the meiotic recombination landscape. In summary, our data expands our knowledge of *PRDM9* diversity in humans and demonstrates that minor *PRDM9* variants may play an under-appreciated role in shaping patterns of human recombination.

PrgmNr 3363 - Characterization of the Evolutionary Forces Acting on Genomic Regions Associated with over 600 Human Complex Traits

View session detail

Author Block: **A. LaBella**[1], A. Abraham[1], A. Rokas[1], J. A. Capra[2]; [1]Vanderbilt Univ., Nashville, TN, [2]Univ. of California San Francisco, San Francisco, CA
Disclosure Block: **A. LaBella:** None.
Natural selection has shaped the genetic architecture of many human traits. While the action of specific evolutionary forces on some traits has been identified, the role of different modes of selection across the human phenome remains poorly understood. Genome-wide association studies (GWAS) have greatly advanced our understanding of the genetic architecture of diverse complex traits. Meanwhile, genome-wide scans for diverse signatures of selection (GWSS) have also characterized the imprint of evolutionary forces, including different modes of selection, across the human genome. To address this gap, we developed an approach called MOSAIc that integrates these two approaches (GWAS + GWSS), enabling the investigation of signatures of diverse evolutionary forces on trait-associated genomic regions. Application of our MOSAIc approach to loci identified through a GWAS on spontaneous preterm birth revealed a mosaic of evolutionary forces acting on genomic regions associated with spontaneous preterm birth (LaBella, Abraham, *et al.* 2020, *Nature Comm.* 11: 3731). To gain broader insight into the diversity (or lack thereof) of evolutionary forces shaping complex human traits, we applied our MOSAIc approach to >600 GWAS on a multitude of complex human traits, including diseases across multiple domains, and 11 evolutionary metrics based on sequence constraint, populations differentiation, and allele age. For each trait, we characterized the enrichment of each evolutionary signal compared to matched control regions in the genome that account for linkage disequilibrium, allele frequency, and other confounders. This approach allows us to simultaneously assess the prevalence of multiple evolutionary forces on loci that underlie individual traits as well as between sets of loci that underlie distinct domains of traits. In my presentation, I will describe which forces are detected most frequently across all trait GWASs and within GWASs of specific trait domains. For example, on a subset of high-confidence GWAS we detect pervasive (42/44 traits) and statistically significant enrichments for sequence conservation at trait-associated loci across species and within human populations. I will also discuss several traits whose loci show unique patterns of evolutionary forces and how these results revise our thinking on the evolution of these traits and, more generally, of complex traits.

PrgmNr 3364 - Core promoter similarity in ancient and modern human and in chimpanzee genomes

View session detail

Author Block: **J. L. Dannemiller**; Rice Univ, Houston, TX
Disclosure Block: **J.L. Dannemiller:** None.
Background: Similarity between ancient and modern human DNA sequences has proved useful in understanding the evolutionary history of *Homo sapiens* including major events like *the Out-of-Africa (OoA)* migration. Modern DNA and aDNA sequence similarity probably differs systematically across functional elements within the genome (e.g., exons, promoter sequences, etc.). This study focused on the core promoter region (-50 to +49 bp re: TSS) in Reference and Ancient human genomes (Homo sapiens, *Hs*) as well as in the Chimpanzee (Pan troglodytes, *Pt*) genome. ***Methods:*** The ancient human genome was one of those published by Lipson et al. (2020): a child buried approximately 8000 years ago from the Shum Laka (Cameroon) archeological site. The Reference genome was assembly GRCh38, and the chimpanzee genome was Clint_PTRv2. A novel *follow-on* procedure was used to locate corresponding 100 bp sequences in the Modern and Ancient *Hs* genomes and orthologous sequences in *Pt*. One hundred bp sequences from -150 to -51 bp re: TSS from the Reference genome were used as targets; the Ancient *Hs* and the *Pt* genomes were searched for these targets. A match was declared if there were no more than 2 mismatched nucleotides for a given sequence. A *follow-on* region was then determined by shifting immediately 100 bp downstream: the region from -50 to + 49 bp re: TSS. These aDNA *Hs* and *Pt* core sequences were then compared to the corresponding Reference sequences. There is no purely statistical reason why a match from -150 to -51 bp re: TSS should yield a good match 100 bp downstream. Linkage Disequilibrium, would, of course, predict these to be good matches, but the point is to avoid computing similarity statistics using the target regions because of the biasing effects of the matching requirement. ***Results:*** The Chimpanzee core sequences were slightly better matches to the Modern Reference sequences than they were to the Ancient promoter sequences. Of a total of 893,800 sites compared, there were 363 additional single nucleotide differences between the Ancient and Chimpanzee genomes *vis-Ã -vis* the Chimpanzee/Reference comparison. When conditioning on a nucleotide difference between The Ancient and Modern sequences at a core promoter position, the Chimpanzee nucleotide at that position was more likely to match the Reference allele (67%) than the Ancient allele (29%). ***Conclusions:*** One explanation for these results is that the greater genetic diversity of African genomes relative to non-African genomes (e.g., the Reference) makes the latter more similar to the Chimpanzee outgroup genome. Another way to state this is that a population bottleneck is equivalent to moving a population backward in time toward the MRCA.

PrgmNr 3365 - Estimating average height among populations from polygenic risk scores

View session detail

Author Block: **B. E. Graham**[1], B. Plotkin[2], L. Muglia[3], J. H. Moore[4], S. M. Williams[2,5]; [1]Systems Biology and Bioinformatics, Case Western Reserve Univ., Cleveland, OH, [2]Population and Quantitative Hlth.Sci., Case Western Reserve Univ., Cleveland, OH, [3]Burroughs Wellcome Fund, Research Triangle Park, NC, [4]Dept. of Biostatistics, Epidemiology, & Informatics, Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, [5]Genetics and Genome Sci., Case Western Reserve Univ., Cleveland, OH

Disclosure Block: **B.E. Graham:** None.

The genetic basis of phenotypic variation across populations has not been well explained for most traits. Several factors may cause variability in incidence or prevalence, from differences in environments to divergent population genetic structure. We hypothesized that a population level polygenic risk score (PRS), based on common risk allele frequencies, can explain a substantial portion of phenotypic variation among geographic populations. We applied our population specific PRS (psPRS) to 26 populations from the 1000 Genomes to the phenotype height. For each population, we built a psPRS using the 4208 variants shown to associate with height in large GWASs. The psPRSs, in a linear regression model, explained a significant proportion of trait variance for height in men (r^2 = 0.32, p = 0.0026), but less in women (r^2 = 0.11 in women, which was not statistically significant). As not all variants in a PRS may confer similar, or even any, risk among diverse populations, we also performed a filtering algorithm to assess whether variance explained could be improved using psPRSs with fewer SNPs. Variance explained improved with fewer SNPs in the psPRS and was 0.99 for height in men, using only 548 of the initial 4208 SNPs. In women, the SNP pruning method yielded a set of 188 variants with a strong r^2 value of 0.98. The reduced psPRS models were highly significant in both sexes (p -16). That reducing the number of SNPs improves psPRS performance may indicate that missing heritability is partially due to complex architecture that is not additive, the existence of undiscovered population specific variants, or spurious associations in the current databases. We demonstrated that PRS-based analyses can be used across diverse populations for prevalence prediction when applied appropriately, and that these comparisons may be useful in identifying universal risk variants.

PrgmNr 3366 - FastRecomb: Fast inference of genetic recombination rates in biobank scale data using positional Burrows Wheeler transform

View session detail

Author Block: **A. Naseri**[1], W. Yue[1], S. Zhang[2], D. Zhi[3]; [1]Sch. of BioMed. Informatics, Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [2]Univ. of Central Florida, Orlando, FL, [3]Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX

Disclosure Block: **A. Naseri:** None.

An accurate genetic map, i.e. estimation of recombination rates along a chromosome is a foundation for genetic studies, including gene mapping, population genetics, and genealogical studies. Recombination rates are known to vary among populations, and thus estimation of population-specific genetic maps is important for advancing genetic research into diverse populations. A traditional approach to infer the recombination rates is to use genotype data from a large number of parent-offspring pairs to capture sufficient numbers of meiotic crossover events. However, collecting parent-offspring pairs can be a practical bottleneck. Another approach involves using population samples to compute the average rates of recombination events by implicitly considering the most recent common ancestor. Current methods using any of the approaches are not computationally efficient enough to handle biobank-scale cohorts comprising millions of individuals. As a result, a subset of the samples has to be selected which translates to losing useful information for inferring recombination rates. Here, we present a novel method using positional Burrows-Wheeler transform data structures and algorithms to identify potential recombination breakpoints in very large cohorts efficiently. The more individuals are available in a data set the more likely the calculated recombination rates are closer to the actual values. Since our method can be applied to samples of millions of individuals without requiring extensive computational resources, we expect that it will enable an accurate and population-specific estimation of recombination rates in diverse populations with the increasing availability of genetic data in large-scale cohorts.

PrgmNr 3367 - Flexible, scalable inference with tree sequences and Pyro

View session detail

Author Block: **W. Wohns**[1], Y. Wong[2], B. M. Neale[3], E. Bingham[1], F. Obermeyer[1]; [1]Broad Inst., Cambridge, MA, [2]Big Data Inst., Li Ka Shing Ctr. for Hlth.Information and Discovery, Univ. of Oxford, Oxford, United Kingdom, [3]Massachusetts Gen. Hosp., Boston, MA
Disclosure Block: **W. Wohns:** None.
Tree sequences encode the genealogical history of a sample of genomes and have been increasingly used as a platform for population genetic inference. However, existing approaches are based on traditional probabilistic methods that are optimized for specific problems and cannot scale to large datasets. Recent advances in deep probabilistic modelling and black box variational inference offer a more flexible approach. Here, we present a simple framework for tree sequence-based inference implemented in Pyro, a deep universal probabilistic programming language (Bingham et al. 2020). We demonstrate this approach using stochastic variational inference algorithms implemented in Pyro to jointly infer the age of coalescent events, past population size, mutation rates, and ancestral geographic location as continuous variables. We evaluate the accuracy of this method using coalescent and forward-time simulations, as well as with tree sequence topologies inferred with tsinfer (Kelleher et al. 2019). Our results are compared with methods including tsdate (Wohns et al. 2021) and Relate (Speidel et al. 2019). Where comparisons exist, our methods provide accuracy comparable with or superior to the state of the art, while scaling to the largest available datasets such as the UK Biobank.

PrgmNr 3368 - Guaranteeing unbiasedness in selection tests based on polygenic scores

View session detail

Author Block: **J. Blanc**, J. J. Berg; Univ. of Chicago, Chicago, IL
Disclosure Block: **J. Blanc:** None.
Population stratification is a well-studied problem in genome-wide association studies, leading to biases in the estimated strength of phenotypic association for individual genetic variants. In short, if environmental effects on the phenotype are correlated with ancestry gradients within a GWAS panel, any variant that is stratified along this ancestry gradient will receive a biased effect size estimate. While state of the art methods to correct for stratification are generally effective in reducing the number of significant false positive associations, even subtle biases in effect size estimates can accumulate across loci, leading to systematic biases in polygenic scores. In turn, these biases in the distribution of polygenic scores can lead to false positives in downstream analyses, such as tests for polygenic adaptation or other analyses of among group genetic differences. One approach is to attempt to be overly aggressive in controlling for stratification. However, there is currently no way to tell conclusively if confounding effects have been removed. A second approach is to conduct the GWAS in an evolutionarily diverged sample that is less likely to share population genetic structure with the test panel. This renders potential biases in the effect sizes irrelevant to the test, but comes at the cost of significantly reduced statistical power due to the issue of poor portability of polygenic scores across samples of divergent ancestry. Here using theory from population and statistical genetics, together with simulations, we show how this second approach can be generalized to panels that do share genetic structure, and that it is possible to guarantee the unbiasedness of selection tests without needing to guarantee that the effect sizes are fully unbiased. Specifically, if the researchers performing the GWAS also have access to the panel of test individuals and have identified the specific test to be performed ahead of time, then it is possible to compute a covariate to include in the GWAS, which will guarantee that the test is unbiased. Further, even when the test is not known prior to conducting the GWAS, our theoretical results provide a way to put a lower bound on the amount of stratification that would be needed to generate a positive signal of polygenic adaptation, and to assess whether the set of principal components that were included in the GWAS are sufficient to render the polygenic adaptation test unbiased. More generally, our results have implications beyond tests for selection as any analysis that attempts to quantify the correlation between polygenic scores and demographic or environmental variables is subject to the same type of stratification biases.

PrgmNr 3369 - GWAS on birth year infant mortality rates provides new evidence of recent natural selection

View session detail

Author Block: **Y. Wu**[1,2], S. Furuya[3], Z. Wang[4], J. E. Nobles[2,3], J. M. Fletcher[2,3,5], Q. Lu[1,2,4]; [1]Dept. of Biostatistics and Med. Affairs, Univ. of Wisconsinâ□□Madison, Madison, WI
Disclosure Block: **Y. Wu:** None.
Recent work on natural selection explores relationships between molecular genetic measurements and realized fitness in the next generation, highlighting the still-evolving nature of human populations. We advance this field by taking a novel approach that examines which genetic variants â□□disappearâ□□ as mortality exposure increases. Specifically, we deploy a â□□regional GWASâ□□ (N = 320,784) that links the county-level infant mortality rate (IMR) by place and year in the UK with genetic variants among birth cohorts in the UK Biobank. The IMR is a well-known indicator of the harshness of the environment during gestation and infancy. These cohorts (born between 1936-1970) saw a decline in IMR from above 65 to under 20 deaths per 1,000 live births, with substantial subnational variations and spikes in 1941 during wartime exposures. We identify two genome-wide significant loci *LCT* and *TLR1/6/10*, both of which are well-known selection targets in Europeans. The beneficial alleles at both loci are associated with higher IMR which is consistent with positive selection in tougher environments. Through analyses stratified in each birth year cohort, we found that effect sizes for both loci peak in 1941, demonstrating accelerated selection on these specific alleles in the UK during the mortality conditions caused by the World War II bombing campaigns during the Blitz. Significant genetic correlations are found across multiple domains, reinforcing earlier findings related to fertility, anthropometrics, and cognition and also extending findings into psychiatric conditions and health conditions. Our study directly gives a genome-wide tests on the shift in allele frequencies due to environmental change and provides fundamental new insights into the mechanism and timing of natural selection in a contemporary European population.

PrgmNr 3370 - Increasing Portability of Predictive Gene Expression Models Across Ancestral Populations Using Genetic Variant Fixation Indices

View session detail

Author Block: **R. Sale**; Vanderbilt Univ., Nashville, TN
Disclosure Block: **R. Sale:** None.
The advent of the 1000 Genomes Project has identified estimations of allele frequencies across ancestral populations for several genetic variants. Differences in allele frequencies across ancestral populations can create confounding problems when attempting to detect potentially causal genetic variants for disease such as in genome wide association studies (GWAS). Furthermore, several studies have also sought to interrogate how gene expression may vary across ancestral populations and have revealed that genetics plays an integral role in gene expression differences across ancestral populations. The ability to detect disease associated variants and, by extension, the ability to impute gene expression by leveraging the genetically determined component of gene expression using PrediXcan remains limited in non-European ancestral populations. In order to improve the ability to assess disease risk and impute gene expression levels for disease phenotypes in non-European ancestral populations, we generate polygenic risk scores (PRS) and gene expression prediction models using SNPs determined to be either cross-population or population differentiated. We calculate fixation index for variants from the 1000 Genomes project to determine whether a variant can be categorized as cross-population or population differentiated. SNPs determined to be cross-population can be utilized to build cross-population PRS and cross-population gene imputation models. These models may have decreased ability to predict disease risk and gene expression levels in European populations but have increased ability to predict disease risk and gene expression levels in non-European populations.

PrgmNr 3372 - The genetic diversity reduction due to background selection increases the disease prevalence under the liability threshold model

View session detail

Author Block: **X. Li**[1], J. J. Berg[2], J. P. Novembre[3]; [1]Committee on Genetics, Genomics & Systems Biology, Univ. of Chicago, Chicago, IL, [2]Univ. of Chicago, Chicago, IL, [3]Univ Chicago, Chicago, IL
Disclosure Block: **X. Li:** None.
How different evolutionary processes maintain phenotypic variation is an important question in human genetics. While the importance of background selection in shaping patterns of neutral genetic diversity is well-studied, its influence on the genetic architecture and the prevalence of complex disease is not well understood.
To address this, we extended the liability threshold model to include background selection. In the model, mutational pressure increases the liability while selection acts to reduce it, and the equilibrium disease prevalence arises due to a balance between the two forces. We found that when background selection is included, it alters this equilibrium by reducing the genetic variance for liability, which drives an increase in disease prevalence. To validate our theoretical results, we performed forward-time SLIM simulations and measure disease prevalence with varying intensity of background selection. We found scenarios where, for example, when the diversity reduction due to background selection is roughly 20% (as estimated in humans), the disease prevalence increases 10%.
Background selection also distorts the allele frequency spectrum at linked loci, as rare variants are less impacted.
To examine whether the distortion of the site frequency spectrum of liability sites changes the disease prevalence, we used simulation to vary the number of rare variants while controlling the genetic diversity reduction. Under the scenarios we examined, the degree of distortion of the site frequency spectrum due to background selection has no meaningful effect on disease prevalence.
From these investigations, we conclude that background selection can impact disease prevalence and does so primarily through overall levels of diversity and not its effect on the relative abundance of rare versus common variants.

PrgmNr 3375 - Addressing the Direct-to-Consumer Genetic Testing Knowledge Gap for Non-Genetics Healthcare Professionals

Direct-to-consumer genetic testing (DTC-GT) is a convenient method for people to obtain genetic information. Over nine million individuals have used DTC GT services in the U.S., and primary care and specialty physicians are now encountering patients with questions regarding their DTC-GT results. In a recent survey of Kaiser Permanente physicians, 35% of respondents reported that patients had shared their DTC-GT results with them in the past year. Despite the growing need to manage these patient questions, only 12% of surveyed primary care physicians agree that physicians have sufficient knowledge to help patients understand the results of DTC-GT. In a survey of consumers who shared DTC-GT results with their doctors, 27% disagreed with the idea that their physician understood genetics enough to advise them on the implications of their DTC-GT results. Due to this perceived lack of knowledge, many healthcare professionals are reluctant to tackle genomic medicine in their clinical practice and would seek opportunities to enhance their genomic knowledge. The National Human Genome Research Instituteâ□□s Inter-Society Coordinating Committee for Practitioner Education in Genomics (ISCC-PEG)/ / DTC-GT Project Group consists of a spectrum of genetics professionals who aim to improve the genomic literacy of healthcare professionals and enhance the effective practice of clinical genomic medicine in the area of DTC-GT. The ISCC-PEG DTC-GT Project Group has created a Direct-to-Consumer Genetic Testing for Healthcare Professionals Frequently Asked Questions (FAQ) to be housed on Genome.gov. Non-genetics healthcare professionals were surveyed about the FAQ. They found the FAQ content useful, but remarked that it would be difficult to navigate in real time during a clinical encounter. In addition to the FAQ, the DTC-GT Project Group has participated in the 2021 NHGRI Healthcare Provider Genomics Education Week, presenting an educational webinar and short YouTube videos about DTC-GT. The Project Group is also developing a point-of-care tool for healthcare professionals to facilitate an outpatient encounter pertaining to DTC-GT . The Project Group then created 11 DTC-GT patient scenarios, each of which were used to validate the DTC-GT point-of-care tool. The point-of-care tool has now been implemented in the Qualtrics software, as a proof of concept, with the intention to develop a mobile app/website that can support healthcare professionals as they respond to their patients queries about DTC-GT results. Products and outcomes from the DTC-GT Project Groupâ□□s work will be presented.

PrgmNr 3376 - BorderDNA Resources Project: Strategies for the development and disseminationof educational materials on nonmedical DNA applications in immigration contexts

View session detail

Author Block: **N. Mendoza**[1], A. Larson[2], D. J. Madden[3], S. H. Katsanis[4], Z. Guzman[5]; [1]Oberlin Coll., Oberlin, OH, [2]Northwestern Univ., Evanston, IL, [3]Ann & Robert H. Lurie Children's Hosp. of Chicago, Chicago, IL, [4]Lurie Children's Hosp., Chicago, IL, [5]Anne & Robert H. Lurie Children's Hosp., Chicago, IL
Disclosure Block: **N. Mendoza:** None.
DNA testing and collection are increasing a part of U.S. immigration policies, particularly at the border with Mexico. Confusion on the part of stakeholders and the public around the overlapping uses of DNA data are common. Mis- and disinformation are evident in news coverage and social media discussion on these topics, which could be fueled by political differences on immigration. The BorderDNA Resources Project is an academic working group formed to provide unbiased information on DNA uses in U.S. border contexts. We create and disseminate resources on nonmedical DNA applications for journalists, scientists, government officials, migrant families, and the general public. The working group began with pre-identified points of confusion on three specific DNA applications: (A) DNA as used for investigation of transnational missing persons; (B) detainee DNA collection for the federal DNA database CODIS; and (C) DNA tests to verify family relationship claims at the border. We created a master menu to guide the development of products and outreach strategies for each point including audience, product type (infographic, pamphlet, or video), outlet, and language (English, Spanish, or bilingual). We identified eight products on the three topics, including animated videos, infographics, and print materials. We developed product content tailored to the anticipated audience and outlet, keeping in mind sensitivities of the information. To ensure products were unbiased and suitable for distribution, draft products were shared with potentially biased but contrasting representative experts (e.g., NGOs, government, commercial vendors) for feedback. Products were further refined to incorporate feedback. Two finalized infographics were scheduled to be shared three times via the BorderDNA Twitter and Instagram accounts to test our content development and dissemination strategies. Infographics were formatted for publication on each social media platform. Each of the re-posts were altered with variations in captions, direct mentions, and hashtags to test audience engagement. We then assessed the engagement types and levels monitoring audience responses. Early posts showed limited engagement due to the nascent social media account with only one comment outside the study team and a plateau of engagement three days after publication. Additional infographics, print materials, and animated videos are under development. Our strategies to develop and circulate unbiased educational products on nonmedical DNA applications will help inform science communication strategies in other areas with political charge, complex content, and diverse stakeholder groups.

PrgmNr 3377 - Evaluation of genetic services in the care for adults with tetralogy of Fallot

View session detail

Author Block: **S. Estes**[1], L. Wetherill[2], L. W. Markham[3], S. M. Ware[2], B. M. Helm[1], J. S. Needleman[4], M. Sabra[4], J. Herber[3], G. Ephrem[4], K. Spoonamore[4], S. M. Fitzgerald-Butt[2]; [1]Dept. of Med. and Molecular Genetics, Indiana Univ., Indianapolis, IN, [2]Indiana Univ., Indianapolis, IN, [3]Div. of Pediatric Cardiology, Riley Hosp. for Children at Indiana Univ. Hlth., Indiana Univ. Sch. of Med., Dept.s of Pediatrics and Med., Indianapolis, IN, [4]Krannert Inst. of Cardiology, Dept. of Med., Div. of Cardiology, Indiana Univ. Sch. of Med., Indianapolis, IN

Disclosure Block: **S. Estes:** None.

Background: While prior studies have investigated the prevalence of underlying genetic conditions in adult congenital heart disease (ACHD) patients with tetralogy of Fallot (TOF), no studies have sought to determine the extent to which current guidelines for inclusion of genetic services and genetic testing are being implemented. The most common syndromic cause of TOF is 22q11.2 deletion syndrome (DS), and most babies born with TOF are routinely screened for 22q11.2 DS. However, because most genetic evaluations are conducted in infancy, there remains a potential gap in care for adult patients born with TOF prior to routine genetic testing for this condition. As a result, American Heart Association ACHD care guidelines recommend testing for this deletion in patients with conotruncal CHDs, of which TOF is the most common. **Methods:** We conducted a retrospective chart review of ACHD patients with TOF seen in cardiology clinic during a 5-year period, 2015-19, via examination of cardiac and genetics-related clinic documentation available in the electronic health record. We determined the proportion of patients who had genetic services and genetic testing for 22q, and Fisher's exact tests were used to assess for association between these and patient year of birth (YOB), medical history, and clinical factors. A *p*-value Results: Of the 299 patients, 54 (18%) had received genetic services and 18 (6%) had documented testing for 22q11.2 DS. While patient YOB was not associated with genetic services/testing, developmental/cognitive issues, dysmorphic facial features, extracardiac physical anomalies, biological sex, and other health histories (seizures, nasal speech, and/or hearing/vision loss) were associated with genetic services/testing. When the above variables were analyzed together via a logistical regression model, developmental/cognitive issues, dysmorphic facial features, and extracardiac physical anomalies were significantly associated with having received genetic services/testing. **Conclusion:** Despite current guidelines for genetic testing in all patients with conotruncal CHDs, it is clear that traditional indicators of a syndromic presentation still drive the majority of genetic services/testing in this ACHD population. This is an opportunity for expansion of genetic services/testing to this population as understanding the genetic etiology of TOF in adults can significantly impact their medical screening as well as their reproductive/family planning.

PrgmNr 3378 - Exploring the Use of Family Health History in Black Communities in the Deep South

Family health history (FHH) is an underutilized tool with the potential to influence health behavior within the family context. Family health communication channels within Black families may be an existing pathway to influence health behaviors related to diseases with a strong genetic link. The Families SHARE workbook is a tool designed to encourage communication of family health history about diseases that have a familial pattern. The tool is used to calculate risk and provides recommendations for heart disease, type 2 diabetes, colon, breast, and prostate cancer. Black populations living in southern regions of the United States have high incidence and mortality rates for the diseases included in the Families SHARE workbook. Here, we aimed to evaluate usability and acceptability of the Families SHARE workbook and explored the potential use of the tool to increase awareness of FHH in Black adults living in the southern region of the United States. In addition, we examined if the workbook could improve awareness of family genetic risk information and encourage prevention behaviors in Black adults living in the southern region of the United States. A mixed methods approach was used to evaluate associations and outcomes by evaluating overall workbook use and differences in the workbookâ□□s usability, cognitive and behavioral impact in Black adults living in North Florida. A total of 62 participants completed baseline surveys and 49 participants completed follow up surveys. A total of 10 participants completed semi structured interviews on workbook use and disease awareness. Overall, 79% of participants indicated the ability to use the workbook. Workbook usability outcomes show that eighty-five percent of participants were able to able to assess their own degree of risk. Black women were more likely to share the workbook with others (65% vs.20%; p<.05 and were more likely to be able assess a family members degree of risk vs. p compared black men. an independent samples t-test was conducted examine cognitive behavioral outcomes differences in communication after receipt the families share workbook. participants that understood sd="2.351);" t="2.073" communicate about disease this study shows populations living south may effectively use workbook understand fhh information with for chronic diseases. next steps will seek usage combined sample.>

PrgmNr 3379 - Genetic service provision for men with prostate cancer within a safety-net setting: A qualitative study

View session detail

Author Block: **E. Li**[1], C. Wang[2], G. A. Gignac[1], K. Zayhowski[3], M. Pankowska[1], C. M. Gunn[1,2]; [1]Boston Univ. Sch. of Med., Boston, MA, [2]Boston Univ. Sch. of Publ. Hlth., Boston, MA, [3]Boston Med. Ctr., Boston, MA

Disclosure Block: **E. Li:** None.

Recent changes to the Prostate Cancer Early Detection National Comprehensive Cancer Network Guidelines have expanded the criteria for genetic testing, increasing the number of patients who are eligible for cancer genetics services. Data from large cancer centers indicate that only 40-44% of oncologists have provided referrals to genetic germline prostate cancer genetics care (Loeb et al., 2020; Paller et al., 2019). Less is known about the provision of prostate cancer genetics services within safety-net settings, where resource constraints may impact access for patients. Through purposive sampling of providers who facilitated cancer genetics care at a large, urban safety-net institution, we conducted semi-structured telephone interviews with 15 health care providers (physicians, nurse practitioners, physician assistants, and genetic counselors) from medical and radiation oncology, urology, cancer genetics, and primary care. Facilitators and barriers to delivering genetics care were identified at the patient, provider, and health system levels. At the patient level, providers perceived that patientsâ health knowledge, trust, and attitudes towards genetic testing affected uptake of referrals. Provider-level factors focused on the perceived utility of genetics information for clinical care, knowledge of rapidly changing genetics guidelines, and perceived ability of patients to pay for genetics services. Systems-level barriers included the lack of technological infrastructure to identify potentially eligible patients to cancer genetic counseling, a need for increased staff capacity to facilitate patient completion of genetic testing (i.e., genetic counselors and navigators), and lacking provider education to promote genetics care. Provider-identified opportunities to improve genetics care encompassed the need to 1) establish an identification and referral system to cancer genetics by augmenting institutional medical record systems, 2) increase in the number of personnel to support genetic counseling services, and 3) create tools to enhance patient and provider genetics knowledge. Within a safety-net setting, it is important for providers who facilitate germline genetics care for patients with prostate cancer to understand and respond to the unique needs of their patient community and pursue opportunities that mitigate barriers to accessing genetic services.

PrgmNr 3380 - Genetic-first diagnoses and disease predispositions: Implications for follow-up care

View session detail

Author Block: **C. Jodarski**[1], A. Katz[2], M. Kamen[1], M. Setzer[1], J. Yan[1], L. Jamal[3], K. Jevtich[1], Y. Yu[1], B. Seifert[1], R. Ghosh[1], S. Holland[1], M. A. Walkiewicz[1], M. Similuk[1]; [1]Natl. Inst. of Allergy and Infectious Diseases, Bethesda, MD, [2]Natl. Human Genome Res. Inst., Bethesda, MD, [3]Natl. Cancer Inst./NIH Clinical Ctr. Dept. of Bioethics, Bethesda, MD
Disclosure Block: **C. Jodarski:** None.
As genomic testing, including sequencing and microarray, becomes more common in clinical practice, so will receiving a â□□genetic-firstâ□□ result. We define this result as a likely pathogenic or pathogenic variant in a gene that is unrelated to the primary indication for testing, which can include a secondary finding (SF) from the ACMG gene list. Such results offer the opportunity for early intervention, but due to the difficulty of clinical interpretation in seemingly asymptomatic individuals, the value varies by case. Here we present a series of â□□genetic-firstâ□□ cases from our clinical research at the National Institute of Allergy and Infectious Diseases that emphasize the nuances of such findings: Exome sequencing (ES) was performed on a 12-year-old male with *CYBB*-related chronic granulomatous disease, who also had feeding difficulties and ADHD. A likely pathogenic *OTC* variant was detected, which is a cause of OTC deficiency and a possible explanation for some aspects of this patientâ□□s history. Subsequent biochemical testing was normal. The recommended follow up included repeat biochemical testing during active illness but not dietary modification. This case underscores that a SF sometimes only infers a risk state and does not necessarily lead to a clinical diagnosis or active disease mitigation. A 46-year-old female underwent ES as part of a trio-based analysis for her sonâ□□s phenotype. Her medical history was unremarkable, and family history included a sister with melanoma and a father with metastatic lung cancer. ES identified a pathogenic variant in *TP53*, which is associated with Li-Fraumeni syndrome (LFS). Based on her personal and family history, she was unlikely to have been identified as at-risk for LFS. However, due the identification of this SF, she can receive appropriate screening and management and alert at-risk relatives. A 5-year-old female, noted to be â□□clumsyâ□□, presented for disseminated coccidioidomycosis with brain and pulmonary involvement. ES and microarray detected a 1.330 Mb gain at 17p12 consistent with a molecular diagnosis of Charcot-Marie-Tooth disease that was supported by subsequent nerve conduction studies. Without genetic testing, her peripheral neuropathy could have been misinterpreted as a worsening of her infections. Learning of this result early in her disease course allows for proactive management of her neuropathy. These cases highlight opportunities and challenges of â□□genetic-firstâ□□ results. As genomic approaches become better integrated into clinical practice, thoughtful evaluation and tailored follow-up care will be essential in translating such findings into meaningful recognition and mitigation of disease.

PrgmNr 3381 - Grandmothers save the day: The power of grandmothers to improve care of families with history of cardiomyopathy

View session detail

Author Block: **S. M. Fitzgerald-Butt**, K. Spoonamore, B. Helm, K. Schmit, N. Gralia, E. Geddes, S. M. Ware, J. J. Parent; Indiana Univ., Sch. of Med., Indianapolis, IN
Disclosure Block: **S.M. Fitzgerald-Butt:** None.
Obtaining an accurate, targeted family history (FH) is critical to informing high-quality care for patients being evaluated for personal or FH of cardiomyopathy. This can take substantial time, prompting genetic counselors to seek alternative solutions to gather FH information prior to the multidisciplinary clinic appointments including forms (paper or electronic), chatbots, and/or phone calls. While much energy has been devoted to gathering this pre-clinic FH information, for select patients, there is a benefit to gathering FH information post-clinic. We present a series of three pediatric patients for whom obtaining additional FH information from a grandmother following the initial encounter improved the patientâ□□s/familyâ□□s care. The first patient had a known diagnosis of familial dilated cardiomyopathy (DCM) and reported his sister and father, both deceased, had DCM. While we were aware of the sisterâ□□s DCM diagnosis, a discussion with the maternal grandmother surprisingly uncovered the father did not have DCM. Rather, the maternal FH included multiple relatives with history suspicious for DCM, sudden death, cardiomyopathy, and even heart transplant. The second patient had a maternally-inherited pathogenic variant associated with hypertrophic cardiomyopathy (HCM) identified as a secondary finding on exome sequencing and reported no FH of HCM. Upon contacting the maternal grandparents to arrange cascade genetic counseling/testing, the grandmother reported she previously had a mildly abnormal chest x-ray and EKG for which follow-up was not recommended, her brother had died suddenly after being told he had â□□heart problemsâ□□ and suspicious histories in her father and paternal uncle. The grandmother shared the familial variant and her cardiac evaluation revealed HCM. The last family, while knowledgeable of their significant paternal FH of DCM, were unaware that the great-grandfather had completed genetic testing that identified a likely pathogenic variant. Following a discussion with the grandmother, who allowed access to her medical records, we learned of the specific variant for which she had received counseling but not testing. It was discussions with grandmothers which informed screening and genetic testing recommendations for the correct side of the family, identified an affected individual related to a secondary finding, and enabled targeted genetic testing in each of these respective families. Post-clinic collection of FH information, especially from grandparents, is a useful endeavor. Resources to support these efforts are valuable for genetic counselors.

PrgmNr 3382 - Integrating Ethical, Legal, and Social Implications (ELSI) considerations in the *All of Us* Research Program:Experiences of the ELSI Brain Trust

View session detail

Author Block: **S. Chandrasekharan**[1], S. Sodeke[2], R. Isasi[3], L. Beskow[4], J. Reusch[5], B. Berkman[6], K. Blizinsky[1], The All of Us ELSI Brain Trust; [1]The All of Us Res. Program/NIH, Bethesda, MD, [2]Tuskegee Univ., Tuskegee, AL, [3]Univ. of Miami Miller Sch. of Med., Miami, FL, [4]Vanderbilt Univ. Med. Ctr., Nashville, TN, [5]All of Us Res. Program, NIH, Bethesda, MD, [6]NIH, Bethesda, MD
Disclosure Block: **S. Chandrasekharan:** None.
From its inception, the *All of Us* Research Program has looked critically and prospectively at ELSI considerations, starting with its core values and in its stance toward inclusion, diversity, and participant engagement. The program strives to increase geographical and demographic diversity, while committing to repairing and building trust with groups and communities who have suffered historical harms from, or have been under-represented in, biomedical research (UBRs). It also endeavors to provide diverse and rich data--including genomic, health, social, environmental, and lifestyle data--to foster precision medicine research that advances health and well-being for all. The programâ□□s strong focus on inclusion of individuals from racial and ethnic UBR groups, specifically, aims to alter persistent trends in genomic studies that predominantly include individuals of European ancestry and urban, high socio-economic status groups. This ethos of meaningful, longitudinal inclusion combined with collecting multi-dimensional data from highly diverse populations at a national scale, raises familiar and new ELSI, policy, and regulatory issues. These include scenarios where there are variations in policies and best practices among research initiatives and gaps in knowledge pertaining to these diverse populations. Responsively, the program created an internal working group, the ELSI Brain Trust (EBT), to deliberate on ELSI issues in a timely and contextual way, and inform the programâ□□s design, implementation, and policy development. In this presentation we will provide background on the programâ□□s overall approach for conducting precision medicine research in a diverse cohort and returning genetic results in ways that respect participantsâ□□ choices and enable voluntary decision-making. Using examples of EBT consultations, we will describe ELSI considerations that emerge in areas such as (1) inclusion of vulnerable groups (children and those with decisional impairment), (2) protecting participants and preventing harm while making annotated genomic sequence and sensitive data available to a wide range of research users, and (3) evaluating and continually improving the programâ□□s processes for responsible return of results. We will also share insights from using a consultation model that embeds the EBT within the program, and enumerate potential future challenges, particularly ELSI considerations for emerging areas in genomic research (e.g., use of AI/ML and returning polygenic risk scores).

PrgmNr 3383 - Measuring genetic literacy through familiarity, skills, and knowledge: A longitudinal assessment

View session detail

Author Block: **I. Little**[1], L. Koehly[1], C. Gunter[2]; [1]Natl. Human Genome Res. Inst., Bethesda, MD, [2]NIH, Bethesda, MD
Disclosure Block: **I. Little:** None.
As genomic and personalized medicine is integrated into healthcare, the need for patients to understand and make informed decisions about their genetic risk information increases. Genetic literacy, or oneâ□□s knowledge of genetic principles and their applications, measures an individualâ□□s ability to apply genetic information to their life, including their health. Increased genetic literacy can improve comprehension of genetic tests and therefore increase participation in healthcare services to detect and treat genetic disorders. Increased genetic literacy on both sides can also improve patient-provider communication in this new era of precision medicine. However, measures for genetic literacy vary widely and often assess genetic knowledge exclusively. Because current literature indicates that the populationâ□□s genetic literacy is generally low, there is a need to adequately measure genetic literacy to identify potential gaps and education strategies. A 2015 paper adapted previous surveys into a new measure that assesses genetic literacy in three facets aimed to mirror the way individuals learn new concepts in everyday life. We replicated this measure by distributing a comprehensive survey to a nationally representative sample of 2050 individuals, assessing genetic literacy in the same three facets: familiarity with genetic terms (e.g. heredity, sporadic); accuracy in genetic knowledge (e.g. Is a gene bigger than a chromosome?); and sufficient skills to synthesize information applying genetic information to human health (e.g. What is the purpose of genetic testing?). Results indicated that genetic literacy increased over time. Participants reported only moderate familiarity with genetic terms on a 1 - 7 scale (M = 5.28, SD = 1.38) though it was significantly higher than 2015 (p

PrgmNr 3384 - Patient perspective on return of incidental findings in Africa

Disclosure Block: **S. Prochaska:** None.

Objective: Orofacial clefts (OFCs) are the most common birth defects of the head and neck region, affecting 1 out of 700 live births worldwide. OFCs lead to significant financial, educational, medical, psychological, and cultural problems and may require treatment throughout life. Whole genome sequencing (WGS) is a cost-effective way to identify causal variants across the genome for families with OFC. Our group has generated data from the first WGS effort for OFC in African population. WGS data also provides an opportunity for the identification of secondary findings like sickle cell anemia, G6PD deficiency, and other single gene disorders that may impose medical implications for those in the study or their family members. Secondary findings may impose some burden on families. Therefore, the objective of this study was to determine how to manage incidental findings in a resource-limited setting by determining the interest of OFC families in receiving incidental genetic information and medical risks, including possible identification of infectious disease and the outcomes of those who choose to be informed.**Methods:** In December of 2020, a Qualtrics survey was administered to recruited families from cleft-craniofacial clinics in Ethiopia, Ghana, and Nigeria.**Results:** In the results of the survey as of April 30th, 2021, 109 individuals completed the survey. 93 participants had a household total family income of less than $10,000 (USD). A total of 101 agreed or strongly agreed that they would want to know about secondary findings, 7 did not agree nor disagree, and 1 strongly disagreed. When asked if they felt that there were currently available resources that allowed them to access genetic information that they wanted to know, 10 agreed and 99 disagreed.**Conclusion:** In this pilot, the biggest barrier that we observed was access to genetic information at the OFC clinics in Africa. The validated survey assessed patientâ□□s willingness to receive information regarding secondary findings and available resources in Africa to deal with secondary findings. This is the first ELSI study to document the interest of participants in OFC studies in incidental genetic information and medical risks in an African population.

PrgmNr 3385 - Patients demonstrate high motivation to enhanced cancer screening following genetic counselling

View session detail

Author Block: **K. Stafford**, C. Jani, O. Al Omari, H. Singh, L. Agarwal, A. Dar, M. Lotz, A. D'Angelo, P. B. Lam; Mount Auburn Hosp., Cambridge, MA
Disclosure Block: **K. Stafford:** None.
Background: Early cancer screening has been shown to reduce morbidity and mortality in patients at high risk of cancer. High-risk personal or family history of cancer is usually used as a screening tool to help identify individuals who will benefit from more accurate risk stratification with genetic testing for hereditary cancer syndromes. In this retrospective observational study, we sought to characterize the indications, resulting recommendations, and patient response to the results of genetic counselling.
Methods: We included patients undergoing genetic testing at our hospital between January 2018 and October 2020 (N=237). Medical charts were reviewed to identify patient characteristic, family history, indication for genetic testing, genetic findings, and subsequent management.
Results: Our population had a mean age of 52.5 years (SD=14.8) and was predominantly female (93.4%). The vast majority (195, 82.3%) had a family history of cancer, while 113 (47.7%) had a personal history of cancer, most commonly breast (n=87). Most of the patients met criteria for genetic testing through Hereditary Breast and Ovarian Cancer criteria (n=226, 95.4%). Of the 235 tested, 36 were found to have deleterious mutations (15.3%). The most common resulting recommendation was initiation of yearly breast MRI alongside yearly mammograms (n=100, 42.5%). Other common screening tools implemented included pancreatic cancer screening with MRCP and EUS (n=24, 10%), early initiation of colonoscopy and endoscopy screening (n=20, 8.5%), yearly skin exams (n=10, 4.2%), and initiation of prophylactic hormone therapy for breast cancer (n=10, 4.2%). Several patients had already undergone mastectomy or oophorectomy, however 9 patients (3.8%) were recommended oophorectomy, and 3 (1.2%) were recommended mastectomies. Sixty-two patients (26.4%) were recommended to continue ongoing oncology care while 37 (15.7%) were advised to continue with PCP follow-up and routine screening. Overall, recommendations were well received with 97.5% (n=231) of patients stating intent to follow-through with recommendations.
Conclusions: Enhanced cancer screening recommendations were well received by patients following consultation in a high-risk cancer clinic, with 97.5% intending to follow-through with cancer screening recommendations. Among patients who underwent genetic cancer testing, 15.3% were found to have a pathogenic mutation.

PrgmNr 3386 - Recruitment of diverse participants into a trial of polygenic risk scoring: Enrollment metrics and reasons for decline in the Genomic Medicine at VA (GenoVA) Study

View session detail

Author Block: **A. Antwi**[1], N. Jones[1,2], N. Alexander[1], C. Brunette[1], E. Harris[1,2], J. L. Vassy[1,2,3]; [1]VA Boston Hlth.care System, Boston, MA, [2]Harvard Med. Sch., Boston, MA, [3]Brigham and Women's Hosp., Boston, MA

Disclosure Block: **A. Antwi:** None.

Background: People of non-European ancestry continue to be underrepresented in genomic research despite significant advancements made over the past two decades. Improving the diversity of participants in genomic medicine research is vital to ensuring existing health disparities are not further exacerbated. Here, we present the early results of an enhanced-diversity recruitment strategy for the GenoVA Study.

Methods: The GenoVA Study is a randomized trial of polygenic risk scoring (PRS) for 6 common diseases. Eligible participants are patients of the VA Boston Healthcare System (VABHS) aged 50-70 years without prior diagnosis of atrial fibrillation, coronary artery disease, type 2 diabetes, colorectal, breast, or prostate cancers. Study staff identify potentially eligible participants via electronic health record data query, mail recruitment letters with an opt-out option, confirm study eligibility and obtain informed consent by phone. Non-white, Hispanic, and female participants are oversampled for recruitment to increase enrollment of underrepresented populations at VABHS. Study staff collect reasons for declining participation during the initial phone call. Consented participants provide a biospecimen for PRS calculation and interpretation from a CLIA-certified laboratory.

Results: The GenoVA study aims to enroll 1,074 participants. As of June 7, 2021, a total of 10,501 patients across VABHS were deemed eligible for study participation. Of these, 3040 patients have been contacted, 2797 patients were reached by phone, 2333 did not opt out of recontact, and 395 consented to participation. Of the first 382 enrolled patients, mean (SD) age at enrollment is 59.5 (5.5) years, 32% are women, and 38% are Hispanic or non-white, compared to 12% of women and 14% of Hispanic or non-white patients in the eligible VABHS population overall. Among the 542 participants who actively declined participation, common reasons included having no interest (n=202), time constraints (n=113), health reasons (n=44), disliking research studies (n=28), personal reasons (n=25), not wanting to learn about their genetic information (n=23), privacy or security concerns (n=19), VA or government-specific reasons (n=19), and emotional distress or anxiety about receiving genetic results (n=12).

Discussion: The characteristics of the first GenoVA Study enrollees demonstrate the success of an enhanced-diversity recruitment strategy. As clinical PRS results are now being returned to participants, this greater representation of underserved populations will help to expand the equitable reach of genomic medicine research.

PrgmNr 3388 - Should laboratories report small regions of homozygosity?

View session detail

Author Block: **N. Urraca**[1], S. Holtrop[2], R. Mostafavi[3], L. Holly[1], K. Bosfield[1], J. C. Ward[1], C. W. Brown[1], E. K. Pivnick[1]; [1]Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN, [2]Le Bonheur Children's Hosp., Memphis, TN, [3]St. Jude Children's Res. Hosp., Memphis, TN

Disclosure Block: **N. Urraca:** None.

SNP-array is often used as a first tier test in clinical genetics evaluations and may incidentally identify regions of homozygosity (ROH). Reporting thresholds differ among labs, with most reporting ROH â¥5 Mb. Multiple ROH may suggest identity by descent (IBD) and increased risk for autosomal recessive (AR) disorders in offspring, while a single ROH could be due to segmental uniparental disomy (UPD) or distant consanguinity. While autozygosity mapping in all cases of ROH can aid in identifying genes responsible for disease, genetic counseling for UPD differs from counseling of consanguineous couples regarding potential psychosocial effects, risk of AR conditions in offspring and risk of recurrence. We present 3 cases in which SNP-array initially reported a single ROH >5 Mb, but multiple ROH of 2-5 Mb were found upon closer examination. **Case 1**: 2-day-old with multiple congenital anomalies. SNP-array revealed a 7.67 Mb ROH on chromosome 17. Further analysis detected multiple ROH Case 2: 21 month old with global developmental delay, coarse facies, tachypnea and abdominal distension. MPS urine and enzyme studies were non-diagnostic. SNP-array reported a 5.74 Mb ROH at 1p36.12, which included *FUCA1,* the gene associated with fucosidosis. Parents were from the same small city but denied consanguinity. Upon request, the clinical lab identified a total of 50 Mb of smaller ROH, indicating IBD. **Case 3**: newborn with an extended cystic lymphangioma. A 6 Mb ROH on chromosome 16 was initially identified. Four additional ROH

PrgmNr 3389 - Strategies to increase clinicians in medical genetics: Establishing a pipeline to attract and prepare diverse clinical researchers

View session detail

Author Block: **D. Murray**[1], S. D. Fernbach[2], L. C. Burrage[1], R. Sutton[1], B. Lee[1]; [1]Baylor Coll. Med., Houston, TX, [2]Baylor Coll. of Med., Houston, TX
Disclosure Block: **D. Murray:** None.
In 2014, analyzing Association of American Medical Colleges (AAMC) data, the NIH Physician-Scientist Workforce Working Group reported that within the last few decades, there had been a steady decline in physicians conducting research 5.5% since 2003, along with a lack of diversity in the physician-scientist workforce. The medical genetics residentsâ data in the Molecular & Human Genetics (MHG) department indicates a minimal number of underrepresented groups in the Internal Medicine and Pediatric Genetics tracks. These data underscore the critical need to attract more underrepresented in medicine (UiM) trainees to the scientific and clinical enterprise. In the past three years, the MHG department focused attention on attracting and preparing underrepresented groups to develop and provide innovative training principles to provide UiM researchers the knowledge and ability to apply genetics and genomics to a range of healthcare conditions paving the way to increase health equity. We devised a recruiting strategy to attract and prepare UiM interested in genetics from three sources: (1) those found in our learning environment (summer interns), (2) college campuses, and (3) medical schools. In 2019, a Lunch and Learn seminar was created to introduce genetics and genomics careers to the undergraduate summer students training in MHG laboratories. The following summer, we created the virtual Genetics and Genomics Careers (GGC) series to reach undergraduates around the country and introduce them to these careers. From the three webinars, the following data were collected: 72 students attended, from 4 Texas high schools, 23 U.S. universities, one each from the United States Air Force (USAF) and M.D. Anderson Cancer Center. In addition, we offered a townhall to medical students around the country to learn and discuss the medical genetics pathway. The virtual townhall attracted 54 medical student attendees, with survey respondents from 10 states. Lastly, we wanted to reach first-year medical students to introduce the medical genetics career and recruit for a new summer research internship. In 2021, we visited 1st-year medical students at Meharry Medical College and did outreach activities at the University of Texas - Rio Grande Valley. We recruited two students to the Clinical Research Education Training Program. Employing multiple recruiting strategies demonstrated that underrepresented undergraduate and medical students have an interest in genetics and genomics careers.

PrgmNr 3390 - The Texome Project: Special considerations for developing a rare and undiagnosed disease program for underserved communities in Texas

View session detail

Author Block: **T. Nguyen Dolphyn**[1,2], C. A. Bacino[1,3,4], C. M. Eng[1,4], P. Liu[1,4], Z. Liu[1,2], S. Yamamoto[1,2,5,6], M. F. Wangler[1,2,5], H. J. Bellen[1,2,5,7]; [1]Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, [2]Jan and Dan Duncan Neurological Res. Inst., Texas Childrenâ□□s Hosp., Houston, TX, [3]Texas Children's Hosp., Houston, TX, [4]Baylor Genetics Lab., Houston, TX, [5]Program in Dev.al Biology, Baylor Coll. of Med., Houston, TX, [6]Dept. of NeuroSci., Baylor Coll. of Med., Houston, TX, [7]Howard Hughes Med. Inst., Houston, TX

Disclosure Block: **T. Nguyen Dolphyn:** None.

The Undiagnosed Diseases Network (UDN) has exemplified the role genomic medicine can play in solving medical mysteries and providing families with much needed answers. Due to a number of factors, however, underserved populations and ethnic minorities have not always benefited as fully from large-scale genomics research and the benefits of genomic medicine in general. The Texome Project is a new research program leveraging the study teamâ□□s experience and success in clinical evaluations, sequencing, bioinformatics, and functional studies to implement and expand the reach of personalized genomics and medicine to diverse populations within Texas. Specifically, the program aims to help minority and underserved individuals with low socioeconomic status who have an undiagnosed, suspected genetic disease. To reach a socioeconomically and ethnically diverse cohort, patients and families are recruited through a multi-faceted strategy that includes community outreach and education, partnership with diverse physicians and local community hospitals, and a systematic chart review within the Texas Childrenâ□□s Hospital system to identify patients with public insurance (e.g. Medicaid) and genetic testing denial. Rather than requiring extensive genetics workup or medical record review as criteria for study enrollment, this program reduces barriers by interfacing with providers and families directly to focus on diagnostic needs. Embedded within the study design is a streamlined process to facilitate physical examination, DNA collection, genetic testing and counseling, and return of results, all with telemedicine options to ease logistical or transportation burden for patients. Longitudinal follow-up appointments over 2 years provides patients who remain undiagnosed with access to further bioinformatics analyses and genomic match-making. The follow-up also allows for examination of patient outcomes, medical management, and patient and family attitudes towards genomic medicine whether they receive a diagnosis or not. We have developed a protocol for the Texome Project that is sensitively designed to collect reliable outcome data to explore and understand the barriers and facilitators of implementing genomic and precision medicine in a diverse population. We anticipate this project will highlight the need and value of including underserved and underrepresented patients to further diagnosis and gene discovery in rare disease.

PrgmNr 3392 - Uptake of cancer risk management strategies among women who undergo cascade genetic testing for breast cancer susceptibility: How do they compare to non-cascade testers?

View session detail

Author Block: **S. Makhnoon**[1], L. Brooke[2], K. Mattie[2], R. Volk[1], G. Grana[3], B. Arun[1], S. K. Peterson[1]; [1]The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX, [2]MD Anderson Cancer Ctr. at Cooper Univ. Hlth.Care, Camden, NJ, [3]Cooper Hlth System, Voorhees, NJ

Purpose: A primary rationale for cascade testing for hereditary breast and ovarian cancers (HBOC) is to offer cancer risk management options, including bilateral mastectomy (BLM), salpingo-oophorectomy (BSO), and intensified screening, to persons found to have an inherited predisposition to the disease. At-risk relatives of probands with a pathogenic variant have familial experiences with cancer genetic testing which may shape health beliefs and subsequent health behaviors. Yet, little is known about their genetically-informed cancer risk-reduction behaviors, and long-term outcome data among cascade testers are lacking. This study evaluated: (1) the uptake and timing of cancer preventive surgical and screening strategies between cascade and non-cascade testers, and (2) the association between uptake of cancer risk management strategies and proband characteristics. Methods: Medical records were abstracted for all unaffected women with pathogenic variants in HBOC-associated genes from two cancer hospitals with at least one year of follow-up to compare uptake of surgery and screening between cascade and non-cascade testers. Results: 341 women underwent post-test genetic counseling between 2013 and 2019, of whom 253 were included in the analytic sample. Cascade testers (79.8%) were younger than non-cascade testers (mean=37.6 vs. 43.5 years, p=0.002) and most commonly had a parent with a pathogenic variant (39.1%) followed by siblings (21.3%), and multiple other relatives (20.8%). Women were predominantly non-Hispanic White (81.0%) and underwent testing for *BRCA1* (42.0%) or *BRCA2* (47.2%) variants. Among women ageâ¥40 years, 43% underwent BLM and 71.6% underwent BSO with no significant difference in uptake between cascade and non-cascade testers. Mean time to BSO among cascade testers was shorter among women ageâ¥40 vs Conclusion: Management uptake among cascade testers is high with rates comparable to unaffected *BRCA* positive women. A large proportion of women act on cascade test results and this represents a novel report of utilization of cancer management strategies

PrgmNr 3393 - Colchicine: A Potential Therapy for the HSPB8-related Rimmed Vacuole Myopathy

View session detail

Author Block: **J. Vu**[1], L. Weiss[2], A. Shmara[3], E. Mohanty[4], R. Yan[5], R. Wei[5], C. Cheng[6], V. E. Kimonis[7]; [1]Univ. of California Irvine, Sch. of Med., Dept. Pediatrics, Orange, CA, [2]Univ. of California, Irvine, [3]UCI, Yorba Linda, CA, [4]Univ. of California, Irvine, Orange, CA, [5]Univ. of California Irvine, Irvine, CA, [6]UC Irvine, Irvine, CA, [7]Univ CA Irvine, Orange, CA
Disclosure Block: **J. Vu:** None.
Our lab has recently reported a family with a novel disorder associated with autosomal dominant Rimmed Vacuole Myopathy (RMV) caused by a frameshift mutation: c.515dupC in the Heat Shock Protein family B member 8 (HSPB8) gene. HSPB8 is a chaperone involved in the Chaperone Assisted Selective Autophagy (CASA) complex. HSPB8 in conjunction with BAG3 recognizes and promotes the autophagy-mediated removal of misfolded proteins present in several neurodegenerative diseases. Patients with this debilitating disease exhibit proximal limb-girdle with distal myopathy, muscle atrophy, fatty replacement, and rimmed vacuoles. Our previous studies show that patients with HSPB8 c.515dupC have reduced expression of HSPB8 protein, disrupted TDP-43, and autophagy pathology in patient fibroblasts. Colchicine, after an extensive drug screening project in neuronal cells, has shown to be one of the top drugs to significantly increase expression of HSPB8 as well as block misfolded TDP-43 accumulation. We hypothesize that treating transgenic HSPB8 mutant mice with Colchicine will help to restore normal HSPB8 gene function and block TDP-43 accumulation/mislocalization. Thus, improving motor function and endurance of the HSPB8 mutant mice. We treated our newly created c.515dupC HSPB8 knock-in mouse model with colchicine (0.3 mg/kg/day for 3 months). The dose was derived from a previously conducted dose-response study. After treatment, we have observed (1) significant improvement of muscle pathology by H&E staining (2) increased HSPB8 RNA and protein levels, and (3) a trend of amelioration in rotarod performance in the heterozygous treated group compared with the vehicle group. The results from this study indicate that colchicine has the potential for treating HSPB8 associated rimmed vacuole myopathy.

PrgmNr 3394 - Genome-wide integration assay for rAAV mediated homologous recombination (HR) in human hepatocytes demonstrated precision of *in vivo* gene editing approach

View session detail

Author Block: **J. F. Thompson**, J. Von Stetina, J. Prout, M. Tian, A. Pla, S. Potts, M. Rubin, R. Resendes, G. Cerqueira, J. Wright; Homology Med.s, Bedford, MA
Disclosure Block: **J.F. Thompson:** Salary/Employment; Homology Medicines Inc.
There have been many studies examining the integration of DNA arising from AAV and other viruses into sites throughout the human genome. Most current methods use amplification of sequences on both sides of the integration junction. Typically, specific primers directed to the virus being studied are combined with primers directed at non-specific adaptors ligated to genomic DNA near the junction. However, a variety of artifacts can obscure real integration signals, and these are often caused by a high degree of background amplification or from unintended ligation of free or truncated virus to random genomic DNA during processing. This is particularly a problem with assessing AAV-mediated HR integration sites because, at high doses, episomal AAV may be present at thousands of copies per cell and thus easily amplified or ligated inadvertently. False positive integration signals arising from the very high episomal background may occur more frequently than actual integration events. These issues have led to questions regarding the authenticity of some reported genomic integrations.
To overcome the high episomal background often observed with AAVs, and other known sources of artifactual â□□integrationsâ□□, we have modified previous protocols and combined them with new steps to eliminate the impact of excess vector genomes. Long-read sequencing has been employed to ensure that relevant viral and human genomic sequences are truly present on the same molecule, eliminating index hopping as an issue as seen with short-read sequencing. The mean length of molecules spanning the integration junction that we sequenced is approximately 2 kb and some molecules are over 6 kb. A positive control cell line has been generated with a single inserted DNA via CRISPR. Genomic DNA from this cell line is spiked at known fractional concentrations into genomic DNA from human hepatocytes engrafted in mice so that the frequency of real events can be estimated. These mice were treated with rAAV with a codon-optimized *PAH* gene and homology arms targeted for insertion into intron 1 of human *PAH*. Using these quantitative molecular methods, we are able to calculate the frequency of HR-mediated integration into the desired locus. We see no evidence of integration into any other genomic location, which further supports the precision of this gene editing approach.

PrgmNr 3395 - A New Paradigm for Coordinate-Based, Multipanel Genomic Plotting in R

The R programming language is unparalleled in its ability to transform raw genomic data sets into meaningful biological conclusions through analysis and visualization. However, when it comes to complex, multi-paneled plots, users rely on 3rd party graphic design software to arrange and customize plots. Here we present BentoBox, a coordinate-based genomic data visualization package that introduces a new paradigm in multi-figure plotting in R. Employing grid Graphics and drawing from the practices of base plotting and ggplot2, BentoBox offers precise, programmatic control over the placement, aesthetics, and arrangements of plots through a user-defined page with explicit units of measurement. Its edge-to-edge, containerized visualizations preserve the mapping between user-specified containers and the represented data, ensuring accurate alignment of plots in the same genomic region. Operating entirely within the R environment and tightly integrated with Bioconductor, BentoBox is optimized to quickly and easily read, plot, and arrange multi-omic data for an endless number of use cases. Come join us in changing how we plot in R!

The NIHâ□□s All of Us Research Program[1] aims to collect health data from a million or more participants to create a diverse research resource that accelerates precision medicine. The All of Us Researcher Workbench[2] is a secure, cloud-based platform developed by the Data and Research Center (DRC) through which registered researchers can access and analyze data from program participants including data from electronic health records, surveys, physical measurements, and wearables from ~315,000 participants. The DRC has developed new tools that provide efficient, scalable, and low-cost solutions for processing and managing these data using Google BigQuery as a serverless, cloud-native solution. Advantages of the cloud-based workbench design include enhanced security, speed, scalability and decreased cost.

All of Us researchers can generate project-specific Workspaces, select and annotate cohorts of the All of Us dataset, and export analysis-ready tables to interactive Jupyter Notebooks for analysis. To date >860 researchers from >215 institutions have leveraged this free-to-access platform.

In 2020, All of Us Genome Centers began generating both array genotyping and whole genome sequence (WGS) data from participant biosamples. A critical next milestone towards accomplishing All of Usâ□□ mission is providing analysis tools and a large diverse genomic dataset in the All of Us Researcher Workbench. Within the Workbench, researchers will have the ability to select
All of Us participants that have WGS and/or genotype array data and perform large-scale analyses using standard tools such as Hail or Plink. We anticipate enabling access to the genomics capabilities to all users of the All of Us Researcher Workbench by the end of 2021, including ~80,000 WGS and ~120,000 genotype arrays. Importantly, we anticipate that ~44% of participants with WGS data will be from racial and ethnic communities that have been historically underrepresented in biomedical research.

To ensure genomics community usability of this new â□□bringing researchers to the genomic dataâ□□ paradigm, the All of Us Research Program Science Committee has launched four genomics demonstration projects: Variant Frequency, GWAS, Genetic Ancestry, and Array Polygenic Risk Score. By design these demonstration projects do not aim to make new discoveries. Rather, they aim to validate the All of Us cohort genomics data and tools by replicating known, previously published findings.

Blackman[1]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Univ. of Washington, Seattle, WA, [3]Seattle, WA, [4]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [5]Johns Hopkins Univ., Columbia, MD, [6]North Carolina State Univ, Raleigh, NC, [7]North Carolina State Univ., Raleigh, NC
Disclosure Block: **K.A. Pagel:** None.
Introduction: In-depth analysis of variation from large scale sequencing projects requires accurate and comprehensive annotation of variant properties and application of filters to reduce the search space. Here, we describe the approaches used in the processing and annotation of variation from large scale whole genome sequencing data in a cohort of 5134 cases with cystic fibrosis and strategies to address common pitfalls. Methods: We performed the annotation for each chromosome separately, with the genotype annotations removed to reduce runtime and memory consumption. We used vt to perform variant decomposition and left-normalization to split multi-allelic variants and ensure accurate representation of insertion/deletion variants. We required two annotation tools to provide the curated annotations that are needed to perform rare variant aggregation analysis with variant filtering strategies specified by TOPMed. First, we applied VEP v101 to obtain 5kb upstream and LOFTEE annotations. Next, we used OpenCRAVAT to incorporate annotations for Ensembl Regulatory Build, promoters from GeneHancer and several prediction scores. Annotation source data were obtained from dbNSFP where available, and the primary sources otherwise. Results: Variants that impact more than one gene were annotated separately for each gene, with the MANE canonical transcript used to identify transcript-specific features when available. We applied the TOPMed variant specifications and generated filtered variant aggregate files, with a novel script to assess the characteristics of each variant per transcript. We describe further variant-level characteristics that should be used in curation of the analysis set including minor allele count, allele frequency, and quality. We identify and address multiple factors that impact the quality and accuracy of annotation tools including canonical transcript selection, changes in gene definitions and characterization of multi-allelic variation. Conclusions: We believe that the variant pre-processing and annotation pipeline constructed in this work can serve as a guide on the critical factors to ensure accurate annotation for variation in large scale sequencing projects.This study is supported by CFF grants CUTTIN18XX1, BAMSHA18XX0, and KNOWLE18XX0 and is submitted on behalf of the CF Genome Project.

PrgmNr 3398 - FusionGDB 2.0, fusion gene annotation update aided by deep learning

View session detail

Author Block: **P. Kim**[1], H. Tan[1], J. Liu[1], H. Lee[2], H. Jung[3], H. Kumar[1], X. Zhou[1]; [1]The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [2]Korea Inst. of Oriental Med., Daejeon, Korea, Republic of, [3]Asan Med. Ctr., Seoul, Korea, Republic of

Disclosure Block: **P. Kim:** None.

Gene fusion is one of the hallmarks of the cancer genome via chromosomal rearrangement initiated by DNA double-strand breakage. A knowledge base with the systematic functional annotation of fusion genes is critical for understanding genomic breakage context and developing therapeutic strategies. FusionGDB is a unique functional annotation database of human fusion genes and has been widely used for studies with diverse aims. In this study, we report FusionGDB 2.0, which has substantial updates of contents such as up-to-date human fusion genes, fusion gene breakage tendency score with FusionAI deep learning model based on 20kb genomic sequence around BP area, investigation of overlapping between fusion breakpoints with 44 human genomic features across five cellular roleâ□□s categories, transcribed chimeric sequence and following open reading frame analysis with coding potential based on deep learning approach with Ribo-seq read features, and rigorous investigation of the protein feature retention of individual fusion partner genes in the protein level. Among ~ 126k fusion genes, about 30k kept their ORF as In-frames, which is triple size compared to the previous version, FusionGDB. FusionGDB 2.0 will be used as the reference knowledge base of fusion gene annotations. FusionGDB 2.0 provides seven categories of annotations: Fusion Gene Summary, Fusion Gene ORF, Fusion Gene Genomic Feature, Fusion Protein Feature, Fusion Sequence, Related Drug, and Related Disease.

PrgmNr 3400 - Genomics4RD: An integrated platform to share Canadian deep-phenotype and variant level data for international rare disease gene discovery

View session detail

Author Block: **H. Driver**[1], T. Hartley[1], M. Price[2], O. Buske[3], A. K. Ramani[4], M. Osmond[5], K. D. Kernohan[2], Care4Rare Canada, B. M. Knoppers[6], M. Brudno[7], K. M. Boycott[8]; [1]Children's Hosp. of Eastern Ontario Res. Inst., Ottawa, ON, Canada, [2]CHEO, Ottawa, ON, Canada, [3]Gene42, Toronto, ON, Canada, [4]Hosp for Sick Children, Toronto, ON, Canada, [5]Ottawa, ON, Canada, [6]McGill Univ., Westmount, QC, Canada, [7]Hosp Sick Children/Univ Toronto, Toronto, ON, Canada, [8]Children's Hosp. of Eastern Ontario, Ottawa, ON, Canada

Disclosure Block: **H. Driver:** None.

The low incidence of some rare genetic diseases (RDs) means that data-sets for gene discovery need to be as large as possible; sharing of information between research groups is therefore critical. The Care4Rare Canada Consortium (previously FORGE Canada) is a pan-Canadian network of clinicians and researchers that has been studying undiagnosed RDs for over a decade. In 2018, the consortium launched a 4 year project called C4R-SOLVE, a sub-aim of which was to collect, harmonize, and share both retrospective and prospective Canadian phenotypic and multiâomic data. Here, we introduce Genomics4RD; an integrated web-accessible platform to share Canadian phenotypic and variant-level genetic data between researchers both within Canada and internationally, for the purpose of rare disease gene discovery.

Genomics4RD has been designed to facilitate precision medicine for patients with RDs, by addressing current and projected barriers to data sharing; including concerns about privacy, discrepant study protocols, jurisdiction-specific regulations, social concerns amongst users, and low resources. At the core of Genomics4RD, is an unambiguously structured governance framework that dictates how participant data is stored, tagged (using ADA-M codes), accessed, and withdrawn. This governance framework is linked to a library of consent templates and REB waivers to aid data contributors in releasing data from institutional custodianship. Data storage, authorization, and access procedures have been developed in collaboration with stakeholders to ensure the trusted and secure access of data by external researchers. In collaboration with PhenoTips, the database has been designed to aid users in systematically collecting, prioritizing, and visualizing the phenotypic and genotypic information of participants. All raw multi-omic sequencing data is processed through centralized bioinformatics pipelines, to produce compatible datasets for analyses. The breadth and consistency of data offered by Genomics4RD allows researchers to compare putative disease genes across patients (i.e. single-sided matching), greatly increasing the possibility of disease gene discovery.

Genomics4RD offers modern solutions to combat barriers to data sharing, and allows for international collaborations in RD research. Our platform minimizes risks for patients, clinicians, and researchers, and facilitates greater diagnostic yields for RDs.

PrgmNr 3401 - HGRepo - A comprehensive repository of clinical, lab assay, and genetic data for studies of innate and adaptive immune responses during acute COVID-19 infection and convalescence

Disclosure Block: **J. Barnett:** None.

We describe a unique clinical omics portal (HGRepo) developed to enable collaborative access to longitudinal clinical events and multiple types of biomarker phenotypic data to provide comprehensive profiles of the disease progression in COVID-19 patients. It enabled harmonized representation of data for the NIAID COVID-19 Immune Response international collaboration, which was spearheaded in March 2020 to unveil the innate and adaptive immune responses resulting from SARS-CoV2 infection. The synergistic coalition of > 15 researchers began collaborative analysis of the standardized and curated COVID-19 data in the portal within three months of receipt and published early results in August 2020. Developed on LabKey, HGRepo provides intuitive interfaces for data loading and curation, data export (spreadsheets and API) system administration (e.g., defining tables, role-based user accessioning), browsing, and querying. Iterative implementation helped support evolving consortium needs. Automated data transformation to standardize incoming data in heterogeneous formats from multiple (>15) international sites is performed in close collaboration with clinicians and informatics researchers. The harmonized representation of data is intuitive to clinicians and is also amenable for data science approaches to analysis. Chronological representation of clinical events (such as COVID-19 tests, COVID symptoms, hospitalization) and sample collection and linking of samples to assay data (WGS, RNAseq, serological markers, etc.) enabled users to efficiently and accurately discover relationships between the disease progression and genetics and omics data. The portal also provides access to summarized genetic data derived from Whole Genome Sequencing (WGS), and research serology data. The portal is being used to identify biomarkers as surrogates of disease progression as well as in clinical classification of the disease. As of June 2021, HGRepo includes 6810 subjects and 23671 samples from over 15 sites. Computational processing and analysis of more than 1600 WGS combined with the clinical data in HGRepo have contributed to the discovery of novel variants in immune-related genes that correlate with COVID-19 disease severity. Immunological and virological correlates and predictors of clinical outcomes have been published in five articles to-date. Importantly, these data can be combined with other future studies. We are now using this collaborative framework of development to systematically store standardized data for other NIAID labs and are confident in our ability to rapidly stand-up scientific data management systems for future pandemic studies.

PrgmNr 3402 - New genomic data deposited in dbGaP cross-referenced against NINDS Repository Tourette Syndrome biospecimens

View session detail

Author Block: **L. B. Scheinfeldt**[1], S. Heil[1], A. Green[1], A. Amberson[1], S. Sander-Effron[1], R. Zhang[2]; [1]CORIELL Inst. FOR Med. RESEARCH, Camden, NJ, [2]NIH/NINDS, Rockville, MD
Disclosure Block: **L.B. Scheinfeldt:** None.
The National Institute of Neurological Disorders and Stroke (NINDS) Human Genetics Resource Center was established by the NINDS as a public biorepository of DNA and lymphoblastoid cell lines collected from subjects diagnosed with neurological disorders as well as population controls. Each biospecimen is annotated with associated de-identified clinical and demographic data. Since the establishment of the NINDS Repository, specimens from over 42,000 individuals have been successfully banked at the Coriell Institute for Medical Research and can be accessed through an online catalog (http://catalog.coriell.org/NINDS). The collection includes samples from individuals diagnosed with cerebrovascular diseases (N>12,700), Parkinsonism (N>5,600), motor neuron diseases (N>2,500), Epilepsy (N>6,000), Tourette syndrome (N>4,200), Dystonia (N>3,500), and neurologically normal controls (N>7,500). To date, NINDS Repository samples have been used in over 570 peer-reviewed scientific publications, including genome-wide association studies, whole-exome sequencing studies, and structural variation studies. The genomic data collected by these studies have been deposited in the Database of Genotypes and Phenotypes (dbGaP), a NIH/NLM sponsored restricted-access data repository for studies investigating the contributions of genetic variation to phenotypic variation and disease (http://www.ncbi.nlm.nih.gov/gap). The NINDS Repository catalog includes a resource page devoted to the annotation of genomic data collected from NINDS Repository samples that are available in dbGaP (https://www.coriell.org/1/NINDS/NINDS-Samples-in-dbGaP). Recently, this resource page was updated to include two large-scale dbGaP genomic datasets: one that includes genome-wide SNP data generated from biospecimens donated by 1,880 Tourette Syndrome patients, and another which includes whole exome sequencing data collected from biospecimens donated by 378 Tourette Syndrome patients. An overview of this annotated information can be accessed via a downloadable spreadsheet that details each biospecimen associated with genomic data in a dbGaP study accession, and the corresponding study accession details. This dbGaP annotation resource for the NINDS Repository ensures that existing genomic data collected from Repository samples is easily associated with its original biospecimen and made available for reuse in new genomic studies of Tourette Syndrome, neurological disorders, and human disease more generally.

PrgmNr 3403 - A Finnish-enriched functional DNA variant in an enhancer for *IRF6* is associated with cleft palate

Disclosure Block: **F. Rahimov:** Salary/Employment; AbbVie.

Genetic variation in the Interferon Regulatory Factor 6 (*IRF6*) gene causes and contributes risk for orofacial clefting. Here we performed a genome-wide association study for orofacial clefting in the Finnish population and identified a significant association with rs570516915, a single nucleotide polymorphism that changes a highly conserved nucleotide in a known enhancer for *IRF6*, called MCS-9.7. We found that the risk allele diminishes the activity of the enhancer using reporter assays, and CRISPR-Cas9 edited oral epithelial cells demonstrate rs570516915 decreases expression of *IRF6*. Previous associations at the *IRF6* locus were predominantly observed with cleft lip (CL) or cleft lip with cleft palate (CLP). However, the association with this DNA variant was driven solely by cases of isolated cleft palate (CP) (p -34, OR = 8.65, 95% CI 6.11-12.25). We replicated the association in an independent sample of CP cases from Estonia (p -11). This finding is significant to public health because unlike other countries, the frequency of CP in Finland is higher than the frequency of CL or CLP. Moreover, the frequency of the risk allele for rs570516915 parallels the regional variation of CP prevalence in Finland (p IRF6 harboring rs570516915 is required for proper development of both the palate and the lip, two embryologically distinct processes.

PrgmNr 3404 - Analysis of genetic investigations in newborns with VACTERL spectrum of malformations

View session detail

Author Block: **I. Chacon**[1], A. James[2], R. Mendoza[2], D. Chitayat[3]; [1]Lakeridge Hlth.Oshawa, Oshawa, ON, Canada, [2]Hosp. for Sick Children, Toronto, ON, Canada, [3]Ontario Power Generation Bldg,, 700 Univ. Ave Rm 3-709, Mount Sinai Hosp., Toronto, Ontario,, Toronto, ON, Canada
Disclosure Block: **I. Chacon:** None.
VACTERL association is an acronym that stands for **v**ertebral defects, **a**nal atresia, **c**ardiac defects, esophageal atresia and **t**racheo-**e**sophageal fistula, **r**enal and **l**imb abnormalities. It has a non-random occurrence, usually with a good prognosis following surgical management and with low-recurrence risk. It is a diagnosis by exclusion; however, many environmental, maternal, chromosomal and single gene disorders mimic the same pattern of malformations and therefore a minimum genetic diagnostic protocol should be undertaken to rule out other diagnosis. We developed a genetic diagnostic flow chart for newborns with VACTERL spectrum of malformations, based on the evidence for test diagnostic yield. We reviewed all admissions to our Hospitalâ□□s Neonatal Intensive Care Unit from 2010 to 2018 with three or more of the VACTERL core features. The most common genetic investigation was microarray analysis (68%), followed by chromosome analysis. Taken together, all patients had one of these tests as the first or only test done. The second most common test was DNA analysis for suspected single gene disorder (27.3%), followed by chromosomal breakage studies (20.2%) and whole exome sequencing (13%). Overall, the diagnostic yield of genetic testing was low (4.6%). Only in 6% of the patients a diagnosis was obtained following genetic testing including: Trisomy 18 (2), Cat Eye syndrome (1), Coffin-Siris syndrome (1) and Feingold syndrome (1). The two most informative genetic testing were FISH and chromosome analysis. Microarray analysis had no diagnostic yield (provided no further diagnostic information) with the incidence of VUS being almost 20%. Based on our data analysis and review of the literature, our flow chart recommends that in cases suspected of having VACTERL association who have no facial dysmorphism, CNS malformation, no limb involvement or features of a particular genetic syndrome, genetic evaluation could be deferred to 10-12 months at which time, if no new issues (ex. failure to thrive or developmental delay), no further genetic test is required.

Pathogenic variants in Lysyl-tRNA synthetase 1 (KARS1) have increasingly been recognized as a cause of early-onset complex neurological phenotypes. To advance the timely diagnosis of KARS1-related disorders, we sought to delineate its phenotype and generate a disease model to understand its function in vivo. Through international collaboration, we identified 22 affected individuals from 16 unrelated families harboring biallelic KARS1 likely pathogenic or pathogenic variants. Sequencing approaches ranged from disease-specific panels to genome sequencing. We generated loss of function alleles in zebrafish. We identify ten new and four known biallelic missense variants in *KARS1* presenting with a moderate-to-severe developmental delay, progressive neurological and neurosensory abnormalities, and variable white matter involvement. We describe novel KARS1-associated signs such as autism, hyperactive behavior, pontine hypoplasia, and cerebellar atrophy with prevalent vermian involvement. Loss of *kars1* leads to upregulation of p53, tissue-specific apoptosis, and downregulation of neurodevelopmental related genes, recapitulating key tissue-specific disease phenotypes of patients. Inhibition of p53 rescued several defects of *kars1*$^{-/-}$ knockouts. Our work delineates the clinical spectrum associated with KARS1 defects and provides a novel animal

model for KARS1-related human diseases revealing p53 signaling components as potential therapeutic targets.

PrgmNr 3406 - Congenital heart defects caused by *FOXJ1*

View session detail

Author Block: **M. Padua**[1], B. Helm[2,3], J. Wells[2], A. Smith[1], H. Bellchambers[1], A. Sridhar[4], S. M. Ware[1,2]; [1]Dept. of Pediatrics, Indiana Univ., Indianapolis, IN, [2]Dept. of Med. & Molecular Genetics, Indiana Univ., Indianapolis, IN, [3]Dept. of Epidemiology, Indiana Univ., Indianapolis, IN, [4]Indiana Univ., Indianapolis, IN
Disclosure Block: **M. Padua:** None.
Heterozygous pathogenic variants in the Forkhead box J1 (FOXJ1) transcription factor cause a motile ciliopathy leading to situs inversus, obstructive hydrocephalus, and chronic airway disease. *FOXJ1* is expressed in ciliated cells of the airways, testis, oviduct, central nervous system, and the embryonic left/right organizer. Prior studies indicate ablation or targeted mutation of *Foxj1* in mice, zebrafish and frogs results in a reduced number of motile cilia, which affects the establishment of the left-right body asymmetry. However, congenital heart defects (CHD) resulting from loss of function of this transcription factor have not been well characterized in model organisms or humans. We performed phenotypic characterization of *Foxj1* null embryonic 14.5-17.5 hearts in mice revealing either normal (levocardia; 57%) or abnormal heart looping (43%) such as dextrocardia or sinistral looping (24.6%), ventral looping (heart tube loops forward in the frontal plane;16% of which nearly half displayed a combined ventral/sinistral looping) and no looping or single ventricle heart (2.4%). Further histological analysis showed a wide range of cardiac defects including atrial, ventricular, and atrioventricular septal defects, non-compacted ventricular walls as well as double outlet right ventricle defects. Given the range of CHD findings in mouse, we analyzed a cohort of 279 participants with CHD phenotypes associated with left/right defects using research-based exome sequencing and identified three individuals with predicted damaging missense variants in *FOXJ1*. Subsequently, we identified a hospitalized patient using clinical exome sequencing who had a novel mutation in exon 3 of *FOXJ1* (*c.784_799dup*; p.Glu267Glyfs*12). The patientâ□□s CHD included double outlet right ventricle, ventricular septal defect, trabecular hypertrophy of the right ventricle, and mild left ventricular outflow obstruction. Currently, experiments in *Xenopus laevis* embryos are ongoing for functional analysis of these *FOXJ1* variants. These experiments use the known role of *FOXJ1* as a master regulator of ciliogenesis to assess the ability of the identified variants to form ectopic cilia in the epidermis at developmental stage 26, similar to wildtype *FOXJ1*. These results indicate that in addition to its role as a master ciliogenesis gene, *FOXJ1* plays an important role in cardiogenesis and abnormalities in *FOXJ1* can cause CHD.

PrgmNr 3407 - Loss of *Zic3* impairs planar cell polarity leading to abnormal left-right signaling and heart defects

View session detail

Author Block: **H. Bellchambers**[1], S. M. Ware[1,2]; [1]Dept. of Pediatrics, Indiana Univ. Sch. of Med., Indianapolis, IN, [2]Dept. of Med. & Molecular Genetics, Indiana Univ. Sch. of Med., Indianapolis, IN
Disclosure Block: **H. Bellchambers:** None.
Loss of function of *ZIC3* causes heterotaxy, a disorder characterized by organ laterality defects including complex heart defects. Studies using *Zic3* mutant mice have demonstrated that loss of *Zic3* causes heterotaxy due to defects in establishment of left-right (LR) signaling, but the mechanistic basis for these defects remains unknown. Here, we demonstrate *Zic3* null mice undergo cilia positioning defects at the embryonic node consistent with impaired planar cell polarity (PCP). Cell-based assays demonstrate that ZIC3 must enter the nucleus to regulate PCP and identify multiple critical ZIC3 domains required for regulation of PCP signaling. Furthermore, we show that *Zic3* displays a genetic interaction with the PCP membrane protein *Vangl2* and the PCP effector genes *Rac1* and *Daam1* resulting in increased frequency and severity of neural tube and heart defects. Gene and protein expression analyses indicate that *Zic3* null embryos display disrupted expression of PCP components and reduced phosphorylation of the core PCP protein DVL2 at the time of LR axis determination. These results demonstrate that ZIC3 interacts with PCP signaling during early development, identifying a novel role for this transcription factor, and adding additional evidence about the importance of PCP function for normal LR patterning and subsequent heart development.

PrgmNr 3408 - Novel pathogenic variants, evidence for involvement of *DVL2*, and quantitative phenotypic analyses of Robinow syndrome: WNT signaling perturbation and phenotypic variability

Robinow syndrome (RS) is a genetically heterogeneous disorder with six genes, *DVL1, DVL3, FZD2, NXN, ROR2,* and *WNT5A*, shown to be involved to date; the gene products converge on the WNT/planar cell polarity (PCP) signaling pathway. RS is a skeletal dysplasia with a recognizable pattern of craniofacial and physical characteristics. To further explore the genetic heterogeneity, paralog contribution, and phenotypic variability of RS, we investigated a cohort of 22 individuals clinically diagnosed with RS from 18 unrelated families. Pathogenic or likely pathogenic variants in genes associated with RS, or Mendelian disorders with phenotypic overlap with RS, were identified in all 22 individuals; notably, one individual was found to have a variant in *DVL2,* which has not previously been associated with RS or any other phenotype. We retrospectively collected medical records of subjects in a subgroup of this cohort (N = 16) and examined clinical descriptions of published cases (N = 52) and used these data to perform HPO term-based quantitative phenotypic analyses to investigate paralog contributions and allele-specific phenotypic differences. Individuals with *FZD2* variants clustered into two groups that correlated with pathogenic allele type (missense or truncating), in general individuals having missense variants in *FZD2* are overall more severely affected than those with truncating variants. Moreover, probands with biallelic *NXN* variants clustered together with the majority of probands carrying *DVL1, DVL2,* and *DVL3* variants, blurring the phenotypic distinction between the *NXN*-autosomal recessive and dominant forms of RS. In addition, disease-to-gene and disease-to-disease HPO analyses revealed that RS can be quantitatively distinguished from diseases caused by variants affecting non-RS-associated paralogs of *WNTs*, *FZDs*, or *RORs*; supporting the hypothesis that RS results from perturbation of a very specific pathway. Our study: i) identifies previously undescribed pathogenic variant alleles, ii) provides evidence for a new RS â□□disease geneâ□□ *DVL2*, iii) examines paralog specificity of trait manifestations, iv) delineates allele-specific phenotypic differences, v) provides biological insights into a genetically heterogenous

disorder, and vi) reveals the power of deep phenotypic analyses to tease apart genetically heterogeneous disorders.

PrgmNr 3409 - *De novo TNPO2* variants are associated with developmental delays, neurological issues and dysmorphic features in humans and alter *TNPO2* activity in *Drosophila*

Transportin-2 (TNPO2) mediates multiple pathways including non-classical nucleocytoplasmic shuttling of >60 cargoes, including developmental and neuronal proteins. We identified fifteen individuals carrying *de novo* coding variants in *TNPO2* who presented with global developmental delay (GDD), dysmorphic features, ophthalmologic abnormalities, and neurological features. To assess the nature of these variants, functional studies were performed in *Drosophila*. We found that fly *dTnpo* (orthologous to *TNPO2*) is expressed in a subset of neurons. *dTnpo* is critical for neuronal maintenance and function as downregulating *dTnpo* in mature neurons using RNAi disrupts neuronal activity and survival. Altering the activity and expression of *dTnpo* using mutant alleles or RNAi causes developmental defects, including eye and wing deformities and lethality. These effects are dosage-dependent as more severe phenotypes are associated with stronger *dTnpo* loss. Interestingly, similar phenotypes are observed with *dTnpo* upregulation and ectopic expression of TNPO2, showing that loss and gain of Transportin activity causes developmental defects. Further, proband-associated variants can cause more or less severe developmental abnormalities compared to wild-type TNPO2 when ectopically expressed. The impact of the variants tested seems to correlate with their position within the protein. Specifically, those that fall within the RAN binding domain cause more severe toxicity and those in the acidic loop are less toxic. Variants within the cargo binding domain show tissue-dependent effects. In summary, *dTnpo* is an essential gene in flies during development and in neurons. Further, proband-associated *de novo* variants within *TNPO2* disrupt the function of the encoded protein. Hence, TNPO2-variants are causative for neurodevelopmental abnormalities.

PrgmNr 3410 - *De novo* damaging variants in the microRNA processor *DROSHA* are associated with a severe progressive neurological disorder

View session detail

Author Block: **S. Barish**[1], M. Senturk[1], K. Schoch[2], A. Minogue[3], J. Seeman[3], Undiagnosed Diseases Network, M. F. Wangler[4], S. Arur[3], Y-h. Jiang[5], S. Yamamoto[1], V. Shashi[6], H. DROSHA encodes a ribonuclease that is a subunit of the Microprocessor complex and is involved in the first step of microRNA (miRNA) biogenesis. To date, *DROSHA* has not yet been associated with a Mendelian disease. Here we describe two individuals with profound intellectual disability, epilepsy, white matter atrophy, microcephaly, and dysmorphic features, who carry damaging *de novo* heterozygous variants in *DROSHA*. *DROSHA* is constrained for missense variants and moderately intolerant to loss of function (o/e=0.24). The loss of the fruit fly ortholog *drosha* causes developmental arrest and death in third instar larvae, a severe reduction in brain size, and loss of imaginal discs in the larva. Loss of *drosha* in eye clones causes small and rough eyes in adult flies. One of the identified *DROSHA* variants (p.D1219G) behaves as a strong loss-of-function allele in flies, while another variant (p.R1342W) is less damaging in our assays. In worms, a knock-in that mimics the p.D1219G variant at worm equivalent residue causes loss of miRNA expression and heterochronicity, a phenotype characteristic of the loss of miRNA. Together, our data show that the *DROSHA* variants found in the individuals presented here are damaging based on functional studies in model organisms and loss of this gene in human and fly leads to a severe phenotype involving the nervous system.

PrgmNr 3411 - *De novo* variant in *MRTF-B* is associated with intellectual disability, minor dysmorphic features, expressive language delay, impulse control issues, and fine motor delay

View session detail

Author Block: **J. C. Andrews**[1], O. Kanca[1], D. Li-Kroeger[1], C. Tifft[2], E. Macnamara[3], S. Yamamoto[1], H. J. Bellen[1], M. C. Malicdan[4], M. F. Wangler[1]; [1]Baylor Coll. of Med., Houston, TX, [2]NIH, Bethesda, MD, [3]NIH/NHGRI, Arlington, VA, [4]NIH/NHGRI, Rockville, MD

Myocardin-related transcription factor B (MRTF-B) is a member of a family of genes which serve to potentiate serum response factor (SRF)-dependent transcription and is highly conserved in both vertebrate and invertebrate model organisms. The MRTF-B protein is not currently associated with a human disease but has been shown to be highly expressed in all human tissues save the lung. Here we report a proband with a *de novo* variant in the second RPEL domain of *MRTF-B* with intellectual disability, minor dysmorphic features, expressive language delay, impulse control issues, and fine motor delay. We have generated a fly model of human *MRTF-B*, using a UAS construct carrying either the human reference or variant cDNA. Expression of the UAS-human variant cDNA under the control of the *Nubbin-Gal4* driver was sufficient to induce significant morphological changes in the wing, while the expression of the human control reference cDNA produced only minor changes in the wings posterior crossvein. Expression of *Drosophila Mrtf* using the *Nubbin-Gal4* driver produced a similar change in crossvein length as was observed with the human reference. In *Drosophila*, the SRF ortholog is known as *blistered (bs)* and is known to suppress wing vein formation and promote the development of intervein cells. As exogenous co-expression of *bs* and *Mrtf* has been previously shown to significantly alter wing morphology, we also expressed our human reference and variant cDNA lines concurrently with a UAS-*bs* line. In these experiments we found that wing morphology was highly disrupted when *bs* and the reference human cDNA were co-expressed, while the co-expression of human variant cDNA and *bs* was lethal. To further clarify our findings, we sought and identified two additional probands with variants within or near the second RPEL domain. Expression of these additional variants using *Nubbin*-Gal4 produced changes in the posterior crossvein analogous to the changes observed when our human reference line was expressed. Taken together, these findings suggest that different residue changes within the RPEL domain of *MRTF-B* can have drastically different morphological effects in the fly wing, and our initial *de novo* variant may underly a novel disorder.

PrgmNr 3412 - *SLC6A1 Portal: Genetic variant analysis and educational resource for SLC6A1-related disorders*

Genetic variants in the *SLC6A1* gene, encoding the GABA transporter protein type 1 (GAT1), are among the most frequent causes of complex neurodevelopmental disorders, featuring epilepsy, autism spectrum disorder, and intellectual disability. Currently, clinical, genetic, and molecular data about the *SLC6A1* gene is not connected and distributed across registries, databases, and the literature. To facilitate further research, the translation of research findings into improved patient management and overall awareness, we developed the *SLC6A1*-Portal: A novel online resource containing a unique expert-curated *SLC6A1* dataset alongside user-friendly semi-automated data visualizations. In addition, we incorporated extensive educational resources for families, clinicians, and analytical applications to translate current scientific knowledge aiming to improve the quality of genetic counseling and research opportunities for scientists.We gathered clinical, genetic, and molecular data from 150 *SLC6A1* disorder patients. We also aggregated data from 22 functionally tested variants. In addition, we produced several short educational videos about *SLC6A1*-related disorders, genetics, precision medicine, and related subjects. These videos were translated in >10 languages to mobilize underreported individuals worldwide and create a comprehensive resource for families, researchers, and clinicians.We designed the *SLC6A1*-Portal for three user scenarios: i) Education: We provide a rich information resource for *SLC6A1*-related disorders for professionals and the general public. ii) Variant interpretation: Access to expert-level variant interpretation through novel expert-curated web applications that enable variant pathogenicity classification and genotype-phenotype correlation. iii) Research resource: Throughout the *SLC6A1*-Portal, we provide novel research tools to explore related biomedical data resources. Users will be guided by tutorials with illustrative examples and will not require any programming skills.The *SLC6A1*-Portal infrastructure is scalable and, with increasing data, will guide variant interpretation, research, and education for *SLC6A1*. The *SLC6A1*-Portal will be hosted at http://slc6a1-portal.broadinstitute.org at the time of the meeting. We are actively looking for collaborators contributing to this project.

PrgmNr 3414 - A novel *de novo* variant in *PPP2CA* affecting the 5â□□UTR region causes a syndrome characterized by global developmental delay with specific structural brain abnormalities, congenital microcephaly and dysmorphic features

View session detail

Author Block: **A. Cassidy**[1], K. Treat[1,2], S. Pelletier[1], E. Conboy[1,2], F. Vetrini[1,2]; [1]Dept. of Med. and Molecular Genetics, Indiana Univ. Sch. of Med., Indianapolis, IN, [2]Undiagnosed Rare Disease Clinic, Indianapolis, IN

Disclosure Block: **A. Cassidy:** None.

Introduction: Heterozygous pathogenic variants in the *PPP2CA* gene cause a recently described neurodevelopmental syndrome characterized by global developmental delay, intellectual disability and highly variable features including hypotonia, seizures, dysmorphic features, behavioral abnormalities, and a wide spectrum of structural brain abnormalities. This is a very rare disorder with only 16 patients described worldwide (Raynhout et al., 2019). *PPP2CA* encodes the PP2A catalytic C-Î± subunit of the large PP2A complex which is highly expressed in the brain and regulates neuronal signaling by catalyzing phospho-serine and threonine de-phosphorylation in a plethora of different substrates. All the patients harbor *de novo* variants in *PPP2CA* predicted to affect the catalytic activity, the binding to other subunits in the complex or the protein levels with both loss-of-function or dominant negative mechanisms.**Methods:** A 2-year-old male presented to Undiagnosed Rare Disease Clinic at Indiana University School of Medicine/IUHeath with polymicrogyria, white matter loss resulting in ventriculomegaly, severe upper airway disease, hypotonia, feeding dysfunction and dysmorphic features including hypertelorism, wide nasal bridge, congenital microcephaly, and deeply set eyes. Whole-Exome Sequencing analysis revealed a *de novo* VUS c.-1_2delCAT in *PPP2CA* gene, affecting the 5â□□UTR and absent from public databases of normal variation. To further investigate the variant, we performed *in silico* predictions, and mRNA and protein studies to assess the level of expression. **Results**:The RT-qPCR performed in mRNA extracted from peripheral blood showed no reduction of PPP2CA mRNA levels. *In silico* analyses predicted that c.-1_2delCAT deletion alters significantly the natural Kozak sequence (GCATCATGG>GCATG). Subsequent western blot analysis performed by transfecting HEK293T cells with WT-PPP2CA-HA and 1_2delCAT-PPP2CA-HA, revealed the presence of an alternative 29 KDa N-terminal truncated product caused by a differential usage of a downstream in frame alternative ATG in position +66. This deleted product does not possess the previously characterized critical residues D57,H59 and G60 and could act as a dominant negative or hypomorphic allele. **Conclusion:** Here we report for the first time a novel variant affecting the 5â□□UTR region of the *PPP2CA* gene in a patient with a PPP2CA-related disorder. Taken together, our findings expand the phenotypic and genotypic spectrum of the recently described PPP2CA-related syndrome and illustrates how the analysis of non-coding variants can help inform the disease-causing mechanism and improve the diagnostic yield.

PrgmNr 3415 - Allelic frequency and distribution of *M98K*variant associated with adult-onset open angle glaucoma in Puerto Rico

View session detail

Author Block: **C. PagÃin**, E. Ramirez Aponte, J. Martinez Cruzado; Univ. of Puerto Rico at Mayaguez, Mayaguez, Puerto Rico
Disclosure Block: **C. PagÃin:** None.

Glaucoma is a severe neurodegenerative, hereditary condition that is increasingly prevailing in native Puerto Rican citizens. The purpose of this study is to correlate the *M98k* (rs11258194) missense variant in the *Optineurin* (*OPTN*) protein with Adult-Onset Primary Open Angle Glaucoma (POAG) in Puerto Rico; in addition, determine the distributional mutated allelic frequency throughout the Island. *Optineurin* is an adaptive protein that interacts in various nervous cell processes such as vesicular transportation, signaling and autophagy. By selecting 625 patient samples that span a total of 30 municipalities as a guide of the general population, we were able to genotype the samples by RT-PCR with a TaqMan Assay for SNP rs11258194. The samples were further analyzed through geographic distribution via MapViewer, a map-rendering tool. The results showed a total of 60 mutated alleles (48 heterozygous, 6 homozygous) mainly distributed along the coastline of Puerto Rico. Therefore, heterozygous patients with *M98k* variant present are more prone than wildtype patients to develop a neurodegenerative condition. Further studying will confirm if homozygous patients present POAG or other nervous-related condition such as Amyotrophic Lateral Sclerosis.

PrgmNr 3416 - An integrated machine learning and functional analysis approach for resolution of variants of uncertain significance (VUS) in *STXBP1*

View session detail

Author Block: **J. Calhoun**[1], J. Gunti[1], H. C. Mefford[2], S. Schnell[3], V. Aguiar-Pulido[4], M. E. Ross[5], J. Parent[3], L. L. Isom[3], EpiMVP Consortium, G. L. Carvill[1]; [1]Northwestern Univ., Chicago, IL, [2]St. Jude Children's Res. Hosp., Memphis, TN, [3]Univ. of Michigan, Ann Arbor, MI, [4]Univ. of Miami, Miami, FL, [5]Weill Cornell Med., New York, NY

Disclosure Block: **J. Calhoun:** None.

Variants of uncertain significance (VUS) pose a significant challenge for genetic diagnosis of epilepsy, in that these variants can be classified as neither pathogenic nor benign. In order to address this challenge, we established a highly integrated Epilepsy Multiplatform Variant Predictor (EpiMVP) Center Without Walls to develop precise, single-gene *in silico* pathogenicity prediction tools (EpiPred) for the most common epilepsy-associated genes. We are using machine learning algorithms to discriminate pathogenic from benign variants. This approach will be bolstered by functional characterization of a subset of variants in multiple cellular and animal models. The first gene for study is *STXBP1*, a gene implicated in a range of pediatric-onset epilepsies. We first curated a robust training set for the development of our classifier. This consisted of known benign or likely benign (BLB) missense *STXBP1* variants from the general population (n=128) and known pathogenic or likely pathogenic (PLP) missense *STXBP1* variants from multiple sources, including industry partners (Invitae, GeneDx, Geisenger), Clinvar, and the literature (n=93). Variants were annotated with multiple features (n=19) using *in silico* measures related to evolutionary conservation, protein structure and stability, among others. Our approach employed standard unsupervised and supervised machine learning algorithms to develop an optimal single-gene classifier. Our classifier outputs a score ranging from PLP (high) to BLB (low) and was used to score *STXBP1* VUSs (n=133) collated from ClinVar and industry partners. Our classifier is successful at discriminating *STXBP1* missense BLB and PLP variants (ROC_{AUC} > 0.9). We used four different models to score and then rank each of the 133 VUS. About half of the VUSs (50.3%) were highly concordant across the four models (SD 0.1). We selected eight representative variants for functional modeling. The first iteration of our EpiPred classifier can distinguish between BLB and PLP variants with high specificity. After functional validation in the EpiMVP cellular and animal models, we will improve the predictive power of EpiPred and release this model to the wider scientific and epilepsy community for interpretation of VUS. Our overarching goal is to develop gene-specific classifiers for additional epilepsy-associated genes with an emphasis on non-ion channel genes with the highest volume of VUS and PLP variants identified in routine clinical genetic testing.

PrgmNr 3417 - Biallelic *NAV2* truncating variants cause a neurodevelopmental disorder with cerebellar cortical dysplasia

Disclosure Block: **J.A. Rosenfeld:** Other; Baylor Genetics.

Cerebellar hypoplasia and dysplasia encompass a group of clinically and genetically heterogeneous disorders frequently associated with neurodevelopmental impairment. We report a 7-year-old female with global developmental delay (mostly mild, with gross motor skills most significantly impacted), abnormal brain MRI (marked cerebellar vermis hypoplasia, bilateral cerebellar foliation defects, pontine hypo-dysplasia, splayed thin superior cerebellar peduncles with a molar tooth-like configuration, corpus callosum hypodysgenesis, absent anterior commissure, diffuse dysgyria, agenesis of the olfactory bulbs, mild optic nerve hypoplasia, and enlarged dysmorphic lateral ventricles), ophthalmologic abnormalities (atypical chorioretinal scarring, retinal ischemia, retinal neovascularization, and retinal detachment), polyvalvular heart disease, and dysmorphic features. Trio-based clinical exome sequencing revealed compound heterozygous truncating variants in the neuron navigator 2 (*NAV2*) gene, which was not previously associated with human disease. *NAV2* encodes a member of the neuron navigator protein family, widely expressed within the central nervous system (CNS), particularly abundant in the developing cerebellum, with pivotal functions in cytoskeletal dynamics and neurite outgrowth. *Nav2* hypomorphic mice display cerebellar hypoplasia with abnormal foliation, due to impaired axonal outgrowth. To further explore the possible connection of *NAV2* to human disease, we performed expression studies and migration assays in patient-derived fibroblasts, which confirmed absence of full-length NAV2 and showed perturbed cellular migration. We also evaluated the overall CNS histopathology of the *Nav2* hypomorphic mouse, which revealed multiple developmental anomalies (i.e., cerebellar hypoplasia and dysplasia and corpus callosum abnormalities), strikingly overlapping our probandâ□□s brain findings. Together, these data support recessive loss of function of *NAV2* as a cause for a neurodevelopmental disorder with complex brain malformations, particularly in the cerebellum.

PrgmNr 3418 - Delineation of a neurodevelopmental syndrome caused by *PAX5* haploinsufficiency

The human PAX (Paired Box) family of transcription factors has nine members, all of which are associated with a genetic syndrome, susceptibility to a disease, or a structural birth defect. Currently, the only known disease association for the gene *PAX5* is susceptibility to acute lymphoid leukemia. However, *PAX5* is transiently expressed during embryogenesis in the central nervous system, is highly loss-of-function intolerant (pLI = 1, o/e = 0) and missense constrained (Z = 2.54) in gnomAD, is associated with abnormal posterior midbrain and cerebellum development in mice, and has been suggested as a candidate gene for autism and intellectual disability based on data from large cohort studies. In this study, we describe eight individuals who carry putatively deleterious *PAX5* variants. These include two individuals with interstitial deletions that include *PAX5*, two individuals with frameshift variants that are likely to trigger nonsense-mediated mRNA decay, and four individuals with single nucleotide variants, three of which affect the *PAX5* DNA binding domain. All the individuals in this cohort had developmental delay, intellectual disability and/or autism spectrum disorder. Speech development was particularly affected, with many showing regression in their expressive language abilities and approximately half being non-verbal. Feeding issues and behaviorally-defined psychiatric diagnoses were common, and two individuals have seizures. No structural abnormalities were noted in those who had brain imaging, and no clear pattern of dysmorphic features was apparent. Our findings suggest that *PAX5* haploinsufficiency causes a neurodevelopmental disorder characterized by severe deficits in expressive language development, variable intellectual disability, and autism spectrum disorder.

PrgmNr 3419 - Diagnostic rate and clinical implications of exome sequencing in adults with intellectual disability

View session detail

Author Block: **A. Sabo**[1], D. R. Murdock[2], S. Pereira[3], S. Dugan[1], M. Gingras[3], D. M. Muzny[3], R. A. Gibbs[3]; [1]Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX, [2]Baylor Coll. of Med., Houston, TX, [3]Baylor Coll. Med., Houston, TX

Disclosure Block: **A. Sabo:** None.

Establishing a genetic diagnosis for individuals with intellectual disability (ID) benefits patients and their families as it may inform the prognosis, lead to appropriate therapy, and facilitate access to medical and supportive services. Exome sequencing has been successfully applied in a diagnostic setting, but most clinical exome referrals are pediatric patients, with many adults with ID lacking a comprehensive genetic evaluation. Many adults living with ID might now be able to be diagnosed with modern methods but are not readily accessing the tests due to a lack of access to care, insurance coverage or knowledge of new opportunities. Our aim is to reach this underserved population by recruiting 100 adults with ID and their families. Recruitment sites include non-clinical organizations that provide education and support services for individuals with ID, as well as three clinical sites: Childrenâ□□s Hospital of San Antonio, Emory University, and Transition Medicine Clinic at Baylor College of Medicine. At all sites adults with ID of unexplained etiology with all levels of severity are included to evaluate a low barrier, broad application clinical genetic testing utilizing WES methods. We utilized exome sequencing and analysis, identified SNVs, Indels, and CNVs and performed clinical variant interpretation for each recruited family. Families where exome sequencing analysis identified pathogenic or likely pathogenic variants were invited for an appointment with a board-certified clinical geneticist to discuss the results and any potential medical follow-up. In addition to establishing diagnostic rates we will formally evaluate the impact of a genetic diagnosis on patients and their families, and the clinical utility, including measures related to diagnosis, patient clinical management, and familial and psychosocial implications using recently developed C-GUIDE.

Our published data from the pilot included 5 families of which 3 received a genetic diagnosis. Currently, we have recruited 15 additional families. For one family we have identified a pathogenic stop-gain variant in the POGZ gene. The individual has ID, autism, and visual and hearing impairment, fitting the diagnosis of White-Sutton syndrome. The samples from remaining 14 families are currently undergoing sequencing, and findings from this next phase will be described in this presentation. Our study demonstrates that there is interest in families with adults with ID in receiving a genetic diagnosis and suggests a high yield of exome sequencing (4 out of 6 families) as a diagnostic tool in adult patients with ID who have not undergone comprehensive sequencing based genetic testing.

PrgmNr 3420 - Expanding the Genotypic and Phenotypic Spectrum of CTCF-Related Disorders: 19 new patients andreviews of published literature

View session detail

Author Block: **H. Valverde de Morales**, P. Piwko, J. DiMonda, H-L. Wang, V. Corces, H. Li; Emory Univ. Sch. of Med., Atlanta, GA
Disclosure Block: **H. Valverde de Morales:** None.
Background Monoallelic variants in *CTCF* cause an autosomal dominant neurodevelopmental disorder with a wide range of symptoms affecting brain, craniofacial features, growth and various anomalies. Given the increased application of exome sequencing, a continuously growing number of patients has been identified and further delineation of the clinical spectrum of CTCF-related disorders (CTCFRD) is needed. **Methods** Individuals with monoallelic variants in *CTCF* were recruited through a CTCF family support group, Genematcher and a commercial genetic diagnostic laboratory. The detailed clinical information along with patientâ□□s facial photos at various ages were collected through RedCap under Emory IRB approval. Clinical variables were analyzed across our novel patients and previously published patients. Facial profiles were investigated via DeepGestalt using the Face2Gene tool. **Results** In our study, we have enrolled 31 patients, clinical information was completed for 20, including 19 novel patients from 17 unrelated families and 1 previously reported patient who has updated information. We identified 12 novel variants (4 frameshift, 1 nonsense, 5 missense and 2 small in-frame deletions), which expanded the total variants in *CTCF* from 45 up to 57. Though most variants are de novo, we report one familial case affecting three generations. Common clinical features in our cohort include developmental delay or intellectual disability (18), failure to thrive or feeding difficulties (12), sleeping difficulties (11), intrauterine growth restriction/small gestational age (IUGR/SGA) (11), skeletal anomalies (10), genitourinary anomalies (9), and hypotonia (9). Noticeably, the incidence of autism (9) was higher in our cohort compared to the existing literature (45% vs 30%). Other less common anomalies include teeth abnormalities (7), seizures (5) and palatal abnormalities (4). Some features, such as cardiac defects (4) and microcephaly (0), are not as common as previously reported. Dysmorphology analysis of patients identified broad nasal bridge, deep-set eyes, cupped ear and pointed chin as the hallmark features of CTCFRD. DeepGestalt training from 36 patients at various ages (18 patients from our study and 18 from the literature) is still ongoing. **Conclusions** Our study expands the genotypic and phenotypic spectrum of CTCFRD that can guide genetic counseling and surveillance care. Both dysmorphology and digital analysis could facilitate the early diagnosis of CTCFRD.

PrgmNr 3421 - Expanding the phenotypic spectrum of *EXOSC8*-related neurological disease: Presentation of an Egyptian family with neurodevelopmental disorder due to a novel *EXOSC8* missense variant

Disclosure Block: **I. Herman:** None.

Background: The exosome is a protein complex essential for RNA processing and degradation with a critical role in gene expression. To date, 6 *EXOSC* genes (*EXOSC1*, *EXOSC2*, *EXOSC3*, *EXOSC5*, *EXOSC8*, *EXOSC9*) are linked to human disease. Variants in *EXOSC8* are associated with autosomal recessive (AR) pontocerebellar hypoplasia 1C (MIM #616081), described in only 3 families, which is characterized by a universally progressive infantile-onset neurodegenerative disease with muscle atrophy, brain abnormalities, and death in infancy. Here, we expand the phenotypic spectrum of *EXOSC8*-related disease and describe the clinical and molecular features of a 4th family with neurodevelopmental disorder and survival into adulthood in association with a seemingly milder missense allele.

Materials and Methods: The family was recruited as part of the Baylor-Hopkins Center for Mendelian Genomics research initiative. Study consent was obtained from all participants. Trio exome sequencing (ES) with family-based rare variant analysis was performed.

Results: The proband is a 5 year-old girl born to first cousin Egyptian parents. Early clinical features included neonatal jaundice, respiratory distress, aspiration, cyanosis, and global developmental delay. Neurological examination showed dysarthria, hyperreflexia, dysmetria, intention tremor, borderline intellect, and no signs of amyotrophy or neuropathy. Brain MRI showed cerebellar vermis atrophy. She has an adult maternal aunt and uncle with similar phenotypic features with intellectual disability and wheelchair-bound status. Trio ES revealed a novel homozygous *EXOSC8* missense variant (c.398G>C;p.Trp133Ser), predicted damaging by multiple *in silico* analyses, and the affected amino acid residue is fully conserved across species. Further analysis revealed evidence for identity-by-descent (IBD) with a total absence of heterozygosity (AOH) of 280.1 Mb and AOH block of 16 Mb surrounding the detected variant. Sanger sequencing and segregation analyses confirmed the homozygous status in the proband and affected aunt and uncle.

Conclusion: The exosome complex is essential in human development as pathogenic variations in several exosome cause human disease. Here we provide evidence that â□□milderâ□□ pathogenic *EXOSC8* variant alleles cause neurodevelopmental disabilities with survival into adulthood. As *EXOSC*-related disease is extremely rare and few families have been described for each gene, it is essential to identify and longitudinally follow additional affected individuals within a human allelic series to capture and characterize the full genotype-phenotype spectrum of *EXOSC*-related disease.

PrgmNr 3422 - Genetic heterogeneity in *SARS2* gene in a patient with global developmental delay and spastic paraplegia

View session detail

Author Block: **E. Glenn**[1], E. Vasconcellos[2], P. Jayakar[3]; [1]Nicklaus Children's Hosp., Miami, FL, [2]Wemind Inst., Miami, FL, [3]Miami Children's Hosp, Miami, FL
Disclosure Block: **E. Glenn:** None.
Mitochondrial aminoacyl-tRNA synthetases are an increasingly studied family of genes in which mutations may cause phenotypes ranging from isolated tissue disease to distinct syndromes. Mitochondrial seryl-tRNA synthetase gene (*SARS2*) missense mutations have been particularly identified in HUPRA syndrome. Patient is a 2-year-old hispanic male of first cousins consanguineous union, presenting with global developmental delay, short stature, distal hypertonia, poor weight gain and central hypotonia. Birth history remarkable only for IUGR. Developmental delay noted at 7 months of age. At 2 years of age, he cannot sit or roll, is just starting to reach for objects and lifts head while prone; babbles but is non-verbal. Has not had any regressions. Patient presents short stature, plagiocephaly, strabismus, no facial dysmorphism. Neurological exam shows head lag, with a picture of spastic quadriplegia with opisthotonic posture, bilateral cortical thumbs, tight heel cords, hyperreflexia, including cross adductors, ankle clonus and Babinski signs. MRI Brain showed symmetric signal abnormality in the thalami, periventricular white matter with extension to the perirolandic regions. ECHO, EKG, Renal US, blood gas, uric acid, metabolic panel and karyotype were normal. Swallow study showed aspiration in all consistencies. Microarray significant for short runs of homozygosity totaling 19.8 Mb (6.7% of autosomal genome). Exome sequencing positive for *SARS2* homozygous variant c.1347 G>A p.T449, Likely Pathogenic, biparental inheritance; and *PLEKHG2* c.158 C>T p.T531, homozygous, Variant of uncertain significance (VUS), Biparental Inheritance. *SARS2* gene mutation has been associated with HUPRAS, syndrome (hyperuricemia, pulmonary hypertension, renal failure, and alkalosis syndrome) caused by a homozygous mutation in the *SARS2* gene (612804), which encodes mitochondrial seryl-tRNA synthetase, on chromosome 19q13. Linnankivi, T, et al reported a case of homozygous splicing mutation in *SARS2* presenting with progressive spastic paresis and no HUPRAS phenotype. Our patient fits into a clinical phenotype of progressive spastic paresis rather than HUPRAS since he has no hyperuricemia, renal failure or alkalosis with normal cardiac and renal function tests. This demonstrates the genetic heterogeneity of *SARS2* gene and further exemplifies the sensitivity of the nervous system to partially reduced aminoacylation.

PrgmNr 3423 - Genomics of early onset CNS autoimmune demyelinating diseases: Role for deleterious, rare variants in common immune pathways

Ctr. at Houston, Houston, TX, [5]Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX, [6]Dept. of Pediatrics, Baylor Coll. of Med., Houston, TX, [7]Section of Immunology, Allergy, and Rheumatology, Texas Childrenâ□□s Hosp., Houston, TX

Disclosure Block: **D.G. Calame:** None.

Background: Demyelinating diseases of the central nervous system (CNS) are poorly understood autoimmune syndromes and include multiple sclerosis (MS), neuromyelitis optica (NMO), acute disseminated encephalomyelitis (ADEM), and chronic lymphocytic inflammation with pontine perivascular enhancement responsive to steroids (CLIPPERS). As in other autoimmune disorders, their genetic underpinnings are felt to be complex, with individual risk reflecting additive or synergistic effects of combinations of common alleles with small effect. In contrast, investigation of the role of rare alleles has been limited, despite their often greater effect on phenotype. Relatedly, rare alleles cause monogenic systemic lupus erythematosus (SLE) and are enriched in patients with early onset disease. With this in mind, we experimentally investigated the hypothesis that rare alleles in immune system genes underlie early onset demyelinating disease.

Methods: We recruited 10 families with early onset (â□¤10 years) demyelinating disease who underwent family-based exome sequencing (ES). ES data were analyzed using rare variant parsing and filtering approach. Family members with systemic autoimmune diseases were recruited for segregation analysis.

Results: Five patients had potentially causative variants in known immune disease genes: *TLR7* (c.1521T>G, p.Phe507Leu, NMO), *TNFAIP3* (c.1069C>T, p.Gln357*, NMO), *IFIH1* (c.2525A>G, p.Glu842Gly, ADEM), *PRF1* (c.657C>A, p.Tyr219*; c.272C>T, p.Ala91Val, CLIPPERS), and *UNC13D* (c.2045G>T, p.Arg682Leu; c.2354T>C, p.Val785Ala [*in cis*], CLIPPERS). Novel disease gene candidates were identified in three patients: *DOCK11* (MS), *SYTL2* (CLIPPERS), and *IFIT1B* (vasculitis). *TNFAIP3*:c.1069C>T segregated with the disease trait within a large autoimmune family with considerable intrafamilial phenotypic variability (median onset: 18 years; range 2-46; diseases: NMO, SLE, Stillâ□□s disease, scleroderma). *TLR7*:c.1521T>G was similarly inherited from a mother with SLE. Immune pathways implicated include type 1 interferon (*TLR7*, *TNFAIP3*, *IFIH1*, *IFIT1B*), cytotoxic lymphocyte degranulation (*UNC13D*, *PRF1*, *SYTL2*), B cell homeostasis (*DOCK11*), and NF-ÎºB (*TLR7*, *TNFAIP3*).

Conclusions: We provide evidence that rare alleles in immune genes underlie early onset demyelinating disorders suggesting â□□medical actionability,â□□ e.g. JAK inhibition for *TNFAIP3* haploinsufficiency. Additional studies in larger cohorts will better delineate the role of rare alleles in demyelinating disease and may uncover the pathophysiological basis of these conditions and additional opportunities for pharmacologic intervention.

PrgmNr 3424 - Identifying variant specific phenotypes for *SLC6A1* related disorders

View session detail

Author Block: **K. Jay**[1], J. C. Andrews[1], S. Jangam[1], H. Pan[1], H. J. Bellen[1], S. Yamamoto[2], M. Wangler[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Baylor Coll. of Med., HOUSTON, TX
Disclosure Block: **K. Jay:** None.
The Solute Carrier Family 6, Member 1 (*SLC6A1*) gene was first associated with Doose syndrome in 2015. The patient was carrying a 3p microdeletion and presented with epileptic encephalopathy, intellectual disability (ID), and myoclonic atonic seizures. The first clinical characterization of 34 patients with *SLC6A1* variants was reported in 2018 and the largest case study of patients was presented in 2020. A total of 116 patients with 85 variants were characterized and common phenotypic characteristics include developmental delay, epilepsy, autism spectrum disorder (ASD), and motor dysfunction. Current therapy is focused on seizure suppression however, the GABA transporter type 1 (GAT1) protein has the potential to be targeted directly. Toward this goal, genotype phenotype correlative studies will elucidate the mechanism of transporter dysregulation. We hypothesize both loss of function (LOF) and gain of function mechanisms are responsible for the variable expressivity of *SLC6A1* patient phenotypes. We study *SLC6A1* functional models in *Drosophila melanogaster* utilizing the GAL4-UAS system to express human reference and patient specific variants. We have characterized LOF phenotypes for the fly homolog by evaluating flies with a Trojan GAL4 (TG4) construct, inserted into the first coding intron of the *Drosophila Gat* gene, resulting in severe premature truncation of the *Drosophila* protein. We observe that Gat mutant flies exhibit motor and bang sensitive phenotypes analogous to seizure activity in humans and have a reduced lifespan in homozygous TG4 animals. I will further investigate LOF mechanisms with multiple RNAi targeting *Gat*, utilizing the GAL80ts to delay induction of RNAi in adult flies, allowing us to separate the function of Gat protein throughout development from adult stages. To evaluate patient specific symptoms, we are designing reference and variant constructs for all known recurrent variants previously reported in patients with *SLC6A1* related phenotypes and 5 novel variants collected at the Baylor Genetics lab. Human reference and variant proteins are being expressed with ubiquitous and tissue specific GAL4 driver lines. In parallel we recruit human subjects with *SLC6A1* variants for psychological studies to aid in genotype-phenotype correlation for our functional assays. The models generated will support future studies to predict patient response to GAT1 modulatory therapeutics.

PrgmNr 3425 - KBG Syndrome: Prospective Videoconferencing and Use of AI Facial Recognition in 25 new patients

View session detail

Author Block: **G. LYON**[1], L. Guo[1], J. Park[1], E. Yi[1], T-C. Hsieh[2], P. M. Krawitz[2], E. Marchi[1]; [1]Inst. for Basic Res. in Dev.al Disabilities, Staten Island, NY, [2]Inst. for Genomic Statistics and Bioinformatics, Univ. Bonn, Bonn, Germany

Disclosure Block: **G. Lyon:** None.

Genetic variants in the gene Ankyrin Repeat Domain 11 (ANKRD11) and deletions in 16q24.3 are known to cause KBG Syndrome, a rare syndrome associated with craniofacial, intellectual, and neurobehavioral anomalies. We report 25 unpublished individuals from 22 families, all of whom have a molecularly confirmed diagnosis of KBG syndrome. 21 individuals have de novo mutations, 3 have inherited mutations, and 1 is inherited from a mother exhibiting a low-level of mosaicism. Of these mutations, 20 are truncating (frameshift or nonsense), and 5 are missense. We created a novel protocol for the collection and reporting of the data, including prospectively interviewing these individuals and their families from 8 different countries via videoconferencing by a single clinician, to elucidate the most common phenotypic malformations and developmental anomalies. In addition, the participantsâ medical records, including imaging, were reviewed, and data was compiled and uploaded onto the Human Disease Gene website, with the observed KBG anomalies denoted by Human Phenotype Ontology (HPO) terms. Furthermore, facial photos of the KBG syndrome research participants were obtained and submitted to the Face2Gene website and the GestaltMatcher website. Face2Gene uses convolutional neural networks to identify genetic disorders from a photo by training on thousands of patient images. GestaltMatcher, as an extension of Face2Gene, can quantify the similarity between two patients, enabling us to identify genetic traits and associate them with the most likely genetic disorder. Use of this software may allow for accurate identification of KBG Syndrome using pictures depicting unique craniofacial features. Within our cohort, common phenotypic malformations included short stature, macrodontia, anteverted nares, wide nasal bridge, wide nasal base, thick eyebrows, synophrys and hypertelorism. 72% of participants had gastrointestinal complaints. Three participants were started on growth hormone and had positive results. Behavioral issues and global developmental delays were found in most participants. Neurologic abnormalities such as poor coordination and seizures (44%), indicating the importance of early screening and prophylaxis, were also very common. We have also identified minimally reported symptoms, including recurrent sinus infections (16%), markedly prevalent hearing loss (80%), as well as previously unreported migraines (20%).

PrgmNr 3426 - Loss of function variants in *PUS7* dysregulate protein synthesis and are associated with neurodevelopmental delay, microcephaly, and hyperuricemia

View session detail

Author Block: **K. Garcia**[1,2], T. Han[1,2], A. Kim[1,2], E. Macnamara[2], L. A. Schimmenti[3], E. R. Nicoli[1,2], M. Malicdan[1,2], W. A. Gahl[1,2], C. J. Tifft[1,2]; [1]Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [2]Undiagnosed Diseases Program, Office of the Director, NIH, Bethesda, MD, [3]Clinical Genomics, Mayo Clinic, Rochester, MN

Disclosure Block: **K. Garcia:** None.

Protein translation is a tightly regulated process essential to maintaining homeostasis in all cells and influences gene expression. Modulation of protein translation requires coordination of various translational factors and ribosomal units, which utilize transfer RNA (tRNA) during protein synthesis. Pseudouridine synthase 7 (*PUS7*) catalyzes the conversion of uridine to pseudouridine on many RNAs. Among its targets are residues of tRNAs needed for the function of tRNA fragments (tRFs). tRFs regulate protein translation by inhibiting formation of translation initiation complex, eIF4F. Without *PUS7*, protein synthesis is dysregulated, resulting in a net increase in protein translation. Elevated protein synthesis is a hallmark of cancer and has also been implicated in autism spectrum disorder. Two patients referred to the NIH through the Undiagnosed Diseases Program presented with a neurological disease displaying a phenotype that included postnatal microcephaly, aggressive/self-injurious behavior, global developmental delay, short stature, and hyperuricemia. Although the patients exhibited clinical overlap with Lesch-Nyhan Syndrome, they did not carry pathogenic variants in *HPRT1*. Genome sequencing revealed the siblings were compound heterozygous for novel pathogenic variants in PUS7. The paternal allele carries a missense variant with no effect on protein expression, stability, or localization, but the variant is found within the catalytic domain. The maternal allele carries a splice variant that disrupts the native donor splice site causing mis-splicing of mRNA, which introduces a frameshift mutation and premature termination, resulting in degradation of the transcript via nonsense-mediated mRNA decay. We demonstrated that loss of *PUS7* activity in patient fibroblasts is sufficient to disrupt protein translation and replicated those findings in a *PUS7* knockout HeLa cell line. We then investigated the expression of genes that are potentially altered by dysregulated protein synthesis. We found that patient fibroblasts express elevated levels of MYC protein without increasing cell proliferation. Concurrently, dysregulation of protein synthesis in patient fibroblasts also decreased protein levels of HPRT1, potentially explaining the phenotypic overlap with Lesch-Nyhan Syndrome. We believe that these findings strengthen the correlation between dysregulation of protein translation and complex neurodevelopmental diseases and that the mechanism resembles those previously linked to autism spectrum disorders.

PrgmNr 3427 - Maternal mosaicism for a missense variant in the *SMS* gene that causes Snyder-Robinson syndrome

View session detail

Author Block: **M. Marhabaie**[1], S. E. Hickey[2], K. Miller[1], O. Grischow[1], K. Schieffer[3], S. Franklin[1], D. Gordon[4], S. Choi[1], P. White[1], D. C. Koboldt[2], R. K. Inst. for Genomic Med., Columbus, OH

Disclosure Block: **M. Marhabaie:** None.

There is increasing recognition for the contribution of genetic mosaicism to human disease, particularly since the advent of high-throughput sequencing which enables detection of variation at very low allele frequencies. Here, we describe an infant male who presented at nine months of age with hypotonia, dysmorphic features, congenital heart disease, hyperinsulinemic hypoglycemia, hypothyroidism, and bilateral sensorineural hearing loss. Extensive biochemical and genetic testing - including clinical whole-exome sequencing - failed to provide a diagnosis. The family was enrolled into an IRB-approved research study for trio whole-genome sequencing, which uncovered an apparent *de novo* mutation in the X-linked *SMS* gene. *SMS* encodes spermine synthase, which catalyzes the production of spermine from spermidine. Inactivation of *SMS* gene disrupts the spermidine/spermine ratio, resulting in Snyder-Robinson syndrome. The variant in our patient is absent from the gnomAD database and causes a missense change (p.Arg130Cys) predicted to be damaging by most *in silico* tools. Further, this amino acid change has been described in one patient in the literature and is believed to reduce SMS dimer stability by disrupting the structure of the adjacent spermine binding site. While Sanger sequencing confirmed the *de novo* status in our proband, PCR and deep targeted resequencing to >85,000x depth revealed that the variant is present in the maternal blood at ~3% variant allele frequency. Our findings thus provided a long-sought diagnosis for the family while highlighting the role of parental mosaicism in severe genetic disorders.

PrgmNr 3428 - Novel *PRUNE1* c.933G>A (p.Thr311=) synonymous splice variant induces exon 7 skipping and leads to an atypical presentation of NMIHBA syndrome: Case report and review of the literature

Disclosure Block: **C. Magyar:** None.

Prune exopolyphosphatase 1 (*PRUNE1)* encodes the PRUNE protein, a phosphodiesterase member of the DHH (aspartic acid-histidine-histidine) phosphodiesterase superfamily, which plays a pivotal role in cell migration and proliferation via interactions with beta-tubulin and is highly expressed in the developing fetal brain. In 2015, biallelic *PRUNE1* loss-of-function variants were identified to cause an autosomal recessive neurodevelopmental disorder characterized by delayed development, microcephaly, central hypotonia with peripheral spasticity, and brain structural abnormalities including thinning of the corpus callosum, cerebral and cerebellar atrophy, variable white matter disease, and delayed myelination. Other prevalent co-morbid findings included seizures, visual anomalies, and gastrointestinal complications. This condition is now known as the Neurodevelopmental Disorder with Microcephaly, Hypotonia, and Variable Brain Abnormalities (NMIHBA, OMIM#617481), and to date 46 individuals have been reported in the literature. However, the phenotypic spectrum of *PRUNE1*-related disorders and their causative variants remains to be characterized fully. Here, we report a case involving a novel homozygous synonymous splice site *PRUNE1* NM_021222.1:c.933G>A (p.Thr311=) variant identified in a five-year old male from a consanguineous union with intellectual and developmental disabilities, hypotonia, and spastic diplegia, but with the absence of microcephaly, brain structural alterations, seizures, or ophthalmologic anomalies. This clinically relevant variant was identified after reanalysis of previously reported negative clinical whole exome sequencing (WES). Fragile X, *SLC16A2* sequencing, and oligonucleotide comparative genomic hybridization (CGH) array testing were unremarkable. Fibroblast RNA-sequencing revealed that the homozygous *PRUNE1* NM_021222.1:c.933G>A (p.Thr311=) variant generated an alternate transcript with an in-frame skipping of exon 7. In contrast to the previously identified *PRUNE1* c.521-2A>G splice acceptor variant, the resulting transcript in our proband is predicted to generate a mutant protein. This case represents the first synonymous splice site variant and the third pathogenic variant known to date affecting the DHH-associated domain (DHHA2 domain). These findings extend the genotypic and phenotypic spectrum in *PRUNE1*-related disorders and highlight the importance of considering synonymous and splice site variants in atypical presentations of a known disorder.

PrgmNr 3429 - Role of *VRK1* defects in spinal muscular atrophies like patients with negative *SMN1* finding

View session detail

Author Block: **C. Wu**[1,2], X. Zhao[1,2], D. Castro[3,4], K. Batley[3,4], D. Michelson[5], C. Eng[1,2], L. Meng[1,2], H. Dai[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Baylor Genetics, Houston, TX, [3]Univ. of Texas Southwestern, Dallas, TX, [4]Childrenâ□□s Hlth.Dallas, Dallas, TX, [5]Loma Linda Univ. Med. Ctr., Loma Linda, CA
Disclosure Block: **C. Wu:** None.
Introduction: Historically, defects in *VRK1* were thought to cause autosomal recessive pontocerebellar hypoplasia type 1A (MIM# 607596), a rare form of spinal muscular atrophies (SMA) characterized by severe neurodegenerative disorders affecting growth and function of the brainstem and cerebellum, resulting in little or no development. To date, fewer than 15 cases of *VRK1*-related conditions have been reported in the literature. The spectrum of symptom severity and age of onset are still largely unknown. **Methods:** Experimental procedures and bioinformatics analysis of exome sequencing (ES) were performed following previously described methods. Variant interpretation was performed according to the joint American College of Medical Genetics and Genomics and Association for Molecular Pathology guidelines. **Results**: Patient 1 was a boy who presented in early childhood with progressive limb weakness and loss of motor function, microcephaly, and scoliosis and he progressed in adolescence to severe dysphagia, dysarthria, and respiratory insufficiency. *SMN1* deletion and *IGHMBP2* deletion/duplication tests were negative. ES identified compound heterozygous likely pathogenic variant c.266G>A (p.R89Q) and pathogenic variant c.706G>A (V236M) in *VRK1*. Patient 2 was a 14 yo female presented with peripheral neuropathy, pes cavus, joint hypermobility, and scoliosis. She had three similarly affected sisters (patients 3, 4, and 5, respectively). All sisters had normal cognition, with normal imaging of the brain confirmed in patients 2 and 3. They were all homozygous for c.706G>A (p.V236M) in *VRK1* inherited from the heterozygous parents. Patient 6 was a previously reported 32 yo male with progressive extremity weakness, breathing and swallowing difficulty. He was clinically diagnosed with early-onset amyotrophic lateral sclerosis (ALS). Testing for *SMN1* deletion and Kennedy disease were negative. ES identified compound heterozygous likely pathogenic variants c.356A>G (p.H119R) and c.961C>T (R321C) in *VRK1*. This case represents the mildest presentation among all reported patients with *VRK1*-related conditions. Pontocerebellar hypoplasia was not a consistent finding in these six patients. **Conclusion:** We have presented six patients from three unrelated families caused by biallelic variants in *VRK1*, which demonstrates a wide phenotypic spectrum ranging from muscle weakness to adult-onset ALS. Progressive muscle weakness can begin in different ages, with variable severity, resembling the spectrum of *SMN1*-associated SMA. These results highlighted the importance of *VRK1* evaluation, even when neuroimaging does not suggest pontocerebellar hypoplasia.

PrgmNr 3430 - Role of exome testing in autism spectrum disorder

View session detail

Author Block: **J. Castorena Ibarra**[1], R. Villafuerte[1], D. Aguilar[2]; [1]Escuela de Mediciana y Ciencias de la Salud del Tecnologico de Monterrey, Monterrey, Mexico, [2]Hosp. Zambrano Hellion Tec Salud, San Pedro Garza GarcÃa, Mexico
Disclosure Block: **J. Castorena Ibarra:** None.
Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder. Recently numerous exome sequencing studies had revealed new genes associated with ASD including de novo and hereditary mutations. TAF1 Transcription initiation factor TFIID subunit 1, also known as TATA-box binding protein associated factor 1 gene is critical for the normal function of neurons in the brain. TAF1 provides instructions for making part of a protein called transcription factor IID (TFIID). Recently a new X-linked syndrome (MIM# 300966) characterized by intellectual disability, autistic behaviors and distinctive facial features have been identified in association with pathogenic variants (PV) in TAF1. To date less than 40 cases have been described in 27 families, without including hispanic population.The objective of this abstract is to describe a mexican male infant with ASD and dysmorphias in which exome testing reveal a missense variant in TAF1.Case description: A 2 years 11 months male patient from healthy non-consanguineous parents and without relevant prenatal history. Geneticist evaluation reveals delayed speech and language development as well as craniofacial dysmorphic features. Under clinical suspicion of syndromic intellectual disability, exome testing was required in which a missense variant in TAF1 gene c.2189G>A p.Gly730Glu located in exon 14 was identified. Results: Patient's dysmorphic and behavioral features were compared with those previously described in Chang et al. and Oâ□□Rawe et al in TAF1 PV carriers, showing the most prevalent including global developmental and speech and language delay (95%), motor delay (50%) and hypotonia (70%). Autistic behavior (16%), hypertelorism, retrognathia, bulbous nose (20%) and wide nasal bridge (12.5%). To date 34 PVÂ´s have been described located throughout the gene. Missense variant identified in case described (c.2189G>A p.Gly730Glu) located in exon 14 encodes for an evolutionarily conserved central domain (DUF3591). Previously OÂ´Rawe and Cheng reported 10 PVÂ´s in TAF1 falling within domain DUF3591 which encompasses the TAF1 HAT domain and numerous points of contact with TAF7.The TAF1 missense variant identified by exome sequencing is not present in population databases nor has been reported in the literature. According to MutationTaster and at least five prediction models more, it is predicted to be a damaging or disease-causing variant but according to SIFT and other prediction models is classified as well tolerated or benign variant. However, conflictive interpretation, clinical data strongly suggest X-linked syndrome associated with TAF1 diagnosis.

PrgmNr 3431 - The phenotypic trajectory of 16p12.1 deletion is determined by family history of disease

View session detail

Author Block: **L. Pizzo**[1], C. Smolen[1], M. C. Jensen[1], A. Tyryshkina[1], L. Rohan[1], E. Huber[1], C. Taylor[2], 16p12.1 deletion Consortium, S. Girirajan[1]; [1]Pennsylvania State Univ., University Park, PA, [2]Geisinger Hlth.Systems, Lewisburg, PA
Disclosure Block: **L. Pizzo:** None.
The extreme phenotypic variability associated with copy-number variants such as the 16p12.1 deletion impacts genetic diagnosis and leads to challenges in predicting prognosis and management of affected families. Here, we recruited 146 children and 81 adults with 16p12.1 deletion from 113 families, and performed deep phenotyping through analysis of medical records, detailed clinical questionnaires, phone interviews, and quantitative assessment of cognitive and behavioral domains. We observed that probands manifested a range of phenotypes, including speech delay (73%), developmental delay/intellectual disability (63%), ASD (44%), ADHD (39%), craniofacial features (30%), hypotonia (30%) and multiple other congenital features. Further, probands with nervous system defects were more likely (OR=5.5) to present comorbid psychiatric and behavioral phenotypes (FDR=0.01). In contrast, adults with the deletion showed depression and anxiety (52%), learning difficulties in school (41%), schizophrenic features or bipolar disorder (14%), intellectual disability (11%), and alcohol and/or drug addiction (9%). Moreover, probands presented more severe distributions of behavioral functioning (4.89 SD), communication skill (2.44 SD), and non-verbal IQ (2.25 SD) scores compared to their carrier parents, comparable to those observed among individuals with autism from the Simons Simplex Collection. Next, we studied whether parental phenotypes could predict the phenotypic manifestation in children. K-means clustering of parental phenotypes showed that probands (n=38) with parents who presented cognitive (80%), schizophrenic (64%), depression and anxiety (64%), or addiction features (32%) were more likely to present defects in behavioral (p=0.04) and psychiatric (p=0.03) domains, compared to probands (n=25) whose parents had milder psychiatric features (8-15%). To understand the contribution of family history and rare variants towards phenotypic manifestation, we performed whole-genome sequencing and SNP array analyses of affected families. We observed that probands with a strong family history of psychiatric phenotypes presented a higher burden of loss-of-function mutations in genes intolerant to variation (p=0.01), while no differences were observed for likely deleterious missense mutations, deleted, or duplicated genes. Our work highlights the relevance of family history towards predicting behavioral and psychiatric outcomes in children with 16p12.1 deletion, and suggests that a subset of rare variants contribute towards more severe clinical manifestation of the deletion in the presence of strong family history of disease.

PrgmNr 3432 - The Use of Acetazolamide for Apneic Episodes in a Patient with EEF1A2 Mutation: A Case Report

View session detail

Author Block: **C. Joyce**[1], J. Sheah[2], j. n. peeden[3]; [1]Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN, [2]Dept. of Pediatric Neurology, East Tennessee Children's Hosp., Knoxville, TN, [3]East Tennessee Children's Hosp./Univ. of Tennessee Dept Med., Knoxville, TN
Disclosure Block: **C. Joyce:** None.
OBJECTIVE: Recurrent and significant daytime apnea events resulting in cyanosis and oxygen desaturations were quite problematic in a 6-year-old female with global neurodevelopmental delay due to an EEF1A2 mutation. After many trials the patient was found to be responsive to Acetazolamide in treatment of the apneic episodes.
METHODS: A 6-year-old female presented with recurrent apenic episodes occurring only while awake. Medical evaluation included continuous electroencephalogram (EEG) with events captured, pH probe also with events captured, pulmonary evaluation, magnetic resonance imaging (MRI) of the brain and echocardiogram. These diagnostic tests failed to identify any specific cause of the cyanotic events. Multiple medication regimens were attempted throughout the evaluation period including levetiracetam, baclofen, clonidine, oxcarbazepine, glycopyrrolate, and scopolamine all of which resulted in no improvement of cyanotic events. After secondary causes of apnea had been excluded, acetazolamide was prescribed given a favorable safety profile and case reports of success in Pitt-Hopkins syndrome for similar daytime apneic events. This is the first report of this therapy improving the intensity and frequency of apenic episodes in patients with the EEF1A2 mutation.
RESULTS: Acetazolamide was used in an attempt to ameliorate cyanotic events in a patient with EEF1A2 mutation with success. There is currently no literature in regards to patients with this mutation and the use of acetazolamide.
CONCLUSIONS: This is the first report of a patient with an EEF1A2 mutation responding to Acetazolamide for treatment of day-time apneic episodes.

PrgmNr 3433 - Triple knockout of*Fmr1,Fxr1*and*Fxr2*in Purkinje neurons results in mild behavioral phenotypes and a dramatic reduction of testis weight

View session detail

Author Block: **Y. Gu**, D. L. Nelson; Baylor Coll. of Med., Houston, TX
Disclosure Block: **Y. Gu:** None.

Fragile X syndrome (FXS) is a common cause of intellectual disability and autism due to mutation of *FMR1*. *Fmr1*knockout mice recapitulate major phenotypes of FXS patients and offer a very useful model for studying the function of the FMR1 product, FMRP. Although tremendous advances have been made in understanding FXS in the past several decades, effective treatment of FXS patients remains elusive.*FMR1*has two related paralogs, *FXR1*and*FXR2* which share significant homology and common functional domains. We hypothesize that phenotypes in FXS patients and *Fmr1* knockout mice are altered through compensation by the paralogs, masking the effects of loss of FMRP. Double knockout mice for *Fmr1* and *Fxr2* showed exacerbated behavioral abnormalities and disturbed lipid and glucose metabolism. These phenotypes are absent in either single knockout model, supporting our hypothesis. We recently created a second *Fxr2*knockout model (*Fxr2*KO2) that is a true null along with a conditional version of this allele (*Fxr2*cKO). Global double knockout with *Fmr1*leads to a more severe phenotype: embryonic lethality. Global knockout of *Fxr1*is lethal in the early postnatal period. To study complementation of function in neurons, we developed tissue specific knockout of all three genes directed to Purkinje neurons using L7-Cre and conditional alleles for all three genes. One breeding scheme produced male mice that lacked *Fmr1*and were heterozygous for Fxr1 and Fxr2 in Purkinje neurons and controls lacking the Cre (*Fmr1*cKO/y; *Fxr1*cKO/+; *Fxr2*cKO/+). Several behavioral tests (rotarod, parallel rod foot slip, digital gait, metal mesh flip and mini motor) demonstrated only minor differences. Using a different mating strategy, we produced and analyzed male mice with three genotypes: *Fmr1*cKO/y; *Fxr1*cKO/cKO; *Fxr2*cKO/cKO with or without L7-Cre and *Fmr1*cKO/y; *Fxr1*cKO/+; *Fxr2*cKO/cKO with L7-Cre. Surprisingly, mice lacking all three genes in Purkinje neurons were only mildly affected, they covered a shorter distance at a slower speed than the other two groups in the parallel rod footslip test. Significant differences in several other parameters were present, but Purkinje neuron triple KO mice were not ataxic. Unexpectedly, testis weight in the Purkinje neuron triple KO mice was reduced by ~ 35% compared with other two groups. Previous studies, along with macroorchidism in FXS have suggested a role for these proteins in testis development. These results demonstrate that L7-Cre expression is not confined to Purkinje neurons. It is noteworthy that neurons lacking all three proteins are viable and functional, suggesting alternative models for compensation of function within this gene family.

PrgmNr 3434 - Variation of Serum Metabolome and Exosomal Transcriptome in Acute Ischemic Stroke: Results of the Metabolome in Ischemic Stroke Study (MISS)

View session detail

Author Block: **E. Sidorov**[1], C. Xu[2], S. Goyal[3], J. Garcia[4], C. Seraphin[4], A. Blair[4], D. Gordon[4], J. Chainakul[4], D. K. Sanghera[3]; [1]Oklahoma Univ. of Hlth.Sci. Ctr., Oklahoma, OK, [4]Dept. of Neurology, Coll. of Med., Oklahoma Univ. of Hlth.Sci. Ctr., Oklahoma, OK
Disclosure Block: **E. Sidorov:** None.
Stroke is the second-leading cause of death worldwide and a major cause of serious disability in the US. Oklahoma has the 9th highest rate of stroke in the nation among all states. Previous studies found multiple associations of serum metabolites with acute ischemic stroke (AIS) against controls, but very few studies have evaluated serum metabolites during the acute and chronic phases of AIS. The exosomal RNAs/miRNAs have emerged as biomarkers and therapeutic targets for various diseases, however, their function in stroke remains largely unknown. In this study, we compared the metabolomic patterns of acute and chronic stages of ischemic stroke. In addition, in a subset of individuals, we have also evaluated changes in the serum exosomal transcriptome during the acute and chronic stage of AIS by performing RNA sequencing. We evaluated 1295 serum metabolites on 60 stroke patients at acute and chronic stages of stroke by performing global metabolomics using ultra-high-performance liquid chromatography/mass spectrometry (LC-MS) and gas chromatography/mass spectrometry (GC-MS) at Metabolon Inc. Orthogonal Partial Least Square-Discrimination Analysis (OPLS-DA) and Principal Component Analysis (PCA) were used to inspect group disparity using multivariate data. The OPLS-DA revealed significant separation of acute and chronic stage metabolites, PCA showed no hidden structures. Exosomal miRNA hsa-miR-9-3p and hsa-miR-129-5p were observed to be differentially expressed showing 14.7- and 7.6-fold increase with FDR p-value of $2.83x10^{-6}$ and $2.87x10^{-3}$, respectively, at the acute phase compared to the chronic phase of stroke. Correlation analysis of miRNAs with metabolites revealed ceramides (d18:1/17:0, d17:1/18:0)* and (d18:2/24:1, d18:1/24:2)* and sphingomyelin (d18:2/18:1)* to be strongly correlated with miR-129-5p (r= 0.78-0.84; p

PrgmNr 3435 - A heterozygous gain-of-function variant in *KIF5B* causes osteogenesis imperfecta by disrupting the Golgi-primary cilia axis

View session detail

Author Block: **M. Washington**[1], B. Zhang[2], I. Song[1], L. C. Burrage[3], V. Rossi[1], M. Nonet[2], J. Chen[2], D. Baldridge[2], G. A. Silverman[4], V. R. Sutton[3], J. A. Rosenfeld[1], M. J. Hicks[1], D. R. Murdock[1], H. Dai[1], M. Weis[5], Undiagnosed Diseases Network, D. R. Eyre[5], S. C. Pak[2], T. Schedl[6], B. Lee[3], R. Marom[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Washington Univ. Sch. of Med., St. Louis, MO, [3]Baylor Coll. Med., Houston, TX, [4]Washington Univ. Sch. of Med., St. Louis, MO, [5]Univ. of Washington, Seattle, WA, [6]Washington Univ. Sch. of Med., St Lous, MO

Disclosure Block: **M. Washington:** None.

Kinesin superfamily motor proteins (KIFs) play an essential role in fundamental cellular processes, including transport of secretory vesicles, endocytosis, organelle trafficking, cell cycle and ciliogenesis. Pathogenic variants in KIF-related genes have been implicated in microcephaly, neurodevelopmental disorders, and skeletal dysplasia. Exome sequencing identified a *de novo*, heterozygous variant, c.260C>T (p.Thr87Ile) in *KIF5B*, encoding the kinesin-1 heavy chain, in an individual with osteogenesis imperfecta (OI) of moderate severity. The patient presented with multiple fractures, low bone mineral density, short stature, scoliosis, dentinogenesis imperfecta, and mild hearing loss. Genetic testing for known OI genes was negative. The *KIF5B* variant substitutes a highly conserved amino acid residue within the P-loop of the kinesin motor domain. Other missense mutations in Thr87 were shown to destabilize the P-loop structure and interfere with ADP binding *in vitro*. To better understand the *in vivo* genetic mechanism of *KIF5B* p.Thr87Ile we modeled the variant in the C. elegans ortholog, unc-116, at the corresponding position (Thr90Ile) by CRISPR/Cas9 editing. The *unc*-116 Thr90Ile homozygotes were L1 larval lethal. Furthermore, variant heterozygotes displayed dominant motility and body morphology phenotypes that were not observed in *unc-116* deletion heterozygotes. Together, these data suggest that the *KIF5B* variant is damaging and displaying dominant behavior that is distinct from loss of function. To further assess the cellular consequences of the *KIF5B* p.Thr87Ile variant we performed a microscopy study in primary patientâ□□s fibroblasts and NIH3T3 cells overexpressing the human *KIF5B* mutation. Electron microscopy in patient fibroblasts showed dilated endoplasmic reticulum with granular material, and multiple vacuoles containing cell breakdown products. Immunofluorescence labeling of the Golgi matrix protein, GM-130 revealed abnormal distribution of the Golgi complex. Overexpression of mutated *KIF5B* in NIH3T3 cells was associated with elongation of the primary cilia, as assessed by immunofluorescent staining for acetylated tubulin. Notably, overexpression of the wild type *KIF5B* showed a similar phenotype, while KIF5B depletion using siRNA did not significantly alter the cilia length. Our data support that the *KIF5B* p.Thr87Ile variant is pathogenic and acts via a gain-of-function mechanism to disrupt the secretory pathway and Golgi-primary cilia axis. This study expands the spectrum of KIF-related disorders and emphasizes the critical role of *KIF5B* in skeletal development.

PrgmNr 3436 - Biallelic variants in *LDB3*: A new inheritance pattern for an old cardiomyopathy gene

View session detail

Author Block: **G. Gotway**[1], N. Baez Hernandez[1], C. Uhles[2]; [1]Univ. of Texas Southwestern Med. Ctr., Dallas, TX, [2]Children's Med. Ctr. Dallas, Dallas, TX
Disclosure Block: **G. Gotway:** None.
The *LDB3* gene codes for a PDZ-domain protein with multiple splice forms that localizes to Z bands in striated muscle. Heterozygous variants in *LDB3* were reported in patients with autosomal dominant cardiomyopathy, especially left ventricular noncompaction; however subsequent studies cast doubt on the relation of heterozygous variants to the disease. Knockout models in mice demonstrated that biallelic complete loss of function of Ldb3 causes neonatal death due to cardiomyopathy. However, specific knockout of the long forms of Ldb3 leads to a milder phenotype, with early cardiomyopathy and partial lethality, then improvement in survivors with recurrence in adulthood. We identified a pair of brothers who both developed left ventricular noncompaction cardiomyopathy as newborns, which subsequently improved in both cases. Molecular sequencing of genes associated with cardiomyopathy demonstrated that the only variants they had in common were two variants in trans in the *LDB3* gene. The first variant, c.655C>T (p.R219X), is expected to cause an early truncation that would lead to loss of all isoforms of LDB3. The second variant, c.1798C>T (p.R600X), is predicted to lead to loss of only the long isoforms of the protein. Thus, the variants in these brothers are expected to have the same effect on protein expression of LDB3 as that seen in the mouse model deficient for the long forms of Ldb3. According to gnomAD, variants leading to specific loss of the long forms of LDB3 have a carrier frequency of about 1 in 3,000; variants leading to loss of all isoforms are about half as common. Therefore while variants causing loss of function are too common to cause highly penetrant autosomal dominant disease, the frequency is consistent with these variants being a rare cause of autosomal recessive cardiomyopathy. Given the similarity between our patients and the mouse models of loss of Ldb3, we propose that biallelic variants in *LDB3* cause autosomal recessive cardiomyopathy. Specific loss of the long forms of LDB3 leads to a milder phenotype with neonatal cardiomyopathy that resolves, but could potentially recur at a later time.

PrgmNr 3437 - Combined PMM2-CDG and hereditary fructose intolerance in a child with mild clinical presentation: a case report

View session detail

Author Block: **X. Hong**[1], M. He[2], A. C. Edmondson[1]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Childrenâ□□s Hosp. of philadelphia, Philadelphia, PA
Disclosure Block: **X. Hong:** None.
The patient, who was born to consanguineous parents, first came to medical attention at 6 months of age for failure to thrive in the setting of hepatomegaly with transaminitis, hypotonia, and esotropia. A comprehensive workup was most notable for abnormal carbohydrate deficient transferrin (CDT) study, suggesting a Type I Congenital Disorder of Glycosylation (CDG). Whole exome sequencing revealed homozygous pathogenic variants, c.448G>C (p. A150P), in *ALDOB*, establishing a diagnosis of Hereditary Fructose Intolerance (HFI); and homozygous likely pathogenic variants, c.44G>C (p. G15A), in *PMM2*, concerning for PMM2-CDG. Phosphomannomutase 2 (PMM2) activity was reduced in leukocyte and plasma N-glycan analysis revealed an under-mannosylation profile, indicating functional GDP-mannose deficiency. The diagnosis for PMM2-CDG was thus confirmed.

HFI is caused by deficient aldolase B, which reversibly catabolizes fructose-1-phosphate (Fru-1-P) and fructose-6-phosphate (Fru-6-P). Uncontrolled HFI patients are at risk for hypoglycemia, liver dysfunction and metabolic decompensation and can display Type I CDT patterns, as the accumulated Fru-1-P inhibits GDP-mannose biosynthesis. HFI can be treated effectively with dietary restriction of fructose.

PMM2-CDG is the most common CDG subtype. PMM2 converts mannose-6-phosphate (Man-6-P) to mannose-1-phosphate (Man-1-P), precursor of GDP-mannose. Its deficiency leads to hypoglycosylation of numerous glycoproteins, transferrin included. The clinical presentation of PMM2-CDG varies greatly from severe antenatal presentation with multisystem involvement to mild adulthood presentation. Despite extensive ongoing research, management of PMM2-CDG is still supportive.

The patient had minimal fructose exposure prior to diagnosis and fructose-restricted diet was initiated afterward. Persistent but slowly improving, Type I CDT patterns were observed in the following 4 years. Spontaneous normalization of hypoglycosylated transferrin regardless of clinical presentation has been described for PMM2-CDG. Persistent under-mannosylation N-glycan profiles were also observed, typical for PMM2-CDG and MPI-CDG patients but may also for HFI patients in early infancy. Interestingly, this profile was not detected in two older fructose-restricted HFI patients.

Overall, our patient with combined PMM2-CDG and HFI has a low severity score based on the Nijmegen Pediatric CDG Rating Scale. It may be due to the high residual PMM2 activity from the private *PMM2* variant, p. A150P. Alternatively, the deficiency in aldolase B may compensate PMM2 deficiency through a mechanism yet to be delineated.

PrgmNr 3438 - Implementing genome and transcriptome sequencing methods to improve the diagnosis of Mendelian myopathies

View session detail

Author Block: **V. Ganesh**[1,2], B. Weisburd[1], F. Aguet[1], G. Tiao[1], H. L. Rehm[3,1], A. O'Donnell-Luria[1,4]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Brigham and Women's Hosp., Boston, MA, [3]Massachusetts Gen. Hosp., Boston, MA, [4]Boston Children's Hosp., Boston, MA
Disclosure Block: **V. Ganesh:** None.
Approximately two-thirds of patients with Mendelian myopathies lack a specific molecular diagnosis. Although the adoption of gene panel and exome sequencing in clinical practice improved the diagnostic sensitivity in these diseases, the ability to detect rare variants outpaces our ability to interpret their functional consequences. Transcriptome sequencing (RNA-seq) emerged as a useful technology to improve variant resolution and diagnostic yield in rare diseases. Prior work in the Broad Center for Mendelian Genomics was the first to demonstrate the utility of RNA-seq for genetic diagnosis in Mendelian myopathies. We expand upon this tool by incorporating autoencoder denoising methods (FRASER, OUTRIDER) paired with a web browser visualization tool to identify outlier gene expression and splice variants in a cohort of muscle biopsies from 113 individuals with suspected Mendelian myopathies. Implementation of these methods 1) improved the diagnostic yield in our cohort by 13%, 2) validated the transcriptional effect of variants predicted to affect splicing, and 3) facilitated the identification of new gene-disease associations. This demonstrates the power of RNA-seq in the diagnosis of Mendelian myopathies and provides a method to validate suspected transcriptional effects of noncoding variants. It also demonstrates an improvement in RNA-seq analysis specificity by controlling for latent confounders using autoencoder-based methods.

PrgmNr 3439 - Intravenous fish oil emulsion and fatty acid profiles

View session detail

Author Block: **P. Tanpaiboon**[1], D. Salazar[2], C. Kucera[1], B. Epstein[1], J. Taylor[1], R. Sharma[1], F. L. Lacbawan[2]; [1]Quest Diagnostics, San Juan Capistrano, CA, [2]Quest Diagnostics Nichols Inst, San Juan Capistrano, CA
Disclosure Block: **P. Tanpaiboon:** Salary/Employment; Quest Diagnostics.
Fish oil triglyceride injectable emulsion (OmegavenÂ®) is used as a source of calories and fatty acids in pediatric patients with parenteral nutrition-associated cholestasis (PNAC). This fish oil-based intravenous fat emulsion (FO-IVFE) contains high omega-3 derivatives, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), with high total omega-3 fatty acid (30%-60% of total fatty acids). The percent of composition of EPA and DHA by weight (13%-27%) is higher than soybean-based IVFE (0%). While managing patients with FO-IVFE, fatty acids (FA) status should be monitored regularly to determine the efficacy of treatment and identify essential fatty acid (EFA) deficiency. EFA profiles of patients receiving this product have been reported in several studies; as expected, levels of EPA and, to a lesser degree DHA are markedly elevated. However, the effect of this product on serum levels of branched-chain saturated FA such as phytanic and pristanic acids is less well characterized. At least one study demonstrates the effect of FO-IVFE on levels of branched-chain FA and EFA in preterm infants. We observed characteristic FA profiles including elevated omega-3 derivatives, elevated pristanic and phytanic acids, and decreased linoleic acid in several pediatric patients. Clinical information was available in 12 patients, ages 2 months to 10 years old. All patients received FO-IVFE when the samples were collected. EPA, DHA, total omega-3, and pristanic acids were elevated in all patients. EPA and DHA were the most prominent (10-26 times and 1-4 times the upper limit of normal (UNL), respectively). Pristanic acid levels were (2-20 times UNL) correlated with EPA levels. Phytanic acid levels were elevated to a lesser degree (0-4 times UNL) compared to pristanic acid. Linoleic acid levels were low in all 12 patients. While mild elevations of phytanic and pristanic acids can be seen secondary to diets rich in animal fats or dairy products, moderate to marked elevations are more often associated with peroxisomal disorders. Consequently, FA analysis in patients treated with FO-IVFE could lead to diagnostic pitfalls in some cases, particularly when only very long chain fatty acid (VLCFA) analysis is performed following a positive newborn screen, where the accompanying increases of omega-3 fatty acids would not be reported. In the absence of clinical information, elevated levels of pristanic and phytanic acids in a limited VLCFA panel could be falsely suggestive of an underlying peroxisomal defects. It would be prudent to mention FO-IVFE treatment in the clinical interpretation for any VLCFA sample in which phytanic and pristanic acids are significantly elevated.

PrgmNr 3440 - Lessons learned from a severe Isovaleric acidemia (IVA) patient from hyperammonemia

View session detail

Author Block: **C-H. A. Tsai**, B. Jessica, m. Chou, c. Zimmerman, D. DeMarzo, Y. Enchautegui-Colon; Children's Hosp. Oklahoma, Oklahoma City, OK
Disclosure Block: **C.A. Tsai:** None.
With the execution of expanded newborn screen program nationwide, it is uncommon to see severe hyperammonemia associated with IVA. We present a seven-day-old boy with severe IVA complicated with hyperammonemia. This child was flagged by NBS at day 4, but due to COVID19 and parental skepticism, confirmatory testing was delayed and a leu restricted diet was not followed as instructed. The patient initially presented to the ED with Ammonia of 588 ug/dL which then increased to 1000 ug/dL. This child received carnitine, arginine, carglumic acid (Carbaglu), CRRT and Ammonul. **The Ammonul was not helpful.** Ammonul has two major components sodium benzoate and sodium phenylacetate. Sodium benzoate functions by removing glycine with ammonia which could be harmful for this condition as IVA needs to bind to glycine as a rescue. Sodium phenylacetate binds to glutamine to remove ammonia. However, this patientâ□□s plasma amino acid assay revealed a low glutamine level of 256umol/L. The hyperammonemia was corrected in 15 hours and with the use of Carbaglu there was no rebound of hyperammonemia. Our patient suffered from bone marrow suppression associated to the organic acidemia and required frequent multiple platelet transfusions and GCSF for neutropenia. The management of this patient provides supporting evidence of the many theoretic metabolic â□□factsâ□□ including why Ammonul is not helpful in organic acidemias.

PrgmNr 3441 - Mutational spectrum in a sample of mexican patients with Hunter syndrome

INTRODUCTION: Hunter syndrome or MPS II (OMIM #309900) is an X-linked recessive disease caused by deficiency of iduronate-2-sulfatase lysosomal enzyme, which leads to progressive accumulation of heparan and dermatan sulfate in different organs and tissues. It has a global incidence of 0.69 to 1.19/100,000 live births. *IDS* is the gene involved, it has been missense mutations in 55%, nonsense in 21% and deletions in 20% of the patients. Some patients with more severe phenotypes have total deletions or rearrangements between *IDS-IDS2*. There is only one study in Mexican population in which 36% presents a complex rearrangement.OBJECTIVE: To determine the mutations and deletions frequency in *IDS* gene and IDS2 pseudogene in patients with HS.MATERIAL AND METHODS: 7 DNA samples from patients with clinical diagnosis of HS between 4 and 12 years old were analyzed. The samples were processed by multiplex ligation-dependent probe amplification with SALSA probemix P164-B2 specific for HS and analyzed by Coffalyser software. Patients with no deletion were included for Sanger sequencing for exons 2,3,4,6,7,8 and 9, the chromatograms obtained were analyzed with Chromas software.RESULTS: 28.5% (2/7) of the samples from patients with HS present a complete deletion of *IDS* gene and pseudogene *IDS2*. In the rest of the patients, mutations in intron and exon 3 and in exon 9 were found. For intron 3 the variant found was CS066287 (1/7), located 1 base prior to the exon generating an alteration of the acceptor site for the splicing zone. In exon 3 we found 2 variants NM_000202.5:c.275T>G p.[Leu92Arg] (2/7) and NM_000202.5:c.284_287del p.[Arg95Asnfs*34] (1/7), the first corresponds to and missense variant and the second corresponds to a small deletion of 4 pb with a change of the reading frame. For exon 9, NM_000202.5:c.1229_1229delT p.[Leu410Arg fs*30] was found, it corresponds to a punctual deletion of a T nucleotide.CONCLUSIONS: The frequency of deletions in *IDS* gene and *IDS2* pseudogene of 28.5% observed in these patients is higher than the previously described in the world literature but fewer than the previous report in our population. These deletions have been associated with severe phenotypes at the neurological level; in our sample, these patients have severe and moderate psychomotor delay. In patients with the mutations, we observed a severe phenotype no matter the kind of mutation found. For the other systems, none of them present alterations in ocular level, all except one present alterations in oral cavity, only 2 patients show hearing loss, but everyone presents affectation in the skeletal system, principally in the loss of functionality in hands, kyphosis/scoliosis.

PrgmNr 3442 - Mutations in COL5A1 lead to heritable thoracic aortic disease

To identify novel genes for heritable thoracic aortic disease (HTAD), we developed a new machine learning method to prioritize gene identification based on signaling pathways for known HTAD genes and the topological characters in the protein-protein interaction network. The method also integrates data on both gene mutational constraints from gnomAD exome v2.1.1 and tissue special gene expression from the GTEx v8.1. Using this method, all [insert #) validated HTAD genes were identified, along with 307 additional genes, and the genes were ranked in terms of potential for causing HTAD; *FBN1* (11th) and *COL3A1* (15*th*) ranked in the top 20 and *MYLK* ranked lowest at 280th. Rare (MAF -4) and damaging variants (CADD > 20) in the top 10 genes were assessed in exome data from 445 unrelated and unsolved HTAD families, 23 trios, and 355 patients with early sporadic thoracic aortic dissection (ESTAD). *COL5A1*, the 5th ranked gene, is a known cause of classic Ehlers-Danlos syndrome (EDS; haploinsufficiency and glycine substitions in triple helical region are disease-causing). The following rare variants in *COL5A1* were identified in HTAD and ESTAD cases: (1) A *de novo* coding deletion, p.Thr104del, absent in gnomAD exomes and predicted to be disease-causing by MutationTaster; (2) three rare variants, p.Gly607Arg, p.Gly1270Ser, and Gly1315Val, that alter critical glycines at the COL5A1 triple-helical region. Two of these variants segregate with HTAD in families and one is an ESTAD case; (3) two rare variants, p.Ser1376Pro and p.Pro1566Leu, that segregate with HTAD in two families. Additionally, a recent publication identified two individuals with *COL5A1*, p.Gly1414Ala and p.Gly1144Ala, disrupting triple helical glycines in exomes from 702 patients with sporadic TAD. Previous publications of 34 patients with classic EDS and vascular diseases (8 had TAD) failed to identify any triple-helical glycine substitutions. Thus, applying machine learning to identify putative HTAD genes and assessing exome data from HTAD and ESTAD cases for rare variants in these genes has identified *COL5A1* as a possible HTAD gene, and has the potential to identify further genes for HTAD.

PrgmNr 3443 - Oculocutaneous Albinism: Compound heterozygote genotype-phenotype correlation

Oculocutaneous albinism (OCA) is a group of human autosomal-recessive hypopigmentation disorders characterized by hypopigmentation in the skin, hair, and eyes [1]. OCA1 and OCA2, two of the seven types of OCA, are caused by mutations of the *TYR* and *OCA2* genes, respectively, which are responsible for most oculocutaneous albinism. We are presenting the case of an 11-year-old male Puerto Rican patient who was first evaluated by a pediatric neurologist at age 2 *12* with a history of preauricular tag, strabismus and then diagnosed with language developmental disorder associated to motor apraxia. At age 10 years the patient was referred to Genetics clinic by ophthalmologist due to accommodative esotropia, bilateral hypermetropia, infantile nystagmus, and foveal hypoplasia. The patient was diagnosed with oculocutaneous albinism (OCA) due to *TYR* gene mutations. The diagnosis was made through an albinism gene panel. The patient is specifically diagnosed with OCA 1B, also known as â□□yellow albinismâ□□, though he still presents with hypopigmentation. OCA gene panel showed two variants which are associated with an autosomal recessive *TYR*-related condition. The first is a heterozygous likely pathogenic variant: p.Gly47Asp. The variant is predicted to result in a single amino acid substitution (missense) of glycine to aspartic acid at codon 47 in exon 1 of the *TYR* gene. A known variant at this position, p.Gly47Val, has already been associated with OCA1. A second heterozygous variant of unknown significance: p.Arg402Gln, was documented as well. This variant is predicted to result in a single amino acid substitution (missense) of arginine to glutamine, at codon 402 in exon 4 of the *TYR* gene. This variant has been reported as a common polymorphism with other mutations *in trans* in multiple individuals with autosomal recessive OCA and has also been described as a hypomorphic allele. Nonetheless, this variant has also been reported in trans with known pathogenic TYR variants in unaffected family members of AR OCA pedigrees and the compound heterozygote status of this patient for the TYR gene is responsible for his clinical manifestation in our patient.

PrgmNr 3444 - Sengers syndrome: Novel pathogenic variant in the AGK gene and analysis of phenotypic variability and clinical outcomes

View session detail

Author Block: **M. Caha**[1], C-H. W. Wu[2], L. B. Smoot[3], D. J. Harris[2], A. E. Roberts[3,2], S. Sacharow[2], O. A. Bodamer[2]; [1]Dept. of Pediatrics, SUNY Downstate Hlth.Sci. Univ., Brooklyn, NY, [2]Div. of Genetics and Genomics, Boston Childrenâ□□s Hosp./Harvard Med. Sch., Boston, MA, [3]Dept. of Cardiology, Boston Childrenâ□□s Hosp./Harvard Med. Sch., Boston, MA
Disclosure Block: **M. Caha:** None.
Sengers syndrome is a rare autosomal recessive mitochondrial disease caused by biallelic pathogenic variants in the AGK gene, which encodes the acylglycerol kinase enzyme. The syndrome was originally defined by the triad of hypertrophic cardiomyopathy, cataracts, and lactic acidosis with or without skeletal myopathy. Here, we present a female infant with Sengers syndrome due to a novel homozygous frameshift variant (AGK: c.1141_1142dupGG, p.S382Afs*17), who died at five months of age. Next, we provide a systematic review of the molecularly confirmed cases. We demonstrate variable expressivity and penetrance of the central features of Sengers syndrome as follows â□□ cataracts: 97.30 %, cardiomyopathy: 86.49 %, lactic acidosis: 83.78 %, skeletal myopathy: 62.16 %. Finally, we analyze associations between genotype, biochemical findings, and clinical outcomes, focusing on infantile death. Patients with homozygous nonsense variants had a tendency towards infantile death and lower age of death ($p = 0.02$ and $p = 0.06$). The location of pathogenic variants within AGK domains was not significantly associated with infantile death ($p = 0.52$). However, biochemically, absence of lactic acidosis was significantly ($p = 0.02$) associated with longer survival. Thus, lactic acidosis may potentially serve as a negative prognostic biomarker for Sengers syndrome.

PrgmNr 3445 - Whole genome sequencing of mitochondria: A powerful tool for clinical diagnosis of human mitochondria diseases

Background: Mitochondria are the organelles that, amongst other functions, generate energy for cells. In addition to the human nuclear genome, the mitochondrial genome (mtDNA) is a 16569bp double helix loop that encodes 37 genes. mtDNA is inherited from the mother and mitochondria DNA dysfunction can cause a number of human diseases including mitochondrial myopathy, Maternal Diabetes and deafness (MDD), Leber's hereditary optic neuropathy (LHON), Leigh syndrome and many others.Methods: At Baylor Genetics we have established a Next Generation Sequencing (NGS)-based platform to sequence the whole genome of mtDNA. Long-range PCR of mitochondrial DNA was used to enrich the mitochondrial sequence from the nuclear genome background and was subject to Next Generation Sequencing. NGS data were processed using NextGene software to analyze detected single nucleotide variants (SNV) and large deletions in the mitochondrial genome.Results: Since 2018 we have processed 1732 clinical cases for mtDNA testing, including 843 females, 884 males and 5 unspecified cases; with the patientâ□□s age ranging from prenatal fetus to 86-year-old adults. Sample types included blood, urine, bone marrow, liver, skeletal muscle, fibroblast, amniocytes, buccal swab and extracted DNA. We detected pathogenic or likely pathogenic SNV in 97 cases and large deletions of mitochondria genomic fragments in 161 cases. 10 cases were positive for both SNV mutations and large deletions. 1484 cases were negative for both. Pathogenic variant m.3243A>G in the tRNA Leucine gene is the most prevalent mutation, which was detected 22 times. It is heteroplasmic in all cases reported, ranging from 1.5% to 94.1%.Conclusion: We have developed a robust platform to detect variants ranging from SNV to several kb deletions in the mtDNA. It is a very powerful tool to provide a molecular diagnosis for mitochondrial disorders. We also have gene panel sequencing for nuclear genome-encoded genes that impact mitochondria function, an essential adjunct to diagnose mitochondria-related diseases. Based on these observations, we are currently pursuing multiple directions in order to improve mitochondrial sequencing efficiency and accuracy.

PrgmNr 3446 - *EFEMP1* rare variants cause juvenile-onset open angle glaucoma in families from the Philippines

Glaucoma is the leading cause of irreversible blindness world-wide and exhibits both Mendelian (childhood onset) and complex (adult onset) inheritance. Ten genes are known to cause childhood glaucoma, but in total these only account for disease in approximately 20% of patients. Because most of the childhood glaucoma genes have been identified in European Caucasian populations, to facilitate novel gene discovery we have studied affected families from various geographic regions including the Philippines. As part of this effort, we used exome sequencing to evaluate 14 Filipino juvenile open-angle glaucoma (JOAG) families and identified 3 independent families (35, 2 and 27 members) with rare *EFEMP1* variants (p.N80Y, p.R477C and p.Ter494Glnext*29) co-segregating with disease. None of the rare variants are present in gnomAD and all modify highly conserved amino acids. Affected variant carriers (N= 34) exhibited severe disease with average age of disease onset of 16 years (range 3-43) and 76% developing blindness. Common SNPs near *EFEMP1* have been associated with adult-onset glaucoma (POAG) and a low frequency *EFEMP1* variant (p.R140W; MAF 0.0008%) may contribute to disease risk in one POAG family. Interestingly, a single *EFEMP1* missense allele (p.R345W) is known to cause Malattia Leventinese (ML), an inherited retinal degeneration. *EFEMP1* is an extracellular matrix protein with ocular expression similar to Myocilin, another extracellular matrix protein known to cause JOAG through a mechanism involving protein misfolding and endoplasmic reticulum aggregation. To determine if *EFEMP1* variants exhibit similar effects, we transfected COS7 cells with vectors expressing the three novel *EFEMP1* variants as well as variants associated with POAG and ML. We showed that all three variants found in JOAG patients caused significant intracellular protein aggregation compared to wild type and also the variants associated with the other phenotypes (p.R140W and p.R345W). These results suggest that rare coding *EFEMP1* variants can cause JOAG through a mechanism involving protein aggregation and that the extent of intracellular protein aggregation and retention appears to be the basis for the observed phenotype spectrum. This is the first report of *EFEMP1* variants causing early-onset glaucoma and we show that *EFEMP1* variation appears to be a relatively common cause of childhood glaucoma in these Filipino families. These results underscore the value of ethnically diverse populations for comprehensive detection of disease-causing mutations.

Congenital diaphragmatic hernia (CDH) is a common birth defect that is often accompanied by life-threatening lung hypoplasia leading to respiratory complications. A variety of chromosomal abnormalities, genomic alterations, and sequence variants have been shown to cause or predispose to the development of CDH. Despite these discoveries, the genetic factors underling most cases of CDH remain unidentified. The forkhead box 1 gene (*FOXP1*) encodes a transcriptional repressor involved in tissue regulation and cell type-specific functions during development. Heterozygous *FOXP1* variants have been shown to cause a variety of structural birth defects including central nervous system anomalies, congenital heart defects, congenital anomalies of kidney and urinary tract, cryptorchidism, and hypospadias. Using data from individuals with CDH who carry interstitial deletions, we have defined a CDH critical region on chromosome 3p13 that contains five protein coding genes. Of these genes, only *FOXP1* is 1) expressed in the developing diaphragm, 2) exhibits high loss-of-function intolerance, 3) has a high level of similarity to known CDH genes as defined by a previously published machine learning algorithm. We have also identified two individuals with CDH who carry de novo, pathogenic variants in *FOXP1* that are predicted to trigger nonsense mediated mRNA decay. Since CDH is only seen in a subset of individuals with *FOXP1* haploinsufficiency, it is likely that loss of *FOXP1* functions as a susceptibility factor that contributes to the development of CDH in conjunction with other genetic, epigenetic, environmental, and/or stochastic factors. In conclusion, we define a CDH critical region on chromosome 3p13 and provide evidence that *FOXP1* haploinsufficiency can contribute to the development of CDH in humans.

BACKGROUND Genetic kidney diseases contribute a significant portion of kidney diseases in children and young adults. Nephrogenetics is a rapidly evolving subspecialty, however, in the clinical setting, increased use of genetic testing poses implementation challenges. Consequently, we established a national nephrogenetic clinic at Sheba Medical Center to apply a multidisciplinary model. **METHODS** Patients were referred for clinic evaluation from different pediatric or adult nephrology units across the country, if their primary nephrologist suspected an undiagnosed genetic kidney disease. We determined the diagnosis rate among patients who were referred to the clinic and observed the effect of diagnosis on medical care. We also discuss the requirements of a nephrongenetic clinic in terms of logistics, recommended indications for referral and building a multidisciplinary team. **RESULTS** Over a period of 24 months, a total of 103 probands were evaluated at the clinic, with an age range of 10 days to 72 years. The most common phenotypes included congenital anomalies of the kidneys and urinary tract, nephrotic syndrome or unexplained proteinuria, nephrocalcinosis/nephrolithiasis, tubulopathies and cryptogenic end-stage kidney disease. Over 90% of accepted patients were referred due to clinical suspicion of an undetermined underlying genetic diagnosis. A molecular diagnosis was reached in 34/53 probands for whom genetic evaluation was completed, yielding a diagnostic rate of 64.2%. Of these, over 65% of the diagnoses were made via next generation sequencing (gene panel- or exome sequencing). **CONCLUSIONS** We identified a significant fraction of genetics kidney etiologies among previously undiagnosed individuals which influenced subsequent clinical management. Our results support that nephrogenetics, a rapidly evolving field, may benefit from well-defined multidisciplinary co-management administered by a designated team of nephrologist, geneticist and bioinformatician.

PrgmNr 3449 - Carrier Prevalence of 302 genetic diseases in the Mexican Jewish Community

Disclosure Block: **D. Morgenstern-Kaplan:** None.
Background: The Mexican Jewish community (MJC) is a previously uncharacterized genetically isolated group composed of Ashkenazi, Sephardi and Mizrahi Jews that migrated from different countries in the early 1900s. Historically, these populations have been considered to be at high risk of being carriers of rare genetic diseases. Preconception carrier screening is recommended by the American College of Obstetrics and Gynecology and the American College of Medical Genetics and Genomics to identify carriers and couples who are at risk of having an affected child. The carrier frequencies of most genetic diseases in the MJC and in most Latin-American Jewish communities is unknown.
Methods: We conducted a cross-sectional study of 208 MJC individuals between ages 18-40 years old representing Ashkenazi (AJ), Sephardi-Mizrahi (SMJ), or mixed ancestry (MAJ) origin. We offered saliva-based preconception pan-ethnic carrier screening that examined 302 genes using next-generation sequencing (NGS) to determine the prevalence of carriers. The study protocol was approved by an IRB and a bioethics committee at our institution, and informed consent was obtained from all participants.
Results: The carrier screening results showed that 86.5% of participants had at least one pathogenic/likely pathogenic (P/LP) variant in one of the 302 genes analyzed, with some participants being carriers for as many as seven different genetic diseases. The most common genes with pathogenic variants were HFE (23.5%), CFTR (16.8%), MEFV (11.5%), F5 (10%) and GALT (10%). Furthermore, when analyzed in subgroups, the most common genes with P/LP variants in AJ were HFE (33.7%), WNT10A (11.6%) and CFTR (10.3%). The most common genes with P/LP variants in SMJ were HFE (19.6%), F5(18.1%) and CFTR (16.6%). The most common genes with P/LP variants in MAJ were CFTR (24.6%), MEFV (16.9%) and HFE (15.3%). Finally, 18.2% of couples were identified to be at risk of having an affected child due to a commonly shared variant (73.3% of at-risk couples) or due to two separate P/LP variants in the same gene (26.6% of at-risk couples).
Conclusions: The prevalence of carriers of at least one genetic disease in the MJC was 86.5%, and 18.2% of couples detected were at risk of having an affected child. The study of this population, along with other Latin-American Jewish populations using an NGS based carrier screening panel will help future parents to make more informed reproductive decisions.

PrgmNr 3450 - Congenital diarrhea is a common cause of neonatal crisis and up to ~60% of cases among neonates may be inherited

View session detail

Author Block: **J. Tumolo**, H. Druker, J. L. Weber; Prevention Genetics, Marshfield, WI
Disclosure Block: **J. Tumolo:** Salary/Employment; Prevention Genetics.
Chronic diarrhea is a symptom in a group of clinically and genetically heterogeneous disorders. Studies suggest approximately 7 in 1,000 newborns admitted to neonatal intensive care units are admitted for diarrhea. Of these, approximately 60% of cases are acquired, ~15% are inherited, and the remainder result from an unknown etiology (Passariello et al. 2010. PubMed ID: 20518089). Hereditary congenital diarrhea and enteropathies are characterized by persistent, severe diarrhea that often presents within the first few months of life, is life-threatening, and requires medical intervention in the form of parenteral (IV) nutrition or hydration. At the molecular level, these disorders result from disruption of intestinal epithelial cell function or from immune system dysfunction that secondarily impairs the intestinal epithelium (Canani et al. 2015. PubMed ID: 25782092). While intractable diarrhea is the major clinical feature, congenital diarrheas and enteropathies can have extraintestinal manifestations as well as systemic disease. The early identification of a genetic cause of congenital diarrhea or enteropathy helps to inform a treatment strategy such as hematopoietic stem cell transplantation, enzyme replacement therapy, a special diet or other pharmaceutical support. Forty-one patients (age 2 weeks old to 62 years) with severe diarrhea underwent genetic testing using a 114 gene next generation sequencing (NGS) panel performed in a CLIA approved clinical laboratory. Of the patients tested, 24% were â¤ 30 days old, 51% were CFTR, suggesting these patients had a previously unknown diagnosis of cystic fibrosis. Among definite or potential diagnostic findings, 35% had a disorder related to immune system dysfunction, while 65% were related to disordered epithelial cell function. Importantly, 64% of definite or potential molecular diagnoses were medically actionable. In summary, genetic testing of individuals with severe diarrhea led to a definite or potential diagnosis in 24% of patients but this number increased to 60% in patients presenting in the neonatal period. In 64% of diagnosed patients, the results informed patient care, supporting the clinical utility of early genetic testing in this patient cohort.

PrgmNr 3451 - Diagnostic rate of clinical exome sequencing for CAKUT phenotypes

View session detail

Author Block: **E. Rivera Munoz**[1], J. A. Rosenfeld[1,2], J. E. Posey[1], D. A. Scott[3]; [1]Baylor Coll. of Med., Houston, TX, [2]Baylor Genetics, Houston, TX, [3]Baylor Coll. Med, Houston, TX
Disclosure Block: **E. Rivera Munoz:** None.

Congenital Anomalies of Kidney and Urinary Tract (CAKUT) are estimated to make up 40-50% of pediatric malformations and are a predominant cause of kidney failure in children and young adults. This category of malformations describes a broad range of phenotypes including renal agenesis, duplication of the collecting system, multicystic dysplastic kidney, ureteropelvic junction obstruction, vesicoureteral reflux, and others. CAKUT results from aberrant embryonic development and can be induced by both genetic and environmental factors. Familial studies show that putative pathogenic variants often demonstrate incomplete penetrance and variable expressivity. Although exome sequencing is commonly used to identify a molecular cause in individuals with congenital anomalies, this test is not universally ordered in individuals with CAKUT. Many studies have shown positive results using natural language processors (NLP) to extract phenotypic information from clinical notes. Additional valuable insight may be gained by using these tools that would otherwise require highly labor-intensive processes. Machine learning tools have also been used to harness annotations from knowledgebases to help identify phenotypic expansions in clinically relevant genes. These additional layers of evidence may inform variant interpretation and improve the diagnosis and prognosis of CAKUT.

In the present study, we retrospectively analyzed molecular findings in individuals who were referred for clinical exome sequencing that included one or more CAKUT features. This clinical laboratory dataset contains age, sex, clinical features (as free-text descriptors), and the set of variants that were reported back to referring clinicians as potentially explaining part or all clinical features. Using Doc2HPO, we extracted phenotype terms from free-text and used them to categorize these cases by renal features. From the entire clinical laboratory cohort of ~15,000 individuals, we identified 925 individuals with one or more reported CAKUT features with 95% being non-isolated. The most prevalent features in our cohort were: >1 CAKUT feature (38%), renal hypoplasia/aplasia (12%), renal cyst (11%), abnormal kidney localization (9%), renal insufficiency (6%), abnormal renal pelvis morphology (5%), and nephrolithiasis (3%). Of these cases, 195 (21%) were considered solved with an additional 243 (26%) being classified as possibly or partially solved. The top returned genes included *PKD1*, *PKHD1*, *KMT2D*, *TMEM231,* and *CC2D2A*. Based on these results, we conclude that clinical exome sequencing is an effective molecular diagnostic test for individuals with non-isolated CAKUT.

PrgmNr 3452 - Exome sequencing further implicates disruption of the *NODAL* signaling pathway in laterality defects

Disclosure Block: **M. Dawood:** None.

Heterotaxy is a genetically and phenotypically heterogeneous laterality defect characterized by abnormal left-right patterning with the most common, clinically affected organ systems being the cardiovascular system, gastrointestinal tract, spleen, and liver. Pathogenic missense mutations in *NODAL* have been previously implicated as causative for autosomal dominant heterotaxy (MIM: 270100). Null mutations in *Nodal* arrest mouse embryonic development at the gastrulation stage, but mice with conditional hypomorphic *Nodal* mutants show phenotypes consistent with a perturbed embryonic left-right axis. Here, we analyzed a cohort of 322 proband-only exomes of individuals with clinically diagnosed laterality defects using family-based, rare variant analyses. We found evidence for missense, frameshift, and/or structural variant perturbations in the *NODAL* gene as potential causes of heterotaxy and other laterality defects in 27 unrelated probands. Our data from enrichment analyses of this cohort implicate likely damaging variants in members of the *NODAL* signaling pathway and the broader TGF-Î² superfamily. Further, we reinvestigated the *NODAL* missense mutation NM_018055.5:c.778G>A:p.G260R which was originally described as causative of heterotaxy with reduced penetrance, variable expressivity, and predominantly affecting Hispanic individuals. Mohapatra *et al.* in 2009 first implicated G260R as pathogenic on the basis of three lines of functional evidence, but since then G260R has been reclassified to â□□conflicting interpretations of pathogenicityâ□□ based on the American College of Medical Genetics and Genomics criteria (ClinVar Accession: VCV000008269.9). We describe the underlying basis of the consternation and provide further confirmatory evidence in support of pathogenicity. In aggregate, our study uncovers evidence supporting the prominence of the *NODAL* pathway in embryological left/right axis pattern perturbations and birth defects.

PrgmNr 3453 - Identifying susceptibility genes for congenital diaphragmatic hernia (CDH) using a machine learning algorithm

View session detail

Author Block: **A. Hardcastle**[1], I. M. Campbell[2], V. Varghese[3], N. L. Shannon[4], S. A. McKee[5], P. D. Turnpenny[6], J. Morton[7], J. Eason[8], C. A. Shaw[9], D. A. Scott[9]; [1]Brigham Young Univ., Provo, UT, [2]Children's Hosp. of Philadelphia, Philadelphia, PA, [3]All Wales Med. Campus, Nottingham, United Kingdom, [9]Baylor Coll. of Med., Houston, TX

Disclosure Block: **A. Hardcastle:** None.

Congenital diaphragmatic hernia (CDH) is a common, life-threatening birth defect seen in approximately 1 in 4000 newborns. A molecular etiology can only be identified in a subset of CDH cases. To identify new CDH susceptibility genes, we prioritized candidate genes identified through a search of the DECIPHER database using a machine learning algorithm that integrates data from Gene Ontology (GO), the Mouse Genome Database (MGI), the Protein Interaction Network Analysis (PINA) platform, the Kyoto Encyclopedia of Genes and Genomics (KEGG) molecular interaction network, published miRNA targets, the GeneAtlas expression distribution, and the NIH Roadmap Epigenomics Mapping Consortium. In our search we identified individuals with CDH who carried putatively deleterious sequence variants in *FREM2*, *SMARCA4*, *CREBBP*. All of these genes were shown to have high similarity to known CDH genes using our machine learning algorithm (99.8, 92.2, and 99.7th centile compared to all RefSeq genes, respectively). The role of these genes in diaphragm development is further supported by their expression in the developing mouse diaphragm, by mouse models of CDH development, and/or previously published case reports. Our results suggest that our machine-learning algorithm can be used to identify CDH susceptibility genes, and that loss of *FREM2*, *SMARCA4*, and *CREBBP* function each leads to an increased risk of developing CDH.

PrgmNr 3454 - Increased Expression of ZFPM2 Bypasses SRY to Drive 46,XX Testicular Development: A New Mechanism of 46,XX DSD

View session detail

Author Block: **L. Ragno**[1], D. Yang[1], T. R. Bhatti[2], J. P. Bradfield[2,3], D. K. Bowen[4], K. L. Grand[2], H. Hakonarson[2], T. F. Kolon[4], J. Glessner[2], M. C. Simon[5], N. Skuli[5], M. G. Vogiatzi[2], M. A. Guerraty[6], M. A. Deardorff[2], L. C. Pyle[2]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Div. of Human Genetics, Dept. of Pediatrics, Children□□s Hosp. of Philadelphia, Philadelphia, PA, [3]Quantinuum Res., LLC, Wayne, PA, [4]Div. of Pediatric Urology, Dept. of Urology, Children□□s Hosp. of Philadelphia, Philadelphia, PA, [5]Dept. of Cell and Dev.al Biology, Univ. of Pennsylvania, Philadelphia, PA, [6]Div. of Cardiovascular Med., Dept. of Med., Philadelphia, PA

Disclosure Block: **L. Ragno:** None.

We present a patient with a novel cause of 46,XX ambiguous/androgenous genitalia Differences of Sex Development (DSD). Genome-wide array from blood showed 46,XX with ~35% mosaic duplication of 76.5Mb at chromosome 8q13.2-q24.3, containing 257 OMIM genes including *ZFPM2* and *CYP11B1*. Congenital adrenal hyperplasia testing was negative, testosterone was elevated, and the pro-testicular master regulator *SRY* was absent. The infant had a uterus, one streak ovary (We hypothesized that mosaic ZFPM2 duplication resulted in localized ZFPM2 overexpression and testicular development. In typical testicular development, *ZFPM2* and its binding partner, *GATA4*, drive expression of the *SRY* master regulator. We completed RNA-seq of twelve single-cell clonal fibroblast cell lines from this mosaic individual to identify differentially regulated genes (DRGs). After quality control, three lines representing with and without the duplication were analyzed. Nine (9; 3.5%) genes within the duplicated gene were significantly overexpressed >1.5-fold, versus 78 genes across the rest of the genome (0.47%) (significance pSRY or *CYP11B1* (CAH), as expected. *ZFPM2* was the second most highly overexpressed gene (FC=94.7, p=3.56x10-57). Thirty (30) genes were significantly under-expressed (RSPO1 (FC=-2.26, p=6.0x10-3), and the pro-testicular transcription factor *MAP3K1* was upregulated (FC=2.07, p=3.54x10-5). Yet further genes involved in testicular development were upregulated, including *AKR1C2* (chr10), an enzyme of non-canonical dihydrotestosterone synthesis (FC=2.52, p=7.4x10-3). We have shown that increased *ZPFM2* dosage can induce 46,XX testicular development in a manner not dependent on *SRY*. This contravenes the previous understanding that GATA4/ZFPM2 drives testicular development through *SRY*. *ZFPM2* may modulate numerous critical sex development genes including transcription factors otherwise thought to be downstream of *SRY* (*MAP3K1*, *AKR1C2*). Findings from this single high-yield patient demonstrate that the primary role of *ZFPM2* in testicular development may be independent of *SRY*. This adds *ZFPM2* to the brief (SRY. Overall, new understanding of these genes demonstrates that the role of *SRY* as a â□□master regulator' of testicular development may be less than previously thought.

PrgmNr 3455 - Patient with novel compound heterozygous variants in *NCKAP1L* presents Immunodeficiency 72 with autoinflammation and novel features

View session detail

Author Block: **G. F. Godinez-Zamora**[1,2], E. VÃisquez-Echeverri[3], O. Saucedo-RamÃrez[4], P. Baeza-Capetillo[2,5], V. MorÃin-Barroso[6], J. Aguirre-HernÃindez[2]; [1]Univ. Natl. Infantil de MÃ©xico, MÃ©xico, Mexico city, Mexico, [6]Hosp. Gen. de MÃ©xico Dr. Eduardo Liceaga, Mexico city, Mexico

Disclosure Block: **G.F. Godinez-Zamora:** None.

Nck-associated protein 1-like (*NCKAP1L*) encodes a protein that regulate actin cytoskeleton in hematopoietic cells. Last year, biallelic alterations in this gene were identified as the cause of immunodeficiency 72 with auto inflammation (OMIM 618982), which is characterized by immunodeficiency, inflammation and lymphoproliferation with features of hemophagocytic lymphohistiocytosis (HLH), and atopic disease. Other clinical features include recurrent infections, elevated IgE levels, hepatosplenomegaly, lymphadenopathy, bronchiectasis, and autoimmunity; which were present in known patients since their first years of life. Here we present a patient with two variants in *NCKAP1L* (one of them novel) and some phenotypic characteristics that sets her apart from the 9 patients known in the literature. Our patient is an adolescent female, with no apparent health issues excepting acute pyelonephritis at the age of 4 years. At 14 years, she was diagnosed with systemic lupus erythematosus due to malar rash, arthritis, grade IV proliferative lupus nephritis, high ANA concentration; and Anti-Sm. She present arterial hypertension; difficult to manage, and transient brain ischemic events associated with seizures, which may be secondary to inflammation of the central nervous system. Laboratory workup reported: leucopenia, bandemia, lymphopenia and trombocytopenia. Low levels for C3, C4, hypogammaglobulinemia (IgG, IgM, IgA) and normal IgE. In contrast to the patients described in the literature, she had normal IgE levels, normal hepatic function, and no hepatosplenomegaly. Moreover, she hasnâ□□t presented lymphoproliferation, HLH or lymphadenopathy. Whole exome sequencing was performed. Variants were filtered by depth, allelic fraction, consequence, frequency in public databases, and in a local database. Variants were searched in all known primary immunodeficiency genes, and a compound heterozygous genotype, with two missense variants, was found in *NCKAP1L*:c.1492G>A:p.Val498Met, c.3346G>A:p.Ala1116Thr. The first is a known variant with a very low frequency in gnomAD (4 times in v3.1.1). The second variant is not found in any public databases. A very small number of patients have been diagnosed with immunodeficiency 72. Most share a common set of phenotypic characteristics, and this may suggest that the phenotype may be rather uniform. However, we have identified an adolescent female, with two variants in *NCKAP1L*, who doesnÂ´t have some of the phenotypic alterations observed in the rest of the patients with this disease. These may suggest that the phenotypic spectrum of this immunodeficiency may be broader than initially thought.

PrgmNr 3456 - Precision medicine models for undiagnosed and rare disease

View session detail

Disclosure Block: **L.C. Burrage:** None.

Exome, genome and RNA sequencing have transformed our ability to diagnose patients with suspected genetic disease. These technologies have led to the discovery of hundreds of new disease genes and to phenotypic expansion within known diagnoses. However, up to 70% of individuals with suspected genetic disease remain undiagnosed likely because their disease-causing variant(s) has yet to be discovered or the clinical significance of variants is unclear. The Undiagnosed Diseases Network (UDN) Model Organism Screening Center (MOSC) has demonstrated that various genome modification techniques in model organisms (*C. elegans*, *Drosophila*, *D. rerio*) are important tools aiding in the interpretation of variants of uncertain significance. For example, fly models established the pathogenicity and functional consequences of variants in *CACNA1A* (R1673P and R1664Q) associated with early onset cerebellar ataxia and developmental delay. Studies in the mouse offer a complementary approach to these other model organisms and open new avenues to test therapy and disease mechanism in a mammalian model. Critically, a variety of existing resources from the Knockout Mouse Phenotyping Program (KOMP2) have supported gene discoveries. For example, existing data generated by KOMP2 for *Otud6b*$^{-/-}$ mice supported the pathogenicity of biallelic loss-of-function variants in *OTUD6B*. The finding of perinatal lethality, small size, and ventricular septal defects in the *Otud6b*$^{-/-}$ mice is consistent with the human phenotype, which includes failure to thrive and cardiac defects. Likewise, low bone density in *Copb2*$^{+/-}$ mice supported the pathogenicity of heterozygous loss-of-function *COPB2* variants in individuals with low bone density. Lastly, early lethality and failure to progress to blastocyst stage in *Tonsl*$^{-/-}$ embryos supported the pathogenicity of biallelic hypomorphic variants in this essential gene in individuals with a skeletal dysplasia. Given that fly models can rapidly assess clinical significance of a variant and mouse models can provide insight into variant disease mechanisms and assess treatment strategies in the context of mammalian biology, we established the BCM Center for Precision Medicine Models to capture the benefits associated with each model system and the synergy derived from having two distinct yet complementary functional readouts. The center is working with local, national, and international programs and researchers on the development of precision models that will end the diagnostic odyssey of patients with undiagnosed, rare, and Mendelian diseases and launch pre-clinical studies investigating personalized medicine strategies.

PrgmNr 3457 - Rapid CRISPR/Cas9-based method for functional validation of human disease genes

View session detail

Author Block: **S-J. Lin**, C. Petree, K. Huang, G. K. Varshney; Oklahoma Med. Res. Fndn., Oklahoma City, OK
Disclosure Block: **S. Lin:** None.
Since the completion of the Human Genome Project and the with the decreasing cost of whole-genome sequencing technologies, thousands of whole-exome (WES) and whole-genome sequencing (WGS) projects have advanced our understanding of the causes of genetic disorders as they identify the full spectrum of mutations associated with human disease genes. Human geneticists now face the immense challenge of validating these candidate disease genes. Identifying which candidate genes or loci are pathologically relevant represents a critical barrier that limits our ability to generate relevant human disease models. Model organisms have revolutionized our understanding of the human disease; inactivation of candidate human disease genes in animals (i.e. creating gene â□□knockoutsâ□□) often triggers analogous phenotypes and provides a valuable disease model. CRISPR/Cas9 based methods are being used to screen for phenotypes in F0 (the founding generation) by generating biallelic mutations; we further optimized this strategy to maximize phenotype penetrance and use this method in a high-throughput manner. We combined the mutagenesis and tissue-specific phenotyping approach using transgenic reporter lines to functionally test the candidate disease genes, and identified genes involved in neurodevelopmental, musculoskeletal, vasculature, hearing, and digestive disorders. This strategy has enabled us to screen for hundreds of candidate disease genes rapidly with modest resource investment.

PrgmNr 3458 - Refined SNP haplotype analysis uncovers a potential founder deletion mutation in the *Cerebral Cavernous Malformations* 2 gene

View session detail

Author Block: **C. Gallione**[1], M. R. Detter[2], C. Lee[3], D. A. Marchuk[1]; [1]Duke Univ Med Ctr, Durham, NC, [2]Duke Univ Med Ctr., Durham, NC, [3]Angioma Alliance, Charlottesville, VA
Disclosure Block: **C. Gallione:** None.
Cerebral cavernous malformations (CCM) are vascular malformations consisting of collections of enlarged capillaries occurring in the brain or spinal cord. These vascular malformations can occur sporadically or susceptibility to develop these can be inherited as an autosomal dominant trait due to heterozygous mutation in one of three genes. Over a decade ago, we described a large germline 77.6kb deletion spanning exons 2-10 in the *CCM2* gene found in multiple affected individuals from seemingly unrelated families. Haplotype analysis using linked, microsatellite markers showed that this deletion was present on a common microsatellite haplotype but the deletion may have arisen at least twice independently. In the ensuing decades, many more CCM patients have been identified with this same deletion and in this present study, we examined genomic DNA from 25 reportedly unrelated affected individuals with this deletion. To investigate the origin and relationship of the deletion at base pair level resolution, we sequenced approximately 10 kb upstream and downstream from the recombination junction on the deleted (affected) alleles. All patients showed the identical SNP haplotype across this combined 20 kb interval. Intriguingly, all samples harbor the minor allele at rs7792895 (T=10%, GnomAD) near the deletion, making it even more likely that the deletions have a common origin. In parallel, genealogical records have traced 10 individuals in this current cohort back to five separate pedigrees dating as far back as the 1600-1700â□□s. Based on this new SNP haplotype data and our genealogical investigation, it is likely that these families and the remaining â□□unrelatedâ□□ samples converge on a common ancestor due to a founder mutation occurring hundreds of years ago on the North American continent.

PrgmNr 3459 - Significant burden of *de novo* damaging variants in novel genes in patients with congenital kidney malformations

Disclosure Block: **H. Milo Rasouly:** None.
Background: Congenital kidney malformations (CKM) are one of the most common cause of pediatric kidney failure. While multiple causative genes have been identified, they explain only 10-15% of cases. *De novo* variantsâ (DNV) analysis led to the identification of novel genes for congenital heart defects and neurodevelopmental disorders. We hypothesized that similar analyses could identify new CKM-causing genes. Methods: Patients enrolled through our study on genetics of kidney diseases underwent Exome sequencing (ES) or Genome sequencing (GS). ES was performed on 151 trios (i.e. affected child with CKM and unaffected parent), and GS on 53 additional trios.100 CKM trios were identified from the Deciphering Developmental Delay consortia (ES). The sequences were processed using a BWA/GATK 4.1 pipeline on the CAVATICA platform and annotated through Ensembl VEP. Custom bioinformatics pipelines were then used for data cleaning. Potential enrichment for DNV was analyzed with the denovolyzer package in R. Results: Out of the 304 trios analyzed, 10 cases (3%) had a DNV in one of the 172 genes known to be associated with dominant forms of kidney disease (3.2 fold-enrichment, p-value=1.41 x 10^{-3}). Those 10 cases included one protein-truncating variant (PTV) in *PAX2*, one in *HNF1B* and two PTV DNVs in *KAT6B*. Genome-wide, we observed a significant 2.8 fold-enrichment for PTV DNV (76 DNVs compared to 26.6 expected, p-value=4.3x10^{-15}) and a significant 1.3 fold-enrichment for missenses DNV (248 DNVs compared to 191.5 expected, p-value=5.1x10^{-5}). When constraining the analysis to genes highly expressed in nephron-progenitor cells at 18 weeks of gestation (Human fetus) and not known to be associated with kidney disease in Human, we observed significantly increased enrichment for PTV DNV (8 DNVs compared to 1.2 expected, OR=6.9, p=3.04 x 10^{-5}, list of 593 genes with a pLI>0.9 and a LOEUF>0.35), and for deleterious missense DNV (8 DNVs compared to 3.2 expected , OR= 2.51, p=0.016, list of 229 genes with a mis-z-score > 3.09). Gene-Set Enrichment Analysis uncovered a highly significant enrichment for genes down-regulated in ME-A cells (breast cancer) undergoing apoptosis in response to doxorubicin (FDR=1.5x10^{-11}) and in fibroblasts expressing mutant forms of ERCC3 after UV irradiation (FDR=5.5x10^{-8}).
Conclusions: We detected an excess of *de novo* variants in CKM, supporting potential pathogenetic mechanisms of disease. Globally, the DNV signal was partially driven by novel constrained genes that are highly expressed during early kidney development. Further gene-set analysis and replication in larger datasets may help pinpoint which genes are most likely driving this enrichment.

PrgmNr 3460 - Complex congenital heart defect in a patient with a pathogenic mutation of *TLK2* gene: Coincidental findings or part of the phenotype of TLK2 syndrome?

View session detail

Author Block: **M. Hajianpour**[1], S. P. Yoon[1], J. L. Carver[1], M. Davis[2]; [1]East Tennessee State Univ. - Quillen Coll. of Med., Johnson City, TN, [2]Ballad Hlth.Med. Associates Family Med. Gray, Johnson City, TN

Disclosure Block: **M. Hajianpour:** None.

Proband is a 23 yo male with TLK2-related condition presenting with learning disability/ mild intellectual disability, and behavioral problems (ADHD, anxiety, socializing problems), congenital heart defects (tetralogy of Fallot, pulmonary artery coarctation and atresia), inguinal hernia, cryptorchidism, and dysmorphic features (dolichocephaly, wide forehead, long face, flat facial profile, malar hypoplasia, small ears, prominent nasal bridge, broad nasal tip, and big/tall chin. **Genetic Work-up:** â¢ Chromosome microarray: An 11.5 Mb region of homozygosity (ROH) at chromosome 22 (26415475_37951451). No specific imprinting disorder known with 22q UPD. â¢ Fragile X study: Negative. â¢ Molecular studies for Invitae Congenital Heart Defects and Heterotaxy Panel (89 genes): A variant of uncertain significance: c.1333C>T (p.Pro445Ser) in SPH4A gene (Its pathogenic mutations are associated with autosomal recessive primary ciliary dyskinesia (PCD): **Non-contributory to phenotype**. â¢ Molecular studies for GeneDx Autism/ID panel (2,500 genes): Heterozygous for a pathogenic variant of TLK2 gene: p.Arg123Ter (CGA>TGA): c.367 C>T in exon 7: **Cause of phenotype** (mother is negative for mutation/ fatherâs test pending). Also hemizygous for a maternally inherited VUS in SMC1A gene: c.1545+5G>A: IVS9+5G>A: **Non-contributory to phenotype.** The TLK2 gene (NM_006852.3) encodes a nuclear serine/threonine kinase involved in DNA checkpoint regulation and chromatin assembly. TLK2 Pathogenic variants cause a neurodevelopmental disorder with mild developmental delay, behavioral concerns, GI problems, and dysmorphic facial features. Additional findings include neonatal feeding difficulties, eye problems, recurrent otitis media, epilepsy, hypotonia, brain malformations, musculoskeletal abnormalities, abnormal skull shape, hypertrichosis, and hoarse voice. Most variants are de novo, but inheritance from affected parents has been reported. A broad spectrum of variants, and a few recurrent variants have been reported. A homozygous missense variant has also been reported in one patient with a more severe phenotype.

The developmental delay, LD/ID, behavioral problems, and dysmorphic features in our patient are compatible with those reported in TLK2 syndrome. However, to our knowledge CHD including TOF and pulmonary coarctation and atresia, as well as inguinal hernia and cryptorchidism have not been reported. The CHD in this patients could be part of the spectrum of TLK2 syndrome (mutation-specific), or be coincidental due to mutation of a gene not included in the Invitae CHD/Heterotaxy panel. No OMIM gene in his 22q ROH is associated with CHD either.

PrgmNr 3461 - Partial trisomy of 8q and partial monosomy of 10q as a result of unbalanced translocation in an infant with multiple congenital anomalies - A Case Report

View session detail

Author Block: **M. Rahman**[1], S. Mikkilineni[2], F. Shakil[1], C. KUMAR[2]; [1]WMC, Valhalla, NY, [2]Westchester Med. Ctr., Valhalla, NY
Disclosure Block: **M. Rahman:** None.
Derivative chromosomes are often caused by unbalanced chromosome rearrangements that appear spontaneously or may be inherited from healthy parents carrying balanced reciprocal translocations. Partial trisomy 8q has been reported sporadically in the literature with variable phenotypes. It has been reported that the isolated duplication of 8q22.2-q24.3 is responsible for dysmorphic features such as hypertelorism, microretrognathia, telecanthus, cleft palate, intellectual disabilities and other phenotypic features. Partial monosomy of 10q is a rare abnormality associated with microcephaly, characteristic facial features, intellectual disability. Here we present a new case of a male infant born at 35 weeks gestation to a 22 year old mother. The infant birth weight was 1.8 kg (~5th percentile), length of 43 cm (~1st percentile) with multiple congenital anomalies, tracheo-bronchomalacia, large ventricular septal defect, tachyarrhythmia, patent ductus arteriosus and respiratory failure. He also has vertebral anomaly, cleft palate, omphalitis and undescended testes. The chromosomal microarray and the cytogenetic investigations were indicated. Chromosome analysis performed on GTG banded metaphases prepared from cultured lymphocytes. The cytogenetic analysis revealed a derivative chromosome 10 with additional unidentified material at 10q region and the infantâ□□s karyotype as 46,XY,add(10)(q?26.1). The microarray analysis performed on whole blood showed a 52 Mb terminal duplication from 8q22.1 to 8q24.3 and a 7.3 Mb terminal deletion from 10q26.2 to 10q26.3. The Fluorescence in situ hybridization (FISH) analysis using 8q and 10q subtelomere probes determined that these abnormalities were associated with an unbalanced translocation between 8q and 10q. The microarray findings revealed that the additional unidentified material at 10q was from the long arm of chromosome 8 representing partial trisomy of that region. In addition, terminal deletion of 10q represents partial monosomy of that region. To the best of our knowledge, this unbalanced translocation between chromosome 8q and 10q is the first report of this combination of chromosomal abnormalities. Finally, this case demonstrates the effective use of cytogenetics, chromosomal microarray and FISH studies for the diagnosis and characterization of an unidentifiable 10q region with complex phenotype for clinical management. It is expected that at least one of the parents is a balanced carrier of t(8;10). Chromosomal analysis of both parents was highly recommended to find out the origin of this abnormality for proper genetic counseling, such as recurrence risk and reproductive options.

PrgmNr 3462 - A rapid and low cost NGS-based cytogenomics platform using proximity ligation technology

View session detail

Disclosure Block: **J. Tapper:** None.
Current cytogenomic strategies for determining the cause of genetic disorders requires an assortment of disparate tests applied in a high-cost, time- and resource-consuming, sequential manner. Each test in the cascade - typically made up of karyotype analysis, chromosomal microarray (CMA), and fluorescence *in situ* hybridization (FISH) - has unique limitations. Karyotype analysis offers a genome-wide view of chromosomal anomalies but has limited resolution. CMA offers increased resolution but is unable to identify balanced translocations, inversions, balanced insertions, and to elucidate complex rearrangements. FISH allows only one (or in some cases a few) loci to be interrogated at a time and requires prior knowledge of the suspected rearrangement. Here we present proximity ligation as an alternative to cytogenetics. This technology offers an approach to identify chromosomal abnormalities that overcomes the afore mentioned challenges of the traditional cytogenetic testing paradigm. Proximity ligation methods have become an industry standard in genome assembly used for the scaffolding and phasing of full-length chromosome sequences. Proof of concept data based on over 50 previously characterized clinical samples shows combining proximity ligation chemistry, off-the-shelf, open-source analytics software and our novel convolutional neural net (CNN) detector achieved sensitivity and specificity comparable to existing cytogenomic tests offered clinically. By leveraging the strengths of proximity ligation sequencing our platform enables the rapid, simultaneous detection of the breadth of chromosomal aberrations obtainable through karyotype analysis, CMA, and every possible FISH probe set in a single, low-cost, highly scalable assay.

PrgmNr 3463 - A Retrospective Review of Dominant Variants Identified from the Horizon™ Carrier Screening Test

View session detail

Author Block: **L. Li**, T. Smart, A. Hoang, D. Li, S. Arun, B. Meyers, J. Gray, B. Gall, N. Sanapareddy, D. Keen-Kim; Natera, Inc., San Carlos, CA
Disclosure Block: **L. Li:** Major Stockholder/Ownership Interest; Natera, Inc. Salary/Employment; Natera, Inc.

The Horizon™ carrier screening test is to help couples assess their risk of passing genetic conditions to their children. Carriers of disease-causing variants are typically healthy and most are without familial history. While carrier screening mostly focuses on variants of recessive inheritance (Antonarakis SE, 2019), dominant variants are also occasionally observed. Dominant variants confer a higher risk of passing genetic conditions to offspring (van Dijk PJ, 2016), and importantly can indicate subclinical conditions or risk of later-onset diseases. Undetected dominant variants may be more common than known in the non-clinical population and their impact on phenotypes remains to be determined (Grzymski JJ, 2020). We aimed to catalogue the P (Pathogenic) or LP (Likely Pathogenic) variants of dominant inheritance within historical Horizon carrier screening data and to evaluate the associated incidental benefit in personal healthcare.

All Horizon carrier screening variants submitted in QCI (QIAGEN Clinical Insight, the clinical decision support software for variant interpretation and reporting) as of April 28, 2021 were retrieved. Variants meeting 2 conditions: 1) Mode of Inheritance assigned as Dominant by QCI , and 2) classified as P or LP by Natera curators were included in the analysis. Evidence of dominant inheritance from publications was checked by manual review.

A total of 185,328 variants were used for this analysis, of which 1421 unique ones have a dominant inheritance pattern marked by QCI. The dominant variants classified as P or LP (N=116) by Natera curators were included in the manual check. The analysis showed that dominant P/LP variants were detected in 11 genes associated with 9 phenotypes: Familial Hypercholesterolemia (LDLR); Alport Syndrome (COL4A3, COL4A4 and COL4A5); Familial Hyperinsulinism (ABCC8); Hypophosphatasia (ALPL); Choroideremia (CHM); Charcot-Marie-Tooth Disease with Deafness (GJB1), Alpha-Thalassemia (HBA1), Beta-Hemoglobinopathies (HBB), and Ornithine Transcarbamylase Deficiency (OTC), with the first two phenotypes being the most commonly observed.

Dominant variants, designated by QCI and confirmed by expert curation, were observed in HorizonTM carrier screening. Long term clinical follow up is important to decipher their penetrance and clinical expressivity. Under the guidance of medical professionals, disease-causing dominant variants could provide an incidental benefit to the carrier screening participants' healthcare, provided that there is no phenotype uncertainty and potential treatment or prevention is available (Miller DT, 2021).

PrgmNr 3464 - Contiguous domains of differentially-accessible, single copy sequences along metaphase chromosomes are conserved among multiple tissues

View session detail

Author Block: **S. Hill**[1], P. K. Rogan[2,3], Y. Wang[1], J. H. Knoll[4,3]; [1]Dept Pathology and Lab. Med., Schulich Sch. of Med. and Dentistry, London, ON, Canada, [2]Schulich Sch Med & Dentistry, London, ON, Canada, [3]Cytognomix Inc., London, ON, Canada, [4]Schulich Sch. of Med. and Dentistry, London, ON, Canada
Disclosure Block: **S. Hill:** None.
Background: During mitosis, chromatin engages in a dynamic cycle of condensation and decondensation. Condensation into distinct units to ensure high fidelity segregation is followed by rapid and reproducible decondensation to produce functional daughter cells. Factors contributing to the reproducibility of chromatin structure between cell generations are not well understood. We investigated local metaphase chromosome condensation along mitotic chromosomes within genomic intervals showing differential accessibility (DA) between homologs (MolCytogen 2014,7[70]; MolCytogen 2015,8[65]). DA was originally identified using sequence-defined single copy (sc) DNA probes with fluorescent in situ hybridization (scFISH) in peripheral lymphocytes (GenomeRes 2001,11:1086; AJMG(A) 2003,121:245). These structural differences between metaphase homologs are non-random, stable, and heritable epigenetic marks which has led to the proposed function of DA as a marker of chromatin memory. Here, we characterize the organization of DA intervals into chromosomal domains by identifying multiple DA loci in close proximity to each other, and examine the conservation of DA between tissues. **Results**: We evaluated multiple adjacent scFISH probes at 6 different DA loci from chromosomal regions 2p23, 3p24, 12p12, 15q22, 15q24 and 20q13 within peripheral blood T-lymphocytes. DA was organized within domains, ranging from 16.0 kb to 129.6 kb in length, based on hybridizations of 2 to 4 scFISH probes per domain extending DA beyond the defined boundaries of individual scFISH probes. Transcriptionally inert chromosomal DA regions in T-lymphocytes also demonstrated conservation of DA in bone marrow and fibroblast cells. **Conclusions**: We identified novel chromosomal regions with allelic differences in metaphase chromosome accessibility and demonstrated that these accessibility differences appear to be aggregated into contiguous domains extending beyond individual scFISH probes and to coincide with previously established topologically-associated domain (TAD) boundaries. DA appears to be a conserved feature of human metaphase chromosomes across different stages of lymphocyte differentiation and germ cell origin, consistent with a role in maintenance of intergenerational cellular chromosome memory.

PrgmNr 3465 - Detection of near constitutional genome-wide uniparental disomy in a patient presenting with Beckwith-Wiedemann syndrome and cholestasis

View session detail

Author Block: **G. J. Fischer**[1,2], M. D. Maxwell[3,4], D. Allingham-Hawkins[1], V. Horner[2], N. Mittal[3], A. Quinn[3]; [1]PreventionGenetics, Marshfield, WI, [2]Wisconsin State Lab. of Hygiene, Madison, WI, [3]Univ. of Texas Hlth.at San Antonio, San Antonio, TX, [4]Univ. Hlth., San Antonio, TX
Disclosure Block: **G.J. Fischer:** Salary/Employment; PreventionGenetics.
Genome-wide uniparental disomy (GW-UPD) is characterized by the inheritance of all 23 sets of chromosomes from a single parent. Constitutional paternal or maternal GW-UPD is lethal *in utero* and, in the case of paternal UPD, presents as hydatidiform mole. However, a small number of individuals with apparent GW-UPD have been reported. To date, all reported individuals are female (as an androgenetic lineage is not viable) and mosaic. In the mosaic state, paternal GW-UPD is compatible with life and affected individuals present with Beckwith-Wiedemann syndrome-like phenotypes and multiple tumors. We describe a female patient born at 31 6/7 weeks gestation who was transferred to the NICU with prematurity, respiratory distress, critical hypotension, and hypoglycemia. Physical exam was consistent with Beckwith-Wiedemann syndrome (BWS). Methylation-specific multiplex ligation-dependent amplification (MLPA) (MRC-Holland, Amsterdam) identified hypermethylation at imprinting center 1 (IC1) and hypomethylation at IC2, confirming a BWS diagnosis. At three months old, the patient developed acholic stools, raising concern for cholestasis. A cholestasis next-generation sequencing panel consisting of 76 genes on DNA derived from whole blood returned only apparently homozygous variant calls, with a read fraction percentage ranging from 90-100%. Since the panel used a whole exome probeset, exome-wide copy number variants and loss of heterozygosity could be evaluated. Loss of heterozygosity was observed across every chromosome, suggesting the possibility of GW-UPD. Confirmatory Illumina SNP microarray (San Diego, CA) testing confirmed high-level mosaic (90% or greater) GW-UPD. Given the previous diagnosis of paternal UPD(11), mosaic paternal GW-UPD was assumed, but not confirmed. At least one report of 93% paternal GW-UPD is documented in the literature of DNA derived from blood, with lower mosaic percentages observed in other tissues (PMID: 29636544). Most reports cite 90% or greater GW-UPD in tumor tissue (PMID: 30882989). To our knowledge cholestasis has not previously been reported in association with paternal GW-UPD. Potential genetic mechanisms for this outcome and changes in clinical management for this patient given this diagnosis will be discussed.

PrgmNr 3466 - Inverted genomic triplication structures: two breakpoint junctions, several possibilities

View session detail

Fatih[3], R. A. Gibbs[1], A. Hastie[6], M. Pendleton[7], E. Harrington[8], S. Juul[7], A. Lindstrand[5], H. Y. Zoghbi[9], J. R. Lupski[3], F. J. Sedlazeck[1], D. Pehlivan[3], C. M. Carvalho[2]; [1]Baylor Coll. Med., Houston, TX, [2]Pacific Northwest Res. Inst., Seattle, WA, [3]Baylor Coll. of Med., Houston, TX, [4]Karolinska Inst, Stockholm, Stockholm, Sweden, [5]Karolinska Inst.t, Stockholm, Sweden, [6]BioNano Genomics, San Diego, CA, [7]Oxford Nanopore Technologies, New York, NY, [8]Oxford Nanopore, New York, NY, [9]Baylor Coll. of Med./HHMI/NRI, Houston, TX
Disclosure Block: **C.M. Grochowski:** None.

Genomic inversions are a class of structural variation (SV) that can occur in a copy-number neutral state or as part of a complex SV with copy number variation (CNV). The duplication-triplication/inverted-duplication (DUP-TRP/INV-DUP) structure is a complex SV formed by replication mechanisms and mediated by a given pair of inverted low-copy repeats leading to two breakpoint junctions *in cis.* The origin of the structure occurs either mitotically as a post-zygotic event or in the male germline. This aberration causes a disease state due to CNVs affecting dosage sensitive genes and is found at a high frequency in several cohorts including *MECP2* duplication syndrome (16%), Pelizaeus-Merzbacher disease (20%), Potocki-Lupski Syndrome and others. Surprisingly, the International Cancer Genome Consortium has recently identified this structure as one of the 12 most prevalent SV mutational signatures found in cancer. We sought to resolve the structure of DUP-TRP/INV-DUP genomic rearrangements in patients, using a combination of array comparative genomic hybridization (aCGH), short-read whole-genome sequencing (WGS), long-read WGS (CRISPR-*Cas9* ONT) and optical genome mapping (OGM). This multiomics approach enabled elucidation of the events within each haplotype, with interpretation of each genomic fragment in context of the larger structure. Astonishingly, from studies of 7 individuals carrying a DUP-TRP/INV-DUP, four distinct and previously unknown subtype structures were identified and could be traced back to the inverted repeat used to mediate the event. In the *MECP2* duplication syndrome samples, the inverted segment varied in size from ~40 kb to ~500 kb and included an amplified copy of *MECP2* in 3/7 patients. Importantly, we can now identify precisely which genomic fragments are inverted within this structure. Although we have previously shown a triplication of *MECP2* presents a more severe phenotype, we are now investigating whether the inverted orientation of *MECP2* leads to transcription-level differences that could contribute to clinical variability. In summary, optical genome mapping and long-read WGS approaches facilitated phasing and assembly of a clinically relevant recurrent SV. These methods have relevance in the study of both Mendelian disease and cancer mutagenesis and confirms our hypothesis that inverted low-copy repeats as a recombinant substrate play a critical role in the underlying mechanism of formation for DUP-TRP/INV-DUP events.

PrgmNr 3467 - Library preparation forâ¯DNAseq: The next generation of automation

View session detail

Author Block: **K. Lu**; Beckman, Indianapolis, IN
Disclosure Block: **K. Lu:** Salary/Employment; Beckman Coulter.
Introductionâ¯ â¯ The ability to sequence genomes rapidly and efficiently has had a significant influence on the scientific community, with applications ranging from basic science toâ¯drug development and translational applications. Creating libraries for next-generation sequencing (NGS) is, unfortunately, a time-consuming operation. Keeping meticulous records of adaptors, as well as consistent pipetting,â¯haveâ¯become crucial for successful library preparation.â¯Many of the processes require precise timing and do not have safe stopping points, leading to a veryâ¯longâ¯workdayâ¯for the user.â¯â¯Methodsâ¯ To overcome these challenges,â¯here weâ¯haveâ¯automatedâ¯the Roche KAPAâ¯HyperPrepâ¯Library Preparation kit onâ¯aâ¯Beckman Coulterâ¯Biomekâ¯NGeniuSâ¯next generation library preparationâ¯system.â¯We loaded the system withâ¯8â¯samples of fragmented DNA, at the input concentrationâ¯ofâ¯100â¯ng.â¯We sequenced theâ¯preparedâ¯librariesâ¯onâ¯anâ¯Illuminaâ¯MiSeqâ¯sequencer and analyzed the data usingâ¯BaseSpace.â¯â¯â¯ â¯Resultsâ¯We created libraries using Roche KAPAâ¯HyperPrepâ¯workflowâ¯and all libraries passed the quality thresholds.â¯Our sequencing results showed thatâ¯>98% of reads were paired. Less than 0.30% of reads were duplicates.â¯ Conclusion:â¯ Automation can create successful libraries from Roche KAPAâ¯HyperPrepâ¯Library Preparation kit.

PrgmNr 3468 - A novel intragenic deletion removing the secondary coiled-coil (CC2) domain of *SOX6* in a patient with neurodevelopmental disorder

View session detail

Author Block: **X. Shao**[1], E. Kellom[2], G. M. Rice[3], V. Horner[4]; [1]Wisconsin State Lab. of Hygiene, Univ Wisconsin Madison, Madison, WI, [2]Waisman Ctr., Univ. of Wisconsin Sch. of Med. and Publ. Hlth., Madison, WI, [3]Univ Wisconsin, Middletown, WI, [4]Univ Wisconsin Madison, Madison, WI
Disclosure Block: **X. Shao:** None.
Background: *SOX6* is a member of the *SOX* (Sry-type HMG box) gene family, which encode transcription factors with a high mobility-group (HMG) domain playing critical functions in many developmental processes, including neurogenesis, sex determination and skeleton formation. Variants in half of the 20 *SOX* genes, including *SOX6*, have been associated with human developmental disorders, called SOXopathies. Known functional domains of SOX6 protein include a C-terminal DNA-binding HMG domain that binds to HMG-like sites in the enhancer region of its regulating genes, and two coiled-coil (CC) homodimerization domains, the primary coiled-coil (CC1) domain and the secondary coiled-coil (CC2) domain, of which the CC1 domain is longer and thought to be more critical than the CC2 domain. SOX6 homodimerizes through the coiled-coil domain and further forms a highly stable complex with DNA.
Case Presentation and Genetic Testing: A 27-year-old male with learning difficulty, developmental delay and short stature was referred to our lab for genetic testing. Microarray analysis followed up with long-range PCR and sequencing analysis identified an 8.2-Kb deletion in *SOX6*. This predicted in-frame deletion removes exons 11 and 12 of *SOX6*, with exon 12 encoding the CC2 domain of SOX6. Though this specific deletion has not been previously reported, larger overlapping intragenic deletions and other sequence variants of *SOX6* have been identified in patients with autosomal dominant Tolchin-Le Caignec syndrome, a neurodevelopmental SOXopathy characterized by mild to severe intellectual disability and developmental delay. This novel intragenic deletion in *SOX6* is classified as likely pathogenic using ACMG guidelines.
Discussion: The current documented intragenic deletions in *SOX6* remove either both coiled-coil domains (CC1 and CC2) or only the CC1 domain, while no *SOX6* variant that deletes only the CC2 domain has been reported. Our study reports the first intragenic deletion variant of *SOX6* that removes solely the CC2 domain in a patient with learning and cognitive delay, and our findings suggest that the CC2 domain of SOX6 is also an essential functional domain playing key roles underlying neurodevelopmental disorders.

PrgmNr 3469 - Analysis of single nucleus sequencing in rat amygdala reveals transcriptional and regulatory mechanisms associated with vulnerability to cocaine addiction

View session detail

Author Block: **J. Zhou**[1], F. Telese[1], G. McVicker[2], A. A. Palmer[3], A. Massarat[1], X. Huang[1]; [1]Univ. of California San Diego, La Jolla, CA, [2]Salk Inst. for Biological Studies, La Jolla, CA, [3]UCSD, La Jolla, CA
Disclosure Block: **J. Zhou:** None.
Misuse of addictive substances inflicts a high societal and financial burden and results in tens of thousands of overdose deaths per year. Thus, there is an urgent need to improve understanding and treatment of substance use disorders (SUDs). Long term drug use can lead to addiction, which is characterized by compulsive drug seeking behaviors and a propensity for relapse even after extended periods of abstinence. This is likely due to widespread neurobiological changes caused by chronic drug use which are known to persist even after cessation of drug use. Twin studies have demonstrated that SUDs are highly heritable, indicating that genetic variation mediates differences in drug response and vulnerability to addiction. However, the mechanisms by which genetic factors drive addiction are not well understood. The majority of genetic risk variants for addiction are found in noncoding genomic regions, making it difficult to determine their gene targets and functional effects. Furthermore, most studies of SUDs have been conducted on heterogeneous bulk tissue and cannot detect cell type-specific signals. This has impeded a comprehensive characterization of the molecular features of the cell types involved in the brainâ□□s reward system and the mechanisms by which chronic drug use leads to neuroadaptations in these cellular circuitries. To address this, we analyzed novel single nucleus RNA-seq and single nucleus ATAC-seq datasets generated from the amygdala of outbred rats from a model of extended access to cocaine self-administration. Our analysis revealed distinct brain cell types and subtypes within which we identified cell type specific differentially expressed genes and differentially accessible open chromatin regions (OCRs) associated with vulnerability to cocaine addiction. We also quantified allele specific expression and open chromatin in each cell type, which we use to boost power for mapping cell type-specific eQTLs and caQTLs, and measured enrichment of risk variants for addiction within cell type specific OCRs. These findings help identify the functional effects of noncoding variants. Finally, we developed a deep learning framework to predict the cell type specific effects of genetic variants on chromatin accessibility. This tool can further elucidate the functional effects of noncoding variants and can be used to assist with selecting causal variants from a set of candidates. In summary, we identified novel cell type specific transcriptional and regulatory mechanisms associated with addiction to advance understanding of the molecular basis of SUDs, which can contribute to more effective treatment approaches and improved patient outcomes.

PrgmNr 3470 - Arimoclomolâ□□s effects on Rimmed Vacuole myopathy caused by *HSPB8* gene mutation

View session detail

Author Block: **E. Mohanty**, L. Weiss, R. Yan, A. Shmara, C. Cheng, V. E. Kimonis; UC Irvine, Irvine, CA
Disclosure Block: **E. Mohanty:** None.
Heat shock protein family B (small) member 8 (HSPB8) is a chaperone protein that is induced by harmful stressful events. HSPB8 acts in conjunction with the co-chaperone BAG3, and the HSPB8-BAG3-HSP70 complex enhances the intracellular clearance of all MND-associated misfolded proteins. Mutation in the HSPB8 gene causes Rimmed Vacuolar Myopathy (RVM), which is characterized by distal myopathy, rimmed vacuoles, and early death. Arimoclomol is a potential treatment for HSPB8 myopathy by acting on the heat shock response of cells. Arimoclomol amplifies and prolongs the activated, HSP-producing state of HSF1. This leads to an amplification in the production of cell protective HSPs in physiologically stressed cells, increasing the amount of activity that helps clear protein aggregates caused by the mutation. The dosages of Arimoclomol tested in patient fibroblasts and iPSC-derived myoblasts, and cell survival by the MTT assay demonstrated an optimal dosage of 4 ÂµM. Western blots of fibroblasts and iPSC-derived myoblasts showed a significant increase in the heat shock proteins and reduction of aggregates. The noticeable increase in HSPB8, HSP70, and BAG3 signify amplification of heat shock response and increased protein aggregate clearance. Arimoclomol with a dosage of 120mg/kg/day is administered through drinking water to Hspb8 mice with patient mutation. The mice have shown to tolerate the treatment well, demonstrating a stable body weight and upward trend of improvement in motor tests. The results have shown that there is potential in using Arimoclomol as a treatment for Rimmed Vacuole myopathy and other myopathic related diseases.

PrgmNr 3471 - Characterization of *APOE* Christchurch carriers in 239,390 participants of the UK Biobank with whole exome and/or whole genome sequencing data

View session detail

Author Block: **K. Y. He**[1], E. A. Khramtsova[1], A. Cabrera-Socorro[2], L. De Muynck[2], Q. S. Li[3], B. Smets[2], A. Parrado[1], B. A. J. Sarver[1], H. A. Hejase[1], I. Royaux[4], S. Li[1], M. Black[1], S. Lovestone[2]; [1]Computational Sci., Janssen R&D, Spring House, PA, [2]NeuroSci. Therapeutic Area, Janssen R&D, Beerse, Belgium, [3]NeuroSci. Therapeutic Area, Janssen R&D, Titusville, NJ, [4]Functional Genomics, Computational Sci., Beerse, Belgium

Disclosure Block: **K.Y. He:** Salary/Employment; Janssen R&D.

An ultra-rare *APOE* Christchurch (APOECh) mutation (c.460C>A or p.Arg154Ser) has been hypothesized to protect from *PSEN1*-based autosomal dominant Alzheimerâ□□s disease (AD). The protective effect was observed for a single homozygous individual but not for heterozygous descendants. Presence of the APOECh mutation in heterozygous carriers is associated with dyslipidemia and premature cardiovascular disease (CVD). To date, few studies have reported on the APOECh. The gnomAD v3.1 database includes 7 heterozygous individuals in 76,065 whole genome sequencing (WGS) samples (allele frequency [AF] = $4.6x10^{-5}$), 3 of whom are of Non-Finnish European ancestry and 4 of Latino/Admixed American ancestry. To study the phenotypic spectrum of APOECh carriers, we examined the UK Biobank (UKB) whole exome sequencing (WES; N=200,643) and WGS (N=141,948) data. We observed 14 heterozygous carriers of APOECh in WES (AF=$3.5x10^{-5}$) and 7 heterozygous carriers (AF=$2.5x10^{-5}$) in WGS, with 5 individuals present in both; AF in UKB is consistent with that reported in gnomAD. The 16 unrelated individuals include 12 females and 4 males with last known age ranging from 50 to 72; 15 are European and 1 is Admixed American by genetic ancestry assessment. None of these individuals carry Mendelian mutations in *APP*, *PSEN1*, and *PSEN2* for early-onset AD, and only 1 is a heterozygous carrier of the ApoE4 risk allele. Upon examining ICD-coded clinical history, self-reported illnesses, and parental medical history, none of these individuals have any form of dementia or family history of dementia. There are 6 participants with history of CVD and 5 show abnormal or borderline abnormal lipid biomarker levels according to AHA guidelines, among which 1 is deceased due to acute myocardial infarction, with data not reported in 1 individual. Additionally, there are 4 participants with abnormal lipid biomarkers levels with no reported history of CVD. Eleven individuals have self-reported medication information, 7 have primary care prescription records, and 5 have both sources of information available. No therapies for dyslipidemia were reported for these 16 individuals; the most commonly used drug is proton pump inhibitor (PPI; N=7) and 5 of these users have reported gastrointestinal (GI) disorders. The heterozygous APOE4/APOECh carrier has a medical history of GI neoplasms and PPI use. While the APOECh variant is very rare and larger cohorts are needed to assess its contribution to dementia, dyslipidemia, and CVD, the UKB provides an unprecedented opportunity to follow these carriers and elucidate the underlying role of APOECh in disease etiology.

Individuals with autism spectrum disorders (ASD) exhibit an increased burden of de novo variants in a broadening range of genes. We functionally tested the effects of ASD missense variants using Drosophila through â□□humanizationâ□□ rescue and overexpression-based strategies. We studied 79 ASD variants in 74 genes identified in the Simons Simplex Collection and found 38% of them caused functional alterations. Moreover, we identified GLRA2 as the cause of a spectrum of neurodevelopmental phenotypes beyond ASD in eight previously undiagnosed subjects. Functional characterization of variants in ASD candidate genes point to conserved neurobiological mechanisms and facilitates gene discovery for rare neurodevelopmental diseases.

Disclosure Block: **S.V. Mullegama:** None.

Diagnostic genomic tools, specifically chromosomal microarray analysis and whole exome sequencing (WES) allow for detection of copy number variants (CNVs) or single nucleotide variants (SNVs) in patients with genetic disorders. While these tools are powerful, due to the inherent nature of these tests, they neglect an important region of a gene: the 5â□□untranslated region (5â□□UTR) which is key in the regulation of gene transcription. We hypothesize that it is plausible that CNVs or loss of function SNVs in the 5â□□UTR of dosage-sensitive genes are the underlying cause of the phenotype of the patient due to impaired or altered transcription. To give credence to this hypothesis, we utilized our *MBD5*-associated neurodevelopmental disorder (MAND) patient population. MAND is an umbrella term that that describes a group of disorders that include 2q23.1 deletion syndrome, 2q23.1 duplication syndrome, and *MBD5* SNVs that affect the function of methyl-binding domain 5 (MBD5), and share a common set of cognitive and autism-like behaviors. We recruited a cohort of MAND patients with deletions in the 5â□□UTR region of *MBD5* (**n=44**) to illustrate whether deletions in the 5â□□UTR region of *MBD5* may be the etiology responsible for haploinsufficiency of *MBD5* which is seen in all 2q23.1 deletion patients. Through genotype-phenotype correlation studies, RNA-seq analysis, and mRNA expression analysis, we illustrate that there are specific 5â□□UTR deletions in *MBD5* which result in haploinsufficiency and produce solely an intellectual disability (ID) and autistic phenotype suggesting that deletions in the 5â□□UTR of *MBD5* are a hot spot for ID and autism. Further, our study revealed a possible alternative transcript of MBD5 with a transcriptional start site in the 5â□□UTR of the primary transcript that may impact disease. Thus, it is conceivable that deletions of the start site for the alternative transcript leads to loss of MBD5 function in some cells critical for neurodevelopment. Finally, our study points to the necessity of investigating the 5â□□UTR in dosage-sensitive genes to fully explore the potential for disease-causing variants. In conclusion, the coverage of the 5â□□UTR in diagnostic tests is imperative and requires test development to gain near 100% coverage of the 5â□□UTR especially in dosage-sensitive genes.

PrgmNr 3474 - Functional characterization of 400 acid Î±-glucosidase variants and analysis of phenotype-genotype relationships in Pompe disease

View session detail

Pompe disease (PD) is an autosomal recessive metabolic disorder caused by pathogenic variants in the lysosomal enzyme acid Î±-glucosidase *(GAA)*, leading to partial or complete loss of *GAA* activity. The resulting, progressive accumulation of glycogen in different tissues presents with a broad range of clinical manifestations that differ by age of onset (Infantile, Juvenile, and Adult), severity and disease progression. Timely diagnosis of PD involves detection of *GAA* deficiency and *GAA* sequence analysis, and is critical so that therapy can be initiated to prevent early mortality. However, the number of rare variants of unknown significance (VUS) identified in *GAA*, and lack of functional data for these variants, complicates their interpretation as well as the prediction of age of onset and severity for babies identified at birth. Here we describe the largest single functional study of *GAA* missense variants to date (n = 400). We apply the weight of evidence for ACMG-AMP functional criteria codes PS3 and BS3, thus facilitating the clinical interpretation of *GAA* variants. We observed that 15/16 (94%) of tested variants annotated as pathogenic or likely-pathogenic in ClinVar had activity levels below 15% wild-type activity. We found that 94/364 (26%) of tested VUS (absent, or annotated as having uncertain significance or conflicting interpretations of pathogenicity in ClinVar) reduce *GAA* activity to levels similar to those observed in known disease-causing mutations and may have possible disease relevance. We also curated PD patient genotype and age of onset data from the literature (n = 818 patients). We apply a combinatorial phenotype matrix previously presented for metachromatic leukodystrophy, that, given a patientâ□□s alleles, predicts disease severity and onset. We made several observations for PD, the most striking of which was that there are several genotype combinations consisting of two pathogenic, although mild in impact, alleles that may not lead to a discernible disease phenotype. Overall, it is hoped that this work will advance the understanding of genotype-phenotype correlations in PD, helping genetic counseling and future therapies in families affected with the disease.

PrgmNr 3475 - Genetic regulation of gene co-expression in human prefrontal cortex

Background: Organizing disease-relevant variants and genes by shared biological relationships provides an informative additional strategy to investigate the systems and pathways underlying genetic risk for psychiatric disorders. Moving from a gene to systems-level interpretation of GWAS findings is an important next step to define the regulatory networks and cell types implicated in psychiatric disorders, and improve reproducibility in the context of allelic and locus heterogeneity. Current eQTL methods are limited in their ability to characterize the effects of variants on distant genes. While cis-eQTLs have been thoroughly characterized in the prefrontal cortex, trans-eQTL discovery has been limited due to the considerable multiple testing burden of testing for relationships between every variant and gene in the genome. However, trans-eQTLs can also provide key insights into how GWAS variants exert their effect. By studying groups of co-expressed genes, we overcome the strict significance threshold of a trans-eQTL search; co-expression modules are leveraged for dimensionality reduction and allow for the study of distant variant effects on gene co-regulation.**Results:** The primary analysis was conducted in 491 individuals of European ancestry from the CommonMind Consortium dataset**.** 715 total co-expression modules were identified through multiscale embedded gene co-expression network analysis (MEGENA). Modules contained an average of 72.2 genes (SD=187.2). Significant associations between single nucleotide polymorphisms (SNP) and the first principal component of a co-expression module (i.e. co-eQTLs) were identified for 107/715 modules at a per module Bonferroni threshold of p Conclusion: Our results show successful identification of SNPs associated with changes in gene co-expression for 15% of tested co-expression modules, representing both cis and trans SNP-gene relationships. This project aims to determine the effect of common genetic variants on gene co-regulation in the prefrontal cortex, in a targeted effort to assign novel functional roles to psychiatric disorder GWAS risk loci and promote the development of improved diagnostics and therapeutic targets.

PrgmNr 3476 - Identifying novel evolutionarily conserved regulators of dopamine metabolism using a forward genetic screen in Drosophila melanogaster

Neuronal communication is indispensable for proper brain function, and neurotransmitters are a core signaling component for this process. Dysregulation of the neuromodulator dopamine (DA), for example, leads to social and behavioral impairments in animal models and neurological and neuropsychiatric disorders in humans. Understanding the cellular and molecular mechanisms that regulate DA synthesis, secretion and metabolism is paramount to finding better treatments for patients with DA-related disorders. Moreover, identifying novel regulators of DA can provide a list of candidate genes for human neurological and psychiatric disorders.
Since core components of DA synthesis and secretion are highly conserved, we performed a forward genetic screen in *Drosophila melanogaster*. Using tissue-specific RNAi and chemical mutagenesis/clonal analysis, we identified 123 genes that affect cuticle pigmentation, a DA-dependent phenotype in insects. 85% of these genes are conserved between flies and humans. Knockdown of many of these genes in DArgic neurons led to alterations in basal activity measured by Drosophila Activity Monitors (DAM), suggesting a role for them in DA regulation in the brain as well as epidermal cells. A cohort of 23 genes from the cuticle screen was selected for further DA measurement using High Performance Liquid Chromatography (HPLC) based on strength of phenotypes and neurological disease association. We observed a significant change in total head dopamine in 5 fly genes corresponding to 8 human genes: *AP-1*

PrgmNr 3477 - Interrogating strategies to link CRISPR screens to neurodegenerative disease

View session detail

Author Block: **B. van de Geijn**[1], E. Peguero Sanchez[2], V. Ramaswamy[1], J-P. Fortin[1], M. McCarthy[1], T. R. Bhangale[1]; [1]Genentech, South San Francisco, CA, [2]Roche, Warsaw, Poland

Genome-wide pooled CRISPR screening has emerged as a powerful tool to elucidate the mechanisms underlying disease genetics. Integrating these screens with genome-wide association studies (GWAS) can validate relevance to diseases of interest, identify causal genes/cell-types, and identify disease-relevant processes. However, many methodological challenges remain. To address these, we identify best strategies to: link screens to disease, integrate protein-protein interaction networks, known pathways, and account for essential genes. We demonstrate the potential of the approach by comparing 52 screens against GWAS for four neurodegenerative diseases: Parkinsonâ□□s disease, Alzheimerâ□□s disease, Multiple Sclerosis, and Amyotrophic Lateral Sclerosis.

We determine the optimal strategy for linking genesets to disease (gs2d) with GWAS. We test strategies based on: stratified LD score regression (Finucane et al. Nat Gen 2015), MAGMA (de Leeuw et al. PLoS Comp Bio 2015), and fine-mapping (Wang et al. RJSS 2020). While GWAS results are at variant level, CRISPR screen results are typically at gene-level. Since linking variant-to-gene (v2g) remains a substantial challenge, we evaluate various options: windows around genes (Finucane et al Nat Gen 2015), activity-by-contact (Fulco et al. Nat Gen 2019, Jagadeesh et al. biorXiv), and expression modification prediction (Wang et al. medRxiv). To establish a standard set of positive controls, we match Online Mendelian Inheritance of Man (OMIM) catalog genesets with corresponding disease GWAS summary statistics. We assess each strategy for power and calibration under ideal, noisy, and control conditions. Based on initial comparisons, we find MAGMA strategies significantly outperform the others.

We apply the best gs2d strategy to screens from the CRISPR brain project (Tian et al. Nat Neuro 2021) as well as neurodegenerative disease related screens we conducted. We reprioritize the original screen results using random walk with restart on protein-protein interaction networks, which has been shown to improve geneset enrichment (Fang et al. Nat Gen 2018). We then identify enriched pathways within these reprioritized sets. Finally, we link genes from each screen and enriched pathway to disease. We find statistically significant associations including those between Parkinsonâ□□s disease (PD) and neuronal-specific lysosomal function, lipid homeostasis, oxidative stress, and ferroptosis. We thus provide human genetic evidence for the role of these processes known to be involved in PD. In summary, we provide a framework for integrating screens with disease while testing the best strategies for each piece.

Neurodevelopmental disorders (NDDs) represent the largest category of Mendelian disease traits with a wide array of features including developmental delay/intellectual disability, structural brain anomalies, epilepsy and neurobehavioral/neuropsychiatric problems. Concomitantly, >80% of all human genes are expressed during brain development and/or are critical for brain function. Despite the surge in gene discovery fostered by next generation sequencing, the majority of NDD cases remain molecularly undiagnosed. Our previous exome sequencing (ES) in 128 Turkish NDD families (TBM1) yielded 41 candidate NDD genes. Of note, 6 out of 19 of genes, which we considered to have phenotypic expansion were found to have deleterious variants in an additional locus to that of the primary molecular diagnostic locus/gene (i.e. multilocus pathogenic variation, MPV). We observed that MPVs, mainly driven by identity-by-decent (IBD) causing â□□genomic blocksâ□□ of Absence of Heterozygosity (AOH), are present in much higher ratios in this cohort, and hypothesized that IBD may represent a genetic/genomic mechanism for intra- and interfamilial variability, especially in admixed populations with an elevated coefficient of consanguinity. To investigate this hypothesis, ES and whole genome sequencing (WGS) were now conducted in a second cohort consisting of 254 Turkish NDD kindreds [234 newly enrolled (TBM2) and 20 families whom remained unsolved from TBM1]. We implemented family-based rare variant analyses using internally established stringent variant prioritization criteria with in-house developed (HMZDelFinder and NMDEscPredictor) and/or publicly available bioinformatic tools (e.g. xAtlas).A molecular diagnosis was rendered in 181 out of 254 families (75%). Of note, out of 181 â□□solvedâ□□ families, deleterious variants were identified in 226 distinct genes. We propose 86 genes in which deleterious variants are candidate causative for an NDD phenotype. Importantly, based on objective variant prioritization criteria, we identified 54 families (54/181=29%) with MPV, mostly driven by AOH due to IBD. We established molecular diagnoses in 5/20 families that remained â□□unsolvedâ□□ in the TBM1 cohort mainly using additional bioinformatic tools and studying expanded family members. Our study shows the astonishing contribution of MPV in Mendelian disease traits and also underscores the tremendous genetic heterogeneity of nervous system development and function. The study also contributes several novel â□□candidate NDD genesâ□□ and further demonstrates the diagnostic utility of reanalysis in unsolved cases.

PrgmNr 3479 - Modeling the Impact of Alzheimerâ□□s Disease Genetic Risk on Microglia States and Functions

View session detail

Author Block: **M. Therrien**[1], M. Dolan[1], S. Jereb[1], T. Kamath[1], S. Marsh[1], M. Johnson[1], E. Macosko[1], K. C. Eggan[2], B. Stevens[1]; [1]Broad Inst., Cambridge, MA, [2]Stowers Med. Inst/HHMI, Cambridge, MA
Disclosure Block: **M. Therrien:** None.
Microglia, the brainâ□□s resident immune cells, are highly dynamic and reactive to environment and genetic challenges. More than 40 genomic loci have been linked to late onset Alzheimerâ□□s disease (AD) and many risk genes are highly expressed in microglia. Our goal is to connect insights from genetic association studies to new ways of functionally modeling the cellular and molecular causes of disease to enable predictive tracking and targeting of detrimental immune cell states in patients in the early stages of disease. Single cell transcriptomic studies reveal diverse microglial states in human and mouse brains, however we currently lack specific approaches to track and manipulate specific populations of microglia in Alzheimerâ□□s and other diseases. To answer this question, we turned toward human iPSC-induced microglia (iMGL) and single cell transcriptomics.Single cell transcriptomics revealed the presence of multiple microglia states (up to 17) when iMGLs are stimulated with different brain-relevant challenges, including apoptotic neurons, synaptosomes, myelin and amyloid. Moreover, alignment of these data using Liger (Welch et al. Cell 2017) shows these states are similar to the ones observed in human and mouse in vivo, revealing several disease associated states, including disease -associated microglia (DAM). We also observed changes in microglia states depending on the challenge and genetic background.Together, our data identified key elements causing the formation of DAM and how AD risk genes affect disease -associated states and functions. This work will open the door to the identification of modulators of DAM and highlight new therapeutics avenues of AD.

PrgmNr 3480 - Molecular Dynamics Simulations and Markov State Models Reveal Metastable States and Isoform-Dependent Kinetics in Apolipoprotein E Risk and Resilience Alleles

View session detail

Author Block: **W. Martin**, F. Cheng; Cleveland Clinic, Cleveland, OH
Disclosure Block: **W. Martin:** None.

Apolipoprotein E (ApoE) is the primary cholesterol and lipid transporting apolipoprotein in the central nervous system (CNS). Human genetics studies have demonstrated that the Îµ4 isoform, which differs from the common Îµ3 isoform only by a substitution of an arginine for cysteine at position 112, is the highest genetic risk factor for late-onset Alzheimer Disease (AD), while the Îµ2 isoform, differing only by a cysteine at position 158 as opposed to arginine, is protective. Further, the ApoE Îµ3 Christchurch mutation has been proposed to confer resistance to autosomal dominant AD. Evidence supports a direct interaction with AÎ² oligomers as well as colocalization with oligomers near AÎ² plaques. While significant progress has been made in investigating the properties of ApoE, there is more to be uncovered regarding how these single amino acid variants so drastically impact AD risk. It has previously been proposed that a salt bridge between Arg 61 and Glu 255 is key to the structural difference in Îµ4 due to the arginine at position 112 forcing Arg 61 into a more solvent-accessible direction, while a cysteine at 112 allows Arg 61 to remain within the helix bundle. Mutation of Arg 61 to threonine (or Glu 255 to alanine) â□□rescuedâ□□ Îµ4, causing it to function similarly to Îµ3. However, the solved structure of a monomeric mutant of Îµ3, which has been demonstrated to be functionally equivalent to the wild type, did not have such an interaction present; instead, an Glu 255 interacts with Lys 95 and is spatially distant from Arg 61. Additionally, it has been proposed that a significant conformational transformation is required upon lipidation, with most models proposing an extended conformation whereby the protein wraps around the hydrophobic tails of a lipid disc. To date, the monomeric mutant is the only full-length solved structure for ApoE. This leaves unanswered questions regarding the supposed conformational differences between the isoforms. Here, we have implemented long-timescale molecular dynamics simulations (totaling 100 microseconds, 5 replicates at 2 Î¼s each and a single 15 Î¼s simulation for each isoform) and Markov state models to investigate the isoform-dependent differences in the molecular kinetics of ApoE. The isoform-specific metastable states elucidated by our simulations could shed light on why each isoform interacts differently with AÎ², has a preference for different sized lipid discs, and the impact of Arg 61 on the intramolecular interactions in the Îµ4 isoform. This study could reveal conformational states which may be modulated by small-molecule structure correctors, potentially not only ameliorating the risk conferred by Îµ4 with respect to Îµ3, but possibly Îµ2.

PrgmNr 3481 - Mutations Near the N- or C-Terminus of AHDC1 are Associated with More Mild Xia-Gibbs Syndrome Phenotypes

View session detail

Xia-Gibbs Syndrome (XGS; MIM# 615829) was initially described in four severely affected individuals with *de novo* mutations in the 1603 amino acid AT-Hook DNA Binding Motif Containing 1 gene (*AHDC1*), leading to predicted truncated protein synthesis. In just four years, our HIPAA-compliant XGS Registry has identified 280 sequence-confirmed XGS families worldwide and accrued detailed clinical records and research consents from 90. Through the XGS Registry we have: i) documented XGS clinical heterogeneity and that most XGS individuals are severely affected, requiring life-long care; ii) identified core XGS phenotypes (i.e. a clinical synopsis) including speech delay, intellectual disability (ID), developmental delay and hypotonia (PMID 29696776); iii) associated the risk of secondary XGS features of scoliosis and seizure with the position of the *AHDC1* mutation (PMID 33644933); iv) identified XGS patients with missense mutations in *AHDC1,* where mutation position relative to functional domains was a key factor supporting their diagnosis (*Submitted for publication*) and; v) resolved putative XGS diagnoses in individuals with large genomic deletions (*in preparation*). Here, we describe ten XGS individuals harboring truncating variants with mild phenotypes, challenging the established paradigm that all *AHDC1* truncation mutations result in â□□severeâ□□ XGS. A 14 year old male being evaluated for epilepsy was identified with a paternally inherited *AHDC1* truncating mutation at codon 108. This XGS father and child have mild learning disabilities, modest memory loss and sub-clinical sleep apnea. An unrelated 38 year old individual, with a *de novo* stop-gain mutation at codon 136, obtained a college degree and employment. Two 15 year old identical twin females with a *de novo AHDC1* frameshift beginning at codon 1325 have very mild dysmorphism, mild/moderate autism spectrum disorder and hypotonia, but function with good conversational language skills. The remaining XGS putatively-mild individuals are less than 10 years old, complicating the assessment of their long-term clinical outcomes, but many have the ability to speak more than 200 words and a diagnosis of autism, rather than ID.
Together these observations support a â□□polarity of mutation effectâ□□ model wherein truncating mutations close to either the N- or C-terminus of the AHDC1 protein may lead to an overall mild XGS clinical outcome. Further, the data indicate the power of the patient Registry to provide insights into genotype-phenotype correlations, and the value of expanding both the number of registrants and depth of clinical feature ascertainment over the natural history of individuals with XGS.

PrgmNr 3482 - Personalized structural biology reveals the molecular mechanisms underlying heterogeneous epileptic phenotypes caused by *de novo* KCNC2 variants

View session detail

Author Block: **S. Mukherjee**[1], T. Cassini[2], B. Li[1], N. Hu[3], T. Yang[3], W. Shen[3], C. W. Moth[1], D. C. Rinker[1], J. H. Sheehan[4], Undiagnosed Diseases Network, R. L. Macdonald[3], D. M. Roden[3], J. Meiler[5,1,6], G. Kuenze[6], J. A. Phillips[3], J. A. Capra[7,1]; [1]Vanderbilt Univ., Nashville, TN, [2]Chevy Chase, MD, [3]Vanderbilt Univ. Med. Background. DNA sequencing is now common in diverse clinical contexts, from rare diseases to cancer. However, sequencing often fails to provide actionable insight, due to the challenge of proposing and validating testable hypotheses about the effects of variants of unknown significance (VUS). Here, we describe a â□□personalized structural biologyâ□□ (PSB) approach that addresses this challenge by leveraging recent innovations in the determination and analysis of protein 3D structures.
Results. We illustrate the power of the PSB approach in an individual from the Undiagnosed Diseases Network (UDN) with developmental epileptic encephalopathy (DEE) symptoms who has a novel *de novo* VUS in *KCNC2* (p.V469L), the Kv3.2 voltage-gated potassium channel. A nearby *KCNC2* variant (p.V471L) was recently suggested (without functional evidence) to cause DEE-like phenotypes. We find that both variants are located in the conserved hinge region of the S6 helix and likely to affect protein function; however, despite their proximity, computational structural modeling suggests that the V469L variant is likely to sterically block the channel pore, while the V471L variant is likely to stabilize the open state. Biochemical and electrophysiological analyses demonstrated heterogeneous loss-of-function and gain-of-function effects, respectively. Using computational structural modeling and molecular dynamics simulations, we revealed the molecular basis for these distinct effects.
Conclusions. Our results implicate *KCNC2* as a causative gene for DEE and delineate the molecular basis for the heterogeneous clinical phenotypes for the two proximal variants. This demonstrates how the PSB approach provides a broadly applicable analytical framework for individualized hypothesis-driven interpretation of protein-coding VUS suspected to contribute to disease.

PrgmNr 3483 - *MPDZ*, a potential causal gene for the bone mineral density association at chromosome locus 9p23, regulates *in vitro* osteoblast function and *in vivo* bone mass accrual

View session detail

Author Block: **A. Buo**[1], J. Stains[2], C. R. Farber[3]; [1]Univ. of Virginia, Charottesville, VA, [2]Univ. of Maryland, Baltimore, Baltimore, MD, [3]Univ Virginia, Charlottesville, VA
Disclosure Block: **A. Buo:** None.
Osteoporosis is a highly debilitating disease of low bone mass and increased fracture risk. To combat the rising prevalence of the disease, research endeavors have increasingly focused on elucidating the underlying genetic determinants modulating bone health. Genome-wide association studies (GWASs) have proven to be very effective in this regard, collectively discovering hundreds of genetic loci that are associated with changes in bone mineral density (BMD). However, the identities of the variants and genes that are causal for many of these BMD GWAS associations have yet to be determined. One locus, located at human chromosome 9p23, contains a lead variant (rs12340775; $P = 3.8 \times 10^{-10}$) that resides in intron 3 of the Multiple PDZ Domain Crumbs Cell Polarity Complex Component (*MPDZ*) gene. Utilizing data from the Genotype-Tissue Expression (GTEx) consortium, we observe that this BMD variant is also a colocalizing expression quantitative trait locus (eQTL) for *MPDZ* expression in cultured fibroblasts, thereby establishing a possible causal link between differences in *MPDZ* expression and the BMD association at this locus. Here, we present initial evidence for a novel role for *MPDZ* in the regulation of bone mass accrual in mice, thus supporting its involvement in driving the genetic BMD association at 9p23. Given that *MPDZ* is expressed in osteoblasts and not osteoclasts, we hypothesized that *MPDZ* functionally regulates osteoblast function and impacts bone mass accrual. To test this, we used *Mpdz*-floxed mice to generate primary osteoblast cultures and *in vivo* mouse models that were deficient in *Mpdz* expression. By transducing *Mpdz*-floxed mouse calvarial osteoblasts with adenovirus expressing Cre recombinase, we show that Cre-mediated knockdown of *Mpdz* impairs the formation of mineralized nodules as well as reduces the expression of key osteoblast markers. Furthermore, we used the global Cre driver mouse E2a-Cre to generate mice that were heterozygous for one functional *Mpdz* allele ($Mpdz^{\hat{I}\square/+}$) and performed micro-computed tomography (MicroCT) analysis of skeletal specimens to pinpoint differences in bone microarchitecture. MicroCT reveals a 23% reduction (P Mpdz$^{\hat{I}\square/+}$ mice in comparison to sex-matched wildtype controls. Together, these results demonstrate that *Mpdz* impacts in vitro and *in vivo* bone function and further underscores *MPDZ* as the likely causal gene influencing the BMD association at 9p23.

PrgmNr 3484 - A Novel Role for HAPLN1 in Skeletal Development

View session detail

Author Block: **C. Patel**[1], A. Khanshour[2], Y. Kidane[2], R. Cornelia[2], J. J. Rios[3], C. A. Wise[4]; [1]Univ. of Texas Southwestern, Dallas, TX, [2]Scottish Rite Hosp. for Children, Dallas, TX, [3]Texas Scottish Rite Hosp. for Children, Dallas, TX, [4]Texas Scottish Rite Hosp, Dallas, TX
Disclosure Block: **C. Patel:** None.
Adolescent idiopathic scoliosis (AIS) is a common spine deformity of childhood. Despite its high heritability, few risk-associated loci have been identified. Using a multi-ethnic genome-wide association study meta-analysis, we detected significant association of alleles within genes involved in cartilage development. Here, in a collaboration with the Gabriella Miller Kids First Initiative, we performed whole-genome sequencing of 72 AIS families, which identified rare co-segregating nonsynonymous variants in the *HAPLN1* (p.(Gly336Ser) and p.(Cys304Ser)) gene in two families. *HAPLN1* encodes the Hyaluronan and Proteoglycan Link Protein 1, a protein that binds hyaluronic acid and proteoglycans in the extracellular matrix (ECM) and is thought to stabilize and hydrate cartilage and intervertebral disc. *In vitro* evidence also suggests that an amino-terminal peptide cleaved from HAPLN1 stimulates ECM production. The *HAPLN1* p.(Cys304Ser) variant is predicted to disrupt an evolutionarily-conserved disulfide bridge in the carboxy-terminal loop domain of HAPLN1. To evaluate a possible deleterious effect of the p.(Cys304Ser) allele, we transiently expressed epitope-tagged mutant mouse *Hapln1*^{C306S}, orthologous to the human variant, and a truncated protein lacking the C-terminal loop domain (*Hapln1*^{C306fs*5}) in HEK293T cells. While western blotting detected wild type (WT) Hapln1 protein in the cell lysate, media, and ECM fractions, mutant Hapln1^{C306S} protein was detected only in the lysate and media, and the truncated Hapln1^{C306fs*5} protein was detected only in the cell lysate. Immunofluorescence (IF) microscopy further demonstrated that mutant Hapln1^{C306S} protein was not integrated into the ECM. We engineered mice harboring the *Hapln1*^{C306S} or *Hapln1*^{C306fs*5} alleles using CRISPR/Cas9 gene editing. *Hapln1*$^{C306fs*5/C306fs*5}$ mice were born alive but died shortly after birth, exhibiting a chondrodysplastic phenotype with shortened limbs and dome-shaped head. Although *in vitro* evidence suggests mutant *Hapln1*^{C306S} fails to localize to the ECM, homozygous *Hapln1*$^{C306S/C306S}$ mice were viable, born at expected Mendelian ratios, and showed no significant skeletal abnormalities up to one year of age. Consistent with our *in vitro* results, IF analysis of neonatal spine and long bones failed to detect Hapln1 protein in the growth plates of *Hapln1*$^{C306S/C306S}$ or *Hapln1*$^{C306fs*5/C306fs*5}$ mice, while Hapln1 was readily detected in the hypertrophic zone of the growth plate in control mice. Collectively, our data suggest a novel function for HAPLN1 that is independent of its role in the ECM, and that loss of ECM-associated HAPLN1 may contribute to inherited AIS.

PrgmNr 3485 - A SNP associated with risk for non-syndromic orofacial cleft affects expression of *FOXE1* in an oral epithelium cell line

View session detail

Author Block: **P. Kumari**[1], R. Friedman[2], S. W. Curtis[3], E. J. Leslie[3], M. A. White[2], B. A. Cohen[2], R. A. Cornell[1]; [1]Dept. of Anatomy and Cell Biology, Univ. of Iowa, Iowa city, IA, [2]Dept. of Genetics, Washington Univ. in St. Louis, St. Louis, MO, [3]Dept. of Human Genetics, Emory Univ., Atlanta, GA
Disclosure Block: **P. Kumari:** None.
Genome-wide association studies and linkage analyses have identified two loci near *FOXE1* where single nucleotide polymorphisms (SNPs) in non-coding DNA are associated with risk for non-syndromic orofacial cleft. We predict that a functional subset of such SNPs have allele-specific effects on the activity of oral epithelium enhancers and the rest are merely in linkage disequilibrium with the functional subset. We previously identified a candidate for a functional SNP in one of the loci and here focus on the other. We tested 11 SNPs in this locus for their effects on enhancer activity in a massively parallel reporter assay (MPRA) in the GMSM-K human fetal oral epithelium cell line, and tested a top-scoring SNP from the MPRA in traditional luciferase reporter assays. One SNP, (rs10984103), had allele-specific effects in both MPRA and luciferase assays and lies in chromatin marked as an active enhancer by chromatin marks and nucleosome accessibility. The SNP lies in a predicted binding site for GRHL3 which is interesting because a SNP in an exon of *GRHL3* is associated with risk for non-syndromic cleft palate only. We use CRISPR-mediated homology directed repair to engineer clones of GMSM-K cells to be homozygous for either the risk-associated or non-risk associated alleles of the SNP. In the cells harboring the risk allele relative to those harboring the non-risk allele, expression of *FOXE1* (determined by qRT-PCR), binding of GRHL3 (determined by ChIP-qPCR), and the H3K27Ac signal were all reduced. This study suggests a mechanism for how common variants at *GRHL3* and *FOXE1* affect risk for orofacial cleft. This study also illustrates a generalizable method to screen non-coding SNPs associated with orofacial cleft for those that are functional. This study is funded by NIH DE027362, USA.

PrgmNr 3486 - Clinical application of long-read sequencing technology for unsolved cases of neurodevelopmental disorders

View session detail

Author Block: **S. Hiatt**[1], J. M. J. Lawlor[1], L. H. Handley[1], C. B. Plott[1], E. Partridge[1], L. B. Boston[1], M. Williams[1], J. Jenkins[1], K. M. Bowling[2], J. Grimwood[1], J. Schmutz[1], G. M. Cooper[1]; [1]601 Genome Way, Huntsville, AL, [2]HudsonAlpha Inst. for Biotechnology, Huntsville, AL

Disclosure Block: **S. Hiatt:** None.

Exome and genome sequencing (ES/GS) have proven to be effective tools for the diagnosis of neurodevelopmental disorders (NDDs), many of which are due to highly penetrant, often *de novo,* variation. However, while discovery power and diagnostic yield of genomic testing have consistently improved over time, most NDDs cannot be attributed to currently detectable genetic variation.

One potential approach to overcome variant detection limitations in short-read technology is to use long-read sequencing. We and others have recently assessed long-reads produced using the Pacific Biosciences circular consensus sequence technology, called HiFi, which are both long (>10 kb) and highly accurate (>99% bp accuracy). HiFi reads exhibit better alignment to the reference assembly, leading to more accurate and comprehensive variant calls, including for both SNVs and structural variants (SVs). Furthermore, HiFi reads allow for production of high-quality, phased *de novo* assemblies with N50 values approaching that of hg38. These phased assemblies are critical in understanding complex structural variation, including two of six probands in our initial study.

Building upon the success of our recent pilot project, we are continuing to generate HiFi genomes in probands with unexplained NDDs. These individuals had been previously sequenced with a standard short-read approach, and often been subject to numerous additional clinical tests, yet still lack a molecular diagnosis. We are generating 20-25x CCS coverage for ~8 probands each month, with a current aggregate total of 17 probands. We are using these data to identify disease-causal variants in each proband including SNVs, SVs, and expansions of repeat regions. For each proband, we also create *de novo* assemblies, using short-read data from each parent to facilitate phasing.

As early studies have shown that structural variation may represent a significant source of diagnostic variation in these probands, we are currently developing an in-house database of SVs that will aid in filtration of common variation identified with our HiFi based process. We are anticipating substantial improvements to the analysis of HiFi data and believe this will lead to a major improvement in rare disease diagnosis.

While the initial rates of observation of variants of clinical and research interest (2 of 6, 33% in our cases) in NDD trios were very promising, an extension of this pilot, with over 100 probands sequenced within a year will aid in our understanding of the strengths and diagnostic potential of this approach.

PrgmNr 3487 - Functional interpretation of TAB2 missense variants

Loss of function mutations in TAB2 (or TAK1 binding protein 2) have been associated with structural heart disease. We reviewed 11 new patients carrying TAB2 null variants from Baylor Genetics Laboratory (BGL) and found a high incidence of broad spectrum of additional developmental abnormalities beyond congenital heart defects, expanding the clinical spectrum of TAB2 haploinsufficiency. Importantly, most missense variants of TAB2 are currently classified as variants of unknown significance in ClinVar. The few reported as pathogenic are also without detailed functional analysis. Thus, we set out to establish a functional assay to assign pathogenicity of missense TAB2 variants. TAB2 has been shown to activate NF-ÎºB and MAPK signaling pathways. We tested the normal allele and additional 47 variants using luciferase reporter assays for NF-ÎºB or AP1 activity in HEK293T cells. These variants were chosen from both BGL and gnomAD database to capture a broad spectrum of variants. Four have been previously reported in the literature as pathogenic (Q230K, P208S, E569K and Q540R), one non-sense variant Q127X, one presumed benign due to high prevalence (H158Y) and 41 variants with unknown significance. We found that NF-ÎºB reporter assay is only able to identify one novel variant (C684Y) as complete loss of function, similar to the non-sense allele and GFP control. All the other alleles show comparable activities. In contrast, the AP1 reporter was able to assign all the known pathogenic variants correctly. Previously reported Q230K, Q127X, C684Y and 5 other variants show complete loss of function. Previously reported P208S shows partial loss of function. We were also able to identify the previously reported E569K and Q540R as gain of function (>2.5 fold). These two variants together with other gain of function variants in TAK1 have previously been reported in patients with autosomal dominant frontometaphyseal dysplasia, a distinct condition from those with TAB2 haploinsufficiency. The normal allele and H158Y show normal AP1 activity. Altogether in the 41 variants of unknown significance, we reclassified 6 complete loss of function, 20 partial loss of function, 10 normal function and 6 partial gain of function. As individuals with partial gain of function (

PrgmNr 3488 - Germline variation in the human immunoglobulin heavy chain locus contributes to inter-individual variability in the expressed antibody repertoire

View session detail

Author Block: **O. Rodriguez**[1], Y. Safanova[2], C. Silver[1], W. Gibson[1], D. Tieri[1], K. Shields[1], J. Kos[1], H. Ke[3], M. Emery[4], G. Deikus[4], R. Sebra[4], K. Jackson[5], S. D. Boyd[6], M. Smith[1], W. Marsco[3], C. T. Watson[1]; [1]Univ. of Louisville, Louisville, KY, [2]Univ. of San Diego, San Diego, CA, [3]Dana-Farber Cancer Inst., Boston, MA, [4]Icahn Sch. of Med. at Mount Sinai, New York, NY, [5]Stanford Univ., Stanford, CA, [6]Stanford Univ Med Ctr, Stanford, CA
Disclosure Block: **O. Rodriguez:** None.
Antibodies (Abs) consist of two identical heavy and light chains and are critical for an effective immune response. The heavy chain is encoded by genes at the immunoglobulin heavy chain (IGH) locus, one of the most structurally complex regions of the human genome, characterized by elevated levels of single nucleotide variants (SNVs) and large structural variants (SVs). There is mounting evidence that polymorphisms within IGH influence inter-individual variation in the expressed Ab repertoire, which may contribute to differences in Ab function in human health and disease. However, the extent to which genetics influences the Ab response has not been characterized. We followed an expression quantitative trait locus framework to identify IGH variants that affect the expressed naive (IgM) and memory (IgG) Ab repertoires in peripheral blood. Using a targeted long read sequencing approach, we generated paired IGH genomic and Ab repertoire sequencing datasets for 166 healthy donors (Asian, n=30; Hispanic, n=20; African American, n=20; Caucasian, n=96). We found that, within the naive IgM repertoire, 2,830 SNVs in IGH were significantly associated (P-5) with variation in usage for 66% (29/44) of commonly used (>0.001% of repertoire) variable (IGHV) genes. Identified variants included both coding and non-coding SNVs, as well as six common SVs and rare deletions spanning up to 19 genes. We found variants were either associated with single IGHV genes, or multiple genes, in some cases revealing complex long-range effects. For example, we identified an intergenic SNV associated with the usage of five genes (*IGHV3-33*, *IGHV3-53*, *IGHV4-59*, *IGHV3-66*, and *IGHV1-69*) that span a distance of >400Kb. Interestingly, the SNV reference allele frequency differed between populations (African, 0.78; European, 0.34). We also observed complex interactions between variants located within multiple regions of the locus. For example, the usage of IGHV4-38-2 was impacted by a SV and multiple SNPs separated by ~900 Kb. Finally, 85% (2,426/2,830) of significant IgM SNVs were also associated (P-5) with IGHV usage in the IgG repertoire, indicating that genetic factors influencing V(D)J recombination also have downstream impacts on the repertoire following antigen stimulation. Our study is the first to comprehensively characterize links between IGH polymorphism and inter-individual variation in the Ab repertoire, revealing an underappreciated role for IGH variants in the immune response. These findings set a foundation for investigating the molecular mechanisms influencing Ab repertoire development, and will ultimately provide insight into Ab-mediated immunity in disease.

PrgmNr 3489 - High Throughput Trafficking Assay Identifies Novel Loss and Gain of Function Variants in the Potassium Channel Gene *KCNE1*

View session detail

Author Block: **A. Muhammad**[1,2], T. Yang[2], M. A. Blair[2], L. D. Hall[2], K. Matreyek[3], D. M. Fowler[4], D. M. Roden[2], A. M. Glazer[2]; [1]Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Univ. Med. Ctr., Nashville, TN, [3]Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [4]Univ of Washington, Seattle, WA
Disclosure Block: **A. Muhammad:** None.
Introduction: *KCNE1* encodes a 129-amino acid transmembrane subunit of I_{Ks}, a potassium current important for cardiac repolarization. Loss-of-function variants in *KCNE1* can cause long QT syndrome, associated with fatal arrhythmias. Clinical testing has identified large numbers of variants of uncertain significance (VUSâ□□s) in *KCNE1*, necessitating novel approaches to accurately classify variants at scale.
Objective: We conducted a massively parallel cell surface abundance assay on a library of nearly all possible amino acid variants in *KCNE1*.
Methods: Using degenerate primers at each codon, we used inverse PCR to create a comprehensive library of variants in *KCNE1* with an extracellular HA tag. The library was expressed in a one-variant-per-cell format using a Bxb1 landing pad in HEK293 cells engineered to stably express *KCNQ1*, the other subunit of I_{Ks}. Cells were stained with a fluorescent anti-HA antibody and sorted into 4 equally populated groups of increasing surface abundance using flow cytometry. High throughput sequencing of barcode DNA from cells in each group was used to quantify the frequency of variants across the four groups, and surface abundance of KCNE1 was quantified using a weighted average, with possible values from 0 to 3. WT-like trafficking was defined as scores within the 95% confidence interval of the mean for synonymous variants.
Results: The library represented 80.1% of all possible missense variants in KCNE1. Surface abundance scores of these variants were normally distributed (1.53Â±0.43). Previously published trafficking-deficient variants had low scores in the assay. Most mutations at amino acids 35-38 reduced KCNE1 surface abundance, whereas positions 47-59 in the transmembrane helix had decreased surface abundance when mutated to most polar or charged amino acids. Surface abundance also decreased for aromatic or larger aliphatic amino acids introduced in the cytoplasmic domain at positions 79-114 which some reports implicate as a binding site for KCNQ1. We also identified variants across the protein with a novel, gain-of-function phenotype, increasing I_{Ks} at the cell surface. Nonsense variants before amino acid 57 in KCNE1 reduced surface expression, but nonsense variants after amino acid 57 had WT-like scores. Of variants currently classified as VUS, 23% had a trafficking score greater or less than WT-like.
Conclusion: Using deep mutational scanning, we interrogated ~2,000 variants in a clinically important ion-channel subunit, KCNE1. Our data provide structural insights and functional information to facilitate interpretation of VUSâ□□s, and uncover a gain-of-function phenotype suggesting a novel arrhythmia mechanism.

PrgmNr 3491 - Hyperproliferative lymphatic sprouting caused by an NRAS mutation can be rescued by targeting PI3K/AKT and RAS/MAPK signaling pathways in cell-based modeling systems

View session detail

Author Block: **M. Battig**[1], M. March[1], L. Matsuoka[1], S. Sheppard[1], C. Kao[1], C. Seiler[2], D. Li[1], H. Hakonarson[1]; [1]Ctr. for Applied Genomics, Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Aquatic Zebrafish Core, Children's Hosp. of Philadelphia, Philadelphia, PA
Disclosure Block: **M. Battig:** None.
Generalized lymphatic anomaly (GLA) and its more aggressive subtype kaposiform lymphatic anomaly (KLA) are intractable lymphatic malformations that are associated with severe clinical symptoms and poor prognoses. These lymphatic malformations occur primarily in bones, viscera, and thoracic and abdominal cavities, and will lead to complications such as organ compromise, pleural and pericardial effusions, and ascites. In patients with KLA, effusions and ascites are often hemorrhagic. The etiologies of these diseases are not fully understood, though studies have begun to identify causal genetic variations. In particular, a somatic mutation in *NRAS* (c.182A>G:p.Q61R) was recently found in tissue samples of GLA and KLA patients. *NRAS* encodes the GTPase N-ras, which serves an important role in lymphangiogenesis by regulating cell proliferation. To understand how this mutation may affect lymphangiogenesis, we expressed the mutation in human dermal lymphatic endothelial cells (HDLEC) and characterized their biochemical and functional activity. Immunoblotting of PI3K/AKT and RAS/MAPK signaling cascade components revealed that p.Q61R leads to increased activity in both pathways. Moreover, the activity could be restored using the MEK inhibitor trametinib and the mTOR inhibitors rapamycin (mTORC1 inhibitor) and OSI-027 (mTORC1 and mTORC2 inhibitor). In lymphatic sprouting assays, spheroids of HDLEC expressing NRAS(p.Q61R) exhibited a significantly greater number of capillary-like structures in comparison to the wild-type control. This hyperproliferative phenotype could be rescued by using either OSI-027 or trametinib, as seen by a reduction in the number of sprouts emanating from the spheroid and their length. Moreover, OSI-027 and trametinib, when applied together, inhibited increased sprouting at lower concentrations. These findings indicate that complex lymphatic anomalies may arise from mutations activating multiple signaling pathways involved in the growth of lymphatic endothelial cells, and that inhibitor-based therapies may benefit patients with these diseases, particularly if multiple signaling pathways are being targeted.

PrgmNr 3492 - Seeking answers for ocular disease: Characterizing intronic variants of uncertain significance using a minigene system

View session detail

Disclosure Block: **C. Leavens:** None.

Exome and genome sequencing is quickly becoming standard healthcare practice for many rare diseases; however, effectively interpreting genetic variants remains a challenge. Variants of uncertain significance (VUS) are frequently included on clinical sequencing reports, however their clinical relevance is unclear, posing a challenge for clinicians and patients seeking a molecular diagnosis. In most cases, VUS require additional family studies or functional assays to resolve the uncertainty. One large group of VUS are intronic variants predicted by *in silico* analyses to potentially affect pre-mRNA splicing. In partnership with a clinical laboratory, a cursory database analysis identified nearly 1,000 reported VUS which may impact splicing and require a functional assessment. Our pilot analysis focused on 30 variants with the strongest *in silico* splice disruption predictions in genes associated with ocular diseases. A well-characterized minigene system was used to assess the predicted splice defect (PMID: 28679633; 16925019). Briefly, the minigene system involves cloning a single gene segment into a plasmid vector which is then transfected into eukaryotic cells. Processed mRNA transcripts are then sequenced to determine the effects of the variant on splicing. To date, we have completed transfection of nearly a third of the variants, with a potential splicing impact observed in at least 5 variants. We will present our minigene assay findings in comparison to the *in silico* predictions. Ultimately, our findings may impact variant interpretation and the clinical diagnosis for each patient.

PrgmNr 3493 - Single-cell RNA sequencing of red and black melanocytes uncovers new pathways in pigmentation and disease

View session detail

Author Block: **H. Berns**, D. Watkins-Chow, W. Pavan; NIH, Bethesda, MD
Disclosure Block: **H. Berns:** None.
Melanoma is the most lethal form of cutaneous cancer, and variants in the melanocortin-1-receptor (MC1R) are associated with greater than 60% increased disease risk. Some human MC1R loss-of-function/hypomorphic variants produce disproportionately high levels of red-yellow pigment (pheomelanin), and individuals carrying these variants present with fair skin, poor tanning response, and increased susceptibly to melanoma development. Activation of photoprotective black-brown pigment (eumelanin) production downstream of MC1R is well established, however, there is still much to be learned regarding global gene expression changes upon activation or inhibition of MC1R. Thus, we aimed to characterize gene expression profiles of primary melanocytes isolated from mouse models with differing levels of MC1R activation by comparing red melanocytes, from a Lethal Yellow (Ay/a) mouse, with black melanocytes, from a Non-agouti (a/a) mouse. Using a single-cell RNA-sequencing approach, we identified 568 differentially expressed genes between these two primary melanocyte populations (FDR

PrgmNr 3494 - A computational approach for detecting physiological homogeneity in the midst of genetic heterogeneity

View session detail

Author Block: **P. Zhang**; The Rockefeller Univ., New York, NY
Disclosure Block: **P. Zhang:** None.
The human genetic dissection of clinical phenotypes is complicated by genetic heterogeneity. Gene burden approaches that detect genetic signals in case-control studies are underpowered in genetically heterogeneous cohorts. We therefore developed a genome-wide computational method, network-based heterogeneity clustering (NHC), to detect physiological homogeneity in the midst of genetic heterogeneity. Simulation studies showed our method to be capable of systematically converging genes in biological proximity on the background biological interaction network, and capturing gene clusters harboring presumably deleterious variants, in an efficient and unbiased manner. We applied NHC to whole-exome sequencing data from a cohort of 122 individuals with herpes simplex encephalitis (HSE), including 13 cases with previously published monogenic inborn errors of TLR3-dependent IFN-Î±/Î² immunity. The top gene cluster identified by our approach successfully detected and prioritized all causal variants of five TLR3 pathway genes in the 13 previously reported cases. This approach also suggested candidate variants of three reported genes and four candidate genes from the same pathway in another 10 previously unstudied cases. TLR3 responsiveness was impaired in dermal fibroblasts from four of the five cases tested, suggesting that the variants detected were causal for HSE. NHC is, therefore, an effective and unbiased approach for unraveling genetic heterogeneity by detecting physiological homogeneity.

PrgmNr 3495 - A statistical analysis framework to test the presence of allelic imbalance from a genomic region using allelic count data

View session detail

Author Block: **J. Choi**, D. M. Brown, B. M. Wilk, M. Gajapathy, E. Worthey; Ctr. for Computational Genomics and Data Sci. (CGDS) Dept. of Pediatrics, UAB Sch. of Med., Univ. of Alabama at Birmingham, Birmingham, AL
Disclosure Block: **J. Choi:** None.
Mosaicism is a biological phenomenon characterized by coexistence of genetically distinct cell populations in an individual developed from a single zygote. Diverse forms of mosaicism have been recognized from individuals with developmental disorders and cancer. For example, developmental disorders can be seen from individuals with mixploidy where diploid cells coexist with triploid cells due to prezygotic or postzygotic errors. On the other hand, in cancer, accumulation of somatic mutations can result in mixture of normal diploid cells with cancer cells, which exhibit arbitrary degree of chromosomal abnormalities and ploidy levels.One way to identify mosaicism in an individual is through examination of existence of allelic imbalance in affected tissue. Besides molecular cytogenetic analysis by fluorescence in situ hybridization, single-nucleotide microarrays and next-generation sequencing (NGS) techniques have been used to detect genomic regions with allelic imbalance arising from various forms of mosaicism. For instance, the previous research [1] has demonstrated that the pattern of alternative allele fractions across genomic region from NGS data can be used to identify individuals with mixploidy and to estimate the mixture proportion of diploid and triploid cells, which was shown comparable to cytogenic analysis.
With the motivation to extend the previous research [1], we developed a statistical analysis framework to detect the presence of systematic deviation of alternative allele fractions in a genomic region from an individualâ□□s genomic data with respect to those from a set of reference genomic data for which, no known abnormality is reported. To test the feasibility, we simulated allelic count data for a set of reference genomic data as well as that for individuals carrying a broader and subtler forms of mosaicism where in addition to a majority of normal cells, a minority of abnormal cells is assumed to have a variable allelic count ratio that leads to a shift in allelic balance. We showed that the statistical analysis framework based on a regression analysis technique applicable for a count data can achieve 80% of power to detect the presence of about 5 - 10% abnormal cells carrying the majority of possible allelic imbalance allowed for a given ploidy level, when genomic loci subject to the allelic imbalance span sufficiently large region and the over-dispersion of the count data is small enough. We are currently investigating ways to improve the detection power based on the current framework and to determine utility when coupled with low coverage whole genome sequencing.

PrgmNr 3496 - Assessing Short-Read Utility for SVs

View session detail

Author Block: **A. ENGLISH**[1,2], V. Menon[1], R. Flickinger[2], G. A. Metcalf[1], R. A. Gibbs[1], F. J. Sedlazeck[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Spiral Genetics, Seattle, WA
Disclosure Block: **A. English:** Salary/Employment; Spiral Genetics.
Structural Variation (SV) is a major source of genomic variation and the cause of multiple genomic diseases. SVs (insertions/deletions larger than 50bp) are difficult to identify within Illumina short-read data, prompting the use of long-read sequencing. Despite the overall success of long-read methods for detecting SVs, the data generation costs and sample requirements are limiting. Improved characterization of the performance of short-read sequencing for SV detection - including a detailed comparison with long-read methods, the impact of different genome references, and the source of sample data - can therefore enhance routine SV analyses. We leveraged previously published long-read, haplotype-resolved Human genome assemblies to create high-confidence sets of SVs (hcSVs) from 36 individuals from 5 ethnicities, employing 3 different references (Hg19; GRCh38; CHM13). Using 156 short-read samples of the same individuals from 2 previously published projects, we assessed the performance of two SV discovery methods (BioGraph, Manta) across the hcSVs. We also tested the â□□genotypabilityâ□□ of hcSVs using short-reads by leveraging two graph-reference based genotypers (BioGraph, Paragraph). We found that the average Human genome contains 26,672 SVs (10k deletions, 16k insertions) compared to GRCh38 and 24,525 SVs (12k deletions, 12k insertions) compared to CHM13. We note an increase in the SV counts in samples of African ancestry (~29k GRCh38 SVs) compared to those of non-African ancestry (~25k GRCh38 SVs). The short-read methods are able to discover ~70% of hcSVs and accurately genotype ~80%, highlighting that the underlying signals for SVs are conserved across sequencing technologies. However, for SV discovery we observe a bias against mid to large-sized insertions. Recovery improves for SV genotyping, but relies on an initial list of known hcSVs over which to genotype. We find that ~10% of hcSVs occur near or across genes, and of these, ~90% are accurately identifiable by short-read sequencing. This work highlights that while short-read sequencing captures fewer SVs than long-reads, much of the signal elucidated by both approaches may still allow for a better understanding of SVs and their geno- and phenotypic implications when appropriate tools and analytical methods are employed.

PrgmNr 3497 - Copy-Number Variation of CTCF Binding Sites Associates with Diverse Clinical Phenotypes

View session detail

Author Block: **C. Tubbs**[1], L. Han[2], M. Benton[3], E. McArthur[1], J. Capra[4], D. Ruderfer[2]; [1]Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Univ. Med. Ctr., Nashville, TN, [3]Baylor Univ., Waco, TX, [4]Univ. of California at San Francisco, San Francisco, CA
Disclosure Block: **C. Tubbs:** None.
Background: CCCTC-binding factor (CTCF) is an integral component in the formation of chromatin contact domains that underlie 3D genome structure. There is increasingly strong evidence for the utility of this organization in the proper regulation of gene expression. Recently, we have observed signatures of purifying selection acting against copy-number variants (CNVs) that disrupt CTCF binding sites. These events hold the potential to dysregulate the expression of many genes through the alteration of 3D genome organization. Gene misexpression driven by this mechanism has been causally linked to a variety of rare limb malformities and, in several cases, been shown to contribute to the pathology of developmental disorders and cancers. However, we lack a comprehensive understanding of when and how CTCF disruption by CNVs contributes to variation in common traits and disease. **Methods:** We address this gap by quantifying the relationship between CNVs, CTCF binding sites, and human traits using 56,112 genotyped individuals of European descent in BioVU, Vanderbiltâ□□s biobank linked with electronic-health records (EHR). We identified 398,131 rare (AF 20kb) CNVs, consisting of 175,475 deletions and 222,656 duplications. Individuals in our cohort, on average, carried 3.74 CNVs that covered 447kb of sequence. To determine how these CNVs impact CTCF binding sites, we curated CHIP signal from ENCODE across 89 human tissues to yield a final genome-wide set of 153,535 sites. Finally, to understand the relationship between CNV disruption of CTCF and human traits, we defined 1,865 clinical phenotypes using diagnostic billing codes ascertained from EHR data (â□□phecodesâ□□). **Results:** We hypothesize that variation in CTCF is deleterious and contributes to common disease risk through changes in chromatin topology. We assessed the association between CNVs that overlap CTCF binding sites with the clinical phenome defined by phecodes using a logistic regression model adapted from PLINKâ□□s CNV-enrichment test. We found significant associations between CNVs that disrupt CTCF binding sites and 79 phecodes across 13 clinical phenotype domains, all of which survived multiple testing correction (Bonferroni, p Conclusion: Our findings reveal a diverse array of clinical phenotypes that are enriched for CNVs that have overlap with CTCF binding sites. Ongoing work will aim to isolate and disentangle the direct contributions of CNVs altering CTCF to these traits.

PrgmNr 3498 - Evaluation of long-reads across challenging medical relevant genes and its implications for All of Us

Disclosure Block: **M. Mahmoud:** None.

The overall heritability explained by genetic studies to date is low for most complex diseases. Several common variant studies have suggested associations with loci in proximity to complex genomic regions that, in aggregate, harbor ~400 relevant medical genes (eg. *SMN1*, *RHCE*, *NCF1*, *LPA*, *TPO*, *TNNT1* and *HLA*), many of which are refractory to alignment using short-read genome sequencing. The emergence of long-read technologies hold great promise for detection and phasing of short (SNVs) and structural variants (SVs) to disentangle the complex interactions of these mutations. Unfortunately, the error rate and high costs limit availability and application in clinical sequencing. The All of Us Research Program long-read project aims to widen our understanding of the sequence diversity in complex genomic regions that potentially have direct implications on discovery of variation in medically relevant genes. We have previously identified 395 genes that are inaccessible using short-reads, which are also found in genetic panels and are highlighted in multiple studies citing their medical importance. Moreover, mutations in these genes cause different diseases such as Cancer, spinal muscular atrophy, and Rh Deficiency Syndrome. Using these genes, we investigate the benefits and limitations of long-reads across 27 samples including 4 trios using Illumina, PacBio HiFi and Oxford Nanopore Technology (ONT). Each sample was sequenced with one flow cell, enabling a systematic comparison across the technologies. Assessing the boundaries of ONT and PacBio HiFi across these 395 medical relevant genes revealed that we can haplotype-resolve SVs and SNVs across a majority (80%) of these genes, including *LPA*, with a complete loss of coverage in 3 autosomal genes (eg. *CORO1A*) and 14 genes on chrY (eg. *CDY1*). A few of these genes are interestingly sample-dependent, thus underlying their complexity compared to a reference issue. We identified a slight advantage for ONT attributable to their longer read length for mapping to repeats, such as HLA, but exhibit a higher indel error rate compared to PacBio HiFi. For at least 85.50% of genes, we were able to phase SNV and SV to study the trans vs. cis relationships of coding and noncoding effects. This study presents the strength and limitations of long-reads and their potential role to improve clinical WGS sequencing. Although cost and availability are still significant limitations, long reads can improve SNV and SV detection in clinical settings. These findings have clear implications for All of Us, human adaptation, and translational research. In our presentation, we will highlight these insights and share our progress in the All of Us program.

PrgmNr 3499 - Framework and analysis of cell-specific expression contributions to Mendelian Disease

View session detail

Author Block: **J. Whitlock**[1], T. Soelter[2], K. McPherson[2], T. Howton[1], V. Oza[2], B. N. Lasseigne[2]; [1]Univ. of Alabama at Birmingham, SOM, birmingham, AL, [2]Univ. of Alabama at Birmingham, SOM, Birmingham, AL

There are approximately 10,000 Mendelian diseases affecting 25 million Americans. Mendelian diseases are caused by germline aberrations that are present in all cells of the body but typically manifest in a number of tissues. Despite advances in genomic sequencing, gaps remain in translating individual genomic variation to observed phenotypic outcomes in rare mendelian disease. As a result, nearly a third of Mendelian diseases have unknown molecular bases. Moreover, for the remaining two-thirds, how molecular variation leads to disease is poorly understood in one-third of cases. There are multiple hypothesized drivers of tissue-specificity such as gene expression, regulatory networks, and non-cell-autonomous based mechanisms. Additionally, studies have proposed some diseases are not driven solely by tissue-specific expression, but rather underlying cell-specific disease manifestations. These remain unidentified or masked in bulk RNA-sequencing data. Many of these mechanisms remain largely uninvestigated across multiple cell or tissue types in a normal state. With this, comes a lack of understanding of the impact patient-specific variants may have on altering healthy patterns and leading to disease. A handful of tissue-specific gene expression tools exist. However, there is only one method for calculating cell-specific expression of genes, and it lacks a package for widespread application. Here, using renal and neurological associated human Mendelian disease genes in OMIM as a test set, we assess cell-type contributions to bulk RNA-sequencing data and develop a framework for assessing mechanisms behind cell-specific gene expression.

PrgmNr 3500 - Haplotype resolved LPA and Kringle repeats to study minorities across the USA

Heart disease is the number one cause of death in the United States and many risk factors are highly heritable, including levels of Lp(a) lipoprotein. Circulating levels of Lp(a) have been associated with risk of coronary heart disease (CHD) and stroke. Apolipoprotein(a), a precursor to Lp(a), is encoded by the LPA gene, and LPA includes multiple copies of the Kringle repeats (IV) that are negatively correlated with its expression. The analysis of LPA and the kringle IV repeats is often hindered with short reads due to its repetitive and complex nature, however previous studies have identified two single nucleotide polymorphisms that are strongly associated with an increased level of Lp(a), a reduced number of Kringle repeats, and an increased risk of cardiovascular disease. However, this association isnâ□□t well replicated in non-caucasian ethnicities, so the utility is limited when using these variants to assess the genetic risk of cardiovascular disease in certain populations. We found this to be true in our clinical cardiovascular genomics project, HeartCare. In this study, despite the presence or absence of the indicative SNPs, several non-Caucasian participants had unpredictable Lp(a) protein levels overall, highlighting that the linkage of the SNP and the kringle IV repeat numbers are not conserved across all ethnicities and further study of the LPA gene is needed to establish accurate genetic risk profiles for cardiovascular disease in diverse populations. We selected 20 Caucasians (10) and Hispanics (10) individuals that have extremely high or low levels of Lp(a) protein levels for long-read Oxford Nanopore sequencing. We were able to call SNVs and the tandem duplications of the kringle IV repeats together with other smaller Structural Variants (SVs) present in several participants. We were able to haplotype resolve the entire locus enabling investigation of candidate SNVs in linkage disequilibrium with the number of kringle IV repeats and the amount of linkage disequilibrium present in Hispanics. Using these genomic findings, we identified SNVs and copy number calls in a very large sample of Hispanics and non-Hispanic whites (N=14,111) and relate these variations to plasma Lp(a) levels. These data provide valuable insight into the genetic architecture of plasma Lp(a) levels across diverse populations.

PrgmNr 3501 - Identification of allele-specific KIV-2 repeats among multi-ethnic groups and association with LP(a) measurements

View session detail

Author Block: **S. Behera**[1], X. Chen[2], L. S. Kanikkannan[3], V. K. Menon[1], G. A. Metcalf[1], B. Yu[3], M. A. Eberle[2], E. Boerwinkle[3,1], C. M. Ballantyne[4], R. Kaplan[5], C. J. Rodriguez[5], F. J. Sedlazeck[1]; [1]Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX, [2]Illumina Inc., San Diego, CA, [3]Sch. of Publ. Hlth., Univ. of Texas Hlth.Sci. Disclosure Block: **S. Behera:** None.
Studies on the human *LPA* gene have found evidence that the kringle IV type 2 (KIV-2) variable number tandem repeats (VNTR) variant is one of the controlling factors of lipoprotein(a) [Lp(a)] isoform size. The *LPA* gene including the KIV-2 variant determines the Lp(a) level (a high number of KIV-2 repeats is associated with low Lp(a) concentration) and has strong associations with cardiovascular diseases. Nevertheless, it remains challenging to determine the number of KIV-2 repeats in whole-genome sequencing (WGS) data due to the repetitiveness of KIV-2. Lp(a) is currently widely studied among Europeans with recent papers reporting clear associations with cardiovascular risk. However, it remains challenging to extend these insights to other ethnicities including Hispanics due to the lack of genetic and phenotypic data available on non-Europeans. Thus, an allele-specific copy number (CN) estimation of KIV-2 is needed to improve the genetic diagnosis and understanding of the impact of KIV-2 on cardiovascular risk across ethnicities.

Using data from different cohort studies, we aim to study the association of KIV-2 repeats with the Lp(a) concentrations and cardiovascular risk prediction. To achieve this, we developed a novel approach to directly assess KIV-2 levels derived from the Illumina WGS dataset. We benchmarked this method carefully against Pacbio HiFi based assemblies to ensure high accuracy and precision. We used a WGS dataset of randomly selected 3,020 participants (samples sequenced on Illumina HiSeq X and mapped to GRCh38 reference sequence) from multiple ethnic groups including 1000 European samples, 1019 African-American samples from the Atherosclerosis Risk in Communities (ARIC) cohort study, and 1001 Hispanic samples from the Hispanic Community Health Study and the Study of Latinos (HCHS/SOL).

Our tool estimated the summed copy number of both alleles in all samples and performed haplotype phasing of ~46% of the samples (45.9% Europeans, 51.3% African-Americans, and 40.5% Hispanics). The frequency distribution of CN estimates among three ethnic groups shows that the African-American group has a higher percentage (~70%) of samples that are in KIV-2 repeats ranging from 20 to 40 versus ~45% for the Hispanic group. Using these newly-derived KIV-2 CN estimates, we will present the results of our association study, which utilizes protein measurements as well as health records from each of these individuals. We will present details about the method and the differences we were able to identify across the different ethnicities. Especially the latter has the potential to improve diagnosis of cardiovascular disease risks among understudied ethnicities.

PrgmNr 3502 - Knowledge based artificial intelligence for variant pathogenicity prediction for Mendelian disorders

View session detail

Author Block: **D. Mao**[1], R. Al-Ouran[1], C. Liu[1], L. Wang[1], C. Deisseroth[1], S. Kim[1], L. Li[1], P. Liu[1], B. Yuan[2], S. Yamamoto[1], M. F. Wangler[3], B. Lee[3], Undiagnosed Diseases Network, Baylor Genetics, H. J. Bellen[1], Z. Liu[4]; [1]Baylor Coll. of Med., Houston, TX, [2]Seattle Children's Hosp., Seattle, WA, [3]Baylor Coll. Med., Houston, TX, [4]Duncan Neurological Res. Inst., Baylor Coll. of Med., Houston, TX
Disclosure Block: **D. Mao:** None.
Every year thousands of patients, with potential rare genetic disorders, face uncertainty when healthcare providers are unable to discover the cause for their symptoms. The Undiagnosed Diseases Network (UDN) seeks to provide answers for patients and families affected by these mysterious conditions. The process of defining pathogenicity currently requires labor-intensive manual searches of a variety of databases and web resources. This manual process is time-consuming, subject to inter-user variability and variations in the depth or quality of the databases. It also requires broad expertise across multiple biological and informatics domains. Here, we created a systematic, comprehensive search engine, MARRVEL (Model organism Aggregated Resources for Rare Variant ExpLoration, http://marrvel.org), that mines all the critical information for variant analysis and presents it in a succinct, user-friendly way. MARRVEL integrates human databases (OMIM, gnomAD, ExAC, ClinVar, Geno2MP, DGV, and DECIPHER) and seven model organism databases from yeast to mammals. Furthermore, we are also developing a Knowledge-based Artificial Intelligent system (MARRVEL-AI) to prioritize and identify novel disease-causing coding variants. The interpretability of a machine learning method inversely correlates with its accuracy for complex tasks. To circumvent this, we are combining different models of artificial intelligence with complementary strengths, such as expert system and random forest. With only a small training data set, our model achieved high accuracy in identifying disease-causing variants for UDN cases.

PrgmNr 3503 - MetaRNN: Differentiating rare pathogenic and rare benign missense SNVs and InDels using deep learning

View session detail

Author Block: **C. Li**[1], D. Zhi[2], K. Wang[3], X. Liu[4]; [1]Coll. of Publ. Hlth., Univ. of South Florida, Tampa, FL, [2]Univ. of Texas Hlth.Sci. Disclosure Block: **C. Li:** None.
Separating rare pathogenic and rare benign variants from a large list of candidate mutations in next-generation sequencing experiments is an essential task in exome-sequencing-based Mendelian disease studies. This task is especially challenging for mutations that can cause changes in amino acid (AA) sequences, namely, nonsynonymous single nucleotide mutations (nsSNVs) and non-frameshift insertion/deletions (nfINDELs) while being exempt from definite and severe consequences. In this study, we present the pathogenicity prediction models MetaRNN and MetaRNN-indel to help identify and prioritize these two types of mutations using deep learning and context annotations. Twenty-eight high-level annotation scores and allele frequency features were used to represent the properties of each mutation and a recurrent neural network was adopted to extract feature information from a +/- 1 codon window around the affected codon. Trained using the ClinVar database, the MetaRNN and MetaRNN-indel models outperformed state-of-the-art competitors across all test datasets. Additionally, MetaRNN and MetaRNN-indel scores are comparable and well-calibrated to be combined for an integrated (nsSNV+nfINDELs) rare-variant burden test for genotype-phenotype association. MetaRNN executables and pre-computed scores are available at http://www.liulab.science/MetaRNN.

PrgmNr 3504 - Participation of rs9138 and rs1126616 of *SPP1* gene in gender-specific predisposition in the development of systemic lupus erythematosus

View session detail

Author Block: **A. Rivera-Cameras**[1,2], A. Ruiz-RamÃrez[1,2], I. DÃivalos- RodrÃguez[1,2]; [1]DivisiÃ³n de GenÃ©tica, Centro de InvestigaciÃ³n BiomÃ©dica de Occidente, IMSS., Guadalajara, Mexico, [2]Doctorado en GenÃ©tica Humana, CUCS, Univ. de Guadalajara, Guadalajara, Mexico
Disclosure Block: **A. Rivera-Cameras:** None.
INTRODUCTION: Systemic lupus erythematosus (SLE) is a condition of the immune system. Itâ□□s characterized by exaggerated B-cell and T-cell response, loss of immunity, production and removal of defective antibodies. Sex hormones and environmental influences can contribute to genetically predisposed immune system dysfunction. **OBJETIVE:** Analyze the participation of the variants rs9138 and rs1126616 in gender-specific predisposition in systemic lupus erythematosus. **METHODOLOGY:** The eQTL calculation of the variants was performed in 54 tissues reported in GTEx (V8), were selected as true eQTL when they presented an m-value >0.9. A variant-disease association (VDA) was made in DisGenet platform, based on a VDA score that ranges from 0 to 1 according to how much the association is supported in the different sources (UNIPROT, CLINVAR, GWASCAT, GWASDB). **RESULTS**: It was found that both variants presented an m-value >0.9 only in the testis tissue, with a marked difference in all other tissues, since the rest remained below 0.1. In the variant-disease association, the three diseases with the highest scores for each variant are mentioned, rs1126616 was associated with colorectal carcinoma, urolithiasis, and systemic lupus erythematosus (SLE). rs9138 had an association with rheumatoid arthritis, colorectal cancer, and neoplasms. No statistically significant difference was found between the mean values of the VDA score for the variants (p=0.565, N=20). **DISCUSSION:** The positive association between testicular function and the development of SLE has been previously seen, particularly when there is testicular hypofunction.[1] The key role of the rs9138 variant, in triggering high levels of IFN-Î± and secreted phosphoprotein 1 (SPP1)[2], as well as the remarkable role that IFN-Î± levels play in the development of rheumatological diseases has been seen, many research groups have even proposed that the increase of this cytokine is sufficient to induce SLE.[3] In our opinion, the variant rs1126616 has not been proposed before in the gender-specific predisposition for SLE, but this variant has been correlated as a risk factor for lupus nephritis.[4] The results obtained from the association of the variants with the tissues are interesting for the positive association between testicular hypofunction and SLE, support the hypothesis that low testosterone levels can influence the development of male SLE. It suggests that men with SLE have a higher risk of comorbid, this may justify its consideration in the treatment of patients, this information opens up avenues for future research focused on different tissues.

Identifying disease-critical tissues and cell types has deepened our understanding of disease etiology and may direct efforts to develop treatments (Hakselman et al. 2020 Nat Rev Genet). However, methods that aggregate cells by cell type may fail to capture heterogeneity in scRNA-seq data. Here, we introduce a new approach, single-cell Disease Relevance Score (scDRS), to evaluate the polygenic disease enrichment of individual cells in scRNA-seq data.

scDRS evaluates whether an individual cell has excess expression levels across a set of disease-relevant genes inferred from GWAS, using an appropriately matched empirical null distribution to compute P-values. First, scDRS converts disease GWAS summary statistics into a set of disease-relevant genes using MAGMA (de Leeuw et al. 2015 PLoS Comp Biol). Second, scDRS computes a disease score for each cell as a weighted average expression of disease-relevant genes, with weights inversely proportional to gene-specific technical noise; it also computes a set of control scores for each cell using matched control genes. Finally, scDRS computes disease association P-values for each cell based on the empirical null distribution of control scores across cells. scDRS is well-calibrated in null simulations and well-powered in causal simulations.

We applied scDRS to GWAS summary statistics for 60 diseases and complex traits (average N=297K) in conjunction with Tabula Muris Senis mouse scRNA-seq data (N=300K cells) (The Tabula Muris Consortium 2020 Nature). We reached three main conclusions. First, scDRS results aggregated at the cell-type level recapitulated known biology but also produced novel, biologically plausible findings, associating cardiomyocytes to lymphocyte count and pancreatic beta cells to intelligence. Second, scDRS identified subpopulations of disease-associated cells that are not captured by cell type annotations, including diverse subsets of regulatory T cells and T helper 17 cells associated with inflammatory bowel disease (IBD) and subtypes of neurons associated with schizophrenia (SCZ). Interestingly, scDRS determined that the association with IBD was correlated with effector gradient across T cells (gradient from naÃ¯ve to effector phenotypes) and the association with SCZ was correlated with the spatial dorsal/proximal axis across neurons within the hippocampal CA1 region; scDRS can reveal continuous gradients of cell-disease signals that may be overlooked by cell type-

level analyses. Third, genes whose expression levels across cells were correlated with scDRS scores in disease-critical cell types were strongly enriched for gold-standard drug target and Mendelian disease genes.

PrgmNr 3506 - Resolving the landscape of human genetic variation at the protein domain level using 454,803 exomes from the UK Biobank

View session detail

Author Block: **Y-P. Lai**[1], M. R. Miller[2], C. L. Hyde[3], A. Malarstig[4,5], E. Fauman[2], X. Chen[2]; [1]Early Clinical Dev., Pfizer, Cambridge, MA, [2]Pfizer, Cambridge, MA, [3]Pfizer, Groton, CT, [4]Karolinska Inst., Stockholm, Sweden, [5]Worldwide Res. and Dev., Pfizer, Stockholm, Sweden
Disclosure Block: **Y. Lai:** None.
Recent efforts of sequencing UK Biobank participants have provided us a unique opportunity to understand the human genetic architecture and variation, especially the biological roles of rare, functional variants in a general population. Here, we have systematically summarized the genetic variation in 454,803 humans not only at the transcript level, but also for all protein domains within each transcript. We categorized variation by allele frequencies and functional consequences, including putative loss-of-function (pLoF), missense, in-frame indels, and synonymous variants. We applied a statistical model to estimate cumulative Poisson probability to identify genes with extreme distribution of pLoF variants, and more importantly, to identify domains within each gene that have more or less than expected number of pLoF variants. As a result, we confirmed pLoF-intolerant genes previously reported by gnomAD indeed have lower pLoF mutational diversity rates (defined as the number of functional variants in an exonic region to the length of the region) than the pLoF-tolerant genes. We also evaluated the mutational diversity rates on protein domains and subsequently explored the utility of leveraging this information for identifying optimal units for conducting gene-based association tests using phenotypic traits in the UK Biobank. In sum, we characterized human genetic variation in protein-coding genes and protein domains with a focus on rare, functional variants in exomes. The analysis paves the way for a better understanding of roles of functional variants in protein domains and provides insights to identify and validate new drug targets through human genetics.

PrgmNr 3507 - The Genetic Architecture of Genome-scale Metabolic Networks

View session detail

Author Block: **N. Santhanam**[1], D. Uzuner[2], A. Oommen[3], T. Cakir[2], M. Thambisetty[4], H. Im[1]; [1]The Univ. of Chicago, Chicago, IL, [2]Gebze Technical Univ., Gebze, Turkey, [3]Natl. Univ. of Ireland Galway, Galway, Ireland, [4]NIH, Baltimore, MD
Disclosure Block: **N. Santhanam:** None.
Genome-scale metabolic models seek to reconstruct the totality of biochemical reactions within cells using stoichiometric constraints and mass balance. Integrating genomic, transcriptomic and other omic data into this network promises to provide a more holistic view of the processes that connect them and their role in disease etiology. To date, the genetic architecture underlying individual metabolic reactions in humans is not well understood. Here, we sought to fill this gap by performing genome-wide association study (GWAS), transcriptome-wide association study (TWAS) and heritability studies of genome-scale reaction scores associated with individual metabolic reactions.
We gathered transcriptome data from 255 (GTEx brain) and 336 (Common Mind brain) individuals and reconstructed personalized metabolic models from the latest version of human genome-scale metabolic network, Human-GEM, using the iMAT algorithm. To determine whether 13,416 reactions from GTEx included in Human-GEM were modulated by genetic factors, we then calculated heritability and performed a GWAS analysis of each reaction score. Moreover, we wanted to discern which genes were driving the significant SNP reaction score associations. To do so, we employed PrediXcan analysis, a gene-based association software to compute associations between omic features and a complex trait. With PrediXcan, we predicted expression of GTEx genotype data using prediction models from psychENCODE data that was derived from temporal and frontal cortex data. Predicted expression was then used to determine association with the set of 13,416 metabolic reactions. For the heritability analysis, we used genotype information from the Common Mind Consortium, provided by psychENCODE which included 2,712 reactions. We then determined heritability of these predicted Reaction Scores using a restricted maximum likelihood approach in GCTA.
Our analysis revealed that biochemical reaction scores are genetically modulated. We determined 751 unique SNPs that were associated with reaction scores and 1611 SNP-reaction score pairs at the Bonferroni corrected threshold for p-values. The PrediXcan analysis found a total of nine genes: CYP2D6, CYP2D7, DTX4, FAM109B, LINC00634, NAGA, PKNOX1, SLC25A5P1 and WBP2N that were significantly associated with reaction scores after Bonferroni correction. Moreover, we determined that the reaction scores are indeed heritable with a mean heritability of all reaction scores as 0.037. Understanding these gene-reaction score pairs may further elucidate the genetic regulation of abnormal metabolism underlying complex diseases such as Alzheimerâ□□s disease.

PrgmNr 3508 - The structural landscape of constrained sites in the human proteome

Disclosure Block: **B. Li:** None.
Quantification of patterns of protein-coding genetic variation within and between species is a cornerstone of evolutionary and functional analyses, and it is a main component of methods for interpreting variants of unknown significance. However, current approaches for quantifying constraint on proteins either focus on individual sites or the whole protein, without accounting for the functional context of the sequence: 3D structure. Recent growth in databases of genetic variation and protein 3D structure enables the synthesis of protein spatial context into the estimation of site-level constraint. Here, we describe a new framework, called COSMIS, for quantification of the constraint on genetic variation in 3D neighborhoods of each protein site based on a mutation-spectrum-aware statistical model of the expected number of variants. We use the COSMIS framework to analyze the distribution patterns of > 1.88 million human standing missense variants across > 2 million sites, covering 47% of all canonical transcripts of the human proteome. We demonstrate that the COSMIS score is accurate in predicting variant pathogenicity and gene essentiality. We further show that COSMIS performs significantly better than a range of 1D sequence-based metrics, such as the MTR score, while also providing biophysical insight into the potential functional roles of constrained sites. To demonstrate the utility of the COSMIS framework, we apply it to detect constrained sites in ion channels and predict the pathogenicity of recently characterized variants using custom-built homology models. We make our constraint maps freely available and anticipate that the structural landscape of constrained sites identified by COSMIS will facilitate interpretation of protein-coding variation in human evolution and prioritization of sites for mechanistic or functional investigation.

PrgmNr 3509 - Transposable element mediated rearrangements are prevalent in human genomes

View session detail

Author Block: **P. Balachandran**[1], I. A. Walawalkar[1], J. I. Flores[1], J. N. Dayton[1], P. A. Audano[1], C. R. Beck[1,2,3]; [1]The Jackson Lab. for Genomic Med., Farmington, CT, [2]Dept. of Genetics and Genome Sci., Univ. of Connecticut Hlth.Ctr., Farmington, CT, [3]Inst. for Systems Genomics, Univ. of Connecticut Hlth.Ctr., Farmington, CT

Disclosure Block: **P. Balachandran:** None.

Transposable elements (TEs) comprise more than half of the human genome, yet their role in genomic instability remains poorly understood. Two TEs can act as substrates for ectopic DNA repair, leading to TE-mediated rearrangements (TEMRs) that differ from retrotransposition events by duplicating or deleting the DNA between TEs. TEMR can result from homologous recombination repair (possibly nonallelic homologous recombination) or non-homologous end joining (NHEJ). Since most TEMR studies have focused on disease-associated events or comparative genomics, genome-wide estimates of TEMR are still not well established. To comprehensively identify TEMRs, we implemented an ensemble pipeline comprising multiple tools and filters on the short-read and long-read whole genome sequencing (WGS) data of three extensively characterized individuals from the Human Genome Structural Variation Consortium. In the three individuals, we identified 4458 nonredundant high-quality deletions and duplications with both long and short read support. Of these variants, 2200 (~50%) were due to retrotransposition and 374 (~8%) were TEMRs, consisting of 300 *Alu-Alu* and 74 L1-L1 rearrangements. Additionally, we found that 30X short-read WGS data is sufficient to identify nearly 90% of deletion and duplication TEMRs. We used a combination of PCR validation and computational techniques to reconstruct breakpoints at nucleotide resolution for the 374 TEMRs, and found that ~90% of deletions and duplications had junctions in TEs on the same strand/orientation of DNA. By mapping the two TEs at the junctions against their corresponding consensus sequences and identifying the position where the left and right breakpoint of a TEMR occurred, we categorized 78% of TEMR as homologous recombination and 22% as NHEJ. This computational approach significantly reduces the burden of manual curation of TEMR, and will be useful in future large-scale studies. We found that *Alu-Alu* and L1-L1 TEMRs occur within regions of relatively high *Alu* and L1 density (p Alu elements are prevalent and are responsible for 80% of TEMRs, they have a notable effect on genes and may contribute to human phenotypic diversity. Through this study, we show that TEs not only affect the genome through retrotransposition but are also a substrate for genetic rearrangements disproportionately affecting genes and may be responsible for phenotypic differences, diseases, and human evolution.

PrgmNr 3510 - Ultra-fast genome-wide association analysis for Alzheimer's Disease in 200,000 exomes from UK Biobank

UK Biobank (UKB), a large prospective population-based initiative, has collected extensive phenotypic data of half a million participants, aged 40-69 years, from the UK. The resource also includes various genetic data, including genome-wide genotype array, whole exome sequencing (WES), and whole genome sequencing (WGS) data for each participant. With this ultra-high dimension data size projected to grow into 15 TB, UKB launches a cloud-based Research Analysis Platform, allowing more than 20K researchers around the world to access them more readily. The platform not only offloads the storage requirement by removing the need of duplicating the data to additional infrastructure, but also provides scalable cloud computing resources. It enables more independent researchers to perform large-scale data analysis such as genome-wide association studies (GWAS), developing advanced machine learning and artificial intelligence techniques. Alzheimerâ□□s Disease (AD) has been causing more than 1 in 9 people aged 65 and older with dementia. There is no effective cure and the care is expensive. In this study, we performed a GWAS on AD using UKB data on the cloud-based platform, starting from data delivered to our UKB application to calculating the summary statistics. From the WES data of 200K samples released lately, we derived a binary trait, AD-by-proxy, based on each participantâ□□s ICD-10 code and their parental diagnoses and ages. We found 22,406 cases and 123,569 controls, after quality controls of the genotype and phenotype data. We applied REGENIE, a machine learning based method, for fitting the whole-genome regression model and testing for associations. Compared with Jansen, et al., we rediscovered variants associated with AD, including the well-known variants in *APOE*, and extended to more coding variants. The entire analysis took less than 12 hours of wall-clock time, which is made possible by both the efficiency of the algorithm and the scalability of the cloud environment. To learn more from the powerful UKB database, we further streamlined this computational-intensive analysis flow as a pipeline, which allows us to extend the analysis to dozens of other phenotypes and traits of interest.

PrgmNr 3511 - Unique Sequence Detection: a novel variant genotyper spanning the full spectrum of genetic variants

View session detail

Author Block: **K. Wong**, A. Rostamianfar, Z. Langley, M. Cusack, A. Ondov, A. Y. Zhou, S. Topper, J. Van Den Akker; Color Hlth., Burlingame, CA

Accurately detecting pathogenic germline variants is crucial for clinical-grade genetic testing. However many remain difficult to detect due to their sequence context or structural complexity. Genotyping has been shown to yield better performance than naive variant calling, particularly with short-read data. The ability to genotype validated and functionally annotated variants can also simplify downstream reporting. Current algorithms, however, are typically limited in their scope of detection. Here, we introduce a novel algorithm, Unique Sequence Detection (USD), to genotype the entire spectrum of variants, ranging from single nucleotide variants (SNVs) to complex structural variants (SVs).

USD operates in two distinct phases: (1) a one-time unique sequence generation step where unique (variant-specific) sequences are constructed based on previously well-characterized variants and (2), a pattern matching step where an alignment file is scanned to identify reads supporting the constructed unique sequences. During the first step, variant-specific sequences are designed algorithmically by evaluating a list of candidate sequences encompassing the variant. Each sequence is constructed of three parts; a â□□coreâ□□ sequence that spans the variant and needs to be matched exactly in the detection step, and left and right â□□flankingâ□□ sequences. The USD algorithm is tolerant of variation in the flanking sequences to provide resilience against co-variants and sequencing errors. For large variants, unique sequences are generated for each breakpoint. If applicable, co-insertions in complex variants are included in the design.

Leveraging clinically reported pathogenic variants, we demonstrate that USD is able to genotype challenging SNVs and indels that were missed or called incorrectly by commonly used variant callers, typically due to high GC content or nearby homopolymers. Over a set of 668 structural variants, USD achieved a recall of >0.9 with a precision >0.99, correctly genotyping deletions, tandem duplications, inversions, insertions, complex rearrangements, and gene conversions. USD especially outperformed other genotypers for deletions/duplications with large co-insertions or resulting from homologous recombination.

Taken together, USD is a comprehensive genotyper that enables accurate detection of variants of all sizes and complexities. It serves to boost detection of known pathogenic variants using either targeted or whole genome short-read sequencing platforms. Most importantly, subsequent observations of validated variants can be added regularly, thereby continuously improving the overall sensitivity of genetic testing.

PrgmNr 3512 - Analysis of concordance of genetic variants across sample types

View session detail

Author Block: **A. Cheng**, Y. Bordiya, L. Manley, T. Jayaweera; Thermo Fisher Scientific, Austin, TX
Disclosure Block: **A. Cheng:** Salary/Employment; Thermo Fisher Scientific.
Recent developments in nucleic acid extraction procedures from diverse sample types have opened the possibility of diagnostic and research applications using various kinds of tissues and body fluids. Currently, several techniques and sample types are being used for nucleic acid extraction, including bronchoalveolar lavage fluid, nasal swabs, brush biopsies, pharyngeal swabs, feces, blood, and saliva. Of these, saliva has emerged as a promising sample type for diagnosis of infectious diseases and genetic applications, including genotyping for personalized medicine, rare disease diagnosis, ancestry prediction, and research on oral cancers. Blood, buccal swabs, and saliva are the three main sample types used for extraction of gDNA to be used for next-generation sequencing (NGS) or qPCR. Blood has historically been the common sample choice for gDNA extraction due to the high quality and quantity of DNA yield. Recently it has become clear that there is an increasing need to utilize noninvasive sample types such as buccal swabs or saliva. Moreover, saliva and buccal swab samples are more economical in their shipping and storage options than other media such as whole blood, serum, and plasma. Saliva samples also require less manipulation compared to blood, serum, plasma, and other sample types. However, data for the concordance between different sample types, especially using the same extraction chemistry and workflows, is limited. To determine if common human genetic variants in a population can be detected consistently across sample types, DNA was extracted from 25 different donors with matched whole blood, buccal swab, and saliva samples. Nucleic acid was extracted and analyzed for quality and quantity of extracted DNA. Concordance among genetic variants across donors was observed using the Ion AmpliSeqâ□¢ Exome panel sequencing workflow and qPCR. We found that extraction from three sample types (whole blood, buccal swabs, and saliva) using the MagMAXâ□¢ DNA Multi-Sample Ultra 2.0 Kit produced high-quality eluates yielding enough DNA for downstream qPCR and NGS applications. When analyzed on the NanoDropâ□¢ Spectrophotometer, eluates showed high purity by consistent A260/A280 and A260/A230 absorbance ratios. Extracted DNA showed consistent genotyping concordance with qPCR, as well as variant calling concordance with whole-exome sequencing across matched sample types. Results from this study show that saliva collection is a cost-effective and noninvasive sampling method that can be used for high-sensitivity downstream applications such as genomic variant calling via qPCR, and NGS with Ion AmpliSeq exome sequencing workflows.

PrgmNr 3513 - Automating Illumina RNA Prep With Enrichment Using Beckman Coulter i7 Hybrid Automated Workstation

View session detail

Author Block: **S. Savant**, R. Pares, M. Giner, R. Nelson; Beckman Coulter Life Sci., Indianapolis, IN
Disclosure Block: **S. Savant:** Salary/Employment; Beckman Coulter.
The Illumina RNA Prep with Enrichment assay is a flexible target enrichment next generation sequencing (NGS) kit for use with targeted RNA sequencing and respiratory viral detection, including detection of the novel SARS-CoV-2 virus. The workflow allows for purified total RNA samples (10-100 ng input) or RNA from formalin-fixed paraffin embedded (FFPE) or degraded samples (20-100 ng input). RNA is reverse transcribed to complementary DNA (cDNA), which is then tagmented using Illuminaâ□□s Enriched Bead-Linked Transposomes to create larger inserts and indexed using IDT for Illumina DNA/RNA Unique Dual (UD) indexes. Libraries can be processed through enrichment by pooling samples down to a 3-plex or as a single-plexed library. The targeted enrichment portion of the assay uses a single 2-hour hybridization to allow for rapid capture and enrichment of the library pools. The entire manual workflow from cDNA synthesis and library preparation to targeted enrichment can be performed in a single day. In this poster, we describe and demonstrate the automated performance of the Illumina RNA Prep, (L) Tagmentation with Enrichment using the Illumina Respiratory Virus Oligos Panel v2 on the Biomek i7 Hybrid Genomics Workstation. The automated method can support cDNA synthesis and library construction between 1 to 96 samples and targeted enrichment and capture between 1 to 96 library pools, allowing users to pool libraries as either a 3-plex or a single-plex. The automated library and enrichment process of 96 samples/32 3-plex pools can prepare libraries for sequencing in approximately 12 hours total time with 45 minutes of hands-on time.

PrgmNr 3514 - Automating Twist Bioscience Modular Library Preparation and Targeted Enrichment Protocols Using Beckman Coulter Automation

Author Block: **R. Pares**[1], A. Sahm[2], M. Giner[1], E. Tavkin[1], R. Gantt[2], T. Han[2]; [1]Beckman Coulter Life Sci., Indianapolis, IN, [2]Twist BioSci., San Francisco, CA
Disclosure Block: **R. Pares:** Salary/Employment; Beckman Coulter.
Targeted enrichment of next generation sequencing libraries allows for a cost-effective focus on regions of interest when compared to whole genome sequencing. Hybridization-capture based enrichment is one of the most utilized technologies for targeted enrichment. While hybridization-capture based enrichment can provide a high degree of uniformity and variant detection, it typically involves complex, labor-intensive workflows that can take several days to complete. In this poster, we describe the automation of Twist Bioscienceâ□□s highly modular library preparation and hybridization-capture targeted enrichment chemistries with the use of the Twist Human Core Exome panel on the Beckman Coulter Biomek i7 Hybrid liquid handling platform. The method is capable of preparing up to 96 high quality NGS libraries from human genomic DNA using either enzymatic or mechanical fragmentation workflows and either Twistâ□□s Combinatorial Dual Indices or Universal Adapter System. Libraries can be enriched as either a single plex or pooled together up to an 8-plex using either Twistâ□□s standard or fast hybridization targeted enrichment protocols, resulting in enriched libraries that are ready to be sequenced on Illumina sequencing platforms. All major processes are performed on the system, allowing for maximum user walk away time and a workflow that can be performed in as little as a single day.

PrgmNr 3515 - Automation of NGSâ¯library preparation: Generate high quality libraries with less hands-on time

The relationship between germline variation and biology is complex. As our DNA sequence is interpreted through layers of the epigenome, the transcriptome and post transcriptional modification the relationship between variation and these intermediate data layers becomes increasingly complex. While the transcriptome serves as an accessible biomarker that can be easily assayed in tissues, cell types and now single cells, itsâ inconsistent and relatively weak correlation to protein level makes it difficult to ascertain biological insight from changes in the timing or amount of gene expression under disease or treatment conditions. High throughput proteome-wide technologies have improved rapidly in recent years, and mass spectrometry performed using data independent acquisition (MS-DIA) methods now allow for the simultaneous accurate profiling of thousands of proteins from a single sample. This has allowed the relationship between genetic variation and the proteome to be analyzed on genome-wide and proteome-wide scale. Two approaches are available; (i) harnessing a large reference database generated from donors with both proteomics and genetic variation data available for pQTL identification, (ii) applying these newly identified pQTLs to large population scale GWAS cohorts for the identification of genetically predicted protein levels for the identification of proteins associated with disease. In this study we have combined locally generated MS-DIA data from 110 high grade serous ovarian tumors with 169 publicly available tumors from the CPTAC study to identify a set of 398 pQTLS (P

PrgmNr 3517 - Impact of DNA contaminants on next-generation library preparation

View session detail

Author Block: **L. Saunders**, A. Dubinsky; Beckman Coulter Life Sci., Indianapolis, IN
Disclosure Block: **L. Saunders:** Salary/Employment; Beckman Coulter Life Sciences.
Nucleic acid purification and clean-up are critical steps for genomics applications, including library prep and next-generation sequencing (NGS) in genome engineering experiments. Variability in the quality of sample extraction methods can result in differential removal of inhibitors, or reaction contaminants and diminish NGS library preparation quality, as well as downstream data quality. To maximize sample recovery and create more consistent results, efficient removal of inhibitors or contaminants is critical during nucleic acid isolation and purification. In this study, we will use two common DNA extraction technologies (1) magnetic bead-based clean-up, and (2) silica-based columns, for their ability to extract total genomic DNA, and remove contaminants, from human muscle and skin samples. In addition, we will evaluate the effect of residual contaminants such as melanin, collagen and myoglobin on downstream applications such as NGS library prep and read quality metrics. The findings in this study demonstrate the importance of extraction chemistry on sample quality and downstream genomics applications. We also demonstrate the utility of magnetic bead-based- protocols as a superior, reliable, rapid and automatable method to isolate high quality DNA and remove contaminants.

PrgmNr 3518 - Integrated multi-omics analysis of thyroid cancer reveals key molecular pathways involved in tumor formation and metastasis

View session detail

Author Block: **S. Wu**[1], A. Sanghi[1], D. Ramazzotti[1], S. Chen[1], L. A. Orloff[1], M. M. Kasowski[1], M. P. Snyder[2]; [1]Stanford Univ., Palo Alto, CA, [2]Stanford Univ, Stanford, CA
Disclosure Block: **S. Wu:** None.
Thyroid cancer is one of the most common endocrine cancer with a continuously increasing incidence worldwide. Thyroid cancer has the lowest mutational burden among all cancers; however, it exhibits a high degree of heritability. The Cancer Genome Atlas (TCGA) study, one of the most comprehensive studies for thyroid cancer to date, profiled the mutations and transcriptome of 496 primary tumors, and identified two dominant molecular subtypes: BRAF-like and RAS-like. In this study, we performed deep multi-omics profiling (genomics, ATAC-seq, RNA-seq, proteomics, metabolomics, lipidomics) of 27 matched normal thyroid glands, 31 thyroid primary tumors, and 31 lymph node metastasis samples from 36 thyroid cancer patients. We observed dramatic molecular profiling differences between primary tumor/metastasis and normal samples, whereas not between primary tumor and metastasis samples. Transcriptomic, proteomic, metabolomic and lipidomic analyses revealed a dynamic choreography of molecular and cellular events that present three different changing patterns: cancer progression, tumor formation and tumor metastasis. These involve processes such as cell cycle and cell proliferation, cancer-related signaling pathways, immune response, metabolic reprogramming (including Warburg effects, dysregulated energy metabolism, carbohydrates, nucleotides, amino acids and lipids, etc), decreased thyroid hormone biosynthesis. Interestingly, activation of the AhR (aryl hydrocarbon receptor) signaling pathway was found to occur during tumor formation at transcript and protein levels, and we also detected the significant increase of tryptophan catabolite kynurenine, the endogenous tumor-promoting ligand of AhR, from our metabolomics data, indicating AhR signaling pathway and tryptophan catabolism may be the novel drug targets of thyroid cancer. Overall, our results reveal key genomic, molecular and cellular events during thyroid cancer formation and metastasis and its potential molecular mechanisms.

PrgmNr 3519 - Mitigating effects of blood disease pathologies that compromise specificity of gene expression signatures for radiation exposure

View session detail

Author Block: **P. K. Rogan**[1,2], E. J. Mucaki[1], B. Shirley[2]; [1]Western Univ., London, ON, Canada, [2]CytoGnomix Inc, London, ON, Canada
Disclosure Block: **P.K. Rogan:** Major Stockholder/Ownership Interest; CytoGnomix Inc.. Receipt of Intellectual Property Rights/Patent Holder; CytoGnomix Inc..
Background. Combinations of expressed genes can discriminate radiation-exposed from normal control blood samples by machine learning based signatures (with 8 to 20% misclassification rates; PMID 29904591). These signatures can quantify therapeutically-relevant as well as acute accidental radiation exposures. The prodromal symptoms of Acute Radiation Syndrome overlap those present in some viral infections. We recently showed that these radiation signatures produced unexpected false positive misclassification of influenza and dengue infected samples (PMID 33299552). Methods. This study investigated recall by previous and novel radiation signatures independently derived from multiple GEO datasets [GSE6874, GSE10640, GSE85570, GSE102971] on common and rare non-malignant blood disorders and blood-borne infections (thromboembolism [GSE19151], S. aureus infection [GSE30119], malaria [GSE117613], sickle cell disease [GSE35007], polycythemia vera [GSE47018], and aplastic anemia [GSE16334]). Normalized expression levels of signature genes is input to machine learning-based classifiers to predict radiation exposure in other hematological conditions. Results and Discussion. Except for aplastic anemia, these confounders modify the normal baseline expression values, leading to false-positive misclassification of radiation exposures in 8 to 54% of individuals. Shared changes predominantly in DNA damage response and apoptosis-related gene transcripts in radiation and confounding hematological conditions compromise the utility of these signatures for radiation assessment. These confounding conditions are known to induce neutrophil extracellular traps, initiated by chromatin decondensation, fragmentation and often, programmed cell death. Ribovirus infections are proposed to deplete RNA binding proteins, inducing R-loops in chromatin which collide with replication forks resulting in DNA damage and apoptosis. To mitigate the effects of confounders, we evaluated predicted radiation positive samples with novel gene expression signatures derived from radiation-responsive transcripts of secreted blood plasma proteins whose expression levels are unperturbed in these confounding conditions. Conclusions. This two step approach identifies and eliminates misclassified samples with underlying hematological or infectious conditions, leaving only samples with true radiation exposures. Diagnostic accuracy is significantly improved by selecting genes that maximize both sensitivity and specificity in the appropriate tissue using combinations for each of these classes of signatures.

PrgmNr 3520 - Untargeted metabolomics on the diet behaviors and their genomic interaction among Mexican Americans

View session detail

Author Block: **S. Chung**[1], D. Aguilar[1], E. L. Brown[1], C. L. Hanis[1], C. F. Burant[2], C. Evans[2], G. Jun[1]; [1]Dept. of Epidemiology, Human Genetics & Environmental Sci.(EHGES), Sch. of Publ. Hlth., Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [2]Michigan Regional Comprehensive Metabolomics Resource Core, Univ. of Michigan, Ann Arbor, MI
Disclosure Block: **S. Chung:** None.
Diabetes is a gradually progressing disease. 33.9% of adults in the U.S. have prediabetes, but 90% do not know their condition. Prediabetes is reversible by lifestyle changes such as diet. Diet is one of the essential environmental factors contributing to the development of prediabetes, but the effect of nutrient intake on glycemic traits in prediabetes remains unclear. Moreover, the influence of interactions between genes and diet on metabolites needs additional studies. This study aims to determine whether the impact of genes on glycemic traits-related metabolites differ according to diet behaviors among Mexican Americans. A total of 616 individuals were recruited from Starr County, Texas, and 170 samples were analyzed for preliminary analyses. Untargeted plasma metabolomic profiles were analyzed to obtain >6,000 metabolites. All the metabolomic data was standardized and log-transformed. Data for diet behaviors obtained using a semi-quantitative food frequency questionnaire were categorized based on the standards in the fat avoidance scale. Genetic variants were analyzed previously from imputed GWAS data. The association between diet behaviors and metabolites was analyzed by ANOVA model adjusted age, gender, and BMI. The association between metabolites and glycemic traits was also analyzed by linear regression model adjusted age, gender, and BMI. Gene-diet behavior interactions were analyzed using a linear model by PLINK 2.0. Sphingomyelin 32:2 showed a statistically significant association with different kinds of milk consumption (P=3.34E-07). 19 unnamed metabolites showed statistically significant associations with spread, milk, hamburger, and trimfat subgroups;1 metabolite in the spread group, 8 metabolites in the milk consumption group,1 metabolite in the hamburger consumption group, 9 metabolites in trimfat group. Two metabolites associated with trimfat were also associated with glucose intolerance groups and were also highly correlated with leucine and isoleucine (r2>0.7). We found that 36 metabolites associated with fasting glucose, one with 2-hour post glucose load, and 20 metabolites associated with HbA1C. In the Gene-diet behavior interaction analysis, Margaric acid, Eicosatrienoic acid, Cortisol, Lysophosphatidylethanolamine 18:2, and Lauric acids showed the top 5 highest signals (p-value

PrgmNr 3521 - *Best practices for trans-ethnic, meta-analytic transcriptome-wide associations: lessons from the Global Biobank Meta-Initiative*

Disclosure Block: **J. Hirbo:** None.
Large population-based or clinical-case based biobanks offer context to deploy genome-wide associations (GWAS) at scale. The Global Biobank Meta-Initiative (GBMI), through its genetic and demographic diversity, provides a strong opportunity to study population-wide and ancestry-specific genetic associations. A key challenge in GWAS is interpreting and mapping GWAS-significant variants to genes or epigenomic features. Transcriptome-wide association studies (TWAS) are a critical tool to boost detection power for and provide biological context to genetic associations by integrating GWAS signals with predictive genetic models of tissue-specific gene expression. TWAS involves three general steps: (1) training per-gene predictive models of tissue-specific expression in the eQTL dataset using genetic variants, (2) imputing tissue-specific genetically-regulated expression in the GWAS cohort with either individual-level genotypes or summary statistics and a linkage disequilibrium (LD) reference panel, and (3) estimating statistical associations between genetically-regulated expression and trait. Besides what is encountered in GWAS, TWAS presents unique challenges, especially in a trans-ethnic and meta-analytic setting like the GBMI. In this work, we present the GBMI TWAS pipeline in Asthma (n=1,800,785) using 5 tissues in GTEx with genetic and expression data of more than 70 samples from both European and African ancestry samples: subcutaneous adipose (n=71), tibial artery (n=76), skeletal muscle (n=86), sun exposed lower leg skin (n=73), and whole blood (n=80). We explore the performance of the ancestry enriched samples relative to total available samples for these GTEx tissues. We outline a framework for TWAS in a trans-ethnic, meta-analysis across multiple biobanks and explore practical considerations for all the three TWAS steps: ancestry specificity of expression models and LD reference panels, meta-analytic techniques for detection of gene-trait associations, and follow-up tests and analyses for biological context. Our framework can be applied to various phenotypes to study population-wide and ancestry-specific genetic associations mediated by tissue-specific expression. Our work provides a strong foundation for adding tissue-specific gene expression context to biobank-linked genetic association studies, allowing for ancestry-aware discovery to accelerate genomic medicine.

PrgmNr 3522 - Accurate profiling of forensic autosomal STRs using the Oxford Nanopore Technologies MinION device

View session detail

Author Block: **C. Hall**[1], R. Kesharwani[2], N. Phillips[1], F. Sedlazeck[2], R. Zascavage[3]; [1]UNT Hlth.Sci. Ctr., Fort Worth, TX, [2]Baylor Coll. of Med., Houston, TX, [3]Univ. of Texas at Arlington, Arlington, TX
Disclosure Block: **C. Hall:** None.
The high variability characteristic of short tandem repeat (STR) markers is harnessed for human identification in forensic investigations. Despite the power and reliability of current typing techniques, sequence-level information both within and around STRs are masked in the length-based profiles generated. Forensic STR profiling using next generation sequencing (NGS) has therefore gained attention as an alternative to traditional capillary electrophoresis (CE) approaches. In this proof-of-principle study, we evaluate the forensic applicability of the newest and smallest NGS platform available, the Oxford Nanopore Technologies (ONT) MinION device. Although nanopore sequencing on the handheld MinION offers numerous advantages, including on-site sample processing, the relatively high error rate and lack of forensic-specific analysis software has prevented accurate profiling across STR panels in previous studies. Here we present STRspy, a streamlined method able to produce length- and sequence-based alleles designations from noisy, long-read data. To demonstrate the capabilities of STRspy, seven reference samples (female: n = 2; male: n = 5) were amplified at 15 and 30 PCR cycles using the Promega PowerSeq 46GY System and sequenced on the ONT MinION device in triplicate. Basecalled reads were processed with STRspy using a custom STR database containing alleles reported in the STRSeq BioProject NIST 1036 dataset. Resultant STR allele designations and flanking region SNP calls were compared to the manufacturer-validated genotypes for each sample. STRspy generated robust and reliable genotypes across all autosomal STR loci amplified with 30 PCR cycles, achieving 100% concordance based on both length and sequence. Furthermore, we were able to identify flanking region SNPs with >90% accuracy. These results demonstrate that nanopore sequencing platforms are capable of revealing an additional level of variation in and around STR loci with sufficient read coverage. As the first method to successfully profile the entire panel of autosomal STRs amplified by a commercially available kit, STRspy significantly increases the feasibility of using nanopore sequencing in forensic applications.

PrgmNr 3523 - Development of a highly multiplexed RNA in situ hybridization assay for spatial transcriptomic mapping of formalin-fixed paraffin-embedded tissue

View session detail

Author Block: **H. Ji**, M. Yu, H. Lu, L-C. Wang, S. Zhou, B. Zhang, X-J. Ma; Advanced Cell Diagnostics, Newark, CA
Disclosure Block: **H. Ji:** None.
Single cell transcriptomics combined with spatial mapping with RNA in situ hybridization (ISH) holds great promise in resolving heterogeneous tissues at cellular resolution and providing insights into cellular organization and function of diverse cell types in healthy and disease states. ACDâ□□s RNAscopeÂ® represents a major advancement in RNA ISH approaches with its proprietary double-Z probe design and signal amplification that enables highly specific and sensitive target RNA detection. To meet the need for higher multiplexing capability for comprehensive spatial studies dealing with complex and heterogenous tissues, we have previously developed RNAscope HiPlex assay that is capable of multiplex fluorescent detection of up to 12 targets in fresh frozen tissue sections. In this assay, after target probe hybridization and a series of highly effective signal amplifications for all 12 targets, the signals are detected iteratively using a cleavable fluorophore, where in each iteration single RNA transcripts for up to four target genes are visualized as punctate dots in four distinct fluorescent channels.
We present here an upgraded version of the HiPlex assay (HiPlex v2) that can be applied to a wider range of tissue samples including fresh frozen, fixed frozen and formalin-fixed, paraffin-embedded (FFPE) tissues. To achieve this objective, a novel FFPE reagent was developed that can effectively quench tissue background autofluorescence (AF), and thus allowing for a high signal-to-noise ratio to provide single-molecule ISH detection. The novel FFPE reagent minimally affects tissue morphology and signal, and the signal is robust and stable across all iterative rounds for at least up to 2 weeks of assay run. As an example, we demonstrate that HiPlex v2 can detect commonly used immune-oncology markers (such as CD68 and IFNg) in various human cancer tissues, showing its potential for various cancer research applications. Finally, the HiPlex Image Registration Software used to merge images from multiple rounds was also upgraded to incorporate a new background removal algorithm, which provides an additional method of AF removal in registered images. Overall, our new HiPlex v2 assay holds unique advantages over other multiplex fluorescent assays in that up to 12 targets can be detected simultaneously on the same sample, allowing for a streamlined workflow and high performance in complex tissue context. In the new era of single cell biology and spatial transcriptomics, HiPlex v2 assay can be a powerful tool to analyze the spatial organization of cell populations and thus provide a deeper insight into the novel cell populations and their functions.

PrgmNr 3524 - DRIVE: Distant relatedness for identification and variant evaluation

View session detail

Author Block: **J. Baker**[1], H-H. Chen[2], Q. S. Wells[3], D. C. Samuels[4], J. E. Below[5]; [1]Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Univ. Med. Disclosure Block: **J. Baker:** None.
Rare variants can be a challenge to accurately detect in many genotyping assays. Identity by descent (IBD), or the concept of pairs of individuals sharing a region of the genome that originated from the same ancestor, can be leveraged to provide additional information that can raise confidence in rare variant genotyping calls in pairs of individuals. In the present study, we used IBD sharing between individuals within Vanderbilt Universityâ□□s biobank, BioVU, to identify networks of people who shared IBD segments around an autosomal dominant pathogenic rare variant. We focused on the rare variant RBM20 Arg636His, which has been shown to cause a Mendelian form of dilated cardiomyopathy (DCM), a disease characterized by cardiac dilation and contractile dysfunction that can lead to heart failure. RBM20 is an RNA binding and splicing regulation protein that is highly expressed in the heart. Participants were identified as carrying the DCM variant on Illuminaâ□□s Mega-Ex array. A network of five individuals was identified as sharing an IBD segment of over 20 centimorgans around the variant. These IBD segments were identified by hap-IBD. All five of these had diagnoses of DCM and other cardiac related phenotypes within their medical records. The presence of the RBM20 variant was confirmed in all five individuals by exome sequencing. A network of two individuals who shared a unique IBD segment within BioVU was also identified. These individuals were genotyped as carrying the DCM variant but only one individual was confirmed by exome sequencing. This methodology allowed us to identify high confidence carriers of the rare variant through IBD sharing around the variantâ□□s genomic location.

PrgmNr 3525 - Enabling faster and more cost-effective drug discovery through flexFS™: A highly durable, elastic, and scalable cloud-native file system

View session detail

Author Block: **G. Planthaber**[1], M. Colosimo[1], A. Poliakov[1], M. Matz[1], S. Sarangi[2], Z. Pitluk[1]; [1]Paradigm4, Waltham, MA, [2]Waltham, MA
Disclosure Block: **G. Planthaber:** Salary/Employment; Paradigm4. Receipt of Intellectual Property Rights/Patent Holder; Paradigm4.
The proliferation and availability of multi-omics and single cell data along with cutting-edge analytical tools is dramatically changing the drug and biomarker discovery landscape. As datasets become larger and algorithms become more data and computationally intensive, there is a complementary need for faster, more flexible, and less expensive data storage. Often multi-disciplinary teams need concurrent access to these data in a reliable, efficient, secure and durable fashion. Data must be encrypted and allow access control while supporting analytics and machine learning clusters that need rapid streaming of data. In this poster we introduce flexFS™, an elastic cloud-native file system that offers the cost effectiveness of S3 with the ease-of-use of a POSIX file system. flexFS seamlessly services 1000â□□s of hosts across the network. As an illustration of scalability, we present results from a large burden test performed with UK Biobank data and run using the REVEAL™: Biobank application backed by flexFS. The burden test was performed on 52,821 genes comprising of 5,091,192 variants, 541 phenotypes, and used 14 covariates. flexFS also provides accessible and reproducible archival and reference data storage. In addition to discussing performance details, we will present time and cost comparisons and present additional scenarios for utilization of flexFS.

PrgmNr 3526 - Enabling Real Time Analysis of Single-Cell Genomic Data with Accelerated Computing

View session detail

Author Block: **A. Lal**, C. Nolet, R. Ilango, T. Dyer, J. Zedlewski, J. Israeli; NVIDIA, Santa Clara, CA
Disclosure Block: **A. Lal:** None.

Single-cell sequencing experiments measure the molecular properties of individual cells, enabling high-resolution genomic and transcriptomic studies. Analysis of single-cell data requires high speed and interactivity to allow easy data exploration, clustering and visualization at different scales, and detailed comparisons between cell types. The growth of data has made analysis increasingly difficult, with datasets of over 1 million cells now possible.

Here we present open-source Python pipelines that dramatically accelerate single-cell data analysis. Our pipelines are built upon RAPIDS (https://rapids.ai), a free, open-source software suite for GPU-accelerated data science.

As a demonstration, we analyzed single-cell RNA-seq data from 1 million mouse brain cells. Compared to a state-of-the-art pipeline using the Scanpy library on 32 CPU cores, we achieved significant acceleration for every step, including 178x faster t-SNE visualization, 98x faster UMAP, and 2000x faster Leiden clustering, on a Tesla A100 GPU. We were able to cluster all cells in under 2 seconds and run the complete analysis in under 10 minutes, compared to 3.5 hours. We also developed a GPU-accelerated single-cell ATAC-seq pipeline that includes many of the same steps.

To make data exploration even easier, we developed an open-source GPU-powered cell browser that runs within a Jupyter notebook. In this browser, users can apply RAPIDS to visualize a single-cell dataset, select groups of cells, and analyze the selected cells. To our knowledge, this is the first tool to enable real-time, in-browser single-cell analysis at scale. Finally, we enabled AtacWorks, a deep learning tool to enhance epigenomic data, to run interactively as part of our single-cell ATAC-seq pipeline. This demonstrates how deep learning can be integrated with RAPIDS to provide end-to-end GPU pipelines that improve accuracy as well as speed.

Our open-source tools allow researchers to explore massive datasets in real time, and to iterate rapidly over algorithms and parameters to achieve better results. All of our demonstrations are publicly available as Jupyter notebooks at https://github.com/clara-parabricks/rapids-single-cell-examples.

PrgmNr 3527 - Improving rare variant calls from genotype array data: the Million Veteran Program Return Of Actionable Results (MVP-ROAR) Study

View session detail

Author Block: **Y. Shi**[1], M. Danowski[1], P. Devineni[1], D. Dochtermann[1], J. L. Vassy[2], S. Pyarajan[3], Million Veteran Program; [1]VA Boston Hlth.care System, Boston, MA, [2]Harvard Med. Sch. at VA Boston Hlth.care System, Boston, MA, [3]

Disclosure Block: **Y. Shi:** None.

Background: Familial hypercholesterolemia (FH) is an autosomal dominant condition characterized by low-density lipoprotein cholesterol (LDL-C) elevation and early cardiovascular disease. Despite an estimated prevalence of 1:311, ~90% of individuals with FH remain undiagnosed. Ongoing curation efforts are improving the ability to identify pathogenic variants associated with FH, most commonly in the *LDLR* gene. For this reason, the Million Veteran Program (MVP) launched the Return Of Actionable Results (ROAR) trial to study the processes and outcomes of identifying, verifying, and reporting FH-associated variants to MVP participants from their MVP chip data (Axiom Biobank Array of ~723K variants enriched for known disease-associated SNPs). However, among the first 8 participants with FH-associated variants identified from genotyping, only 5 participantsâ variants were confirmed by sequencing at a commercial laboratory. Here we describe the development and implementation of a novel quality control (QC) process to improve the detection of FH-associated variants in MVP genotype array data. **Methods**: We considered a list of 36 *LDLR* variants classified as pathogenic or likely pathogenic by a commercial laboratory, using American College of Medical Genetics and Genomics-Association for Molecular Pathology (ACMG-AMP) criteria. We developed a QC process to validate rare heterozygous genotypes (rareHets) called on the MVP chip. QC parameters were generated by the Rare Het Adjustment (RHA) Algorithm, which was triggered when fewer than four rareHets were called per batch of ~4500 participants. Next-generation sequencing (NGS) research data were available for 7 participants; a support vector machine (SVM) was built to minimize false positive calls, using genotypes from NGS as truth. Results were additionally compared to those from ROAR participants who had undergone commercial laboratory confirmation by gene sequencing. **Results**: Out of 529 *LDLR* rareHets initially detected by standard genotype calling among 469,170 MVP participants, the RHA Algorithm removed 151 as NoCall. Among the remaining 378, the SVM predicted 300 as high confidence calls. 100% call concordance between the QC pipeline and NGS was observed in all 7 participants with available research NGS data and between the QC pipeline and commercial gene sequencing for all 4 participants with confirmatory test results. **Conclusions**: We developed a QC process to reduce the rate of false positive rareHet calls from genotype array data. This improved analytic validity is a critical step before considering returning results to participants and to realize the potential of population precision health.

PrgmNr 3528 - Integration of WGS & RNA-seq as an efficient approach for novel variant discovery in complex genetic cases

View session detail

Author Block: **S. Audet**[1,2], E. Bareke[2], C. Michaud[1,2], V. Triassi[1,2], N. Legault-Cadieux[1], L. Touma[3], V. Ferraro[3], A. Duquette[2,3], M. TÃ©treault[1,2]; [1]Univ. of Montreal, Montreal, QC, Canada, [2]CHUM Res. Ctr., Montreal, QC, Canada, [3]CHUM, Montreal, QC, Canada
Disclosure Block: **S. Audet:** None.
This pilot study aims to develop an integrative analysis method that allows for an increased diagnosis success rate of rare genetic mutations. Moreover, identification of novel genes associated with Episodic Ataxia (EA) and evaluation of new AI-generated prediction algorithm, for a more robust variant examination, will ensue from the investigation.
Characterized by sporadic loss of voluntary movement coordination, EA typically manifest with a late onset as well as high clinical and genetic heterogeneity, setting additional hurdles to diagnosis. While four genes have been linked to the eight subtypes of EA, many patients are left without molecular diagnosis due to the limitations of individual DNA-sequencing methods, which can be mitigated by the functional overview that RNA-seq offers.
EA patients lacking molecular diagnosis despite in-depth examination were recruited in Montreal. Whole-Genome and RNA-sequencing was performed on blood samples to identify variants, differential expression, splicing events and repeat expansion. Multiple recent pathogenicity prediction algorithms were chosen to be tested concurrently to standard ones.
Candidate variants were identified for each patients according to pathogenicity scores, rarity of the genetic events, and known functional as well as clinical information for a given altered gene. Among the findings are truncations, missenses, and alternative splicing in genes already associated to either Spinocerebellar Ataxia or Spastic Paraplegia. In addition to being present in both datasets, validation of these interesting genomic events has been performed through Sanger Sequencing of both DNA and RNA. The available functional information from RNA-seq suggests abnormal mRNA expression, and is supported by the Sanger Sequencing as well as a traditional qPCR. A meta-analysis of our patientsâ transcriptomic profiles could also uncover commonly affected pathways in EA development.
This project should provide more defined diagnosis, leading to better quality of life, better understanding of prognosis and better management of care for patients. It will also promote the integrative approach for a larger spectrum of disorders and might eventually lead to new therapeutic strategies.

PrgmNr 3529 - Introduction of a walk-away automated Roche NGS workflow solution: Integrated KAPA library preparation, KAPA target enrichment and the AVENIO Edge instrument

View session detail

Author Block: **P. Wadia**, E. Malfarta, A. Liang, J. Lefkowitz, S. Sharma, D. Emani, P. Ton, B. Morck, T. Williams, J. Dasgupta, A. Fararooni, A. Moghaddasi, A. Al-Ariemy, M. Pintor, B. LaRochelle, N. Razavi, P-L. Janvier; Roche, Pleasanton, CA
Disclosure Block: **P. Wadia:** Salary/Employment; Roche.
Introduction: By automating and simplifying NGS workflow steps, a variety of diagnostic applications become practical and robust, thus increasing the efficiency of precision medicine. The AVENIO Edge* instrument provides a complete walk-away automated NGS library prep solution with on-deck QC from extracted nucleic acid with minimal hands-on time and flexibility for KAPA Target Enrichment. Feasibility of an NGS workflow with zero pipetting steps using Roche KAPA Library Preparation and KAPA Target Enrichment reagents with an AVENIO Edge instrument was explored. **Methods:** Performance, carry-over contamination rate, turn-around time, DNA quantitation module testing, were representative experiments comparing automated vs. manual capture workflows using Roche KAPA HyperCap Workflow v3.0 reagents on the AVENIO Edge instrument. Representative panels including KAPA HyperExome Panels were tested with pre-capture and post-capture pooling workflows using genomic DNA. Sequencing data was analyzed through internal pipelines and included percent reads on-target, fold-80 base penalty, mean target coverage, total duplicate rate, 90th/10th percentile ratio, mean insert size. **Results:** The AVENIO Edge Quant kit results and sequencing metrics were similar between automated and manually prepared samples for all representative panels. No significant differences were observed from reagent lot-to-lot, run to run & between instruments with minimal contamination across runs. Average turn-around-time for 24 sample processing was ~31 hours. **Conclusions:** We successfully demonstrated the integration and performance of the complete Roche KAPA HyperCap Workflow V3.0 leveraging KAPA Library Preparation and KAPA Target Enrichment reagents on the AVENIO Edge instrument, enabling the broader adoption of NGS in precision medicine and ultimately improving patient outcomes. *AVENIO Edge is currently in development. The data presented here are not intended for diagnosis or patient management. For Research Use Only. Not for use in diagnostic procedures.

PrgmNr 3530 - Investigation of a dysmorphic facial phenotype in patients with Gaucher type 2 and 3

View session detail

Author Block: **E. Daykin**[1], N. Fleischer[2], M. Abdelwahab[3], N. Hassib[4], R. Schiffmann[5], E. Ryan[1], G. J. Lopez[1], E. Sidransky[1]; [1]Med. Genetics Branch, NHGRI, NIH, Bethesda, MD, [2]FDNA Inc., Boston, MA, [3]Cairo Univ. Pediatric Hosp., and Social and Preventive Med. Ctr., Kasr Elainy Hosp., Cairo, Egypt, [4]Orodental Genetics Dept., Human Genetics and Genome Res. Div., Natl. Res. Ctr., Cairo, Egypt, [5]Baylor Res Inst, Dallas, TX

Disclosure Block: **E. Daykin:** None.

Gaucher disease (GD) is an autosomal recessive lysosomal storage disorder usually classified into three distinct types: non-neuronopathic (GD1), acute neuronopathic (GD2) and chronic neuronopathic (GD3). Discriminating between the types in a newly diagnosed child can be challenging due to the vast heterogeneity of clinical presentations and the limited genotype-phenotype correlation. Patients with GD2 often face a long diagnostic odyssey given the rarity of this disease. New technologies have enabled pilot newborn screening programs and widespread parental carrier testing, facilitating earlier diagnoses but exacerbating the need for prompt discrimination between the Gaucher types in order to implement appropriate management and establish prognosis. Interestingly, parents of babies with GD2 and physicians treating patients with GD3 have observed that affected children often share facial features. DeepGestalt is a deep learning algorithm that analyzes patient photos using facial recognition algorithms employing artificial intelligence to generate lists of genetic syndromes with similar morphologies. Analyzing 103 photos of 47 patients with GD2 and 143 photos of 86 patients with GD3, we generated receiver operating characteristic (ROC) curves comparing patient photos to age, sex, and ethnicity-matched controls. We then compared our GD2 cohort to our GD3 cohort through binary analysis and ran a multiclass comparison of our GD2 and GD3 cohorts, along with 133 photos of 48 patients with GD1. All areas under the curve (AUC) of the ROC curves were $\geq$ 0.89 (p values

PrgmNr 3531 - Multiple *de novo* copy number variant (M*dn*CNV) driven mirror traits and blended phenotype

Disclosure Block: **H. Du:** None.

A unique mutational phenomenon described by Liu *et al*. highlighted individuals with variable congenital abnormalities and multiple (n â¥ 4), large (>100 kb), *de novo* copy number variants (M*dn*CNV) throughout their genomes. The M*dn*CNV phenotype is ultra-rare and detected in 5/60,000 individuals referred for genome-wide clinical microarray. The variable congenital abnormalities observed in individuals with a M*dn*CNV phenotype are thought to be caused by the copy number change of different critical driver gene(s). To understand the mutational mechanism underlying the M*dn*CNV phenomenon, we leveraged long (LR-WGS) and short (SR-WGS) read whole genome data with integration and visualization tools to characterize the mutational signatures of *de novo* mutations (DNM) using a trio approach in an unpublished M*dn*CNV family. Eight *dn*CNVs of average length ~1 Mb were mapped in the proband. Biparental origin of constitutive *dn*CNVs (4:4) supports early perizygotic mutagenesis as the cause of genome-wide hypermutation. Sequence microhomology/microhomeology was present at 6/8 breakpoint junctions. *De novo* SNVs (6/79) and *de novo* indels (1/12) are enriched within 4 Mb of the *dn*CNV regions, suggesting microhomology-mediated break-induced replication, a replicative recombination-repair, as the process underlying M*dn*CNV formation. Gene content of the affected genomic regions were analyzed using the human phenotype ontology (HPO) to identify potential driver gene(s). Of the genes encompassed by *dn*CNVs, our proband has highest phenotype similarity score with published reports of *NSD1* and *SMARCC2* variants, suggesting the observed trait manifestation may be driven by gene dosage effects at multiple loci as a form of multilocus pathogenic variation (MPV). Of the known phenotypic traits of *NSD1* variants, our proband has opposite features, i.e. mirror traits, compared to individuals with a diagnosis of *NSD1* deletion syndrome. Our study highlights the multimodal genomic analysis approach in characterizing DNM. Moreover, we demonstrate the utility of quantitative phenotypic analysis to identify contributory, disease-associated genes within a background of genome-wide *dn*CNV, and provide evidence for duplications at two genomic loci containing triplosensitive genes that contribute to the probandâ□□s blended phenotype.

PrgmNr 3532 - Rapid endpoint PCR: Improving amplification speed without sacrificing specificity

View session detail

Author Block: **A. Waite**, A. Taft; Promega, Fitchburg, WI
Disclosure Block: **A. Waite:** Salary/Employment; Promega.
End-point PCR is essential for gene amplification and its global use continues to grow alongside other popular PCR technologies (qPCR, ddPCR, etc.). Within large-scale screening studies, speed to result is becoming increasingly important. Recent advancements in instrumentation have led to potential improvements in turnaround time, but limitations in reagent capabilities and speed remain a roadblock.
This study describes the development of a new reagent formulation targeted towards faster end-point PCR. Currently, the conventional PCR process may take 90 minutes. Utilizing the new formulation with â□□fastâ□□ thermal cycler programming can improve timing to 30 minutes or less. We will demonstrate a newly optimized master mix that is able to reduce the reaction time to

PrgmNr 3533 - Sequence-based assessment of mitochondrial DNA oxidative damage in cognitive impairment: Shedding light on health disparities in Mexican Americans

View session detail

Author Block: **D. M. Reid**[1], R. C. Barber[2], Z. Zhou[3], N. R. Phillips[1]; [1]Microbiol., Immunology, and Genetics, Graduate Sch. of BioMed. Sci., UNT Hlth.Sci. Ctr., Fort Worth, TX, [2]Graduate Sch. of BioMed. Sci., UNT Hlth.Sci. Ctr., Fort Worth, TX, [3]Biostatistics & Epidemiology, Sch. of Publ. Hlth., UNT Hlth.Sci. Ctr., Fort Worth, TX

Disclosure Block: **D.M. Reid:** None.

The aging population (65+) is rapidly expanding, leading to increased prevalence of age-related diseases (e.g., cardiovascular disease, metabolic disorders, cancer, and neurodegenerative diseases). Alzheimerâ□□s Disease (AD) is the 3rdleading cause of death in aging adults in the U.S., and age is the greatest risk factor. The U.S. Hispanic/Latinx population is expected to substantially expand through the year 2060 compared to their non-Hispanic/Latinx white (NHW) counterparts, resulting in the projected number of AD cases in the Hispanic/Latinx population to quadruple. Distinctively in the Mexican American (MA) population, diabetes, depression, stroke, and obesity are prevalent risk factors for developing cognitive impairment; however, reasons for the association between cognitive decline and these comorbidities remain unclear. Studies have shown correlations between commonly observed AD pathological changes and DNA damage. The mitochondrial genome is particularly vulnerable to DNA damage due to its close proximity to reactive oxygen species (ROS), which accumulate with age. Lifestyle and/or metabolic health may contribute directly to age-related risk for neurodegeneration. We are interested in determining if abnormal mitochondrial function, as indicated by oxidative DNA damage, is associated with cognitive impairment in MAs. Oxidative damage to guanine (G) forming 8oxoG, is one of the most prevalent DNA lesions. Here, we investigate the mtDNA 8oxoG mutational load in participants of the Texas Alzheimerâ□□s Research and Care Consortium (n=577) using Illumina-based NGS. We compare the 8oxoG load among in MAs and NHWs with AD, mild cognitive impairment, type-2 diabetes (T2D), and/or comorbidity (cognitive impairment with T2D). Our data indicates 8oxoG mutational load is significantly higher in MAs than in NHWs and is associated with cognitive function, sex, and education. Analysis of 8oxoG mutational â□□hotspotsâ□□ were not significantly associated with cognitive phenotypes in MAs or NHWs. Stratified analysis for 8oxoG mutational load in MAs suggests significant elevation when comparing cognitive impairment to normal controls. For future work, we propose nanopore sequencing technology as an improved alternative to current detection and quantification methods and provide preliminary proof of concept results for this method in analysis of oxidative mtDNA damage. Understanding the extent and implications of oxidative mtDNA damage may aid our understanding of the differences in manifestation of age-related cognitive decline in MAs as compared to NHWs.

PrgmNr 3534 - TowardsIsoform Resolution Single-Cell Transcriptomicsfor Clinical Applications Using Highly Accurate Long-Read Sequencing

View session detail

Author Block: **E. Tseng**[1], J. G. Underwood[1], A. S. Nanda[2], V. Ramani[2], S. Furlan[3]; [1]Pacific BioSci.s, Menlo Park, CA, [2]UCSF, San Francisco, CA, [3]Univ. of Washington, Seattle, WA
Disclosure Block: **E. Tseng:** Salary/Employment; Pacific Biosciences.
Single-Cell RNA-Seq (scRNA-Seq) emerged for the characterization of gene expression differences between different individual cells, which holds promise in clinical applications such as cancer, neurodegenerative, and immunological diseases. However, to date most scRNA-Seq methods employ short-read sequencing platforms that can only offer gene-level information, which would miss critical isoform information that could be markers for disease or development.
PacBio long-read transcript sequencing, (Iso-Seq method) can characterize full-length isoforms and has been used in bulk RNA studies to identify alternative splicing, fusion genes, and allele-specific isoform expression. Recently, the Iso-Seq method has been applied to the 10X Genomics single-cell platform to study postnatal mouse brain regions. This work identified distinct splicing patterns that differentiated by cell type, a phenomenon that would have gone undetected using short reads.
To explore the Single-Cell Iso-Seq method for potential enablement of clinical applications in a cost-efficient manner, we evaluated two techniques to improve the yield of single-cell molecules on the 10X Genomics platform. We tested our method on two human PBMC samples and showed that we can obtain a 6-fold throughput increase of 8-9 million full-length cDNA molecules per SMRT Cell 8M on the Sequel IIe System with identifiable barcodes and unique molecular identifiers (UMIs). The long-read data showed near perfect concordance with matching short read data on captured single cells and molecule abundances. We were also able to recapitulate similar cell type clustering as the short reads. The full-length isoform information revealed distinct expression levels in T cells and a wide diversity of splicing patterns not observable through 3â□□ tagging methods. Furthermore, as with bulk Iso-Seq analysis, allele-specific isoform expression and full-length transcript-based ORF prediction are possible and could lead to important discoveries for clinical applications.

PrgmNr 3535 - Attitudes on pharmacogenetic results as secondary findings among medical genetics providers

View session detail

Author Block: **M. N. Bartos**[1,2], S. A. Scott[1,3], E. W. Jabs[1], H. Naik[1]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]The Univ. of Alabama at Birmingham, Birmingham, AL, [3]Stanford Univ., Palo Alto, CA
Disclosure Block: **M.N. Bartos:** None.
As evidence increases supporting the potential utility of pharmacogenomics and the growing interest in implementing pharmacogenomic-guided prescribing, incorporating pharmacogenomic variants as secondary findings into clinical sequencing tests is increasingly under consideration. Therefore, we explored clinical provider perceptions on the utility of receiving pharmacogenomic results as secondary findings, specifically evaluating internal medicine and pediatric-geneticist attitudes towards it and their comfort with comprehension, interpretation, and result translation. Four focus groups were conducted with 12 geneticists, and standard thematic analysis conducted. All participants had experience ordering sequencing tests; however, the majority (10/12) did not or rarely order pharmacogenomic tests or prescribe medications with established response variability. Half of the participants had low comfort interpreting results without the support of clinical resources, whereas the other half were comfortable interpreting results and navigating available resources independently. The most frequently discussed positives of receiving pharmacogenomic results as secondary findings included prevention of adverse drug reactions in adults; grateful patients who are information seekers; the ability to prescribe more effective treatments rapidly; and appreciation of great advances in knowledge and guidelines of pharmacogenomics in recent years. Negatives included laboratory reporting issues, such as not following guidelines or an incorrect interpretation provided on a report; laboratory marketing to individuals without prior pharmacogenetic knowledge or targeting populations; pharmacogenomics findings buried in lengthy reports in patientsâ charts; and pharmacogenomics testing only applicable to select populations such as adults or patients treated with certain medications. The most desirable pharmacogenomic resources discussed were the creation of an electronic health record clinical decision support tool to assist with identifying and implementing pharmacogenomic results; a specialized pharmacist as part of the care team; more pharmacogenomic training during medical/graduate school; and well-written interpretation of pharmacogenomic results included on laboratory reports. Importantly, this novel focus group study determined that a majority of participants (10/12) agreed that it is reasonable to consider adding certain actionable pharmacogenomic genes to the ACMG secondary findings list; however, this was qualified with a need for additional resources supporting implementation.

PrgmNr 3536 - Connectivity Map Analysis of a Single-Cell RNA-Sequencing Derived Transcriptional Signature of mTOR Signaling

View session detail

Author Block: **N. Mahi**, M. Medvedovic, J. Yu; Univ. of Cincinnati, Cincinnati, OH
Disclosure Block: **N. Mahi:** None.

In the connectivity map (CMap) approach to drug repositioning and development, transcriptional signature of disease is constructed by differential gene expression analysis between the diseased tissue or cells and the control. The negative correlation between the transcriptional disease signature and the transcriptional signature of the drug, or a bioactive compound, is assumed to indicate its ability to â□□reverseâ□□ the disease process. A major limitation of traditional CMap analysis is the use of signatures derived from bulk disease tissues. Since the key driver pathways are most likely dysregulated in only a subset of cells, the â□□averagedâ□□ transcriptional signatures resulting from bulk analysis lack the resolution to effectively identify effective therapeutic agents. The use of single-cell RNA-seq (scRNA-seq) transcriptomic assay facilitates construction of disease signatures that are specific to individual cell types, but methods for using scRNA-seq data in the context of CMap analysis are lacking. Lymphangioleiomyomatosis (LAM) mutations in TSC1 or TSC2 genes result in the activation of the mTOR complex 1 (mTORC1). The mTORC1 inhibitor Sirolimus is the only FDA-approved drug to treat LAM. Novel therapies for LAM are urgently needed as the disease recurs with discontinuation of the treatment and some patients are insensitive to the drug. We developed methods for constructing disease transcriptional signatures and CMap analysis using scRNA-seq profiling and applied them in the analysis of scRNA-seq data of lung tissue from naÃ¯ve and sirolimus-treated LAM patients. New methods successfully implicated mTORC1 inhibitors, including Sirolimus, as capable of reverting the LAM transcriptional signatures. The CMap analysis mimicking standard bulk-tissue approach failed to detect any connection between the LAM signature and mTORC1 signaling. This indicates that the precise signature derived from scRNA-seq data using our methods is the crucial difference between the success and the failure to identify effective therapeutic treatments in CMap analysis.

PrgmNr 3537 - Explainable machine learning for adverse drug reactions

View session detail

Author Block: **C-F. Lin**, P. Ngyun, D. Quang, J. Chin; Res. Lab, DNAnexus Inc., Mountain View, CA
Disclosure Block: **C. Lin:** Salary/Employment; DNAnexus Inc..
The advancement of pharmacogenomics (PGx) has led to the establishment of gene-drug specific dosing guidelines. Implementing such guidelines in clinical settings can reduce the incidence of adverse drug reactions (ADRs). Unfortunately, dosing guidelines are only available for a small fraction of the over 20,000 prescription drug products approved for marketing. Furthermore, while some ADRs are predictable from the drugâ□□s known pharmacology, others are not. UK Biobank, with its wealth of real-world clinical data, questionnaires, and genomic data for nearly half-million volunteers, provides a valuable resource for studying ADRs. We set out to do this by building and explaining machine learning models for predicting ADR risk for individuals.
We included anthropometric measurements, verbal interview questions related to medical history, lab test results, and ICD10 codes in the main and secondary diagnoses. We devised an algorithm to select ICD10 codes and transformed them into features for modeling. For genomic features, we focused on rare variants within characterized protein domains in the known â□□ADMEâ□□ (absorption, distribution, metabolism, and excretion) genes and â□□Very Important Pharmacogenesâ□□ curated by PharmGKB. We also included Polygenic Risk Scores calculated using a number of conditions and data we selected from the PGS catalog.
We chose LightGBM (a decision-tree based gradient boosting framework) as our tool for modeling. We applied the SHAP (SHapley Additive exPlanation) package to the modeling results. SHAP explains the learned model by estimating how much does one feature impact the prediction results. Not only does this indicate which features are potentially more relevant, it also reveals unintended structure in the data, which we encountered and had to rectify in the process. Among the top impactful features, there were assorted blood assay results and number of medications, etc. The top two, however, were related to mental states.
Additionally, we have explored the use of admixture models on rare variants to visualize and identify sets of genes that are involved in specific ADR types in a concerted way. In particular, we used CountClust, which was developed for RNA-seq analyses and uses Grade of Membership models (aka Latent Dirichlet Allocation).

PrgmNr 3538 - Identifying the genetic contributors of efficacy and adverse metabolic effects of thiazide diuretics in African Americans from the Genetics of Hypertension Associated Treatments (GenHAT) study

View session detail

Author Block: **N. M. Davis Armstrong**[1], V. Srinivasasainagendra[1], R. M. Tanner[1], B. A. Hidalgo[1], H. K. Tiwari[1], D. K. Arnett[2], M. R. Irvin[1]; [1]Univ. of Alabama at Birmingham, Birmingham, AL, [2]Univ. of Kentucky, Lexington, KY
Disclosure Block: **N.M. Davis Armstrong:** None.
African Americans (AAs) have a higher prevalence of hypertension (HTN) compared to whites, presenting with a more severe form due to earlier onset and more rapid vascular damage. AAs respond better to diuretics compared to beta blockers or ACE inhibitors, yet the reason is not well understood. While thiazide diuretics continue to be a first-line antihypertensive, there is clinical significance to adverse metabolic effects linked to thiazide use, including incident diabetes and hypokalemia. The GenHAT study is an ancillary study of the Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT). DNA from participants was extracted and hybridized to Illumina Multi-Ethnic AMR/AFR BeadChip arrays. Quality control was performed at the sample and variant level, resulting in the inclusion of 4,297 AAs taking chlorthalidone, a thiazide diuretic, and 969,031 genotyped variants. Upon imputation using the NHLBI TOPMed Freeze 8 reference panel, over 20 million variants with minor allele counts >20, imputation quality scores >0.3, and genotype probabilities >90% were retained for association analysis. Outcomes of interest included systolic (SBP) and diastolic (DBP) blood pressure response over 6 months, fasting glucose response (FG) over 24 months, and serum potassium response (K) over 2 months. Linear regression models for the response of all outcomes were performed in PLINK2 and adjusted for age, sex, baseline measure, and genetic ancestry. A total of 14 variants (3 SBP, 2 DBP, and 9 FG) exceeded statistical significance at pCDHR2 and *MINDY3-CUBN* gene regions for SBP, *LINC02211-CDH9* intergenic region for DBP, and *GIMAP1-GIMAP5* for FG analyses. While many of the variants identified had no previous association with HTN or drug response, variants located within *CDH9*, *MINDY3-CUBN*, and *GIMAP* gene regions were of particular interest. *CDH9* variants have been previously associated with coronary artery calcification in an AA meta-analysis, while variants in *CUBN* have been linked to albuminuria and coronary artery disease. The *GIMAP* GTPase family are potential modifiers in autoimmune diseases including diabetes, and have reported associations with triglycerides, von Willebrand factor, C-reactive protein, and fibrinogen levels. Replication for these variants is ongoing using data from the International Consortium for Antihypertensive Pharmacogenomics Studies (ICAPS) to determine whether these variants can help identify individuals at risk of poorer drug response or unfavorable metabolic changes.

PrgmNr 3539 - Investigation of matrisome genes within the druggable genome

View session detail

Author Block: **J. E. Brown**[1], M. Shuey[2], E. Gamazon[3], N. J. Cox[4]; [1]Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Univ. Med. Ctr., Murfreesboro, TN, [3]VUMC Clare Hall, Univ. of Cambridge, Nashville, TN, [4]Vanderbilt Univ Med Ctr., Nashville, TN

Disclosure Block: **J.E. Brown:** None.

The functions of extracellular matrix-related genes are structural support and biochemical or biomechanical cues for cells or tissues. Based on results of studies of the phenotypic consequences of loss of genes that traffic fibrillar collagens to enable them to perform their roles in the extracellular matrix, we hypothesized that matrisome genes contribute to risk of neuropsychiatric disease in addition to other medical phenome. While extracellular matrix-related genes are a subgroup of all genes, this subgroup contains a wide variety that can be further broken down for comparisons. One such way to coalesce genes within the matrisome gene set is to focus on those within the druggable genome. Using the Illuminating the Druggable Genome (IDG) development levels, each gene was notated as Tdark (virtually unknown target with no known drug or small molecule activities), Tbio (target with no known drug or small molecule activities), Tchem (target has at least one ChEMBL compound), or Tclin (target has at least one approved drug). Within the matrisome gene set, we have identified 25 Tclin genes and 68 Tchem genes. Using PredixVU, the application of PrediXcan on Vanderbiltâ□□s biobank BioVU, we are able to identify associations between phenotypes and predicted gene expression for any given gene. Preliminary explorations were limited to Tclin matrisome genes within the 10k EUA PredixVU dataset. Genes with enriched phenotype sets include *SERPINC1* (increased gene expression associated with cancer and macular degeneration), *IL6* (increased gene expression associated with various cardiac issues), and *PLAT* (increased expression associated with secondary malignancies). Genes associated with neuropsychiatric disorders include *VEGFA*, *IL6*, *EGLN1*, and *IL23A*. Further investigations will use the 70k EUA PredixVU dataset and will expand to include Tchem matrisome genes. We will quantify this enriched phenome associated with these Tclin and Tchem matrisome genes using Mendelian randomization. This work will potentially allow for expanded use of the drugs and compounds associated with the matrisome genes within the druggable genome.

PrgmNr 3540 - Long-read amplicon sequencing of the polymorphic *CYP2D6* locus

View session detail

Author Block: **L. Zhu**, J. Harting, A. M. Wenger, Z. Kronenberg, P. Baybayan; Pacific BioSci.s, Menlo Park, CA
Disclosure Block: **L. Zhu:** Salary/Employment; Pacific Biosciences.
The *CYP2D6* gene affects the metabolism of ~25% of prescribed drugs in the United States. Therefore, it is necessary to identify the individual *CYP2D6* genotypes for the improvement of personalized medicine. However, current prevalent technologies, e.g., clinical microarray and qPCR, have limitations in genotyping the ~8 kb region at the highly variable *CYP2D6* locus. This study presents a simple long-range PCR method combined with PacBio HiFi sequencing for identifying duplications, deletions, polymorphisms, and gene conversions of the *CYP2D6* gene.
A two-step barcoded PCR approach was developed, including a first-step long PCR using gene-specific primers tailed with M13 sequences and a second-step amplification with barcoded M13 primers. This approach has been applied on 22 Coriell pharmacogenomics reference samples and 41 human saliva samples. Barcoded amplicons were pooled together for SMRTbell library preparation, sequenced on the PacBio Sequel II and IIe Systems. HiFi reads generated from PacBio sequencing were analyzed by the pbaa (PacBio amplicon analysis) pipeline. Nearly all (>99%) HiFi reads were on target for *CYP2D6*. Our results demonstrate that the long-range PCR in this study is robust and reliable to genotype real-world human samples. Furthermore, the pbaa analysis can process long amplicon HiFi reads efficiently. Overall, the sequencing results demonstrate that HiFi reads of 8-10 kb long with a median accuracy >99.9%, provide base-level resolution for identifying polymorphisms, indels, and gene conversions in the highly variable gene region. This study indicates the potential use of PacBio HiFi sequencing in clinical research applications.

PrgmNr 3541 - Targeting Alzheimerâ□□s Disease drug development via network analysis of GWAS data

View session detail

Author Block: **M. Mews**[1], B. Kunkle[2], L. Dumitrescu[3], T. J. Hohman[3], W. S. Bush[4]; [1]Systems Biology and Bioinformatics, Dept. of Nutrition, Case Western Reserve Univ., Cleveland, OH, [2]Univ. of Miami, Miami, FL, [3]Vanderbilt Univ. Med. Ctr., Nashville, TN, [4]Case Western Reserve Univ., Cleveland, OH
Disclosure Block: **M. Mews:** None.
Alzheimerâ□□s disease (AD) is the most common neurodegenerative disorder, affecting more than 30 million patients globally, but currently there exists a severe lack of effective drug treatments for AD even after 30 years of research; the FDA has just approved the first AD-drug aducanumab, which targets beta-amyloid, but its clinical effectiveness is still under heavy scrutiny. In our study, we focused on identifying potentially novel AD drug targets using a network-based approach that leverages existing, curated knowledge. We focused our analysis on 25 seed genes identified and validated as associated with AD in the largest AD meta-analysis to date by Kunkle *et al.* 2019. Subsequently, we leveraged existing high-confidence experimental and curated database entries from StringDB to identify functionally interacting partners of these seed genes. We further restricted our analysis to gene partners classified as known or predicted druggable gene targets according to the Drug Gene Interaction database (DGIdb). We excluded gene partners that were themselves seed genes and also four known early-onset AD genes (*PSEN1/2*, *APP*, and *MAPT*). These gene partner sets were subsequently analyzed in the context of the druggable genome via the generalized gene-set analysis tool MAGMA using two primary study sources of GWAS summary statisticsâ□□the previously mentioned Stage 1 results of the AD meta-analysis for AD risk (N = 63,926) and four analyses of a dataset derived from studying cognitive and global resilience to Alzheimerâ□□s disease by Dumitrescu *et al.* 2020 filtered to include either all participants (N = 5,108) or solely those with unimpaired cognition (N=3,820). These analyses test the hypothesis that variants within druggable gene partners may contribute to AD risk or protection. Two gene sets from the Stage 1 results analysis approached nominal significance, *CLU* gene partners (N = 76, p = 0.051) and *ADAMTS1* gene partners (N = 26, p = 0.055), whereas a single gene set, *PICALM* gene partners (N = 33, p = 0.031), was nominally significant when analyzing cognitive resilience in the context of cognitively unimpaired individuals. Driver gene partners associated with the *PICALM* gene set include known druggable genes *AAK1* (p = 0.017), *EGF* (p = 0.044), *GAK* (p = 0.007), and *IL7R* (p = 0.056) and the predicted druggable gene *TXNDC5* (p = 0.044). These findings suggest that future AD drug prioritization efforts may be more fruitful if researchers focus on druggable genes functionally adjacent to GWAS hits.

PrgmNr 3542 - Worse COVID-19 outcomes in patients with the hemoglobin beta sickle allele due to existing comorbidities and new acute events

View session detail

Author Block: **S-W. Luoh**[1], A. Verma[2], L. Gao[1], J. Minnier[1], The VA Million Veteran Program, S. Iyengar[3]; [1]VA Portland Hlth.Care System, Portland, OR, [2]Corporal Michael Crescenz VA Med. Ctr., Philadelphia, PA, [3]Louis Stokes Cleveland VA Med. Ctr., Cleveland, OH
Disclosure Block: **S. Luoh:** None.
Introduction. The sickle cell trait (SCT) in the hemoglobin beta gene (HbS; rs334) affects millions of Americans, especially African Americans (AA; minor allele frequency [MAF]=7.8%) and Hispanic Americans (HA; MAF=1%). We investigated the impact of SCT on the severity and sequelae of COVID-19 infection in the VA Million Veteran Program (MVP). Pre-COVID diseases and laboratory findings present in electronic health records (EHR), as well as acute events following 60 days of COVID-19 infection, and their mediating effect on COVID-19 mortality among SCT patients were examined. **Methods**. Pre- and post- COVID-19 clinical data on genotyped MVP participants (SCT+ = 2,729, SCT-= 129,848; COVID+=13,841, COVID-=118,736) was extracted from EHR. Outcomes analyzed were: severe disease (or mortality) vs. not severe (or survival). Ethnic-specific firth logistic regression for SCT was performed on European (EA), African (AA), Hispanic (HA) and Asian (ASA) groups, adjusting for sex, age, age2, and 20 genetic principal components. Ethnic-specific phenome-wide association (PheWAS and LabWAS) for SCT captured 20+ years of comorbidities and historical laboratory values and was used to contrast effects of COVID-19. Multiple testing corrections were applied. **Results**. HbS is associated with increased COVID-19 mortality in AA (N=3,749; OR=1.8 [1.14-2.84], p=0.01) with a similar trend in HA. PheWAS revealed significant associations of rs334 with phecodes for pulmonary embolism, chronic renal disease, diabetic kidney disease, hypertensive renal disease, gout, sickle cell disease/trait, and hemolytic anemia (FDR p Conclusions. SCT is associated with an elevated risk of mortality with COVID-19 infection. Both pre-existing chronic medical conditions and new acute events after COVID-19 may contribute to adverse COVID-19 outcomes with SCT.

PrgmNr 3543 - A Single-Assay Solution for Expanded Carrier Screening Relieves Existing Workflow Constraints and Provides More Comprehensive Analysis

View session detail

Author Block: **S. Statt**, J. Kemppainen, M. Church, C. Edwards, J. Turner, J. Janovsky, S. Filipovic-Sadic, J. R. Thibert, B. Hall, L. Chen, T. Markulin, J. Hernandez, J. Wisotsky, B. C. Haynes, G. J. Latham; Asuragen, Austin, TX
Disclosure Block: **S. Statt:** Major Stockholder/Ownership Interest; Asuragen.
More than a million individuals have been tested using Expanded Carrier Screening (ECS) since the first commercial assay was launched in 2009. Conventional methods like short-read sequencing either miss or poorly cover many genes or gene regions; a recent study found that 20.4% of pathogenic/likely pathogenic variants were â□□technically challengingâ□□ by NGS. Consequently, analysis of problematic and high-prevalence carrier screening genes requires specialized non-NGS methods, creating inefficient workflows and subpar detection rates, limiting access to only high throughput sophisticated labs. We sought to create a mid-sized panel that combines routine NGS targets with non-NGS targets in a single workflow that can enable broad access to ECS assays. To do this, we paired novel long-range PCR with long-read nanopore sequencing and algorithms that offer more comprehensive yet streamlined ECS analysis.
Samples were initially evaluated using the most challenging genes from the mid-sized panel as a proof-of-concept, namely *FMR1*, *F8*, *CYP21A2*, *HBA1/2*, *GBA* and *SMN1*. Genomic DNA was amplified, barcoded, pooled, prepped by ligation sequencing kit (ONT) and ran on R9.4.1 flow cells (ONT) using either the MinION or Mk1C. A custom pipeline resolved CGG genotypes and AGG interruptions in *FMR1*. For other genes, a bespoke sequence deconvolution method reconciled paralogous sequences, where applicable, along with pathogenic variants. We accurately detected multiple classes of pathogenic variation across 24 Coriell cell-line and residual whole blood samples, including large structural variants (such as inversions), SNVs, short tandem repeats, INDELs and CNVs. *FMR1* CGG repeats were accurately categorized as normal, intermediate, premutation or full mutation; they also fell within reference AmplideX PCR/CE *FMR1* Kit (RUO) precision ranges by repeat count. AGG interruptions were concordant with independent analyses, and informed a broad range of intergenerational expansion risk. Complex *CYP21A2* gene conversions, pseudogene fusions, and *CYP21A2/CYP21P1* gene copy numbers were correctly determined using as few as 100 reads per allele. *SMN1* analysis identified copy numbers ranging from 0 to â□¥4 in agreement with orthogonal assay calls.
The data demonstrate feasibility for a single-platform, multiplexed panel workflow that can accurately resolve different classes of challenging variants, and scale to include more conventional carrier genes. This method has the potential to address real-world gaps in carrier screening by integrating a nanopore sequencer with tailored PCR reagents and software for use in diverse laboratory settings.

PrgmNr 3544 - Cord blood DNA methylation gestational age estimation applied to dried blood spot DNA methylation

View session detail

Author Block: **K. Polinski**[1], S. Robsinson[1], D. Putnick[1], W. Guan[2], S. Mumford[1], E. Yeung[1]; [1]NICHD/NIH, Bethesda, MD, [2]Univ Minnesota, Minneapolis, MN
Disclosure Block: **K. Polinski:** None.
Objective: DNA methylation (DNAm) â□□clocksâ□□ have been used to predict gestational age (GA) at delivery and are typically applied to cord blood DNAm. Yet, dried blood spots (DBS) are routinely collected for newborn screening and have utility for investigating epigenomic features. Therefore, we estimated GA based on cord blood DNAm from the EPIC 850K array and compared clocks on DBS DNAm in an independent dataset.
Methods: EAGeR is a preconception cohort that followed women attempting pregnancy and throughout pregnancy for women who conceived. Clinical GA was determined using a combination of ultrasound, fertility monitor information, last menstrual period, and clinical assessment. Cord blood DNAm data was available in 391 singletons. Array-wide associations between clinical GA and DNAm beta values were identified using multivariable robust linear regression in the training dataset (70%, n=274). False discovery rate (FDR) significant CpG probes were then added as predictors in an elastic net regression of GA in which alpha was set to 0.5 and lambda was chosen using 10-fold cross-validation on the training dataset. The resulting CpG probes (i.e. EAGeR clock) were used to estimate DNAm GA in EAGeR and subsequently in an independent cohort (Upstate KIDS). Upstate KIDS includes 855 singletons and twins with DBS DNAm from the EPIC array. GA was based on birth certificate estimates.
Results: The average GA at birth in EAGeR was 38.9 weeks (SD 1.53; Range 31.1-44.8). We identified 10328 CpG probes associated with GA with FDR significance (**Conclusion:** Despite few overlapping CpG probes (11/225, 5%) in GA clocks from different cord blood DNAm datasets, the correlation to clinical GA in an external sample using DBS was similar. The correlation with clinical GA in preterm deliveries was reduced, potentially indicating that differences in clinical GA and DNAm GA may be biologically relevant in terms of cellular maturity and may have potential implications for development outcomes.

PrgmNr 3545 - Developmental genomics of congenital limb malformations: further evidence for gene dosage effects

View session detail

Author Block: **R. DUAN**[1], H. Hijazi[2], Y. Bayram[3], E. Karaca[4], D. R. Bertola[5], S. Isikay[6], E. Y. Gulec[7], H. K. Eker[8], Y. Sahin[9], Z. Ocak[7], H. Du[1], J. M. Fatih[1], G. Akay[1], S. Gu[10], Baylor-Hopkins Center for Mendelian Genomics, S. N. Jhangiani[11], Z. Coban-Akdemir[1,12], D. Pehlivan[1], R. A. Gibbs[11], J. E. Posey[1], C. M. Carvalho[13], J. R. Lupski[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Johns Hopkins, Baltimore, MD, [3]King of Prussia, PA, [4]Sanford Imagenetics, Sioux Falls, SD, [5]Inst. da Crianca, Sao Paulo, Brazil, [6]Gaziantep Univ., Gaziantep, Turkey, [7]Kanuni Sultan Suleyman Training and Res. Hosp., Istanbul, Turkey, [8]Dr Faruk Sukan Maternity and Childrenâ□□s Hosp., Konya, Turkey, [9]Necip FazÄ±l City Hosp., Kahramanmaras, Turkey, [10]Hong Kong S.A.R., China, [11]Baylor Coll. Med., Houston, TX, [12]The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [13]Pacific Northwest Res. Inst., Seattle, WA
Disclosure Block: **R. Duan:** None.

Congenital limb malformations represent a broad spectrum of intrauterine developmental perturbations involving the upper and/or lower extremities, which can occur as a deformation, disruption, or an isolated developmental event (i.e., malformation) or be a manifestation of a partial trait, i.e., endophenotype, of a Mendelian condition. Phenotypic manifestations of extremity anomalies can involve anterior-posterior (AP), dorsal-ventral (DV), or proximal-distal (PD) planes of the body axes of development and can be associated with complex genetic etiologies. Genetic heterogeneity, reduced penetrance and variable expressivity have all been described in families. Using family-based genomics and rare variant analyses, we applied exome sequencing (ES) combined with whole-genome array-based comparative genomic hybridization (aCGH) to investigate 14 families with limb defects. Studies in 8 out of 14 families revealed likely pathogenic single nucleotide variants (SNVs) or copy number variants (CNVs) at previously reported â□□disease associated lociâ□□: *BHLHA9*, *HOXD13, GLI3, WNT10B* and *NPR2*. Multi-locus pathogenic variation (MPV) was observed in one family seemingly driven by the absence of heterozygosity (AOH) resulting from identity-by-descent (IBD); total AOH = 89.1Mb in a child of parents from the same small village, but with no known consanguinity. Notably, breakpoint junction analyses for 2 novel pathogenic duplication CNVs of *BHLHA9* were demonstrated to be generated by *Alu/Alu*-mediated rearrangement (AAMR). Interestingly, homozygosity for *BHLHA9* duplication CNV was observed in association with a more severe limb malformation, the Gollop-Wolfgang Complex. We propose a gene dosage model at this locus potentially underlies both the reduced penetrance and the more severe phenotype observed with homozygous duplication. Further studies will explore whether genes acting in the Apical Ectodermal Ridge (AER) may be particularly vulnerable to stochastic fluctuations in expression during development in the distal proximal plane and whether such a â□□gene dosage expression modelâ□□ significantly contributes to limb anomalies.

PrgmNr 3546 - Potential additive effect of fetal HR*APOL1*genotype and micronutrient deficiencies

View session detail

Author Block: **W. Bruner**[1], R. Davis[1], C. L. Simpson[2]; [1]Universtiy of Tennessee Hlth.and Sci. Ctr., Memphis, TN, [2]Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN
Disclosure Block: **W. Bruner:** None.
Background: Preeclampsia (PE) is a hypertensive disorder of pregnancy that is associated with micronutrient deficiencies. Fetuses carrying two *APOL1* high risk (HR) variants is also associated with PE risk. We hypothesized a potential additive effect between HR *APOL1* genotype status and nutritional deficiencies would place individuals at a higher risk of developing PE. We assessed PE-associated risk of micronutrient deficiencies based on fetal *APOL1* genotype in pregnant African American women.
Methods: We used data from the Conditions Affecting Neurocognitive Development and Learning in Early Childhood (CANDLE) project and performed analyses using multivariate logistic regression to examine the association of PE with 2nd and 3rd trimester plasma folate and 25-hydroxy vitamin D concentrations. Concentrations were dichotomized into high or low categories. Folate deficiency was defined as a concentration less than 6 ng/mL. 25-hydroxy vitamin D deficiency was defined as a concentration less than 20 ng/mL. Further analyses assessed whether the inclusion of fetal *APOL1* genotype status modified the micronutrient association with PE.
Results: Compared to pregnancies with fetal LR status and high 3rd trimester vitamin D levels (reference group), the risk for preeclampsia was elevated among fetal LR/low vitamin D (OR 1.88; 95% CI 0.83,4.22), fetal HR/high vitamin D levels (OR 2.43; 95% CI 0.71, 8.28), and was highest for pregnancies with fetal HR/low vitamin D levels (OR 5.41; 95% CI 1.87,15.66). When assessing folate, compared to pregnancies with fetal LR status and high 2nd trimester folate levels, the risk for preeclampsia was elevated among fetal LR/low folate (OR 2.29; 95% CI 0.75,7.04) and among fetal HR/high folate (OR 1.95; 95% CI 1.03, 3.71). We were not able to assess 3rd trimester folate deficiency and fetal HR genotype due to low sample size.
Conclusions: Our findings are suggestive of a potential additive effect between low 25-hydroxy vitamin D and fetal HR *APOL1* genotype. Similar potential additive effect was found between low folate and fetal HR genotype.

PrgmNr 3547 - A novel polygenic score for microglial activation enhances models of Alzheimer's disease neuropathology

View session detail

Author Block: **E. Tio**[1], M. Milic[1], P. L. De Jager[2], D. Felsky[1]; [1]The Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada, [2]Columbia Univ Med Ctr, New York, NY
Disclosure Block: **E. Tio:** None.
Neuroinflammation and the activation of microglia are among the earliest changes in Alzheimerâ□□s disease (AD). However, lack of direct access to living brain tissue has impeded the development of biomarkers of microglial states. To solve this, genetic markers may offer a non-invasive route to estimating burden of microglial activation in living people.
We recently performed a genome-wide association study (GWAS) of morphologically activated microglia measured postmortem in two regions of human cortex (midfrontal and inferior temporal). Based on these GWAS summary statistics, we used the clumping and thresholding method (PRSice-2) to calculate novel microglial activation polygenic risk scores (micPRS) in imputed genotype data from *n*=939 participants from the Alzheimer's Disease Neuroimaging Initiative (ADNI). For comparison, we calculated standard AD PRSs using summary statistics from the International Genomics of Alzheimer's Project (IGAP). Linear models were used to test associations between each PRS and AD diagnosis, ADAS-Cog scores at baseline, and cerebrospinal fluid (CSF) and brain imaging (AV45 and AV1451 PET SUVR) measures of amyloid and tau, with appropriate covariates including genomic principal components.
Our top inferior temporal micPRSs showed significant positive associations with all phenotypes ($3.57x10^{-4}$ fdr -2). Conversely, our midfrontal micPRSs showed significant associations with only PET amyloid ($P_{fdr} = 9.14x10^{-3}$). We then compared models including both micPRSs and the IGAP-derived AD PRS against models with just the latter. Our inferior temporal micPRSs significantly contributed to models of cognition and both amyloid and tau measured with PET and tau measured in CSF ($8.93x10^{-4}$ fdr -2, $9.50x10^{-3}$ 2 -2). However, they did not significantly improve models of CSF amyloid over and above the baseline AD PRS. Our midfrontal micPRS improved only models of PET amyloid ($3.68x10^{-3}$ fdr -3, $1.37x10^{-2}$ 2 -2).
This PRS-based approach to estimating microglial activation burden in living people produced results which resemble the associations of microglial activation with AD pathology identified directly in postmortem tissue. We also found that the addition of micPRS to models including only the AD PRS significantly improved predictions of multiple AD biomarkers. However, we observed strong variability in PRS performance across SNP inclusion p-value thresholds. Thus, further evaluation is required to establish the reliability of a microglial PRS in predictive models of AD.

PrgmNr 3548 - A novel test for parent-of-origin effects in population samples leveraging multiple phenotypes

View session detail

Author Block: **T. Head**[1], M. P. Epstein[2]; [1]Dept. of Biostatistics and Bioinformatics, Emory Univ., Atlanta, GA, [2]Emory Univ., Atlanta, GA
Disclosure Block: **T. Head:** None.

There has been long-established interest in identifying variants within the human genome that exhibit parent-of-origin effects (POEs) wherein the effect of an allele on phenotype expression depends on the parental origin of that allele. POEs can arise from many different phenomena including genomic imprinting and have been documented for many complex traits such as type 2 diabetes and body mass index. Traditional tests for POEs required family data to determine parental origins of transmitted alleles for analysis. For genome-wide association studies, most of which are performed on unrelated individuals for which allelic parental origin is unknown, the study of POEs has required more sophisticated statistical methods that exploit genetic patterns that we anticipate observing if a POE exists at a given locus. For example, Hoggart et al. [PLoS Genetics: e1004508] recognized that the existence of a POE results in increased phenotypic variance among heterozygotes compared to homozygotes and developed a novel population-based test based upon this observation. Here, we extend this method for identifying POEs to accommodate multiple phenotypes, which are increasingly collected in GWAS given widespread evidence of pleiotropy. We show that, in the presence of a POE, the covariance patterns among multiple phenotypes will differ between homozygotes and heterozygotes. We can assess such differences using a method that tests whether the phenotype covariance matrix among homozygotes differs from the analogous covariance matrix for heterozygotes. Our method is robust to non-normality of phenotypes and can easily adjust for population stratification and other non-genetic confounders. We evaluated our method through simulation studies and observed appropriate type I error and power to detect POEs when they exist. We further note that our method is orthogonal to standard tests of association between a SNP and multiple phenotypes and thus provides complementary information that can be used to assess top findings. Finally, we applied our method to GWAS studies of quantitative traits related to type I diabetes, post-traumatic stress disorder, and facial morphology and identified several variants of suggestive significance for follow-up investigation.

PrgmNr 3549 - A powerful and resource-efficient pipeline for association analysis of large-scale whole-genome sequencing studies

Disclosure Block: **Z. Li:** None.

Introduction

With the emergence of large-scale whole-genome sequencing (WGS) data, there is a pressing need to identify genetic components of complex traits. It is resource-demanding to perform association analysis of hundreds of millions of variants, especially for the rare variant analysis.

Methods

We propose a resource-efficient analysis pipeline, STAARpipeline, for phenotype-genotype association analyses of WGS data, including single variant analysis and variant-set analysis. The single variant analysis in STAARpipeline provides valid individual *P* values of variants given a MAF or MAC cut-off, for example, MAC â¥ 20. The variant-set analysis in STAARpipeline includes gene-centric analysis and non-gene-centric analysis of rare variants. The gene-centric coding analysis provides five genetic categories: putative loss of function (pLoF), missense, disruptive missense, pLoF and disruptive missense, and synonymous. The gene-centric noncoding analysis provides eight genetic categories: promoter or enhancer overlaid with CAGE or DHS sites, UTR, upstream, downstream, and noncoding RNA genes. To achieve this, we develop FAVORAnnotator to functionally annotates the variants using the FAVOR database and generate an annotated genotype file for the input of STAARpipeline. The non-gene-centric analysis includes sliding window analysis with fixed sizes and dynamic window analysis with data-adaptive sizes. STAARpipeline also provides analytical follow-up of dissecting association signals independent of known variants via conditional analysis. We applied the STAARpipeline to analyze four quantitative lipid traits (LDL-C, HDL-C, TG, and TC) in 30,138 samples from the NHLBI Trans-Omics for Precision Medicine program.

Results

All analyses scale well in computation time and memory. The computation cost for STAARpipeline of each trait on 30,138 related samples are as follows: 1.5 hours for 200 2.10 GHz computing cores with 6 Gb memory of single variant analysis for variants with MAC â¥ 20; 2.5 hours and 15 hours for 200 cores with 5 Gb memory of gene-centric coding and noncoding analysis, respectively; 11 hours for 200 cores with 11 Gb memory of sliding window analysis; 20 hours for 800 cores with 15 Gb memory of dynamic window analysis. STAARpipeline takes 24 hours to summarize these results and perform conditional analysis of significant findings using one core with 25 Gb memory. We discover several conditionally significant associations with lipids, including a novel finding of an intergenic region near *SLC22A3* associated with total cholesterol.

Summary

The STAARpipeline is a fast and scalable tool for association analysis of extensive WGS studies.

PrgmNr 3550 - A quantile integral linear model to quantify genetic effects on phenotypic variability

Disclosure Block: **J. Miao:** None.
Detecting genetic variants associated with the variance of complex traits, i.e. variance quantitative trait loci (vQTL), can provide crucial insights into the interplay between genes and environments (GxE) and how they jointly shape human phenotypes. Robust vQTL findings can be used to prioritize candidate variants in GxE analysis. The genome-wide summaries of genetic effects on phenotypic variability (vPGS) also has the potential to aggregate information across numerous genetic loci and improve both statistical power and biological interpretability of GxE studies. We introduce a novel statistical framework named QUAIL to estimate genetic effects on the variance of quantitative traits. Our approach directly addresses several limitations of current vQTL methods, including a lack of robustness to non-Gaussian phenotypes and confounding effects on both trait levels and trait variability. In addition, QUAIL can be applied to both categorical and continuous predictors. Through extensive simulations and analyses of real data, we demonstrate that QUAIL provides robust, powerful, and computationally efficient vQTL mapping. Applied to UK Biobank (N=375,791), QUAIL identified 11 novel vQTL for body mass index (BMI). Top vQTL findings showed substantial enrichment for interactions with physical activities and sedentary behavior. Followed up in three well-powered longitudinal cohorts (total N= 21,961), the vPGS based on QUAIL show superior predictive performance on both population-level and within-individual BMI variability compared to existing approaches. Overall, QUAIL is a unified framework to quantify genetic effects on the phenotypic variability at both single-variant and vPGS levels. It addresses critical limitations in existing approaches and may have broad applications in future gene-environment interaction studies.

PrgmNr 3551 - A resource-efficient tool for phenome-wide rare variant association analysis in large-scale whole-genome sequencing studies, with application to TOPMed metabolomics data

View session detail

Author Block: **X. Li**[1], Z. Li[1], E. V. Feofanova[2], C. Quick[1], H. Zhou[1], S. M. Gaynor[1], A. C. Morrison[2], E. Boerwinkle[2], J. I. Rotter[3], B. Yu[2], X. Lin[1], TOPMed Metabolomics and Proteomics Working Group; [1]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [2]The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [3]Lundquist Inst., Harbor-UCLA Med Ctr, Torrance, CA
Disclosure Block: **X. Li:** None.

Introduction

Large-scale whole-genome sequencing (WGS) studies have enabled the analysis of rare variants (RVs) associated with complex human traits. Phenome-wide association study (PheWAS) of WGS data provides a unique opportunity to identify the pleiotropy effect of RVs on multiple traits. Due to the vast number of RVs in WGS studies, it is computationally expensive to apply the RV analysis pipeline to analyze a large number of traits, one at a time. Existing PheWAS pipelines are designed for genome-wide association studies and focus on single-variant analyses of common variants. Scalable PheWAS pipelines for RV association analysis of WGS data are currently lacking.

Methods

We propose STAARphewas, a powerful and resource-efficient tool for RV PheWAS in large-scale WGS studies. STAARphewas accounts for population structure and relatedness for both continuous and dichotomous traits by fitting the generalized linear mixed model using sparse genetic relatedness matrices. It then provides various strategies for grouping coding and non-coding variants based on functional categories, and incorporates multiple numerical functional annotations (for example, annotation principal component scores) to further increase power using the STAAR framework. To reduce the computation cost in PheWAS, we propose a new analytical strategy in STAARphewas that allows for data preprocessing and analysis of multiple traits simultaneously. STAARphewas only requires extracting the genotype and functional annotation data once when analyzing multiple traits, which substantially reduces the computation cost while maintaining exactly the same results compared to analyzing RV associations of each phenotype one at a time. In addition, STAARphewas provides conditional analyses to identify RV-set signals independent of nearby common variants.

Results

We applied STAARphewas to identify RV-sets associated with >100 quantitative metabolomics traits in ~12,000 related samples from the NHLBI Trans-Omics for Precision Medicine program Freeze 8 data. STAARphewas saves at least 10x computation time than existing methods, requiring 7 hours and 18 hours for 10 cores with 8 Gb memory per trait of gene-centric coding and noncoding analysis, respectively. We detected several genome-wide significant RV associations with metabolomics.

Conclusion

We propose STAARphewas as a resource-efficient framework for phenome-wide rare variant association analysis, while incorporating multiple variant functional annotations to further improve power. The STAARphewas pipeline provides an essential solution for RV PheWAS in large-scale WGS studies.

PrgmNr 3552 - An extended fine-mapping framework to identify causal genes from transcriptome-wide association studies (TWAS)

View session detail

Author Block: **S. Zhao**[1], W. Crouse[1], K. Luo[2], M. Stephens[1], X. He[1]; [1]Univ Chicago, Chicago, IL, [2]Chicago, IL

Disclosure Block: **S. Zhao:** None.

While GWAS have identified a large number of loci associated with complex traits, causal genes in these loci often remain unknown. TWAS propose to nominate candidate genes by testing associations of cis-genetic components of gene expression, inferred from expression QTL (eQTL) data, with the trait. While widely popular, TWAS may find associations in non-causal genes, when their eQTLs are shared with other nearby causal genes (co-regulated genes), or have pleiotropic effects on the phenotype. Methods have been proposed to better integrate eQTL and GWAS data. Colocalization methods test if gene expression and GWAS share the same causal variants. These methods usually assume a single causal variant for both gene and trait, are sensitive to parameters, and still cannot guarantee causality. Mendelian Randomization (MR) methods, on the other hand, use cis-eQTLs as instruments to test causality of gene expression on phenotype. MR, however, is difficult to apply in this setting because of the small number of instruments and their correlations due to linkage disequilibrium. We propose a strategy to identify causal genes from joint eQTL-GWAS analysis. Our method (causal-TWAS, cTWAS) is a regression model where response is phenotype, and covariates include cis-genetic components of expression of all nearby genes and genotypes of all nearby variants. By having expression and variants in the same model, cTWAS accounts for co-regulation among genes, and pleiotropic effects where variants directly act on the phenotype without affecting any gene. To make inference, we use a Bayesian variable selection approach with sparse priors for the gene and variant effects. cTWAS extends a fine-mapping method, SuSiE, to estimate these prior parameters from genome wide data and infers causal genes in any specific loci. We simulate using real genotype data from UK Biobank, under a realistic genetic architecture where gene expression explains a small percent of heritability. Under this scheme, existing methods (TWAS, SMR, coloc) all suffer from high false positive (FP) rates. In contrast, cTWAS produces calibrated FP rates while maintaining good power. We are now applying cTWAS to UKBB GWAS summary statistics. cTWAS is available in an efficient and easy-to-use R package.

PrgmNr 3553 - An iterative approach to adjustment for covariates in genetic association studies using GWAS summary statistics

View session detail

Author Block: **O. Vsevolozhskaya**[1], D. W. Fardo[1], X. Tong[2]; [1]Univ. of Kentucky, Lexington, KY, [2]The Natl. Inst. of Environmental Hlth.Sci., Durham, NC
Disclosure Block: **O. Vsevolozhskaya:** None.
Adjustment for covariates or correlated secondary traits in genome-wide association studies (GWASs) is common practice and has at least two purposes: (1) to account for potential confounding factors that can bias SNP effect estimates, and (2) to improve statistical power by reducing residual variance. Researchers routinely adjust for covariates such as age, gender, and the first dozen genetic principal components. Additional covariate adjustments may include heritable secondary outcomes with the motivation of identifying the direct genetic effect of the variant on the primary outcome of interest. For example, one may be interested in discovery of SNPs directly influencing insulin resistance while adjusting for an individual's body mass index. This adjustment for the secondary outcome is warrant if a genetic variant is associated with both the primary outcome and the covariate used for adjustment. However, if a genetic variant only influences the covariate and not the primary outcome, adjusting for the covariate induces a spurious association between the genetic variant and the primary outcome. In practice, when performing GWASs for a cohort with comprehensive genotyping and phenotyping (e.g., in electronic health record or phenomewide association study), it is difficult to exhaust all reasonable covariate adjustments without leading to an unintended bias introduced with respect to the primary outcome. It is also impractical to assume a single desired model across all researchers querying the resulting database of results. Thus, statistical approaches that can adjust for covariates based on reports of marginal associations or recover marginal associations from reports of covariate-adjusted associations, without having to re-run GWAS, are of interest. Here, we detail a statistical procedure that allows a researcher to perform these tasks back and forth almost instantaneously, given access to the original data. In case one does not have access to the original data but only the GWAS summary statistics, we provide theory of and simulation study results of approximated adjustments and marginalization.

PrgmNr 3554 - Ancestry-matching cases to controls from the GLAD database to accelerate genetic research in under-represented populations

View session detail

Author Block: **D. M. Veliz-Otani**, D. Loesch, B. Mitchell, S. J. Kittner, T. O'Connor; Univ. of Maryland Baltimore, Baltimore, MD
Disclosure Block: **D.M. Veliz-Otani:** None.
Background. Latino populations are under-represented in GWAS and use of the available samples is constrained by data privacy concerns. Development of a platform that provides allele frequencies from ancestry-matched controls to generate summary association statistics would contribute to closing this diversity gap by reducing the recruitment burden. We tested the performance of a proof-of-principle procedure that matches cases to controls from Genetics of Latin American Diversity (GLAD) database, a large collection of publicly available Latin American genomes. **Methods.** We obtained genotypes of 942 ischemic stroke cases from the Stroke Genetics Network (SiGN) and 18,102 potential controls with appropriate informed consent from GLAD. All subjects self-identified as Latino/Hispanic. Genotypes of SiGN samples were imputed through the Michigan Imputation Server-1.2.4. and ~9M SNPs remained after QC. Principal components were estimated by PCAiR and kinship coefficients by PCRelate. The final sample size was 927 cases and 12,956 potential controls after filtering out related subjects. We did a greedy n:1 control:case matching (1â¤ n â¤4) based on the Euclidean distance of the first 10 PCs weighted by their eigenvalues. Association was tested by a generalized linear mixed model using GENESIS, both with and without PCs as covariates. All models included sex, and age (for controls) or age at stroke (for cases). In a separate run, we added as covariates the phenotypes used as the ascertainment basis for each GLAD cohort (diabetes, asthma and hemophilia). If an ascertainment variable was unavailable for a cohort, we assumed the condition was absent in subjects from such cohort. **Results.** The distribution of the first three PCs of cases and matched controls was similar, for all values of 1 â¤n â¤4. Results of GWAS with and without PCs as covariates were virtually identical. The genomic control inflation factor (λ_{GC}) was 1.086 for the 4:1 GWAS without PCs nor ascertainment phenotypes as covariates. This model replicated only one known risk gene (*C10orf143*), but identified 16 previously unreported loci, likely false signals due to ascertainment bias or batch effect. The model including ascertainment phenotypes as covariates had a λ_{GC} value of 0.976, and identified 3 loci, none previously associated with ischemic stroke. **Conclusion.** Ancestry-matching by Weighted Euclidean distance on the PCA space reduces biases due to population stratification, but fails to adjust for other sources of confounding, such as ascertainment bias or batch effects. A platform that generates summary statistics of matched controls must account for other sources of confounding.

PrgmNr 3555 - Bayesian estimation of Allele-Specific Expression (ASE) in the presence of phasing uncertainty for identifying genes with aberrant expression

View session detail

Author Block: **X. Zou**[1], K. Patterson[2], University of Washington Center for Mendelian Genomics, A. Iyengar[1], P. S. Kishnani[1], G. E. Crawford[1], T. E. Reddy[1], A. S. Allen[1], W. H. Majoros[1]; [1]Duke Univ., Durham, NC, [2]Univ of Washington, Seattle, WA

Disclosure Block: **X. Zou:** None.

Many genetic causes of the rare disease involve changes in gene expression. While noncoding variants are difficult to interpret, allele-specific expression (ASE) is one indicator of a possible genetic regulatory effect. Current methods for detecting ASE are hampered by the difficulty of accurately phasing heterozygous sites within a gene. We describe a novel Bayesian hierarchical model, BEASTIE, that circumvents this problem by jointly modeling ASE and phasing so that they can mutually inform each other. We show that BEASTIE is more accurate than existing approaches that use a single variant or assume a single phase. In addition, we illustrate BEASTIEâ□□s utility in a clinical setting by analyzing 6 glycogen storage disease (GSD) patients who lack a genetic explanation of their disease after routine clinical sequencing. We identify one patient with significant ASE in AGL expression, a known cause of debrancher enzyme deficiency, in patients GSDIIIa.

PrgmNr 3557 - Consistent summary counts based rare variant analysis for discovery of germline predisposition genes using public genotype summary data as controls

View session detail

Author Block: **W. Chen**[1], G. Wu[2]; [1]St Jude Children's Res. Hosp., Memphis, TN, [2]262 Danny Thomas Place, Memphis, TN
Disclosure Block: **W. Chen:** None.
It is common that sequencing resources are invested on cases with few or no matched controls of healthy individuals, which hinders the discovery of germline predisposition genes through case-control association tests. To circumvent this problem, genotype summary counts from public datasets, such as gnomAD, can serve as convenient controls for rare variant association test. However, systematic inflation and false positives can arise if confounding factors, such as pipeline differences and population structure, are not well addressed. We propose a framework for Consistent summary Counts based Rare Variant burden test (CoCoRV) to address these challenges. It consists of several novel elements: consistent variant processing allowing state-of-the-art variant QC, association test accounting for different ethnic groups, improved association test inflation estimation for better assessment of systematic inflation, and a novel method to detect variants in high linkage disequilibrium using summary allele counts which is critical for removing false positives. When applied to pediatric brain tumor and acute lymphocytic leukemia, top genes include known cancer predisposition genes and an interesting new candidate gene. When applied to the brain tumor patients in The Cancer Genome Atlas (TCGA), we discovered and statistically validated two genes associated with brain tumor. One was TP53, a known cancer predisposition gene but missed by a previous TCGA germline analysis and the other gene *ABCB8* is likely a novel cancer risk gene. Given that potential confounding factors are well controlled after applying the framework, our tool provides a highly cost-effective solution to discovering risk genes enriched with pathogenic rare variants.

PrgmNr 3558 - DeepRsq: an improved imputation quality metric via a machine learning method

View session detail

Author Block: **Q. Sun**[1], Y. Yang[2], C. Fuchsberger[3], Y. Li[4]; [1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Sun Yat-sen Univ., Guangzhou, China, [3]Eurac Res., Bozen, Italy, [4]Univ North Carolina, Chapel Hill, NC

Disclosure Block: **Q. Sun:** None.

Background: Genotype imputation is an approach broadly used in genetics studies to estimate missing genotypes with the aid of a reference panel, but not all variants in the reference panel can be well imputed. As an estimate of the true imputation quality (true R2), researchers rely on variant-level statistics provided by the various imputation tools. However, these standard quality metrics (referred to hereafter as Rsq) have been found less informative for low frequency (minor allele frequency (MAF) Methods: We propose deepRsq, a novel machine learning enhanced quality metric by using an eXtreme Gradient tree Boosting (XGBoost) algorithm to effectively incorporate information from other variant-level features. Specifically, deepRsq considers a total of 81 variant-level features, including 11 population genetics statistics (e.g., Fst) from six major continental populations, minor allele counts (MAC) and MAFs in five major continental groups estimated from the Trans-Omics for Precision Medicine (TOPMed) cohorts, the 2nd - 4th moments of the five MACs, as well as the estimated MAF and Rsq in imputation target cohort. We divide the variants into three categories: common (MAF > 5%), low frequency (MAF in [0.5%, 5%]) and rare (MAF Results: We applied deepRsq to the Cystic Fibrosis cohort (n=5095) with whole genome sequencing data available, which serves as the truth for evaluating the performance of the two quality metrics. We found that deepRsq leads to much improved performance. For example, deepRsq increases the squared Pearson correlation with true R2 by 15.3% - 47.9% and decreases the root mean square error by 20.1% - 49.5%. We further applied deepRsq to UK Biobank European ancestry participants with whole exom sequencing (WES) data (n=99,990) where imputation was performed using genotyping array markers and WES data were used for evaluation purpose. We found that deepRsq rescues a larger number of decently-imputed signals that would have been filtered out by Rsq, and more effectively removes badly-imputed variants than Rsq. We further assessed deepRsqâ□□s performance in six additional multi-ethnic cohorts, observing similarly promising improvement. **Conclusion**: Our extensive evaluations demonstrate that deepRsq outperforms Rsq for post-imputation quality control. We anticipate that deepRsq will be valuable for future genotype imputation tasks.

PrgmNr 3559 - ExPheWas: a browser for gene-based pheWAS associations

View session detail

Author Block: **M-A. Legault**[1,2], L-P. Lemieux Perreault[2], M-P. Dube[2,1]; [1]UniversitÃ© de MontrÃ©al, Montreal, QC, Canada, [2]Montreal Heart Inst., Montreal, QC, Canada
Disclosure Block: **M. Legault:** None.
The identification and characterization of genetic associations with human phenotypes can improve our understanding of disease etiology and support the discovery of novel therapeutic targets.
The UK Biobank is an excellent resource for such research. It includes >500,000 participants with available genotypes and linkage to health records including cancer, hospitalization and death registries. We used this cohort to conduct a phenome-wide association study (pheWAS) of all protein coding loci. We implemented a gene-based principal component analysis approach based on common genetic variants from 19,114 protein coding regions and tested their association with 1,210 phenotypes including anthropometric measurements, laboratory biomarkers, algorithmically-defined cardiovascular outcomes and health records. The results of this analysis are publicly available in a user-friendly browser https://exphewas.statgen.org.
As a proof of concept, we characterized the 137 genes associated with atrial fibrillation at a false discovery rate of 1%. Using enrichment analysis, the genes identified were strongly enriched for relevant biological processes such as cardiac muscle contraction (P_{adj}=9.5 Ã 10^{-6}) and antiarrhythmic drug targets in the ChEMBL database. By further investigating possibly novel genes, we prioritized MYOT as a likely atrial fibrillation gene. In ExPheWas, this gene is strongly associated with heart rate (P=8.6 Ã 10^{-31}) and atrial fibrillation (P=4.9 Ã 10^{-11}). MYOT is a component of sarcomeric Z-disks and mendelian mutations of this protein are associated with cardiomyopathy.
ExPheWas is a database of gene to phenotype associations that may be used for follow-up of genetic studies and for enrichment analysis.

PrgmNr 3560 - Gene-based association approach in family samples using GWAS summary statistics

View session detail

Author Block: **X. Xu**[1], P. Wang[2], N. Liu[3]; [1]Indiana Univ. at Bloomington, Bloomington, IN, [2]Bloomington, IN, [3]Indiana Univ., Bloomington, IN
Disclosure Block: **X. Xu:** None.
Genome-wide association studies (GWASs) have led to rapid growth in detecting associations between diverse phenotypes and genes. Owing to a great number of GWAS summary statistics publicly accessible nowadays, plenty of gene-based association tests have been proposed to require GWAS summary statistics only rather than utilizing individual-level genotypes. However, these adaptive association tests are limited to unrelated individuals. Challenges in performing gene-based association tests with summary statistics still exist in family samples. Meanwhile, the linear mixed model has been increasingly expanded in GWAS to handle the relatedness in the samples because of its flexibility and effectiveness. Still, how to perform gene-based association tests with GWAS summary statistics estimated from the linear mixed model remains unknown. To address these two challenges, in this study, we show that the correlation matrix between the marginal Z scores, which is estimated by the linear mixed model, can be approximated by the linkage disequilibrium matrix of the associated SNPs due to the block diagonal structure of the kinship matrix. Thus, the existing summary data-based methods for unrelated individuals can be directly applied to family samples without any modifications. Simulation results further demonstrate that the proposed procedure could also well control the type I error rate in a variety of situations. In a practical setting, we exemplify the proposed approach with dental GWAS data.

PrgmNr 3561 - Gene-burden tests, gene-environment interactions and time-to-event data analysis within an efficient whole genome regression framework for large-scale biobanks

View session detail

Author Block: **J. Mbatchou**[1], Y. Zou[2], A. Ziyatdinov[3], J. L. Marchini[4], Regeneron Genetics Center; [1]Regeneron Genetics Ctr., TARRYTOWN, NY, [2]Univ. of Chicago, Chicago, IL, [3]Regeneron Genetics Ctr., Regeneron Pharmaceuticals, Tarrytown, NY, [4]Regeneron Genetics Ctr., Tarrytown, NY
Disclosure Block: **J. Mbatchou:** Major Stockholder/Ownership Interest; Regeneron Pharmaceuticals. Salary/Employment; Regeneron Pharmaceuticals.
The past decade has seen an unprecedented rise in the amount of phenotypic data available through the use of electronic health records and self-reported information. Large-scale biobanks have provided unique opportunities for researchers to make novel findings as well as validate existing targets and discover new indications for existing therapies. These biobanks provide rich phenotypic information, including time-to-event (TTE) data which not only inform on disease status but also incorporate age at onset information, which can provide better power in association analyses compared to using standard binary outcomes. They also constitute a rich data resource to explore and identify gene by environment (GxE) or gene by gene (GxG) epistatic effects, which require environmental exposure information as well as larger sample sizes for sufficient power. We have previously proposed REGENIE as an efficient computational method to analyze both quantitative and binary traits (including highly imbalanced traits) in large-scale biobanks that can highly reduce the computation time, all the more when thousands of phenotypes are to be analyzed, while accounting for population structure and relatedness. We have added three major new features to the REGENIE method 1) a flexible set of gene-based tests that utilize variant annotation files which are ideally suited for the analysis of the UK Biobank Exome sequencing dataset; 2) flexible GxE and GxG interaction tests for quantitative and binary traits, where we use robust standard errors and heteroscedastic linear models to prevent from inflation due to violations in homoscedastic assumption for quantitative traits; 3) an efficient approach for the analysis of TTE data which shares similar computational benefits as the REGENIE approach for binary traits and can handle highly censored phenotypes through a fast Firth-based association test within a Cox regression model framework. We demonstrate the performance of the proposed features through simulations and real data application in UK Biobank with up to ~400,000 samples. We also highlight the computational benefits of our method when run on multiple TTE phenotypes compared to several existing methods as well as contrast its performance against a case-control analysis approach within a logistic regression framework.

PrgmNr 3562 - Gene-environment interaction testing using machine learning approaches and robust test statistics: a sex-specific risk score component for lung function

Disclosure Block: **J. Hecker:** None.

Rationale: Genome-wide association studies (GWAS) have identified thousands of genetic variants associated with complex traits. However, the effect of a genetic variant on a complex trait can be influenced/modified by environmental exposures. The identification and understanding of such gene-environment interactions can provide new insights into the pathways and mechanisms. Existing methods for gene-environment interaction testing consider single variants or polygenic risk scores, suffering from low statistical power or limited biological interpretation. Furthermore, misspecified environmental main effects can invalidate interaction results. We propose a flexible framework for gene-environment interaction testing for quantitative traits that can adaptively screen for interactions while providing robustness against misspecifications.

Methods: Our approach is based on sample splitting and the utilization of so-called multiply-robust test statistics. Sample splitting allows to screen for potential interactions between multiple SNPs and environmental factors, combine signals, and test them in different parts of the data. The design of the test statistics provides robustness against misspecifications of environmental main effects and enables alternating the roles of screening and testing datasets, restoring efficiency. One important example is testing for interaction between an environmental factor and polygenic risk score SNPs.

Results: In extensive simulation studies, we demonstrate that our approach controls the type 1 error rate in a wide range of scenarios, including population stratification, gene-environment correlation, misspecified environmental main effects, heteroscedasticity, and non-normal error distributions. We also applied our approach to lung function data in the UK Biobank. For FEV_1, FVC, and FEV_1/FVC, we analyzed gene-environmental interactions between previously identified GWAS hits and multiple environmental factors, including sex, pack-years of smoking, and current smoking. For all three traits, we observed a highly significant interaction with sex (pConclusions: We propose a robust and flexible framework for gene-environment interaction testing for quantitative traits. In an application to UK Biobank data, we identified sex-specific associations between sets of SNPs and lung function.

Funding: National Heart, Lung, and Blood Institute [K08HL136928, U01HL089856, U01HL089897, P01HL120839, P01HL132825]. National Human Genome Research Institute [R01HG008976, 2U01HG008685]. This research was conducted by using the UK Biobank resource under application number 20915.

PrgmNr 3563 - HaploSoup: IBD-based encoding for improved PCA genome matching

View session detail

Author Block: **R. Laboulaye**[1], V. Borda[2], B. Guo[3], D. Loesch[4], T. D. O'Connor[1]; [1]Univ. of Maryland Sch. of Med., Baltimore, MD, [2]Univ. of Maryland Sch. of Med., Petropolis, Brazil, [34]Univ. of Maryland Baltimore, Baltimore, MD
Disclosure Block: **R. Laboulaye:** None.
Background: The advent of biobanks enables leveraging existing genomic data for use as controls for GWAS or admixture mapping studies. This is particularly useful for underrepresented populations such as Latin Americans whose studies often have lower sample sizes than comparable European studies. Retrieving suitable controls from a biobank requires a genome matching approach that can adequately differentiate individuals by population, a difficult challenge for Latin American populations where continental admixture can dominate fine-scale variation in Native American ancestry. While this is typically done by searching in a principal component space generated directly on genomic variants, we develop an IBD-based encoding that is applied prior to PCA to create a search space that better separates fine-scale populations and yields better matching results.
Methods: Population structure can be inferred through patterns of haplotype sharing. While LD pruning yields variants that each represent a larger haplotype, when applied to data with a variety of admixture proportions, it can erase haplotypes that constitute fine-scale structure. As an alternative, we propose HaploSoup, an IBD-based encoding that allows PCA to operate directly in haplotype segment space. Given a set of samples, we use the Positional Burrows Wheeler Transform to align our sequences and find all maximal length segment matches. We then apply a greedy reconstruction criteria to iteratively select representative segments to add to our encoding. The segments are scored according to their length and the as yet uncovered portion of the data that they cover. The selected set of segments is used to transform our samples from binary vectors of variants to binary vectors of segments, which can then be reduced with PCA.
Results: We evaluate our encoding approachâ□□s ability to improve genome matching for Latin Americans using both simulated and 1000 Genomes Project data. The evaluation uses a subsampled population as a query and measures how many of the matched genomes come from the correct population. We use principal components generated on genomic variants as a baseline and perform matching using a variety of distance metrics. We simulate admixed American populations with varying admixture proportions and find that HaploSoup improves matching accuracy from 74.2% to 86.9%. We then use the Latin American 1000 Genomes populations, MXL, CLM, PUR, and PEL, to repeat our experiment and find that our encoding improves matching accuracy from 53.6% to 66.9%. The Julia implementation of HaploSoup is highly parallel and can easily be added as a preprocessing step to existing matching pipelines.

PrgmNr 3564 - High-dimensional regression of continuous secondary traits under extreme phenotype sampling

View session detail

Author Block: **L. Ford**[1], H. Shen[2], H-W. Deng[3], C. Xu[1]; [1]Univ. of Oklahoma Hlth.Sci. Ctr., Oklahoma City, OK, [2]Tulane Univ, New Orleans, LA, [3]Tulane Univ., New Orleans, LA
Disclosure Block: **L. Ford:** None.
Introduction: To reduce high costs associated with genotype sampling, statistical methods have been developed to improve efficiency of parameter estimation on smaller samples. Extreme phenotype sampling has been shown to improve statistical power by using only extremes of the primary phenotype distribution as compared to random sampling and case-control methods. Secondary phenotype traits can also be evaluated after sampling extremes of the primary trait to further reduce cost. Maximum likelihood methods have already been developed to evaluate continuous secondary traits under extreme phenotype sampling. However, these likelihood approaches are unreliable under high-dimensional regression (i.e., joint modeling of genetic factors or a large number of covariates with a relatively small number of observations). Our objective is to develop a novel method than can address the high-dimensional problem in secondary trait analysis.
Methods: In our preliminary study, we conducted simulations with randomly generated data. The generated data included primary phenotype, secondary phenotype, and gene expression information. Data were generated for 1,000 individuals of which 200 were sampled for analysis by extreme phenotype sampling. Previously developed maximum likelihood estimation models were applied to determine the association between the secondary phenotype and a primary gene expression of interest. The data was generated in a way that the primary gene expression of interest, in truth, had no association with the secondary phenotype trait. From 1,000 simulations per scenario, we calculated the type I error (at an alpha level of 0.05) as the number of genes increased. We considered scenarios with 10, 100, 500, and 1000 gene expressions.
Results: We found that increasing the number of genes in the model led to an increase in the type I error. The type I error was 5.4% for 10 genes, 6.6% for 100 genes, and 16.3% for 500 genes. With 1,000 genes in the model the likelihood function was non-finite and could not be maximized.
Conclusion: The current likelihood methods for analyzing secondary traits under extreme phenotype sampling cannot be used to handle large numbers of factors jointly, like gene expressions. This limitation motivates the development of high-dimensional methods to analyze such data. This development could lead to improved statistical power and reduced cost in gene association studies.

PrgmNr 3565 - Human Genetics Structure Activity Relationship (HG-SAR): A novel methodology to link human genotype-phenotype associations to high throughput functional activity data and validate targets for human disease

Author Block: **M. R. Miller**[1], X. Chen[1], H. Kim[1], A. Mancini[2], S. Stephan[3], X. Leroy[3], C. Normand[2], C. L. Hyde[4], J-P. Fortin[1], E. Fauman[1]; [1]Pfizer, Cambridge, MA, [2]Domain Therapeutics, Montreal, QC, Canada, [3]Domain Therapeutics, Strasbourg, France, [4]Pfizer, Groton, CT
Disclosure Block: **M.R. Miller:** Salary/Employment; Pfizer, Inc.
Large scale efforts to perform exome and whole genome sequencing have identified millions of novel genetic variants and hundreds of new genetic associations. Exome-sequencing specifically can help us to pinpoint the causal gene for an association by identifying coding mutations associated with a trait or disease. However, many of the variant-phenotype associations identified by exome sequencing are with missense variants with unknown function, leaving the questions of the direction and strength of the effect unanswered. In order to fully exploit the power of naturally occurring mutations, we present a novel target validation approach: *Human Genetics Structure Activity Relationship* (HG-SAR). This method leverages the power of human genetics by linking the molecular, cellular, and clinical consequences of rare missense variants to accelerate the discovery of novel disease relevant targets and pathways. Focusing on the GPCR family, we functionally characterized over 2400 missense mutations across 42 GPCRs. All the variants selected for functional characterization were identified in at least one subject in the UK Biobank, allowing us to correlate the variant in-vitro function with phenotypes of interest. Follow-up HG-SAR analyses allow us to regress the variant-phenotype data in a gene against the functional read-out for each variant, which can help to establish whether a gene is causal for a trait/disease, as well as establish directionality and the geneâ□□s maximal potential therapeutic impact. As a positive control, we have applied this method to MC4Rand demonstrated a linear relationship between impaired MC4R G_{15} signaling and body weight. For each 10% decrease in MC4R G_{15} signaling, bodyweight increases by 0.76 kg. We next applied this method to GIPR, a gene with known GWAS associations with BMI for which the direction of effect was unclear. HG-SAR established that loss of GIPR signaling activity is associated with decreased body weight, establishing the directionality for modulating this target. This novel human target validation strategy, likely applicable across all protein families, is an exciting new method to identify and validate potential drug targets.

PrgmNr 3566 - Identity-by-descent mapping in biobank-scale datasets

View session detail

Author Block: **L. E. Petty**[1], R. Bohlender[2], H-H. Chen[3], J. Baker[4], G. Evans[5], J. E. Below[1], C. D. Huff[6]; [1]Vanderbilt Genetics Inst., Vanderbilt Univ. Med. Ctr., Nashville, TN, [2]1155 Pressler Street, Houston, TX, [3]Vanderbilt Univ. Med. Ctr., Nashville, TN, [4]Nashville, TN, [5]NASHVILLE, TN, [6]U.T. MD Anderson Cancer Ctr, Houston, TX

Disclosure Block: **L.E. Petty:** None.

Identity-by-descent (IBD) mapping is a gene mapping approach that utilizes IBD segments to identify loci that are enriched for sharing in disease cases compared to controls. This approach allows for detection of loci that harbor variants that are too low frequency for imputation to perform well, which may have a greater penetrance than common variants well-powered for genome-wide association studies (GWAS).

We have developed a tool for performing biobank-scale IBD mapping, IBDMap. We leverage IBD segment data, detected using an external segment detection tool, and perform permutation-based testing to determine enrichment of IBD sharing by comparing rates of sharing in case-case pairs to rates in case-control pairs at each segment breakpoint, genome wide. Calculations for each breakpoint are performed independently and parallelized via a process queue. A complementary Python package performs map-reduce on multiple rounds of permutations, for computational efficiency in large-scale datasets. IBDMap performs flexible multiple testing correction, utilizing a permutation-based family-wise error or false discovery rate approach to account for the correlation structure. We also introduce a new haplotype-based approach which filters IBD segments that are unlikely to harbor rare, pathogenic variants due to high population frequency.

We applied IBDMap to a range of cardiovascular phenotypes in BioVU, Vanderbiltâ□□s DNA biobank with linked electronic health records. Using diagnostic billing codes, we determined case status for 69,819 European ancestry individuals genotyped on the MEGA^{EX} array for myocardial infarction, atherosclerosis, dyslipidemia, dilated cardiomyopathy, and atrial fibrillation. We then applied IBDMap for each phenotype to consensus IBD segments detected using iLASH, hap-ibd, and GERMLINE. We identified regions on chromosome 2 and 8 with genome-wide significant enrichment of IBD sharing in atherosclerosis cases.

In a â□□gold standardâ□□ set of 112 genes with 207 established, highly penetrant pathogenic variants for Mendelian diseases, all but one were detected by applying IBDMap to the traits in BioVU. In GWAS of the traits in the same samples using Firth regression in PLINK2, only 83% of the genes had at least one variant significantly associated with the trait, demonstrating greater power for detection of these highly penetrant loci in IBD mapping. We evaluated the IBDMap haplotype filtering approach with these 112 genes, and found that it resulted in an ~2-fold increase in -log10 p-value in the same BioVU samples. Our results demonstrate the potential of our IBD mapping approach for gene discovery.

PrgmNr 3567 - Individuals with limited healthcare interactions may degrade polygenic risk score analyses

View session detail

Author Block: **S. Kulm**[1], A. R. Marderstein[1], J. G. Mezey[2], O. Elemento[1]; [1]Weill Cornell Med., New York, NY, [2]Cornell Univ, Ithaca, NY
Disclosure Block: **S. Kulm:** None.
Polygenic risk scores (PRSs) are a simple to understand, easy to produce measure of an individual's genetic susceptibility to disease. While studies have shown that individuals with high PRSs are significantly more likely to experience disease, many do not. These false positives hinder clinical integration of PRSs. As few, if any, studies have examined individuals with extreme PRSs in a systematic way, we endeavored to find features that associate to this false positive status.
In the UK Biobank, we computed PRSs for 23 diseases, selected through cross validation in a 246,062 person training phase. Within a 162,119 person testing phase the addition of a PRS to a logistic regression model containing age and sex significantly increased the corresponding AUC of 21 diseases. For each disease, we then compared 100 true positive individuals with the highest PRSs to 100 false positive individuals with the highest PRSs. Examining longitudinal features across all diseases revealed that false positives were more likely to be younger (69.4 to 71.4 to years, P -16), visit the hospital less often (7.4 to 15.2 visits over the course of the study, P -16), and visit the hospital less recently (4.8 to 3.2 years since last visit, P -16). Next, 9107 non-longitudinal, curated features were analyzed by regressing each to the disease status of the 200 individuals with extreme PRSs. Common significant features included the number of self-reported non-cancer illnesses (significant to 6 diseases), followed by self-report of other serious medical condition (5 diseases), overall health rating (3 diseases), and consumption of aspirin (3 diseases). Certain disease-specific features were noteworthy, and may indicate that some individuals may have incorrectly self-reported their disease status, including bread type for celiac disease ($P = 1.8 \times 10^{-6}$), insulin use for type II diabetes ($P = 6.9 \times 10^{-7}$) and urate levels for gout ($P = 9.7 \times 10^{-12}$).
Qualitative studies of comprehensive biographies of the highest PRS false positives illuminated a common characteristic among many significant features: frequency of interactions with the health system. This finding may be interpreted to suggest that some false positive individuals with extreme PRSs may have a disease but are not observed in a way that creates a biobank recognized diagnosis - a problem likely not unique to the UK Biobank. Accurately identifying and removing such individuals from analyses may further improve PRS research in general and expedite its uptake into clinical practice.

PrgmNr 3568 - Interactive Visualization of Relatedness and Ancestry Inference

View session detail

Author Block: **Z. Zhu**, A. W. Manichaikul, S. S. Rich, W-M. Chen; Univ. of Virginia, Charlottesville, VA
Disclosure Block: **Z. Zhu:** None.
The algorithms for estimating kinship and Identical-By-Descent (IBD) segments in the KING software tool have been widely used to identify relatedness in a genetic dataset. Various visualization plots produced from KING have been informative in presenting the inferred relatedness both at the individual level and at the summary level for the entire data, and have provided further inference and understanding of a genetic dataset beyond the kinship and IBD algorithms. However, limitations still exist, including: 1) In a summary plot for all pairs of relatedness, it is not straightforward to view the detailed IBD segments of a particular relationship pair, as well as to identify to which samples the relationship corresponds, *e.g.,* outlying relatedness is of great interest to data QC and requires follow-up; and 2) In the non-interactive plots, it is not feasible to integrate individual-level IBD segments together with the pedigree information, a feature that would be especially valuable for large pedigrees, since manual integration of various sources of information would be labor-intensive and inefficient. To address these needs, we developed four stand-alone interactive visualization applications (github.com/chenlab-uva/InteractivePlots) that facilitate the existing KING inferences using the R package â□□Shinyâ□□. A user can use the KING output files as input, interact with various summary plots by clicking a dot/line, and then display individual-level details (*e.g.*, all IBD segments of a pair of individuals) instantly on the computer screen. The four applications include: 1) viewing IBD segments interactively in a family. The documented pedigree is plotted next to the inferred relatedness graph (squares/circles for samples and lines for relatedness) which is interactive and able to return the detailed IBD segments when a relatedness line is clicked; 2) viewing IBD segments interactively in the summary IBD plot; 3) viewing the individual-level ancestry information interactively in a summary ancestry plot; and 4) viewing the individual-level Run-Of-Homozygosity (ROH) segments interactively in a summary ROH plot. We applied our interactive visualization applications to ~50,000 UK Biobank samples in families. The time to load data was only a few seconds while the interactive time was instant (

PrgmNr 3569 - Interpretable prioritization of causal genes in unsolved GWAS loci

View session detail

Author Block: **N. Cheng**[1], B. L. Trippe[1,2], C. R. Albors[1], J. C. Ulirsch[1], R. Elzur[1], E. Weeks[1], H. Finucane[1,3]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Massachusetts Inst. of Technology, Cambridge, MA, [3]Massachusetts Gen. Hosp., Boston, MA
Disclosure Block: **N. Cheng:** None.
The polygenic priority score (PoPS) is a statistical approach that leverages polygenic enrichments of gene features to prioritize causal genes at uncharacterized GWAS loci [Weeks et al. 2020 medRxiv]. However, it is still a challenge to gain biological insights using this approach. Here, we modify PoPS to use fewer features and subsequently obtain more interpretable gene prioritization models. Using summary statistics for 58 phenotypes from the UK Biobank, and for schizophrenia from the Psychiatric Genomics Consortium, we compute gene-level association scores using MAGMA [de Leeuw et al. 2015 PLOS Computational Biology]. Then we perform forward stepwise linear regression selecting 50 features to fit the MAGMA scores, producing a predicted MAGMA score for each phenotype, which we call the PoPS-FS (forward stepwise) score.
PoPS-FS performs similarly to PoPS on a gold standard gene prediction task, despite using far fewer features per phenotype (50 vs. 3,000-20,000). We obtain a set of 340 gold standard genes using fine-mapped coding variants for the 58 UK Biobank phenotypes [Ulirsch and Kanai, *In preparation*]. Prioritizing the gene with the highest PoPS-FS score in each GWS locus with a gold standard gene nearby, PoPS-FS correctly prioritizes the gold standard gene 47% of the time (PoPS accuracy = 52%). Prioritizing genes that are highest scoring and also closest to the index variant in their loci, the precision of PoPS-FS goes up to 81% (PoPS precision is also 81%). We call such genes â□□high-confidence prioritized genes.â□□
To interpret our predictions, we decompose each PoPS-FS score into a matrix of contributions from genes and features. This allows us to gain insight into our modelâ□□s decision-making process and potentially learn which genes implicate similar causal mechanisms. For instance, in schizophrenia we learn that the high score our model gives to *CACNA1C*â□□a well-known candidate causal risk geneâ□□is almost entirely due to a feature which annotates the protein-protein interactions with *CACNA2D1.*
In HbA1c, we find that *SMIM1*, *ANK1*, and *SPTB*â□□three high-confidence prioritized genes related to red blood cell formation and functionâ□□are among each otherâ□□s top 10 contributing genes. Furthermore, *G6PC2*, *GCKR*, and *TCF7L2*â□□three high-confidence prioritized genes related to glucose metabolism and type 2 diabetesâ□□are among each otherâ□□s top 10 contributing genes. This suggests the presence of at least two distinct pathwaysâ□□one erythrocytic and the other glucose-relatedâ□□that regulate HbA1c levels, consistent with previous genetic studies of this phenotype. Designing procedures to validate these decompositions is a key future direction for this work.

PrgmNr 3570 - LD Score regression (LDSC) with more comprehensive catalogs of LD scores

View session detail

Author Block: **W. Liu**, B. Rowland, J. D. Rosen, J. Wen, Y. Li; Univ. of North Carolina at Chapel Hill, Chapel Hill, NC
Disclosure Block: **W. Liu:** None.
Background: LD Score regression (LDSC) is widely used for estimating the degree of inflation in genome-wide association studies (GWAS) test statistics, by distinguishing between inflation from polygenicity and confounding biases using GWAS summary statistics. In addition, LDSC estimates heritability, genetic correlation, and partitioned heritability for prioritizing functional annotations.
Objectives: The authors of LDSC released LD scores for ~1.3 million HapMap3 variants separately for European and East Asian samples from the 1000 Genomes Project (1000G) covering only a subset of common variants and few low frequency or rare variants (LFRV). We investigated how LDSC estimates change when including additional variants and using a more comprehensive LD reference panel built from whole genome sequencing data from the NHLBI Trans-Omics for Precision Medicine (TOPMed) Program.
Methods: We computed LD scores using LD calculated for TOPMed European and East Asian subjects and collected GWAS summary statistics for 40 human diseases and traits including BMI, height, blood cell traits, and brain-related disorders and traits for Europeans, and 13 blood cell traits for East Asians. We compared 1000G LD scores and TOPMed LD scores for HapMap3 variants to assess the impact of including additional LFRV in LD scores on LDSC estimates. Next, we compared LDSC estimates using TOPMed LD scores from variants with MAF>1% in TOPMed to only HapMap3 variants. Finally, we compared LDSC estimates using TOPMed LD scores from LFRV to common variants.
Results: We found 10 and 8 studies exhibited evidence of inflation due to confounding bias (LDSC intercept > 1.1, genomic control inflation factor $\hat{\lambda}_{GC}$ > 1.1) using TOPMed LD scores, but not with 1000G LD scores, for European and East Asian GWAS summary statistics, respectively. The LDSC intercept estimate using TOPMed LD scores was 3.1%-39.9% larger than estimates from the 1000G LD scores. In addition, using additional variants with MAF>1% in TOPMed decreased the estimate of the LDSC intercept (0.2%-9.8%). Little inflation for LFRV was observed.
Conclusions: Our evaluations comprehensively assessed the impact of including more LFRV in LD score computation on quantification of inflation factor and will guide the choices of the most appropriate LD scores for different ancestry and/or in different allele frequency categories.

PrgmNr 3571 - Leveraging functional annotation in a fast and powerful eQTL weighted gene-based association test

View session detail

Author Block: **T. Haynes**[1], L. Tran[2], S. Gonzales[2], X. Wang[3]; [1]Texas Academy of Math & Sci., Denton, TX, [2]Univ. of North Texas, Denton, TX, [3]Univ North Texas, Denton, TX
Disclosure Block: **T. Haynes:** None.
With the success of genome-wide association study (GWAS) and next generation sequencing data analysis, vast amounts of GWAS summary data are publicly available. To further utilize the GWAS summary data and increase statistical power in genetic association studies, people have proposed a number of transcriptome-wide association study (TWAS) type methods which use gene expression as a mediating trait linking genetic variations with diseases. Usually, these methods employ two key steps: 1) predicting gene expression levels based on inferred gene expression quantitative trait loci (eQTLs); 2) identifying expression-mediated genetic effects on diseases by associating phenotypes with predicted gene expression levels. The success of these methods critically depends on the first step - identification of eQTLs. However, some eQTLs may not be functional in the corresponding tissue, due to linkage disequilibrium (LD) and the correlation of gene expression between tissues. To increase the interpretability and meaningfulness of the genes detected, we propose an omnibus Test to identify disease-associated Genes leveraging Epigenetic information (TGE). TGE utilizes a Cauchy association test to integrate association evidence demonstrated by three different traditional tests (burden test, quadratic test, and adaptive test) using GWAS summary data with multiple eQTLâ□□derived weights. Through prioritizing genetic variants with tissue-specific epigenetic annotation, TGE can better identify genetic variants that are statistically predictive and biologically functional. The p value of the proposed test can be calculated analytically, and thus it is fast and efficient. We applied our proposed test to two schizophrenia (SCZ) GWAS summary data sets and two lipids trait (HDL) GWAS summary data sets. A significantly higher percentage of eQTLs identified by TGE are inferred to be functional and more are deleterious based on their Combined Annotation Dependent Depletion (CADD) scores. Compared with existing methods, our proposed TGE can identify more traitâ□□associated meaningful genes.

PrgmNr 3572 - Leveraging Health Systems Data to Characterize a Large Effect Variant Conferring Risk for Liver Disease in Puerto Ricans

Broad-scale adoption of genomic data in health systems offers opportunities for leveraging population genetics to better understand disease risk. We explored patterns of Identity-by-Descent (IBD) sharing in a patient population in New York City and noted elevated levels of sharing in Puerto Rican (PR) ancestry participants. In an extension of population-based linkage mapping, we clustered IBD haplotypes by homology within the PR group and used these clusters to perform a phenome-wide association study, where we systematically explored relationships between shared IBD haplotypes and over 10,000 health outcomes derived from the electronic health records. In doing so we uncovered one association that achieved study-wide significance between an IBD-haplotype spanning the ABCB4 locus and severe liver disease. We used genome sequencing and in silico approaches to fine-map the signal to a non-coding variant (c.2784-12T>C) in the gene ABCB4. In vitro analysis confirmed the variant disrupted splicing of the ABCB4 pre-mRNA. Four of five homozygotes had evidence of advanced liver disease, and there was a significant association with liver disease among heterozygotes. Examination of local ancestry on the background of the significant IBD haplotype determined the haplotype to be of European origin. Population-level screening revealed the variant to be at a carrier rate of 1.95% in PR individuals, and extremely rare within some European populations, while otherwise absent globally, suggestive of a PR founder effect. This work demonstrates that integrating EHR and genomic data at a population-scale can facilitate novel strategies for understanding the continuum of genomic risk for common diseases, particularly in populations underrepresented in genomic medicine.

PrgmNr 3573 - Leveraging simulations in extended pedigrees for population genetic analysis

View session detail

Gravel[6]; [1]McGIll Univ., Montreal, QC, Canada, [2]McGill Univ., Montreal, QC, Canada, [3]Broad Inst., Cambridge, MA, [4]Montreal, QC, Canada, [5]Nantes, France, [6]Mc Gill Univ, Montreal, QC, Canada
Disclosure Block: **L. Anderson-Trocme:** None.
Family scale pedigrees have provided useful frameworks for understanding the transmission histories of mendelian diseases. At a population scale, they are increasingly used to bridge the gap between individuals and populations. The present study considers the extended pedigree of the French Canadian population of Quebec compiled from over six million parish records dating back to the first French settlers four centuries ago. We use an extension of msprime [1] to generate genealogically aware simulations at a population scale and evaluate their accuracy by comparing them to over seven thousand genotyped individuals linked to the pedigree. Simulations within the genealogy capture the extensive population structure in the populations, bridging the gap between family and population studies. We show excellent agreement with empirical measures of diversity (such as PCA) and contrast inferred tree sequences from both real and simulated data using a site specific genealogical nearest neighbour statistic [2,3]. Using the spatial information in the pedigree, we show how anisotropic range dispersal and serial founder events have influenced present day population structure. Using the concordance between haplotype-based nearest neighbours with pedigree-based kinship, we explore novel frameworks to study realistic population dynamics and the transmission of risk variants, as well as the inference of ancestral haplotypes.

PrgmNr 3574 - MAST-Decon: Smooth Cell-type Deconvolution Method for Spatial Transcriptomics Data

View session detail

Author Block: **T. Luo**[1], J. Chen[1], H. Zhu[1,2], Y. Li[1,3,4]; [1]Dept. of Biostatistics, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]BioMed. Res. Imaging Ctr., Sch. of Med., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [3]Dept. of Genetics, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [4]Dept. of Computer Sci., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC
Disclosure Block: **T. Luo:** None.
Spatial transcriptomics (ST) technologies have gained increasing popularity due to their ability to provide positional context of gene expressions in a tissue. One major limitation of current commercially available ST methods such as the 10X Genomics Visium platform is that they cannot yet reach single cell resolution. The number of cells within a spatial spot may range from 1 to 200 depending on the biological tissue and ST platform. Therefore, any downstream analysis such as spatially variable gene detection could be confounded by differential cell type compositions across spots. Cell type deconvolution for ST data is critical in order to fully reveal underlying biological mechanisms. Existing ST data deconvolution methods share two common limitations: first, few of them utilize spatial neighborhood information. Existing methods such as RCTD and SPOTlight intrinsically treat each spatial spot as independent of neighboring spots, although we anticipate nearby spots to share similar cell type compositions based on clinical evidence of tissue structures. Such limitation could be amplified when sequencing depths at single spots are relatively low so that borrowing information from neighboring spots is necessary in order to obtain reliable deconvolution results. Second, although Visium data provide us with a histological image which could add additional information regarding spot heterogeneity, most existing methods do not utilize this H&E image. To solve these two limitations, we developed Multiscale Adaptive ST Deconvolution (MAST-Decon), a smooth deconvolution method for ST data. MAST-Decon uses a weighted likelihood approach and incorporates both gene expression data, spatial neighborhood information and H&E image features by constructing different kernel functions to obtain a smooth deconvolution result. We showcased the strength of MAST-Decon through simulations based on real data, including a single-cell dataset of mouse brain primary visual cortex. By introducing spatial smoothness, we were able to correct several spots erroneously inferred by RCTD when the average UMI count per spot is at ~2.5k level. Overall, we were able to improve the Spearman correlation between deconvolution results and ground truth cell-type proportions from 0.757 (RCTD) to 0.823 (MAST-Decon), and reduce RMSE between deconvolution results and ground truths from 0.0491 (RCTD) to 0.0334 (MAST-Decon).

PrgmNr 3575 - Methods for genetic association analysis of mother-child pairs

View session detail

Author Block: **D. Ray**[1], C. Vergara[1], M. Taub[2], G. L. Wojcik[1], C. M. Ladd-Acosta[3], T. H. Beaty[3], P. Duggal[3]; [1]Epidemiology, Johns Hopkins Univ., Baltimore, MD, [2]Johns Hopkins, Baltimore, MD, [3]Johns Hopkins Univ., Baltimore, MD
Disclosure Block: **D. Ray:** None.
Genetic association studies of pediatric outcomes often employ family-based designs. One of the most popular family-based designs is the case-parent trio design that considers a nuclear family of parents and their affected child. This trio design is particularly advantageous for studying relatively rare disorders because amassing adequate numbers of affected children require sampling from multiple populations. This can cause type I error inflation due to population stratification if a population-based design is used. However, genetic information on both parents is often not available; fathers may be missing as they are harder to recruit, and paternity is more difficult to ensure than maternity. While there are a few statistical methods for analyzing mother-child dyad data, it is not clear if one method is advantageous over another under different dyad designs (e.g. case-mother dyads, case-mother/control-mother dyads), and if they provide the same advantage as methods for trio design in protecting against population stratification. Further, type I error and statistical power of most of these methods were evaluated at nominal significance levels only. Recent benchmarking articles on family-based genetic studies have either focused on trios and larger pedigrees or considered only one class of methods. Here we reviewed existing methods for analyzing genome-wide data on dyads and performed extensive simulation experiments to benchmark their type I error and power at stringent error levels against the corresponding trio design under different scenarios. We considered samples from homogenous racial/ethnic populations as well as assumed scenarios where population substructure exists. We also reviewed and evaluated methods for analyzing case-parent trios and mother-child dyads together. We applied these methods on genotyped/imputed data from multi-ethnic mother-child pairs only or trios only (ascertained through a child affected by nonsyndromic cleft lip with or without cleft palate) or a combination of both dyads and trios from the Gene, Environment Association Studies consortium (GENEVA). Results from the GENEVA study corroborate findings from our simulation experiments. Finally, we provide recommendations on which statistical method for dyads to use and under what scenario. This work is motivated by the Environmental influences on Child Health Outcomes (ECHO) study where genome-wide data, mostly on mother-child pairs, are becoming available. Our recommendations will not only help ECHO to select the protocols to use for discovering genetic risk factors of pediatric outcomes but also provide guidelines for other studies with dyad designs.

PrgmNr 3576 - Multiethnic joint analysis of summary statistics from genome-wide association studies

View session detail

Author Block: **J. Shen**[1], L. Jiang[1], K. Wang[1], P. J. Newcombe[2], C. Haiman[1], D. V. Conti[1]; [1]Univ. of Southern California, Los Angeles, CA, [2]MRC Biostatistics Unit, Cambridge, United Kingdom
Disclosure Block: **J. Shen:** None.
Over the last 20 years, Genome-wide Association Studies (GWAS) have been able to identify genetic regions associated with traits and diseases in different populations. As a post-GWAS approach, multiethnic fine-mapping aims to identify underlying causal variants by combining summary statistics and leveraging different linkage disequilibrium (LD) structures across diverse populations. Here, we expand upon our previous approach for single-population fine-mapping through Joint Analysis of Marginal SNP Effects (JAM) to a multiethnic analysis (mJAM). Under the assumption that true causal variants are common across populations, our joint model explicitly incorporates the different LD structures across populations and yields a conditional fixed-effect meta-analysis (FE). To pinpoint causal variants from highly correlated signals efficiently, we incorporate Sum of Single Effects (SuSiE), a Bayesian stepwise selection method, within the mJAM framework. Through simulation studies based on realistic effect sizes and levels of LD, we demonstrate that mJAM performs better than other existing multi-ethnic methods including FE, conditional and joint analysis using summary data (COJO), and multiple study causal variants identification in associated regions (MsCAVIAR). The flexible mJAM framework can be extended to deal with binary disease outcome or missing SNP information in some populations, which is a unique advantage of mJAM over other existing methods. In a real data application, we apply mJAM to recently published summary statistics from a trans-ancestry prostate cancer GWAS.

PrgmNr 3577 - Multi-trait analysis of gene-environment-wide association using MAGENTA

View session detail

Author Block: **L. Luo**[1], J. Shen[1], Z. Tang[2]; [1]Merck & Co., Inc., Rahway, NJ, [2]Univ. of Wisconsin-Madison, Madison, WI
Disclosure Block: **L. Luo:** None.
Many complex traits (i.e., diseases or drug responses) are influenced by the interplay of genetic and environmental factors. Detecting genotype-by-environment interaction (GEI) is fundamental in understanding their etiology and increasing the power to detect complex-trait associated genes. However, it is challenging to identify GEI signals largely due to small effect sizes and limited sample sizes. Aggregating association evidence across multiple variants and multiple traits helps boost the power. Here, we propose MAGENTA (**M**ulti-trait **A**nalysis of **G**ene-**EN**vironmen**T**-wide **A**ssociation), a novel random-effects meta-analysis framework for testing GEI effect and the genetic main and GEI joint effects respectively across a SNP-set and multiple traits. MAGENTA is motivated by the observation that tests for the GEI are closely related to the test of heterogeneity in random-effects meta-analysis with strong heterogeneous genetic effects among environmental groups implying the existence of GEI effects. Compared with single-trait based approaches, MAGENTA gains more power by using genetic correlation information to accommodate the heterogeneous genetic effects among traits. By using summary statistics data across environmental groups as input, MAGENTA is computationally fast and efficient while analyzing large-scale genome-wide GEI association studies. Our extensive simulation studies show MAGENTA controls type I error well and yields stable power across various scenarios. We applied MAGENTA to the UK-Biobank whole exome sequencing data (N=46376) and identified a significant GEI effect between APOE gene and sex on three lipid traits (HDL, LDL and triglycerides), which was missed by single-variant GEI test or other single-trait SNP-set based methods (i.e., MAGEE).

PrgmNr 3578 - Multivariate modeling of direct and proxy GWAS indicates substantial common variant heritability of Alzheimerâ□□s disease

View session detail

Author Block: **J. de la Fuente**[1,2], A. D. Grotzinger[1,3], R. E. Marioni[4], M. G. Nivard[5], E. M. Disclosure Block: **J. de la Fuente:** None.

Genome-wide association studies (GWAS) of proxy-phenotypes using family history of disease (GWAX) can substantially boost power when combined with traditional case-control GWAS across a range of disease traits. The usefulness of GWAX for enhancing GWAS discovery has been particularly noticeable in the context of late-onset Alzheimerâ□□s Disease (AD). However, there is a stark contrast between heritability estimates derived from twin-based approaches and combined GWAX-GWAS meta-analysis of AD. While heritability estimates from twin approaches are approximately 60%, combined GWAX-GWAS meta-analysis of AD indicate very low common variant SNP heritability estimates after excluding the *APOE* region, with the most recently reported estimate of 2.5% on the liability scale coming from the application of LD Score Regression (LDSC) to the largest sample to date. Here, we demonstrate that commonly used approaches for combining GWAX and GWAS data produce dramatic underestimates of heritability, and we introduce a multivariate method for estimating individual SNP effects and recovering unbiased estimates of SNP heritability when combining GWAS and GWAX summary data. Via simulation, we show that our method recovers unbiased estimates of common variant SNP heritability and of individual SNP effects under a variety of circumstances in which standard approaches, including those that correct for the indirect nature of the GWAX, dramatically underestimate these quantities. Using recently released GWAS and GWAX summary data for Alzheimerâ□□s disease (AD), our method estimates the common variant SNP heritability of AD excluding the *APOE* region to be more than double (~6-10%) recent estimates using the same assumptions regarding population prevalence. Moreover, we show the corresponding estimate for biological AD (based on prevalence rate estimates from recently published molecular imaging data) as high as ~20%. Finally, our local SNP heritability analyses indicate that more than 70% of common variant SNP heritability of AD exists outside the *APOE* region, evidencing a polygenic signal that is relatively diffusely distributed across the genome.

PrgmNr 3579 - Novel Global Quantile Regression Based Method for Differential Gene Expression Analysis of Quantitative traits

View session detail

Author Block: **S. Tang**[1], A. S. Buchman[2], P. L. De Jager[3], D. A. Bennett[4], Q. Zheng[5], J. Yang[6]; [1]Emory Univ., Atlanta, GA, [2]Rush Alzheimerâ□□s Disease Ctr., Chicago, IL, [3]Columbia Univ Med Ctr, New York, NY, [4]Rush Univ. Med. Ctr., Chicago, IL, [5]Univ. of Louisville, Louisville, KY, [6]Emory Univ, Atlanta, GA
Disclosure Block: **S. Tang:** None.
High-throughput RNA sequencing (RNA-seq) has been widely used in studies of complex diseases to detect differentially expressed genes with respect to complex traits and diseases. Existing popular methods such as DESeq2 and edgeR are only developed for studying dichotomous traits, which are based on generalized linear regression models with RNAseq read counts as the response variable. Recently, a standard linear regression based test method was proposed for differential gene expression (DGE) analysis of quantitative traits, which takes the trait of interest as the response variable and the RNA-seq read counts as the test covariate.
However, standard linear regression model is limited to only test the association with respect to the mean of the response variable and the test covariate. To account for heterogeneous associations with respect to different quantiles through the entire distribution of the trait, we propose a novel global quantile regression based method to test for differential gene expressions with quantitative traits (GQR-DEseq). GQR-DEseq uses the quantile rank-score test that is an analogous variance component score test to account for response-covariate association across the whole quantile domain of the trait. By simulation studies using real RNAseq data, we compared the performance of GQR-DEseq with the DGE method based on standard linear regression. We considered a monotone negative increasing and a monotone positive decreasing effect size functions (functions of quantiles) estimated from our real data as well as a zero effect size function for null models. Regardless of the direction of effect size functions, GQR-DEseq had higher power than standard linear regression based tests, 54.1% vs. 2.7% with positive effect size, 99.6% vs. 87.8% with negative effect size. Our null simulations showed GQR-DEseq controlled for type I error. These simulation studies show that GQR-DEseq has higher power than the standard linear regression based tests when the covariate-response effect size is heterogeneous with respect to response quantiles.
Further, we applied GQR-DEseq to the RNA-seq data of frontal cortex tissues for studying Alzheimerâ□□s dementia (AD), taking the quantitative rate of cognitive decline as the trait of interest. GQR-DEseq detected 47 significant genes with FDRADAMTS-2 (p-value =3.24Ã□10^{-15}) has been suggested to be a therapeutic target for adult brain disorders such as schizophrenia and Alzheimer's disease.
A free tool of GQR-DEseq will be available on Github which provides a novel resource to detect DGE of quantitative traits.

PrgmNr 3581 - Reconstructing SNP Allele and Genotype Frequencies from GWAS Summary Statistics

View session detail

Author Block: **Z. Yang**, P. Paschou, P. Drineas; Purdue Univ., West Lafayette, IN
Disclosure Block: **Z. Yang:** None.

The emergence of genomewide association studies (GWAS) has led to the creation of large repositories of human genetic variation, creating enormous opportunities for genetic research and worldwide collaboration. Methods that are based on GWAS summary statistics seek to leverage such records, overcoming barriers that often exist in individual-level data access while also offering significant computational savings. Here, we propose a novel framework that can reconstruct allelic and genotypic counts/frequencies for each SNP from case-control GWAS summary statistics. Our framework is simple and efficient without the need of any complicated underlying assumptions. Illustrating the great potential of this framework we also propose three summary-statistics-based applications implemented in a new software package (ReACt): GWAS metaanalysis (with and without sample overlap), case-case GWAS, and, for the first time, group polygenic risk score (PRS) estimation. We evaluate our methods against the current state-of-the-art on both synthetic data and real genotype data and show high performance in power and error control. Our novel group PRS method based on summary statistics could not be achieved prior to our proposed framework. We demonstrate here the potential applications and advantages of this approach. Our work further highlights the great potential of summary-statistics-based methodologies towards elucidating the genetic background of complex disease and opens up new avenues for research.

PrgmNr 3582 - SparsePro: an ultra-efficient Bayesian fine-mapping method integrating summary statistics and functional annotations

View session detail

Author Block: **W. Zhang**, Y. Li; McGill Univ., Montreal, QC, Canada
Disclosure Block: **W. Zhang:** None.

Identifying causal variants from genome-wide association studies (GWASs) is challenging due to widespread linkage disequilibrium (LD). Functional annotations of the genome may help prioritize variants that are biologically relevant, thus improve fine-mapping of GWAS results. However, canonical fine-mapping methods incorporating functional annotations have a high computational cost, particularly when the underlying genetic architecture and LD pattern are complex.

We propose SparsePro, to efficiently conduct functionally informed statistical fine-mapping. Our method enjoys three innovations: First, by creating a sparse low-dimensional projection of the high-dimensional genotype space, we enable a linear direct search of causal variants instead of an exponential search of causal configurations used in existing methods; Second, we adopt a probabilistic framework with an efficient variational expectation-maximization algorithm to integrate statistical associations and functional annotations; Last, we specifically test for the relevance of functional annotations, which improve the robustness when trait-related functional categories are unknown.

We evaluated SparsePro through extensive simulations using UK Biobank genotypes. Under various settings of causal configuration, heritability, LD pattern, and intensity of functional annotation enrichment, SparsePro achieved superior or comparable discriminative power in identifying causal variants compared to state-of-the-art methods, with much improved computational efficiency. With a five-fold enrichment of functional annotations on causal variants, SparsePro achieved the highest overall area under the precision-recall curve (AUPRC) of **0.786**, outperforming the runner-up method PAINTOR with an AUPRC of 0.654. Notably, SparsePro was also **455** times faster than PAINTOR. With irrelevant functional annotations, SparsePro achieved an AUPRC of 0.604. While the runner-up methods, FINEMAP and SuSIE, achieved the same AUPRC, SparsePro was 15 and 44 times faster, respectively. We applied SparsePro to conduct functionally informed fine-mapping of complex trait GWASs, including body mass index, height, type 2 diabetes and breast cancer. We have discovered relevant functional enrichment and promising candidates of causal variants.

In summary, we have developed an ultra-efficient and accurate Bayesian fine-mapping method with the ability to integrate summary statistics and functional annotations. Our method will have broad utility in dissecting disease-relevant functional elements, identifying target genes and increasing the yield of functional follow-up of GWASs.

PrgmNr 3583 - The power of pathway-specific polygenic risk scores

View session detail

Author Block: **S. Choi**[1], J. Garcia-GonzÃ¡lez[1], Y. Ruan[2], J. Johnson[1], H. Wu[1], O. Paul[1]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Broad Inst., Cambridge, MA
Disclosure Block: **S. Choi:** None.
Polygenic risk scores (PRSs) have been among the leading advances in biomedicine in recent years. As a proxy of genetic liability, PRSs are utilised across multiple fields and applications. While numerous statistical and machine learning methods have been developed to optimize their predictive accuracy, all of these distil genetic liability to a single number based on an aggregation of an individualâ□□s genome-wide alleles. This results in a key loss of information about an individualâ□□s genetic profile, which could be critical given the functional sub-structure of the genome and the heterogeneity of complex disease. Here we evaluate the performance of pathway-specific PRSs, in which *k* polygenic scores are calculated across *k* genomic pathways for each individual, and introduce a software, *PRSet*, for computing and analysing pathway PRS. We find that pathway PRSs have similar power for evaluating pathway enrichment of GWAS signal as the leading methods, with the distinct advantage of providing estimates of pathway genetic liability at the individual-level. Exemplifying their utility, we demonstrate that pathway PRSs can stratify diseases into sub-types in the UK Biobank with substantially greater power than genome-wide PRSs. Compared to genome-wide PRSs, we expect pathway-specific PRSs to offer greater insights into the heterogeneity of complex disease and treatment response, generate more biologically tractable therapeutic targets, and provide a more powerful path to precision medicine.

PrgmNr 3585 - Using metagenomics to assess global levels of antimicrobial resistance

View session detail

Author Block: **S. T. Eckert**[1], X. Zhan[2], D. J. Liu[1]; [1]Penn State Coll. of Med., Hershey, PA, [2]UT Southwestern, Dallas, TX
Disclosure Block: **S.T. Eckert:** None.
Antimicrobial resistance (AMR) poses a major public health challenge that leads to nearly 3 million infections and over 35,000 deaths per year in the US alone. This estimate considers only symptomatic instances of antimicrobial-resistant microbes, but as we have learned from recent developments in infectious disease, latent, asymptomatic carriers of infection are much more common than previously thought. These unaffected carriers likely shape the landscape of how AMR infections spread. It is important to gain a deeper understanding of asymptomatic AMR in the general population. Numerous publicly available metagenomic sequencing datasets offer a great opportunity to quantify the extent of asymptomatic AMR infection in the general population. We previously developed a database, VAMPr, which uses pairs of bacterial sequences and antibiotic-resistant/susceptible status as training data. A machine learning model was obtained that accurately predicts AMR status from bacterial sequence variants. To apply VAMPr to metagenomic sequences, we further developed a pipeline, MetaPrism2, to call microbial, amino acid variants from metagenomic sequencing datasets. The pipeline first assembles contigs from metagenomic sequences, which are then realigned to the contigs of known origin. A consensus sequence is then generated from the called variants and contigs, which is then fed into VAMPr to predict AMR status for each bacteria-antibiotic pair. To apply this pipeline, we called amino acids variants and predicted AMR status for a dozen curated metagenomic datasets, totaling 2532 individuals and 10016 samples from various countries. An estimated 94.8% of individuals latently carry at least one bacterial species that is resistant to at least one antibiotic. We further used logistic regression to associate predicted AMR status with various covariates from meta-information including (but not limited to) antibiotic use, age, sex, BMI, and the study condition. Direction of effect for association with antibiotic use depended on which antibiotics the subjects were prescribed. For example, penicillin-class antibiotic use generated more antibiotic resistance to tobramycin (OR=1.55, 95% CI[1.01,2.38], p=0.04), while usage of other antimicrobial groups may lead to increased susceptibility to tobramycin (OR=0.56, 95% CI[0.33,0.97], p=0.037). Another significant association of interest is that of antibiotic resistance with a modifiable risk factor, smoking (clindamycin, OR=5.26, 95% CI [1.15,24.1], p=0.03). Our methods, results, and continued investigation will elucidate the global distribution for AMR status and pinpoint the risk factors for AMR infection.

PrgmNr 3586 - Utility of admixed individuals in genome wide association studies: A test case in COVID-19

View session detail

Author Block: **S. Tuminello**[1,2], N. Hu[1], H. Berk-Rauch[1], P. Cotiza[3], L. Boytard[3], C. Arguelles-Grande[3], P. Zappile[4], E. Guzman[4], A. Heguy[4], I. Osman[3], L. Thorpe[2], A. Chakravarti[1]; [1]Ctr. for Human Genetics and Genomics, New York Univ. Sch. of Med., New York City, NY, [2]Div. of Epidemiology, Dept. of Population Hlth., New York Univ. Sch. of Med., New York City, NY, [3]The New York Univ. Langone Hlth.(NYULH) Ctr. of Biospecimen Res. and Dev., Office of Sci. and Res., New York Univ. Sch. of Med., New York City, NY, [4]Genome Technology Ctr., Div. of Advanced Res. Technologies, New York Univ. Sch. of Med., New York City, NY

Disclosure Block: **S. Tuminello:** None.

Human genetic studies usually stratify subjects by continental ancestry and have historically excluded admixed individuals; yet more than a third of the US population is admixed and will be increasingly so. During the COVID-19 pandemic, biospecimens linked to clinical data were rapidly collected at New York University Langone Health (NYULH) irrespective of ancestry. We demonstrate here how genetic studies of cosmopolitan, admixed individuals can be informative for ancestry-specific risks of COVID-19 severity. Patients were genotyped using 1X whole genome sequencing followed by genotype imputation. 1,538 COVID-19 positive, hospitalized patients were studied in which we identified 59,862,263 genomic variants. 46% of patients were admixed, 198 (13%) were African American, 81 (5%) Hispanic, and 426 (28%) admixed non-African American or non-Hispanic. The remaining 54% were non-admixed and classified as belonging solely to one of five groups: African (193, 13%), American (10, African:0.48, $OR_{African\text{-}American}$:0.65, OR_{Asian}:1.51; rs73064425: $OR_{African}$:0.45, $OR_{African\text{-}American}$:0.63, OR_{Asian}:2.42; estimates not statistically significant). This implies that variants associated with genetic susceptibility to COVID-19 vary by genomic ancestral populations, impacting heterogeneity in outcomes between admixed individuals. We are now estimating local ancestry across the genome to conduct genetic association studies of COVID-19 to estimate ancestry-specific allelic effects.

PrgmNr 3587 - Utilizing phenotype risk scores and genetically-regulated expression in a clinical biobank to investigate the genetic architecture of Mendelian disease genes

View session detail

Author Block: **T. W. Miller-Fleming**[1], A. B. Faucon[2], L. Bastarache[3], N. J. Cox[1]; [1]Vanderbilt Univ Med Ctr., Nashville, TN, [2]Vanderbilt, Nashville, TN, [3]Nashville, TN
Disclosure Block: **T.W. Miller-Fleming:** None.
Background: Mendelian diseases typically arise from rare, coding mutations in single genes and are evaluated in small, family-based studies. Despite the estimation that more than 7,000 Mendelian conditions exist, many are poorly understood and have no treatment. We utilized large-scale data and tools to better understand the genes responsible for Mendelian disease. In this study, we leveraged the dense phenotype information in the Vanderbilt electronic health records (EHR) and biobank to identify individuals that share core features of Mendelian diseases and determine whether the genetically-regulated expression (GREX) of the causal genes were correlated with the disease features. **Methods:** We generated phenotype risk scores (PheRS) for 80,775 patients in the biobank using Human Phenotype Ontology/HPO terms in OMIM (Online Mendelian Inheritance in Man) mapped to phenotypes within the EHR for Mendelian diseases. Using linear regression models, we tested for associations between the PheRS for 2,817 distinct Mendelian diseases with the GREX of the causal gene for each disorder. **Results:** Across the 3,114 gene-disease pairs tested, we identified 292 significant associations between GREX and PheRS, suggesting that common, regulatory genetic variation can contribute to similar phenotypic consequences as rare, coding variation. Our significant findings include: Cystic Fibrosis with *CFTR* ($p=2.99x10^{-6}$), Alzheimer disease with *APOE* ($p=1.45x10^{-4}$), and Hypercholesterolemia with *APOB* ($p=2.60x10^{-4}$). The significant gene-disease pairs were not enriched for recessive or dominant inheritance patterns of disease, loss-of-function or gain-of-function genetic mechanism, or loss-of-function intolerant genes. After conditioning a subset of our analyses on diagnosis status in the EHR, we found that the significant associations were not driven by diagnosed individuals, rather that many individuals with the highest PheRS for Mendelian conditions were not diagnosed within the biobank. **Discussion:** Our findings support the utilization of clinical biobanks and gene expression imputation tools in the study of rare disease. We find that for ~10% of the Mendelian disease genes tested, common, regulatory variation contributes to phenotypic consequences consistent with our previous knowledge of the disease. Additionally, we find that many individuals within the biobank have high PheRS for Mendelian disorders, despite many being undiagnosed. This work suggests that a better understanding of Mendelian disease genes could benefit a much larger proportion of the population than those currently diagnosed with rare, monogenic diseases.

PrgmNr 3588 - A phenome-wide Mendelian randomization study of plasma triglycerides and more than 6,000 diseases and traits

View session detail

Author Block: **S. Bafna**[1,2], G. Rocheleau[1,2], I. Forrest[1,2], A. Duffy[1,2], C. Marquez-Luna[1,2], B. Petrazzini[1,2], H. Vy[1,2], D. Jordan[1,2], M. Verbanck[3], R. Do[1,2]; [1]Charles Bronfman Inst. for Personalized Med., Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Dept. of Genetics and Genomic Sci., Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]UniversitÃ© de Paris, Paris, France
Disclosure Block: **S. Bafna:** None.
Mendelian randomization studies have shown that decreased plasma triglycerides is causally related to decreased coronary artery disease (CAD) risk. This is further supported by triglyceride-lowering therapeutics which have also demonstrated protection against CAD. Phenome-wide Mendelian randomization (MR) can be used to identify additional outcomes causal to plasma triglycerides. The objective of this study is to evaluate potential causal effects of triglycerides on a wide array of disease outcomes and traits by performing a phenome-wide MR analysis in the electronic health record (EHR)-linked UK Biobank and FinnGen Biobank.

We performed phenome-wide MR analyses to test the causal effect of triglycerides on 4,156 and 2,264 diseases and traits using genome-wide association summary statistics in the Pan-UK Biobank and FinnGen Biobank. We identified 141 independent triglyceride-altering genetic variants serving as instrumental variables for four different pleiotropy-aware MR methods: inverse-variance weighted (IVW), MR-Egger and Weighted Median and MR-PRESSO. To determine statistical significance, we set *P* â□□5 for the IVW test after accounting for multiple testing. From this analysis, we discovered causality of plasma triglycerides with 223 traits and diseases in total (183 in Pan-UK Biobank and 40 in FinnGen). Of these, 161 out of the 223 exhibited evidence of horizontal pleiotropic bias (P -4 (0.05/223). We identified known causal relationships, including plasma triglycerides with ischemic heart disease (IVW Î² = 0.30, $P = 1.1Ã□10^{-19}$) and myocardial infarction (IVW Î² = 0.36, $P = 2.7Ã□10^{-15}$). We also identified novel causal relationships including plasma triglycerides with peptic ulcer (IVW Î² = 0.92, $P = 3.1Ã□10^{-8}$), cerebral aneurysm (IVW Î² = 0.93, $P = 5.7Ã□10^{-6}$), enthesopathies (IVW Î² = -0.47, $P = 1.5Ã□10^{-6}$), vertical strabismus (IVW Î² = -0.89, $P = 2.4Ã□10^{-6}$), wet age-related macular degeneration (IVW Î² = -0.58, $P = 7.1Ã□10^{-6}$), among many others.

Phenome-wide MR analyses demonstrate that plasma triglycerides is causally related to a number of diseases. Triglyceride-lowering therapeutics should be considered in the context of these additional causal conditions.

PrgmNr 3589 - Assessing the difference in multiple sclerosis age of onset amongst different racial populations through the use of electronic health records

View session detail

Author Block: **A. Hernandez**[1], F. B. Briggs[2], M. F. Davis[3]; [1]Brigham Young Univ., Provo, UT, [2]Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [3]Brigham Young Univ, Provo, UT
Disclosure Block: **A. Hernandez:** None.
Multiple Sclerosis (MS) is a complex autoimmune disease where the myelin sheath that covers nerve fibers deteriorates and causes nerve damage. MS is most common in individuals of European descent; however, it still affects other populations. Previous research studies have found that the average age of onset for MS in ethnic minorities is 28.6 years, where those of European descent had an average of 32.8 years. Furthermore, studies have shown that non-Hispanic black patients with MS died at an earlier age and have an increasing mortality trend in comparison to white patients with MS. This suggests that MS takes a different toll on individuals depending on race; understanding this difference can aid us in better understanding MS onset and how to better accommodate ethnic minorities with MS. We acquired de-identified electronic health records (EHRs) from Vanderbilt University Medical Center BioVU that were genotyped on the Illumina MEGAex platform. We analyzed age of onset of MS in black and white individuals diagnosed with MS in an aim to identify single-nucleotide polymorphisms (SNPs) associated with earlier onset of MS in Black individuals. After completing quality control (QC), we identified 184 non-Hispanic black individuals and 1540 non-Hispanic white individuals for analysis. Linear regression will be used to identify interactions between known MS risk SNPs associated with age of onset in white and black populations.

PrgmNr 3590 - Bayesian analyses of variant-specific features enable penetrance estimates across cardiac channelopathies

Cerebral and Cardiovascular Ctr., Suita, Japan, [6]Univ. of Pavia, Pavia, Italy, [7]AP-HP PitiÃ©-SalpÃªtriÃ¨re Hosp., Paris, France, [8]Shiga Univ. of Med. Sci., Otsu, Japan

Disclosure Block: **M. O'Neill:** None.

The inability to accurately assess disease risk across carriers of rare variants in cardiac channelopathy genes represents a major impediment to personalized medicine. A common way to adjudicate these variants has been observational, commonly invoking case-control designs. While representing a powerful approach, such methods rely *a priori* on clinical observations which suffer from strong ascertainment bias and heterogenous presentations of variant carriers; the clinical implications for variants can vary strikingly across individuals even when evidence of variant pathogenicity is strong. Sequencing efforts have revealed both a high number of ultra-rare variants in healthy individuals and a much higher burden of rare, definitively annotated disease-causing variants than is compatible with the individual disease prevalence. We propose an inverse model for variant interpretation, whereby variant-specific features inform a disease penetrance prior in a Bayesian framework. Herein we present penetrance estimates for long QT syndrome 1-3 (LQT1-3) and Brugada Syndrome (BrS) based on literature curation of phenotyped individuals, *in silico* predictors, and protein structure-derived features for variants in the causative genes *KCNQ1* (LQT1), *KCNH2* (LQT2), and *SCN5A* (BrS + LQT3). Our results show that penetrance of pathogenic BrS variants is approximately 50%, while those of LQTS cluster near 80%, consistent with a threshold model by which total compensation against an insult from an LQTS-associated variant is less than that for BrS-associated variants. We provide model validation for two genotype-phenotype relationships on an international cohort of 1610 *KCNQ1* variant carriers and 933 *KCNH2* variant carriers. Furthermore, a remarkable heterogeneity of individual residue penetrance can be appreciated across traditionally annotated â□□pathogenic domainsâ□□. Through this framework we found that the innate diagnostic information one learns about a variant from three-dimensional variant location, *in vitro* data, and *in silico* predictors is equivalent to the diagnostic information one obtains by clinically phenotyping 10-20 heterozygous carriers. Altogether, we provide a powerful means by which to assess variant penetrance and inform clinical decision making prospectively, before the observation of an affected or unaffected heterozygous carrier.

PrgmNr 3591 - BrainXcan identifies brain features associated with Alzheimer's disease using large scale genetic and neuroimaging data

View session detail

Author Block: **E. Wu**[1], Y. Liang[1], O. Melia[1], T. S. Brettin[2], A. Brown[3], H. Im[1]; [1]The Univ. of Chicago, Chicago, IL, [2]Argonne Natl. Lab., Lemont, IL, [3]Univ. of Dundee, Dundee, United Kingdom
Disclosure Block: **E. Wu:** None.
Alzheimerâ□□s disease (AD) is a progressive neurodegenerative disease with an enormous health burden on individuals and society with no effective treatment to date. Genome-wide association studies (GWAS) have discovered 75 loci associated with risk of AD implicating amyloid and tau metabolism, endocytosis, innate immunity pathways. However, most loci reside in non-coding regions of the genome, making it difficult to understand their mechanism of action.
Brain magnetic resonance imaging (MRI) is a promising technique for diagnosis and examination of AD etiology and pathology. Previous studies have been successful in identifying whole-brain and temporal lobe, particularly hippocampal, atrophy as powerful indicators of Alzheimerâ□□s neurodegeneration. However, low statistical power and lack of standardized data analysis limit the reliability of these studies. Whether these markers are causal or emerge as a result of disease progression is also unclear without additional analyses.
Here we apply a newly developed method, BrainXcan, which brings together neuroimaging genomic toolsets to identify structural features of the brain involved in the pathogenesis and progression of AD. This allows for discovery of causal features implicated in AD by using prediction weights trained with the uniformly processed UK Biobank's brain MRI image-derived phenotypes and correlating the genetically predicted brain features with disease status.
Applying BrainXcan to Alzheimerâ□□s disease using T1-weighted and diffusion MRI data revealed 11 significant associations among 261 image-derived phenotypes, including increased gray matter volumes in the occipital fusiform gyrus and caudate, as well as features indicating reduced connectivity and white matter tissue integrity consistent with our understanding of neurodegeneration. However, the absence of significant temporal lobe atrophy and other characteristic structural features identified in previous studies warrants further investigation into the genetic basis of these features and the direction of causality in the context of Alzheimerâ□□s disease. Taken together, our results highlight the promise of BrainXcan as a powerful tool to dissect the biology of AD and add new lines of evidence for existing results.

PrgmNr 3592 - Circulating proteins to predict adverse COVID-19 outcomes

View session detail

Author Block: **C-Y. Su**[1,2], S. Zhou[1,2], E. Gonzalez-Kozlova[3], G. Butler-Laporte[1,2], E. Brunet-Ratnasingham[4], T. Nakanishi[1,2], W. Jeon[1], D. Morrison[2], L. Laurent[2], N. Kaufmann[4], M. Merad[3], J. B. Richards[1,2]; [1]McGill Univ., Montreal, QC, Canada, [2]Lady Davis Inst., Jewish Gen. Hosp., Montreal, QC, Canada, [3]Icahn Sch. of Med. at Mount Sinai, New York, NY, [4]Ctr. Hosp.ier de lâ□□UniversitÃ© de MontrÃ©al, Montreal, QC, Canada
Disclosure Block: **C. Su:** None.
Predicting COVID-19 severity is difficult, and the biological pathways involved are not fully understood. To approach this problem, we measured 4,701 circulating human protein abundances in two independent cohorts totaling 986 individuals. We then trained prediction models including protein abundances and clinical risk factors to predict adverse COVID-19 outcomes in 417 subjects and tested these models in a separate cohort of 569 individuals. For severe COVID-19, a baseline model including age and sex provided an area under the receiver operator curve (AUC) of 65% in the test cohort. Selecting 92 proteins from the 4,701 unique protein abundances improved the AUC to 88% in the training cohort, which remained relatively stable in the testing cohort at 86%, suggesting stability of the model. Proteins selected from different adverse COVID-19 outcomes were enriched for cytokine and chemokine receptors, but half of the enriched pathways were not immune-related. Taken together, these findings suggest that circulating proteins measured at early stages of disease progression are reasonably accurate predictors of adverse COVID-19 outcomes. Further research is needed to understand how to incorporate protein measurement into clinical care.

PrgmNr 3593 - Detecting *DHCR7* variants consistent with Smith-Lemli-Opitz syndrome in autism patients

View session detail

Author Block: **J. B. Cordero**[1], R. Y. Cordero[1], E. Tierney[2], F. D. Porter[3], C. A. Wassif[4], C. L. Simpson[5]; [1]Genetics, Genomics, and Informatics, Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN, [2]Kennedy Krieger Inst, Baltimore, MD, [3]NIH, Bethesda, MD, [4]NICHD/HDB/NIH, Bethesda, MD, [5]Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN

Disclosure Block: **J.B. Cordero:** None.

Introduction: *DHCR7* encodes the enzyme that catalyzes the conversion of 7-dehydrocholesterol (7-DHC) to cholesterol. Defective cholesterol synthesis results in low cholesterol and increased concentration of 7-DHC. Mutations in *DHCR7* cause Smith-Lemli-Opitz syndrome (SLOS). Most SLOS patients are compound heterozygotes and present with congenital abnormalities, intellectual disability, and autism. Over 140 different mutations in *DHCR7* have been reported. In this study, we identified the prevalence of individuals with known *DHCR7* variants in MSSNG, an autism genomic database.

Methods: We examined whole genome sequencing (WGS) *DHCR7* variant data from MSSNG subjects with autism and identified individuals with â¥ 2 SLOS *DHCR7* known pathogenic variants. We analyzed lipid and behavioral phenotypic data in subsets of subjects in relation to the WGS analysis results. The frequency of identified individuals with the SLOS *DHCR7* pathogenic variants was then compared with control unaffected family members.

Results: A total of 7187 MSSNG subjects (3425 affected; 3762 unaffected) from 2756 families were included in the study, majority (80%) of which belonged to family trios or quads. Preliminary results from a subset of MSSNG database identified Autism-Genetic-Resource-Exchange (AGRE) subjects as having potentially deleterious *DHCR7* mutations. Analysis for the remaining MSSNG subjects is ongoing.

Conclusion: Early recognition and management of autism patients with SLOS-related *DHCR7* variants can help improve the course of the disorder. Further, the study of autism patients with concomitant *DHCR7* mutations affecting cholesterol synthesis may help elucidate pathways and relationships of autism and lipids.

PrgmNr 3594 - Dissecting the causal relationships between obesity and multiple sclerosis risk

View session detail

Author Block: **E. Misicka**, F. B. Briggs; Case Western Reserve Univ. Sch. of Med., Cleveland, OH
Disclosure Block: **E. Misicka:** None.
Background. Multiple sclerosis (MS) is an autoimmune disease of the central nervous system. Observational studies have demonstrated that higher body-mass index across the lifespan confers MS risk, and genetic instrumental variable (GIV) analyses have confirmed these relationships. How BMI contributes to MS risk is not clear, and it is unknown if other obesity-related traits are also independent risk factors for MS.
Objectives. To examine the causal effects of multiple measures of obesity on MS risk in non-Hispanic whites using genetic instrumental variable analyses.
Methods. Two-sample Mendelian randomization (2S-MR) is a statistical approach that uses summary statistics from genetic association studies to examine causal relationships between multiple phenotypes. Genome-wide association (GWA) summary statistics were obtained for BMI (N=681,275), waist-hip ratio (WHR; N=694,649), visceral adipose tissue (VAT; N=325,123), and the ratio of arm, leg, and trunk fat to total body fat (AFR, LFR, and TFR; N=362,499). GWA summary statistics for MS risk were available for 14,802 cases and 26,703 controls. GIVs for each phenotype were variants with associations that met genome-wide significance (p-8) in the respective studies. GIVs were linkage disequilibrium pruned (r^2**Results.** BMI and VAT were significantly associated with MS risk ($\hat{I}^2_{BMI}$=0.25, p_{BMI}VAT=0.24, p_{VAT}=0.043), and associations persist when removing pleiotropic GIVs ($\hat{I}^2_{BMI}$=0.25, p_{BMI}VAT=0.35, p_{VAT}BMI=0.19, p_{BMI}=0.007). However, VAT did not appear to be associated with MS Risk when accounting for BMI ($\hat{I}^2_{VAT}$=0.09, p_{VAT}=0.24). Mediation analysis did not demonstrate strong reciprocal mediating relationships between VAT and BMI in their relationships with MS risk.
Conclusions. Measures of obesity relate differently to MS risk, suggesting that various forms of body fat may play different roles in MS pathogenesis, and merits further investigation.

PrgmNr 3595 - Evaluation of genetic risk scores for incisional surgeries in primary open-angle glaucoma patients

Primary open-angle glaucoma (POAG) is a complex, degenerative eye disease for which early treatment intervention can mitigate severe visual impairment and blindness. To date, over 125 loci have been associated with POAG, but most of the variants from these loci have small effects and do not individually predict the need for certain POAG treatments. Rather than considering contributions of individual variants, the cumulative impact of these variants can be evaluated via a genetic risk score (GRS). To assess the clinical utility of a POAG GRS for predicting the need for invasive treatments, we tested a GRS based on 127 POAG risk variants from the literature in POAG patients enrolled in the Veterans Affairs (VA) Million Veteran Program (MVP), a large electronic health record (EHR)-linked biobank, who have and have not undergone incisional glaucoma surgeries. Unweighted and weighted GRS were calculated for 5,830 MVP POAG study participants with imputed genetic data and harmonized ancestry and race/ethnicity data, including 2,448 Black or African American (AA; cases=223) and 3,382 white or European American (EA; cases=222) Veterans. Weighted GRS calculations utilized effect estimates reported from published (i) cross-ancestry meta-analyses and (ii) ancestry-specific analyses. For our association analyses, MVP POAG patients with EHR codes for incisional glaucoma surgeries were sub-categorized into 3 case groups based on procedures they had: (1) trabeculectomy, (2) glaucoma drainage implants (GDI), or (3) both procedures. MVP POAG patients without any EHR codes for these procedures were considered controls. We performed association analyses of the weighted and unweighted 127-variant GRS with binary surgery phenotypes via logistic regression using unadjusted models as well as models adjusting for age, sex, and 5 sample-specific principal components. Receiver operating characteristic (ROC) curves were created for all models and statistically compared to evaluate GRS performance. In EA, weighted and unweighted GRS were both significantly associated with GDI. In AA, GRS weighted with ancestry-specific and cross-ancestry meta-analysis effect estimates were significantly associated with trabeculectomies. Ancestry-specific GRS were significantly associated in EA and AA who had undergone both trabeculectomies and GDI. For all three case groups, GRS using ancestry-specific weights outperformed the other GRS approaches we evaluated, suggesting that ancestry-specific GRS better classified patients requiring these invasive treatments. Future studies will aim to develop GRS to predict POAG risk stratification for any type of POAG treatment.

PrgmNr 3596 - Genetic Variation in Genes Associated with GERD in COPD

View session detail

Author Block: **A. Wilson**[1], P. Lakshman Kumar[2], M. Cho[3], B. D. Hobbs[4], H. Tiwari[1], G. Washko[5], S. Lutz[6], C. P. Hersh[7], E. Silverman[3], M-L. McDonald[1]; [1]Univ. of Alabama at Birmingham, Birmingham, AL, [2]Birmingham, AL, [3]Channing Div. of Network Med., Boston, MA, [4]Needham, MA, [5]Div. of Pulmonary and Critical Care Med., Boston, MA, [6]Dept. of Population Med., Boston, MA, [7]Canton, MA
Disclosure Block: **A. Wilson:** None.
Chronic Obstructive Pulmonary Disease (COPD) is one of the leading causes of death globally.Gastroesophageal reflux disease (GERD) is a prevalent (as high as 78%) comorbidity in COPD, and is associated with worse pulmonary symptoms, reduced quality of life, and increased exacerbations. We tested the hypothesis genetic variation is associated with GERD in COPD using a genome-wide association study (GWAS) approach utilizing the BioData Catalyst platform. Stratified, single variant analyses were performed using whole genome sequence data from TopMed in participants with COPD and GERD among African American (AA) (N= 822) and Non-Hispanic White (NHW) (N= 2,842) participants from the COPDGene Study. Significance was defined as p-8. In the NHW population, 6 variants were significantly associated with GERD in COPD. Two variants on chromosome 4 (4:187223386 and 4:187241021) are intergenic to the *AC108046.1* and *AC097652.1* novel transcripts which have been identified as RNA genes of the lncRNA class. Four variants on chromosome 2 (2:29893698, 2:29894085, 2:29896530, and 2:29894808) are intragenic to the *ALK* gene. *ALK*, ALK Receptor Tyrosine Kinase, encodes a receptor tyrosine kinase, which belongs to the insulin receptor superfamily. Among AA participants with COPD, several variants were significantly associated with GERD in COPD. The top variant associated with GERD in COPD was 1:5620209, which is intragenic to *AL365255.1. AL365255.1* is a novel transcript which has been found to be an RNA gene. Another variant significantly associated with GERD in COPD was 1:71792134, which was intragenic to the *NEGR1* gene. *NEGR1* encodes the neuronal growth regulator 1 protein, which is involved in cell adhesion. In conclusion, a number of significant single variants were identified in both NHW and AA populations, which warrant further exploration for their potential utility as biomarkers or therapeutic targets of GERD in COPD.

PrgmNr 3597 - Genome-wide survival analysis of dental caries incidence

View session detail

Author Block: **T. Zou**[1], K. Neiswanger[2], E. Feingold[1,3], B. Foxman[4], D. McNeil[5,6], M. L. Marazita[1,2], J. R. Shaffer[1,2]; [1]Dept. of Human Genetics, Graduate Sch. of Publ. Hlth., Univ. of Pittsburgh, Pittsburgh, PA, [4]Dept. of Epidemiology, Univ. of Michigan Med. Sch., Ann Arbor, MI, [5]Dept. of Psychology, Eberly Coll. of Arts and Sci., West Virginia Univ., Morgantown, WV, [6]Dept. of Dental Practice & Rural Hlth., Sch. of Dentistry, West Virginia Univ., Morgantown, WV
Disclosure Block: **T. Zou:** None.
Objectives: The incidence of dental caries can be influenced by multiple factors including behavioral, environmental and genetic components. The aim of this study was to use survival analysis to identify the potential risk factors and genetic variants associated with dental caries incidence in a birth cohort.**Methods:** The Center for Oral Health Research in Appalachia, cohort 2 (COHRA2) recruited and prospectively followed pregnant women and their children starting in 2011. A total of 909 children were included in this study; each was followed annually from birth with 7 years being the longest follow-up to date in this ongoing study. Annual intra-oral examinations were performed to assess dental caries experience, including the approximate time to first carious lesion. Cox hazards models were used to assess the associations of time to event with self- reported risk factors and 4.9 million genetic variants ascertained using a genome-wide SNP array.**Results:** A total of 196 children (21.56%) had their first primary tooth caries event during the follow-up period. The average survival time was 3.23 years. Household income, home water source, motherâ□□s educational attainment, motherâ□□s tooth brushing frequency, motherâ□□s dental caries experience, breastfeeding status, and breastfeeding duration were individually associated with dental caries hazard in univariate models, while only household income, home water source, and motherâ□□s educational attainment were significantly associated in the multivariate model of all potential risk factors simultaneously. The heritability (i.e., proportion of variance explained by genetics) of the time to event trait was 54.4% (PConclusions: Our findings indicate that household income, motherâ□□s educational attainment, and home water source may be independently-operating risk factors for dental caries incidence, and that the time to event of first carious lesion is heritable. We nominate several suggestive loci for further investigation.

PrgmNr 3598 - GWAS of self-report and imputed phenotypes capture distinct but complementary genetic architecture of stuttering

Developmental stuttering is a common speech disorder characterized by disruptions in the forward movements of speech. Aggregation of large clinically ascertained cases of developmental stuttering for genetic analysis is difficult as stuttering is not often treated in a hospital setting but dispersed through schools a private therapy clinics. Additionally, stuttering has a high rate of recovery in early childhood. These factors have resulted in limited population based-discovery of genetic risk factors for the disorder.To overcome recruitment challenges we assessed the genetic effects of two related phenotypes. First, we utilized a classification and regression tree model built using stuttering comorbidities as predictive features (PheML) to impute the stuttering phenotype in BioVU based on each subjectâ□□s phenotypic profile. Second, we utilized responses from a self-report questionnaire administered through 23andMe INC. Each method amassed a case set large enough to sufficiently power genome-wide association analyses with genome-wide significant signals. We utilized the summary statistics from each of these analyses to develop two separate polygenic risk score (PRS) models to measure genetic liability. Using an independent set of clinically confirmed stuttering cases and matched controls, we demonstrate that each model effectively measures stuttering liability. Confirmed stuttering cases scored significantly higher than matched controls for both the 23andMe PRS model ($p=5.81x10^{-28}$, AUC=0.61) and the PheML model ($p=6.83x10^{-39}$, AUC=0.60). However, the 23andMe model failed to show increased stuttering liability in our PheML stuttering sample set (p=0.08, AUC=0.49), indicating that these methods are capturing two distinct aspects of the overall phenotype.We developed a third PRS model that incorporated the summary statistics from both the 23andMe and PheML analyses, and outperformed each individual model. With this model, clinically validated stuttering cases showed significantly higher genetic liability for stuttering compared to controls ($p = 8.88x10^{-43}$), and the overall predictive ability of the model improved (AUC = 0.657 and AUC = 0.807 for subjects within the top and bottom 5% of liability scores).Using two models for developmental stuttering that capture distinct genetic signatures, we are able to build an integrated model that better predicts true developmental stuttering in the general population. The presence of multiple distinct genetic signatures within stuttering speaks to the polygenicity of this phenotype. By leveraging both signatures we are able to more completely capture true stuttering cases.

PrgmNr 3599 - Identification of Genetic Loci Associated with Cognitive Preservation in the Midwestern Amish

Understanding the biological underpinnings of cognitive preservation despite advanced age is of growing interest as the world population ages. However, most studies of older individuals have focused on diseases, such as Alzheimer disease (AD), instead of on the preservation of cognitive function. To fill this gap, we have initiated studies of older individuals in the Midwestern Amish from Ohio and Indiana, a population that is isolated both genetically and culturally, practicing a conservative lifestyle and endogamy. Studies of the Amish allow us to better control for many confounding variables, and therefore examine more directly for genetic effects. We obtained genomic data on over 900 individuals who are 76 years or older and are judged cognitively unimpaired based on 3MS and CERAD neuropsychological exams. To help inform our analyses, we included genotypes of siblings and parents who are cognitively impaired. With extensive genealogical records, we connected all individuals through a pedigree with over 8,000 individuals across 15 generations. To extract maximal information from this complex pedigree, both a genome-wide association study (GWAS) and linkage analyses are being performed. Two-point nonparametric linkage is underway across all chromosomes using sub-pedigrees generated from the all-connecting pedigree. Overlapping sets of sub-pedigrees have been created by breaking the larger pedigree at different branch points, and by setting the size of sub-pedigrees to different thresholds. Linkage analysis will be performed multiple times across multiple overlapping sets of sub-pedigrees to assess robustness of findings. Average LOD scores will be taken from areas of interest across the different sub-pedigree formations. Regions of suggestive or significant loci will be followed up with multipoint and parametric linkage analyses in these locations. Our preliminary GWAS was completed with the GENESIS R package and identified six suggestive loci (P-5) on chromosomes 5 (rs13177199), 7 (rs140733969), 11 (exm2250129), 13 (rs681938), 15 (rs1347455), and 16 (rs12596728). None of these SNPs fall within previously identified regions associated with risk for AD, but the suggestive SNPs on chromosomes 11 and 16 are near known AD risk genes PICALM and IQCK, respectively. The genomic inflation factor of the GWAS is 0.98, indicating that there is slight over adjustment to the data, most likely due to the high degree of relatedness in the samples.

PrgmNr 3600 - Investigating White Blood Cell Count and Platelet Biology as a Possible Driver of the Comorbidity Between Coronary Artery Disease and Major Depressive Disorder

View session detail

Author Block: **K. Singh**[1], D. E. Gustavson[2], L. K. Davis[3]; [1]Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Univ. Med. Ctr., Nashville, TN, [3]Vanderbilt Univ Med Ctr., Nashville, TN
Disclosure Block: **K. Singh:** None.
Background: Coronary Artery Disease (CAD) has a lifetime prevalence of 35% and is often comorbid with Major Depressive Disorder (MDD). Approximately 40% of people with either CAD or MDD will develop the other condition. Our previous work demonstrated that the polygenic risk score (PRS) for MDD was significantly associated with manifestations of CAD (OR, 1.10, p=1.08x10-5) in a large hospital population. We also identified elevated levels of inflammatory biomarkers including white blood cell and platelet counts in people with high genetic risk for MDD and CAD. Previous work also supports the role of inflammation in both CAD and MDD independently. Taken together, these studies indicate that genetic factors may predispose people to comorbid MDD with CAD, and that inflammation could be an important biological link between the conditions. Here, we have expanded this work to include both phenotypes and quantitative physiological measurements in a multivariate framework.Methods: Our research was conducted using BioVU. BioVU is Vanderbiltâ□□s collection of ~100,000 de-identified DNA samples from Vanderbilt hospitals. We employed LabWAS, a biomarker-based association method to identify labs associated with CAD and MDD comorbidity. We next performed multivariate and mediation analyses by applying Genomic Structural Equation Modeling (Genomic SEM) to the GWAS summary statistics for CAD, MDD, WBC count, and platelet count.Results: Using a Genomic SEM model, we found a single factor in which WBC count and platelet count explained 1% and 16% of the SNP-based genetic correlation between MDD and CAD, respectively. The mediation paths models using the summary statistics data show that WBC and platelets mediate approximately 1% and 13% of MDD-CAD comorbidity. Therefore, WBC and Platelets combined explain 14.4% of the total genetic correlation between MDD and CAD. Hence, these results suggest that genetically regulated WBC count and Platelet count may mediate the MDD-CAD comorbidity. Conclusions: Our findings provide further support for genetically regulated inflammation linking MDD and CAD, particularly WBC count and Platelet count. These results demonstrate that variance in comorbid MDD and CAD is, in part, controlled by genetic regulation of white blood cell and platelet count. We will also present results from current work including multivariate GWAS and expansion of these models to incorporate other inflammatory markers such as CRP, IL10RB and IL6.

PrgmNr 3601 - Joint intron splicing-based transcriptome-wide association study identifies new candidate susceptibility genes for breast cancer

View session detail

Author Block: **G. Gao**[1], P. Fiorica[1], A. N. Barbeira[2], J. McClellan[1], D. Huo[1], H. Im[2]; [1]Dept. of Publ. Hlth.Sci., Univ. of Chicago, Chicago, IL, [2]The Univ. of Chicago, Chicago, IL
Disclosure Block: **G. Gao:** None.

In this study, we proposed a joint intron splicing-based transcriptome-wide association study approach (IntronXcan) that combined information from multiple excised introns in a gene across multiple tissues. IntronXcan used splicing prediction models trained in 47 tissues in the GTEx (v8) data with a multivariate adaptive shrinkage (mash) method, which can jointly estimate effects of splicing quantitative trait loci (sQTLs) in multiple tissues, accounting for correlation among nonzero sQTL effects in different tissues. We applied IntronXcan to the GWAS summary statistics from the Breast Cancer Association Consortium (BCAC) of about 229,000 women of European ancestry. We identified 550 genes significantly (P -^{6}) associated with breast cancer. We replicated 75 of these 550 genes at significance level (P -^{5}) when applied IntronXcan to GWAS summary statistics from an independent dataset on breast cancer extracted from UK Biobank. To determine if these genes are independent of previously identified breast cancer loci, we performed a conditional and joint analysis (COJO) by conditioning summary statistics on previously published (risk) index SNPs within +/- 10 Mb of each significant gene. We then re-performed IntronXcan using the conditional summary statistics. Results showed that 31 of the 75 replicated genes were still significant. We treat these 31 genes as conditionally independent of known breast cancer GWAS loci. Of these 31 genes, 13 novel candidate susceptibility genes are located beyond 500kb from their nearest GWAS index SNP. We similarly performed gene expression-based joint TWAS (S-MultiXcan) that integrated predicted expression data from multiple tissues. We identified 311 genes significantly associated with breast cancer using BCAC summary statistics (P â□□6). Among them, 23 genes were replicated (P â□□5) in our S-MultiXcan analysis of the independent UKB dataset. Six of the 23 replicated genes remained significant after conditioning on previously identified index SNPs. We further performed a meta-analysis to combine BCAC and UKB GWAS summary statistics and then applied splicing-based IntronXcan and expression based S-MultiXcan to the meta-analysis summary statistics. We identified an additional 162 and 68 significant genes, respectively. Our analyses indicated that the splicing based IntronXcan could identify a greater number of significant genes than the gene expression-based S-MultiXcan and individual intron splicing-based TWAS.

PrgmNr 3602 - Overwhelming numbers of patients who carry pathogenic familial hypercholesterolemia variants are predicted to have low clinical risk in the UK Biobank

View session detail

Disclosure Block: **M.D. Osterman:** None.
Alzheimerâ□□s disease (AD) is the most prevalent type of dementia and is currently estimated to affect 5.8 million Americans. Risk for AD is multifactorial, including both genetic and environmental risk factors. Much of AD genomic research has focused on identifying risk variants, primarily in European ancestry populations. After immigration to the United States, the Amish experienced a genetic bottleneck, making it likely that their underlying genetic architecture is different from the broader European ancestry population. Here, we compare the genetic risk for Alzheimerâ□□s disease in an Amish population to a general European ancestry population using polygenic risk scores (PRSs). Our study population is comprised of 1,981 adults recruited from Amish communities in Indiana and Ohio. Subjects were screened for cognitive impairment and further evaluated for AD and dementia. Genotype data were collected using Illumina genotyping chips. Imputation was performed based on a Haplotype Reference Consortium Panel. A non-Amish population of 2,470 adults recruited from clinics in Tennessee, North Carolina, and Florida was used as a comparison group. PRSs were generated using effect estimates of variants from the Jansen et al. (2019) genome-wide meta-analysis of AD weighted by their log-odds ratios and excluding variants within 500 kilobases of APOE. We compared the PRSs by source population and case status, after exclusion of individuals under age 75. Further, we evaluated their predictive ability on AD status with and without sex, age, and APOE genotype covariates. As expected, the results indicated that there exists less variation in PRSs among the Amish population. After standardization of PRSs to a Normal(0,1) distribution, the mean PRS of AD affected Amish (0.040) was lower ($p = 5 Ã□ 10^{-4}$) than the mean PRS of the non-Amish cases (0.324). The mean PRS of the unaffected Amish (0.066) was higher (p -16) than the non-Amish controls (-0.458). The PRS was able to differentiate between non-Amish cases and controls (p -16) but not Amish affection status (p = 0.7). We found that addition of a PRS to an AD prediction model including sex, age, and APOE genotype did not improve area under the curve (AUC) in the Amish but improved AUC in the non-Amish population from 0.765 to 0.812. These results suggest that the Amish have a different genetic architecture than a general European-ancestry population, manifesting itself in less overall variation but also a lower relative importance of APOE. Because the prevalence of dementia in the Amish is similar to the general European population, this suggests that the Amish may harbor unique AD genetic risk variants.

PrgmNr 3604 - Prioritizing causal risk factors for severe COVID-19: an exhaustive Mendelian randomization study

View session detail

Author Block: **Y. Sun**[1], J. Zhou[1,2], K. Ye[3,4]; [1]Dept. of Genetics, Univ. of Georgia, Athens, GA, [2]Sch. of Publ. Hlth., Shanghai Jiao Tong Univ. Sch. of Med., Shanghai, China, [3]Univ. of Georgia, Athens, GA, [4]Inst. of Bioinformatics, Univ. of Georgia, Athens, GA
Disclosure Block: **Y. Sun:** None.
Identifying causal risk factors for severe coronavirus disease 2019 (COVID-19) is critical for its prevention and treatment. Many associated pre-existing conditions and biomarkers have been reported, but these observational associations suffer from confounding and reverse causation. Here, we perform a large-scale two-sample Mendelian randomization (MR) analysis to evaluate the causal roles of many traits in severe COVID-19. Our results highlight multiple body mass index (BMI)-related traits as risk-increasing: BMI (OR: 1.89, 95% CI: 1.51-2.37), hip circumference (OR: 1.46, 1.15-1.85), and waist circumference (OR: 1.82, 1.36-2.43). Our multivariable MR analysis further suggests that the BMI-related effect might be driven by fat mass (OR: 1.63, 1.03-2.58), but not fat-free mass (OR: 1.00, 0.61-1.66). Several white blood cell counts are negatively associated with severe COVID-19, including those of neutrophils (OR: 0.76, 0.61-0.94), granulocytes (OR: 0.75, 0.601-0.93), and myeloid white blood cells (OR: 0.77, 0.62-0.96). Furthermore, some circulating proteins are associated with an increased risk of (e.g., zinc-alpha-2-glycoprotein) or protection from severe COVID-19 (e.g., interleukin-3 receptor subunit alpha). Our study suggests that fat mass and white blood cells may underlie the etiology of severe COVID-19. It also prioritizes potential risk and protective factors that could serve as drug targets and guide the effective protection of high-risk individuals.

PrgmNr 3605 - Rare Variants in Non-coding Regulatory Regions and Non-syndromic Orofacial clefts

View session detail

Author Block: **A. Alade**[1], C. Comnick[1], W. Awotoye[1], E. Zeng[1], C. Pendleton[1], A. Visel[2], K. Paraiso[3], A. Oladayo[4], P. Mossey[5], L. Gowans[6], M. A. Eshete[7], W. Adeyemo[8], T. Naicker[9], C. Adeleke[1], A. Petrin[4], J. Olotu[10], M. Hassan[1], J. Pape[1], P. Donkor[11], T. Busch[1], M. L. Marazita[12], A. A. Adeyemo[13], J. C. Murray[14], A. Butali[15]; [1]Univ. of Iowa, Iowa, IA, [2]Lawrence Berkeley Natl Lab., Berkeley, CA, [3]Lawrence Berkeley Natl. Disclosure Block: **A. Alade:** None.

BACKGROUND Orofacial clefts are the most common congenital birth defects accounting for 65% of all head and neck deformities. To date, Genome Wide Association Studies (GWAS) have identified over 60 common risk loci for non-syndromic orofacial clefts (NSOFCs). Collectively, these loci only explain 20-30% of its heritability. Interestingly, a substantial number of these loci are in the non-coding regulatory regions of the genome. To explain the â□□missing heritabilityâ□□, we investigated putative craniofacial and ectodermal enhancer elements for rare variants with probable etiological implication in the pathogenesis of NSOFCs. **METHODS** We investigated a total of 3178 individuals; 1019 cases (394 had Cleft lip, 415 Cleft lip Â± palate, 205 Cleft palate only, and 5 unknown) and 2159 unrelated controls. Candidate craniofacial and ectodermal enhancer elements were identified from previous literatures and mouse models. A total of 58,449 regulatory regions were considered. Following filtration to include only regions with more than one rare (MAF RESULTS We found a suggestive significant association (p = 0.009, Bonferroni-corrected cut-off for statistical significance was p PRDM16 gene (Chr1:3148388-3149216) with all clefts combined. For the putative ectodermal enhancers, we found a near significant association (p = 3.83e-05 and p = 4.51e-05 respectively; Bonferroni-corrected cut-off for statistical significance was p CRK and *RREB1* genes (Chr17:1358515-1360443 and Chr6:7137252-7138277) with the cleft lip with or without palate phenotype. PRDM16 is a known cleft candidate gene and p300 ChIP-Seq data showed enhancer activity for this region, part of which overlaps with data from ATAC-Seq data in relevant craniofacial tissues. The RREB1 gene codes for a zinc finger transcription factor and deletion of the short arm of chromosome 6 involving this gene present with Craniofacial dysmorphism. *CRK*-knockout mice showed cleft palate phenotype. **CONCLUSION** Our findings suggest a role for rare variants within craniofacial enhancer regions in the complex etiology of NSOFCs.

PrgmNr 3606 - Sex-specific analyses in inflammatory bowel disease in African Americans reveal new loci on chromosomes 4, 5, 6, and 13

View session detail

Author Block: **C. L. Simpson**[1], D. P. McGovern[2], S. Kugathasan[3], T. Haritunians[4], S. R. Brant[5]; [1]Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN, [2]Los Angeles, CA, [3]Emory Univ Sch. of Med., Atlanta, GA, [4]Cedars Sinai Med. Ctr., Los Angeles, CA, [5]Rutgers Robert Wood Johnson Med. Sch., New Brunswick, NJ
Disclosure Block: **C.L. Simpson:** None.
Inflammatory bowel disease (IBD) is a leading cause of morbidity in the US and increasing in prevalence in all populations, including African Americans (AA). Most genetic loci have been identified in European populations, whereas other ethnicities have been underrepresented. IBD consists of 2 main subtypes, Crohnâ□□s Disease (CD) and Ulcerative Colitis (UC). CD is characterized by transmural inflammation and can affect any part of the gastrointestinal tract. UC is typically restricted to the mucosa and only affects the colon. The incidence and prevalence of IBD are different in men and women, with prepubertal girls at lower risk of CD, but post-puberty risk is higher in females. UC rates are similar in males and females under 45, with increased risk for men over 45. Here we present sex-specific and sex-interaction analyses of an AA IBD cohort. Genomewide SNP microarray data from 2345 AA cases of IBD (1646 CD, 583 UC, 116 unspecified IBD) and 5002 controls (derived from Health and Retirement Study and Kaiser Permanente cohorts) were used in sex-stratified, sex-adjusted, and sex-interaction multivariate logistic regression models. P values â□¤ $5x10^{-8}$ were considered genomewide significant (GWS). Integrating sex into the model showed novel GWS signals on 5q23.2 (rs73782531, P=$5.16x10^{-11}$, OR=0.077) and 6p23 (rs731187, P=$2.53x10^{-8}$,OR=0.67) for IBD, both in gene deserts. We found female-specific novel associations with UC on 4q21.21 (rs140502305, P=3.65 x 10^{-8}, OR=3.86), near PRKG2, which regulates intestinal secretion, and a signal on 13q32.1 (rs9584460, P=2.59 x 10^{-9}, OR=2.05) intronic to OXGR1 that interacts with leukotrienes associated with inflammation. A novel male-specific peak was GWS at 12q24.13 (rs3782429, P=2.24 x 10^{-8}, OR=5.69), intronic to RBM19, related to digestive system development in animal models. A significant peak in the HLA region of chromosome 6, long associated with UC, was more significant in males (rs9271737, P=$2.31x10^{-10}$, OR=0.41) than females was (rs9276518 P=$3x10^{-8}$, OR=1.77). In addition, a GWS signal on chromosome 9 intronic to TNC (rs115542730, P=$4.15x10^{-8}$, OR=1.92) was previously identified in our AA GWAS study and expression of which has been shown to be increased in IBD. No interaction effects were observed at the GWS level. Analysis of the X chromosome was also not GWS. Here we identify novel candidate genes in an AA population. Including sex in GWAS models and looking for sex-specific associations in traits with known sex bias can reveal new loci and provide evidence for asymmetric effect sizes in known loci. Further research is required to replicate our findings.

PrgmNr 3607 - The Smoking Independent Causal Effects of Alcohol and Socioeconomic Traits on Lung Cancer Development

View session detail

Author Block: **R. Pettit**[1], J. Byun[1], Y. Han[1], Q. T. Ostrom[2], K. M. Walsh[2], M. L. Bondy[3], R. Hung[4], J. D. McKay[5], C. I. Amos[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Duke Univ., Durham, NC, [3]Stanford, Stanford, CA, [4]Lunenfeld-Tanenbaum Res. Inst., Sinai Hlth.System, Toronto, ON, Canada, [5]Intl. Agency for Res. on Cancer - World Hlth.Organization, Lyon, France
Disclosure Block: **R. Pettit:** None.
Introduction: Lung cancer is heritable and multiple traits have been associated with increased lung cancer susceptibility. Mendelian Randomization (MR) is an epidemiological method to interrogate such associations, estimating causal trait effects using single nucleotide polymorphisms as genetic instruments. MR methods can estimate causal effects independent of secondary exposures, such as smoking, and avoids confounding or reverse causality biases. In our work, we set out to characterize smoking-dependent and independent causal effects of trait lung cancer relationships including â□□educational ascertainmentâ□□ and â□□alcohol useâ□□. **Methods:** To estimate the causal effects of alcohol use and educational ascertainment on lung cancer (LC) we employed univariate and multivariate two-stage mendelian randomization (MVMR) techniques utilizing genome-wide association study summary statistic data from the United Kingdom Biobank (UKBB) and the TRICL-OncoArray LC consortium. We tested several UKBB education and alcohol-related traits for causal effects on overall LC and its histological subtypes. We tested for trait - LC effect modulation via confounding or mediation from smoking-related traits, including smoking â□□age of initiationâ□□, â□□cigarettes per dayâ□□, and â□□smoking cessationâ□□. Using MR and MVMR effect estimation methods, including inverse variance weighting (IVW), weighted median, weighted mode, and mr-egger, we found that alcohol and educational ascertainment traits had direct causal effects on lung cancer development independent of smoking related traits. **Results:** Using the IVW MR method, having no higher education or â□□Qualifications: None of the aboveâ□□ in the UKBB had 5.94 times increased odds of overall lung cancer (95% CI 3.39, 10.39, $p = 4.49x10^{-10}$, 62 SNPs), while â□□Qualifications: College or University degreeâ□□ had a 0.31 decreased likelihood (95% CI 0.23, 0.42, $p = 1.40x10^{-13}$, 169 SNPs). Further, the trait â□□Average weekly beer plus cider intakeâ□□ had an OR of 3.48 (95% CI 2.15, 5.64, $p = 4.08x10^{-7}$, 19 SNPs) with overall lung cancer risk. â□□Alcohol usually taken with mealsâ□□ however had a OR 0.19 (95% CI 0.094, 0.36, $p = 1.06x10^{-6}$, 30 SNPs) with overall lung cancer risk. These trends were modified but remained despite MVMR contingent modeling with smoking-related traits. **Conclusion:** â□□Educational ascertainmentâ□□ and â□□alcohol useâ□□ traits had significant causal relationships with lung cancer development independent of smoking. Characterizing these trait relationships allows for actionable clinician-patient decision-making and positions these traits as candidates to be incorporated in future lung cancer polygenic risk scores.

PrgmNr 3608 - Todayâ□□s genetic risk scores for primary open-angle glaucoma underperform in African-descent participants from the Veteran Administrationâ□□s Million Veteran Program (MVP)

Disclosure Block: **L. Cruz:** None.

Genetic risk scores (GRS) for primary open-angle glaucoma (POAG) have strong clinical utility potential. While POAG GRS associate with case status, diagnosis age, and disease-specific outcomes in European-descent populations, data are limited for African-descent populations despite their higher POAG burden (earlier onset, higher prevalence, increased likelihood of vision loss/blindness). To assess the trans-population performance of POAG GRS based on currently published risk variants, we accessed the diverse Million Veteran Program (MVP), a U.S. Department of Veterans Affairs-sponsored observational cohort study and mega-biobank with electronic health (EHRs) and health survey data currently available for >825,000 Veterans; >450,000 have genome-wide data available. We applied a validated computable phenotyping algorithm to MVP participantsâ□□ EHRs and identified 3,382 and 2,448 POAG cases and 58,832 and 5,665 controls representing European- and African-descent participants, respectively. For each MVP participant, GRS were calculated by summing 127 GWAS-associated POAG risk alleles from the literature as of 2021. Association analyses of unweighted and effect estimate-weighted GRS and binary POAG phenotype were performed via logistic regression unadjusted and adjusted for age, sex, and 10 sample-specific principal components. GRS score deciles and quartiles were tested for association via logistic regression, and receiver operating characteristic (ROC) curves were composed and statistically compared. GRS were significantly associated with POAG in unadjusted and adjusted models at p

PrgmNr 3609 - Transcriptome-wide association studies identify genetic determinants of brain-imaging phenotypes

View session detail

Author Block: **X. Bledsoe**[1], A. Hale[2], D. Zhou[1], E. Gamazon[3]; [1]Vanderbilt Univ., Nashville, TN, [2]Nashville, TN, [3]VUMC Clare Hall, Univ. of Cambridge, Nashville, TN
Disclosure Block: **X. Bledsoe:** None.
Advances in neuroimaging have facilitated an increasingly sophisticated understanding of brain circuitry, morphology, and connectivity. However, genetic determinants of brain structure and function are largely unknown. To understand the genetic basis of these traits, we perform transcriptome-wide association studies (TWAS) using Joint Tissue Imputation (JTI)- PrediXcan for 3,144 neuroimaging-derived phenotypes (NIDP). The resulting associations represent genetically-regulated gene expression (GREx) and GWAS phenotypes. Due to variation in GREx across different tissues, we conducted our analyses using 17 tissue-expression models from GTEx which include 13 major brain regions as well as the adrenal gland, sigmoid colon, transverse colon, and whole blood. Using a strict Bonferroni study-wide significance threshold, we identified 2,359,962 tissue-GREx pairs across 3,144 NIDPs. For select traits, we provide systematic replication using two independent datasets (ENIGMA). The plurality of GREx-NIDP associations are specific to a single tissue model out of the 17 different models included in the analysis. Gene ontology (GO) analysis demonstrates an enrichment in DNA maintenance pathways for GREx genes that are associated with NIDPâ□□s across all measured tissues whereas enrichment in synapse-related pathways for the GREx-NIDP associations are only observed in a single tissue. GO pathways involved in GREx-NIDP associations unique to brain tissue favored cell-cell interactions while those involved in non-brain tissues favored signaling moieties such as hormones, steroids, and chemokine elements. We demonstrate the utility of the GREx-NIDP resource through application to large-scale GWAS meta-analyses of schizophrenia and epilepsy.

PrgmNr 3611 - Utilizing PrediXcan to detect Crohn's disease susceptibility genes in African Americans

View session detail

Author Block: **R. Y. Cordero**[1], S. Kugathasan[2], D. P. McGovern[3], S. R. Brant[4], C. L. Simpson[1]; [1]Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN, [2]Emory Univ Sch. of Med., Atlanta, GA, [3]Los Angeles, CA, [4]Rutgers Robert Wood Johnson Med. Sch., New Brunswick, NJ
Disclosure Block: **R.Y. Cordero:** None.
Multiple genetic risk loci associated with inflammatory bowel disease (IBD) have been identified through genome-wide association studies (GWAS). However, very large sample sizes are essential in GWAS to increase statistical power to detect disease-related loci. The power to detect IBD loci in African Americans (AA) and ultimately identify risk genes has been limited by modest sample sizes. To overcome this challenge, gene-based association methods such as PrediXcan were developed to detect the relationship between genes and traits to reduce the multiple testing burden. We utilized PrediXcan to integrate expression quantitative trait loci (eQTL) from the Genotype-Tissue Expression (GTEx) study and IBD GWAS summary statistics using independent case-control datasets, totaling 843 Crohnâ□□s disease (CD) cases and 1678 controls from unrelated, self-identified AA individuals. An elastic net model in whole blood, transverse colon, small intestine, adipose tissue were used as part of our transcriptome imputation. Our initial results reveal 48 significant associations with CD, with the strongest association coming from *SPDYE6* (p, $4.63x10^{-8}$). Other top associations include *OIT3, BIVM, AC245041.1, HROB, CSNK1G1, ZNF488, RASA4, FAHD2B, LOC102724488,* and *TMEM106A.* We found significant gene associations (*C15orf61, FBXW8, FAM219B, CYP1A1, PARG, ASAH2, SCAMP2, MPI, RPP25, WARS2, KNOP1,* and *PPCDC*) in regions in our AA CD published GWAS (Brant, Simpson, Okou, et al, 2017). Four other loci (*DHX58, MAP3K8, IFI35,* and *RPS6KL1*) were within a megabase of established European loci. Here, we demonstrate how gene-based methods, informed by other â□□omics data, can improve our ability to detect known and novel genes associated with CD in AA.

PrgmNr 3612 - A Translocation t(12;22) in Myxoid/Round Cell Liposarcoma

View session detail

Author Block: **V. Chia**[1], M. Zaki[2], W. Su[1], R. Tang[1], M. Guardiola[3], K. Eastwood[3], C. A. Tirado[4]; [1]UCLA, Los Angeles, CA, [2]Rancho Cucamonga, CA, [3]Baylor Scott & White, Temple, TX, [4]Baylor Scott & White Hlth.System- Temple, Temple, TX
Disclosure Block: **V. Chia:** None.
Myxoid/Round Cell Liposarcoma (MRCL) is characterized as a soft tissue sarcoma that is associated with unusual patterns of metastasis to extrapulmonary sites, such as bones and other soft tissue sites. Here, we present a case of a 48-year-old male patient, diagnosed with MRCL in March 2020. The patient presented with a grade 1 myxoid liposarcoma in his left leg. DNA FISH analysis showed variant rearrangements of the *EWSR1* (22q12) gene and loss of the 5â□□ *DDIT3* (*CHOP* 12q13) gene. The variant rearrangement showed one or two fusions with multiple separated (rearranged) signals. The *DDIT-EWSR1* rearrangement has been reported in MRCL. The variant rearrangements of the *EWSR1* (22q12) gene findings correlate with concurrent conventional cytogenetic findings and were described as nuc ish(EWSR1x2)(5'EWSR1 sep 3'EWSR1x1)[128/100],(5'EWSR1,3'EWSR1)x1~3(5'EWSR1 con 3'EWSR1x1~2)[57/100]. The variant rearrangements of the DDIT3 (CHOP 12q13) gene findings were described as nuc ish(5'DDIT3x1,3'DDIT3x2)(5'DDIT3 con 3'DDIT3x1)[195/200]. Molecular cytogenetic studies also showed a rearrangement of *EWSR1* (22q12) in 64% of nuclei and variant rearrangement in 31.5% of nuclei. A loss of *DDIT3*â□□s (12q13) 5â□□ signal was found in 97.5% interphase nuclei. Molecular pathology results indicated the patient was positive for *EWSR1* (exon 7) and *DDIT3* (exon 2) fusion. The patient underwent radiation therapy pre-resection of the myxoid liposarcoma. The most common form of MRCL is associated with t(12;16)(q13;p11), leading to *FUS-CHOP* and EWS-CHOP fusion proteins acting as aberrant transcription factors. The key element here is that this *DDIT-EWSR1* rearrangement led to a translocation t(12;22)(q13;q12) which is a rare cytogenetic event that led to the development of MRCL in this patient.

PrgmNr 3613 - Amplification of *CCND1* in Invasive High Grade Urothelial Carcinoma

Author Block: **A. T. Reyes**[1], Y. Lin[1], M. Solanki[1], M. Guardiola[2], K. Eastwood[2], A. Cheng[1], C. A. Tirado[3]; [1]UCLA, Los Angeles, CA, [2]Baylor Scott & White, Temple, TX, [3]Baylor Scott & White Hlth.System-Temple, Temple, TX

Disclosure Block: **A.T. Reyes:** None.

Urothelial carcinomas (UC) are the most common form of bladder cancer, resulting from the transformation and excessive proliferation of urothelial cells. Herein, we report the case of ab 82 year old female patient diagnosed with high grade urothelial carcinoma (HGUC). She also presented a liver tumor. Tissue biopsy of a liver mass revealed a poorly-differentiated carcinoma with partial glandular differentiation and regions of a more solid component. Tumor cells were positive for CK7 and MOC31, while negative for CK20, GATA3, TTF1, CDX2, p63, PAX8, HepPar-1, Arginase-1, glypican, and mammaglobin, by immunohistochemical staining. DNA FISH analysis was performed on cells derived from a bladder tumor using the CCND1 (11q13) break apart probe, and the results were described as nuc ish(CCND1 amp)[50], indicating amplification but no rearrangement of *CCND1*. *CCND1* amplification is seen in ~10% of all bladder cancer patients and an independent risk factor of metastasizing cancer. Clinical correlation was indicated.

PrgmNr 3614 - Amplification of *NMYC* in Neuroblastoma

View session detail

Author Block: **S. Bottomley**[1,2], G. E. Yang*[1,2], K. Phan[1,2], A. Lozada[1,2], K. Eastwood[3], M. Guardiola[3], C. A. Tirado[3,2]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]Intl. Circle of Genetics Studies, Los Angeles, CA, [3]Baylor Scott & White Hlth., Dept. of Pathology, Temple, TX
Disclosure Block: **S. Bottomley:** None.
We present a case study of a 20-month old female with a history of poorly differentiated neuroblastoma. Chromosomal analysis of the bone marrow revealed an abnormal karyotype including loss of chromosome 10, additional material of unknown origin on 2p, an interstitial deletion of 14q, a derivative chromosome 1 resulting from an unbalanced translocation involving 1p and 17q; and 50~150 double minute chromosomes in 11 of the 20 metaphase cells examined. This was characterized as 45,XX,der(1)t(1;17)(p13;q11.2),add(2)(p13),-10,del(14)(q24q31),50~150dmin[5]/44,sl,-X,add(3)(p21)[6]/46,XX[9]. DNA FISH analysis revealed amplification of the *MYCN* gene on 2p24.3 in all 50 of the examined nuclei. Increased expression of the *MYCN* oncogene is particularly common in neuroblastoma, as it characterizes approximately 20% of all cases. Expression often increases with tumor progression and is associated with an aggressive disease course and a poor prognosis. Despite advances in our knowledge of how the oncogene contributes to tumor development, it remains extremely difficult to treat directly. More research is necessary to identify feasible targets along the *MYCN* pathway to treat high risk neuroblastoma subtypes.

PrgmNr 3615 - An amplification of *EGFR (*7p12) in a patient with Glioblastoma

View session detail

Author Block: **E. Peng**[1], J. Yee[2], C. Tran[1], J. Glasser[3], K. Eastwood[4], M. Guardiola[4], C. A. Tirado[5]; [1]Univ. of California, Los Angeles, Fullerton, CA, [2]UCLA, IRVINE, CA, [3]The Intl. Circle of Genetic Studies, Fullerton, CA, [4]Baylor Scott & White, Temple, TX, [5]Baylor Scott & White Hlth.System- Temple, Temple, TX

Disclosure Block: **E. Peng:** None.

Glioblastoma Multiforme (GBM) is the most malignant and frequently occurring primary brain tumor out of all of the different types of primary astrocytomas. It presents with an extremely poor prognosis, with a median survival of 14 to 15 months from the diagnosis. Herein, we present an 83-year-old female patient with a right frontal brain mass. A craniotomy for the frontal brain mass was performed, which revealed a tumor with high-grade glioma, necrosis, atypia, and vascular proliferation. The patient was subsequently diagnosed with Glioblastoma Multiforme Grade IV (GBM). Molecular cytogenetic studies showed an amplification of the EGFR gene in 100% nuclei scored. These findings were described as: nuc ish(EGFR amp)[50/50],(MEGF6,TP73,ANGPTL1,ABL2,MAN2B1,ZNF44,GLTSCR1,GLTSCR2,CRX)x2[100]. Amplification of EGFR appears in 40-50% of individuals with Glioblastoma Multiforme Grade IV. Interestingly, although chromosomal deletions involving 1p36 and 19q13 are characteristic molecular features of solid tumors such as oligodendrocytes and mixed oligoastrocytomas, there was no evidence of a deletion of 1p36 or 9q13. Clinicopathologic correlation of these results was recommended.

PrgmNr 3616 - An automated classification system for copy number variants based on 2019 ACMG guidelines

View session detail

Author Block: **J. Ji**[1], R. Schmidt[1], W. Sherman[2], R. Peralta[2], M. Roytman[2], S. Shams[2], G. Raca[1]; [1]Children's Hosp. Los Angeles, Univ. of Southern California, Los Angeles, CA, [2]BioDiscovery Inc., El Segundo, CA

Disclosure Block: **J. Ji:** None.

Introduction: The ACMG, in collaboration with ClinGen, developed and published updated technical guidelines for interpretation and reporting of constitutional copy number variants. The updated guidelines were influenced by the ACMG guidelines for interpretation of sequence variants with a detailed algorithmic approach that looks at various sources of evidence in favor of a variant being pathogenic or benign with each evidence having a numerical weight that is added together to arrive at a final interpretation. Although the guideline is useful in arriving at a consistent classification, manually performing the review for every variant can be prohibitively time consuming. We have evaluated the utility of a software tool that automatically calculates the score for many of the evidence categories described by the guidelines to assess in improvement in review time and consistency in classification. The system provides the case reviewer flexibility to add additional evidence score(s) and modify the scores for each evidence category using professional expertise to arrive at a final interpretation. Methods: We compare both the quality and efficiency of using this system along with the guidelines versus manual classification without the guidelines. This analysis will be performed using 100 constitutional samples that had been previously reviewed and reported before the release of the guidelines. We compare the classification of these samples using the guidelines in the automated manner with manual adjustment and measure the rate of concordance and analyze the differences. We also measure the amount of time required to perform the interpretation using the semi-automated system following the guidelines to the manual approach without the guidelines and present the results. Results: Preliminary data demonstrated concordant results between automated and manual review for 9/10 cases. In addition, it took approximately 5 minutes to evaluate a case with the automated pre-classification system, which was generally faster than that with manual review alone. One case was classified as pathogenic manually but as a variant of uncertain clinical significance by automated system using the new ACMG guidelines requiring further investigation. Conclusions: Automated system for classification of copy number variants can facilitate systematic persistence of points assigned based on the evidence available for each variant. The system then tallies the points to help arrive at preliminary CNV classification. This automated system is quantitative, evidence-based, efficient, and may potentially minimize variability among the reviewers in the clinical diagnostic setting.

Complex tissues such as tumors are comprised of multiple cells types and extracellular matrix. Understanding the composition of immune cells in the tumor microenvironment (TME) can guide therapeutic intervention and predict treatment response. Thorough understanding of tissue dynamics and immune cell characterization requires a multi-omics approach. Simultaneous detection of RNA and protein using in situ hybridization (ISH) and immunohistochemistry/immunofluorescence (IHC/IF) can reveal cellular sources of secreted proteins, identify specific cell types, and visualize the spatial organization of cells within the tissue. However, a sequential workflow of ISH followed by IHC/IF frequently yields suboptimal protein detection because the protease digestion step in the ISH protocol. Here we demonstrate a newly developed integrated ISH/IHC workflow that can substantially improve RNA-protein co-detection to visualize tumor immune infiltrates at single-cell resolution with spatial context. To characterize tumor-infiltrating immune cells in a tumor TMA (tumor microarray), we utilized the RNAscope Multiplex Fluorescence assay in combination with the RNA-Protein Co-detection Kit to detect multiple immune cell populations. Immune cells such as macrophages, T cells and NK cells were detected using specific antibodies against CD68, CD8, CD4 and CD56, respectively. Precise characterization of these immune cells was achieved by using probes against targets such as *CCL5*, *IFNG*, *GNZB*, *IL-12*, *NCR1* etc. that not only help in identifying specific immune cells but also assist in determining their activation states. We identified subsets of T cells such as CD4+ regulatory T cells and CD8+ cytotoxic T lymphocytes. Additionally, we were able to determine the activation states of CD8+ T cells by visualizing the expression of *IFNG* and *GZMB.* Furthermore, infiltrating macrophages were identified by detecting the CD68 protein expression while the M1 and M2 subsets were differentiated by detecting the M2-specific target RNA for *CD163.* Similarly, NK cells were identified by detecting CD56 protein in combination with *CCL5* and *NCR1* RNA expression. Interestingly, the degree of infiltration of the different immune cell populations varied based on the tumor type. In conclusion, the new RNAscope-ISH-IHC co-detection workflow and reagents enable optimized simultaneous visualization of RNA and protein targets by enhancing the compatibility of antibodies - including many previously incompatible antibodies - with RNAscope . This new workflow provides a powerful new approach to identifying and characterizing tumor infiltrating populations of immune cells.

PrgmNr 3618 - Monosomy 21, a rare finding in an elder patient with non-CLL-like monoclonal B-cell lymphocytosis

View session detail

Author Block: **W. Yeh**[1], D. Mrugala[2], L. Nabipur[1], H. Robinson[1], A. Zhao[1], K. Eastwood[3], M. Guardiola[3], C. A. Tirado[4]; [1]UCLA, Los Angeles, CA, [2]Texas A&M Coll. of Med., Houston, TX, [3]Baylor Scott & White, Temple, TX, [4]Baylor Scott & White Hlth.System, Temple, TX

Disclosure Block: **W. Yeh:** None.

Monoclonal B-cell lymphocytosis (MBL) can be classified as either CLL-like MBL, atypical MBL, or non-CLL-like MBL. Non-CLL-like MBL, which makes up less than 20% of MBL cases, is rare and not well characterized. However, an association with splenic marginal zone lymphoma (SMZL) has been suggested. Aberrations such as isochromosome 17q resulting in the loss of p53 and 7q abnormalities have previously been reported. Here we report a case of an 85-year-old man presenting with non-CLL-like MBL. Immunophenotyping revealed a small lambda-restricted B lymphoid population which tested positive for CD19 and CD20, while CD5 tested negative. Patient karyotype showed the presence of monosomy 21 unaccompanied by additional chromosomal changes in 3 of the 35 cells examined. Monosomy 21 as a sole abnormality has rarely been documented in non-CLL-like MBL, which already lacks established cytogenetic features. The significance of this finding remains unknown.

Disclosure Block: **L. Amendola:** None.
Access to cancer genetic testing and services is inequitable. The CHARM study evaluated a multimodal intervention to address healthcare disparities in cancer genetics. Patients from clinics that serve populations with access barriers, who screened at risk for a hereditary cancer syndrome via online, literacy- and culturally-adapted cancer history collection tools (B-RST™ 3.0, PREMM$_5$™), or with limited family history information, were offered exome-based panel testing for cancer risk and medically actionable secondary findings. We used descriptive statistics, electronic health record review, and inferential statistics to explore participant characteristics and findings, healthcare consultations and actions related to P/LP variants disclosed, and variables predicting category of findings, respectively. Of 967 participants consented for genetic testing and sent a saliva collection kit, 841 (87%) returned their kit to the lab. Overall, 40 (5%) participants had a P/LP cancer risk variant, including 10 in *BRCA1/2* and 7 in Lynch syndrome genes; 9 (1%) had a medically actionable secondary finding. For 11/34 (32%) participants disclosed a P/LP cancer risk finding, the variant was previously known in the participant (N=7) and/or their family (N=4). Of 42 participants disclosed any P/LP variant, 16 (38%) were returned after March 1st 2020, when healthcare access limitations due to COVID-19 began. Recommended consultations with medical genetics and other providers were completed for 9/32 and 14/15 participants, respectively, after an average of 17 months post disclosure. Recommended actions (ex. breast MRI) were completed by 17/25 participants. Participant history of breast, ovarian, colon and/or endometrial cancer and score on the PREMM$_5$™ tool were each associated with category of findings (history and colon cancer risk CramÃ©r's V=.11, Fisher's exact=.02; history and breast cancer risk CramÃ©r's V=.13, Fisher's exact=.01; PREMM$_5$™ and colon cancer risk CramÃ©r's V=0.22, Fisher's exact<.001 the charm study approach provided an accessible delivery model for hereditary cancer risk assessment and genetic testing. rate of p variants in genes identified this population informs expectations guidelines results disclosure overlapped with covid-19 related care restrictions however interventions to increase adherence finding recommendations are likely still necessary. adapting provider-facing family history collection tools into patient-facing electronic applications can help identify patients at increased cancer.>

PrgmNr 3621 - Patients with Birt-Hogg-DubÃ© syndrome and papillary renal cell carcinoma reveal a rare intragenic deletion in *FLCN*

View session detail

Author Block: **M. Evans**[1], A. Sisk[2], S. Liu[2], B. Shuch[2], F. Quintero-Rivera[3]; [1]The Univ. of Texas M.D. Anderson Cancer Ctr., Houston, TX, [2]Univ. of California, Los Angeles, CA, [3]Univ. of California, Irvine, CA
Disclosure Block: **M. Evans:** None.
Birt-Hogg-DubÃ© syndrome (BHDS) is an inherited, autosomal dominant, multisystem disorder involving the *FLCN* gene on chromosome 17p11.2. *FLCN* encodes a tumor suppressor protein that regulates the mTOR pathway, and genetic alterations lead to multiple cutaneous, pulmonary, and renal findings with high penetrance and variable expressivity. We describe two unrelated patients with BHDS who developed a renal cell carcinoma (RCC) papillary subtype which is not typically associated with this syndrome, leading to detection of a rare *FLCN* intragenic deletion. A 52-year-old man and a 78-year-old man presented with abdominal and flank pain that they had experienced for up to one year. Both individuals were shown to have multiple pulmonary cysts on imaging, as well as flesh-colored to white papules on the face and neck that were consistent with fibrofolliculomas on biopsy. Moreover, the patients were found to have unilateral kidney tumors, with the younger individual having evidence of lymphadenopathy, inferior vena cava invasion, and pulmonary metastasis. Both patients had surgical resection demonstrating papillary RCC. The overall constellation of findings in these individuals was highly suggestive of BHDS, and genetic testing revealed a p.Lys508del (c.1522_1524delAAG) in-frame deletion in *FLCN* (NM_144997.5). The detected alteration in *FLCN* has been previously reported in only one family of patients with a BHDS phenotype. A functional study has demonstrated that the *FLCN* in-frame deletion p.Lys508del results in a truncated folliculin protein with significantly decreased stability. Moreover, among the more than 55 tumors presented in a retrospective survey of BHDS patients, only one case of papillary RCC was documented. Information regarding the prognosis or behavior of this tumor subtype in BHDS is unavailable; unfortunately, the younger of our two patients passed away from his cancer. Whether p.Lys508del in BHDS is associated with the papillary variant of RCC remains unknown and warrants further investigation.

PrgmNr 3622 - Rapid whole genome sequencing (rWGS) on a novel digital microfluidic system: â□□on demandâ□□ personal automation for diagnosis of critically ill infants

View session detail

Author Block: **Y. Ding**[1], K. Cunningham[2], J. Yoo[2], S. Batalov[1], A. Johnson[1], E. Cervantes[2], A. Barner[2], A. E. Carvajal[2], L. Cheng-Chang[2], S. Margeridon[2], M. Jebrail[2], W. Benson[1], F. Christodoulou[2], S. Kingsmore[1]; [1]Rady Children's Inst. for Genomic Med., San Diego, CA, [2]Miroculus, San Francisco, CA
Disclosure Block: **Y. Ding:** None.
Genetic disorders and congenital anomalies are a leading cause of morbidity and mortality in infants, affecting ~2% of live births in the United States. There is now strong evidence that rapid, clinical Whole Genome Sequencing (rWGS) at presentation of critically ill infants enables precision medicine interventions for many of these genetic diseases that improves outcomes and reduces cost of care. There is now a need to scale rWGS for national adoption. However, manual rWGS library preparation is laborious and lengthy that cannot be delayed for sample batching, and that could benefit from a system that consistently generates high quality DNA libraries for rWGS with minimal manual effort. Here, we report a novel solution: digital microfluidic (DMF)-based system, Miro Canvas. Inter-sample contamination is prevented by constructing libraries within a single-use, electronics-free cartridge. Miro Canvas utilizes electromechanical forces to move, merge, mix and dispense microliter-volume fluids across a surface of patterned electrodes in an automated fashion. We automated 2 PCR-free rWGS library preparation protocols using Miro Canvas (Miro PCR-free WGS libraries with mechanical fragmentation and Illumina DNA PCR-free Prep Kit with tagmentation) and compared quality with standard manual and high-throughput liquid handler-based methods. The input was 500 ng purified genomic DNA samples from reference materials (Coriell Repository NA12878) or patient samples with research consent at the Rady Childrenâ□□s Institute for Genomic Medicine. Library quality was assessed by qPCR or ssDNA Qubit and WGS was performed using NovaSeq6000 systems. Library yield, insert size, and gene coverage was comparable to that of standard methods. In conclusion, a DMF-based system generated high-quality rWGS libraries with minimal manual effort. For singleton, duo, and trio samples from critically ill children, this system provides a novel solution for automated library preparation when waiting for centralized or batched sample processing is not a viable option.

PrgmNr 3623 - Simplified and robust library construction for high-throughput HiFi sequencing for human variant detection

View session detail

Author Block: **H. Dhillon**; Pacific BioSci.s, Menlo Park, CA
Disclosure Block: **H. Dhillon:** Salary/Employment; Pacific Biosciences.
HiFi sequencing is proving to increase understanding of undiagnosed groups in rare and inherited disease research. Laboratories worldwide are adopting HiFi reads due to high accuracy (>Q30) and long read lengths (up to 25 kb) making it ideal for the accurate detection of single nucleotide variants and large structural variants. However, the quantity of DNA available for a cohort can place constraints on a given study especially when the source of the sample is already deceased or access to additional DNA is not possible. In this study, we will address this common problem by providing an alternate workflow such that DNA quantities as low as 0.9 Âµg can be sequenced to generate >10-fold coverage of HiFi data.Currently, standard library preparation protocols for successful HiFi sequencing require 5 Âµg of high-quality, high-molecular weight human genomic DNA (gDNA). Size-selection using traditional gel-based system is recommended to achieve highly accurate long reads with subread lengths between 15 kb -18 kb. Using this approach, post-size selection recovery yield is often low (10%) making it impossible to generate sufficient library from 24 GB of HiFi reads per SMRT Cell 8M run on the Sequel II System. The mean HiFi read lengths were ~16 kb with a median read quality of Q35. Furthermore, a bead-based method enables improvements to automation so that HiFi library construction steps from shearing DNA to size-selection can be fully automated enabling the preparation of up to 96 samples in parallel. In summary, we have developed a simple and fast workflow for generating high-quality HiFi reads on the Sequel II System for human variant detection using challenging real-world samples with limited DNA amount.

PrgmNr 3624 - Utilizing Somatic Tumor Profiling To Identify Candidate Patients For Germline Genetic Testing In A Community Setting Reveals Barriers To Referral To Genetic Counseling

View session detail

Author Block: **S. Darabi**[1], J. Homer[1], C. Weatherill[1], V. Dalili-Shoaie[1], M. Demeure[1,2], D. Braxton[1]; [1]Hoag Family Cancer Inst., Newport Beach, CA, [2]Translational Genomics Res. Inst., Phoenix, AZ
Disclosure Block: **S. Darabi:** Consultant/Consulting Fees/Other Remuneration; oncolense, Bayer.
Background: Between 5 and 10 percent of patients with cancer have an inherited predisposition to cancer. Some patients who harbor pathogenic or likely pathogenic germline variants would not meet current clinical testing guidelines for genetic testing. The use of somatic mutational profiling has increased and has become the standard of care for many cancers, but most somatic profiling tests do not include paired germline testing. The presence of a suspected germline mutation in a cancer predisposition gene requires confirmatory germline testing. We screened somatic molecular profiling results for suspected germline genetic variants in an effort to increase the detection of inherited cancer predisposition gene mutations. **Methods:** We classified potential germline mutations into 3 tiers based on the likelihood of pathogenicity. Per our routine practice of medicine, all somatic sequencing panel results were reviewed based on the IRB-approved protocol for our designated Tier one genes (*ATM, BAP1, BMPR1A, BRCA1, BRCA2, BRIP1, MSH2, MSH6, MUTYH, MYH11, PALB2, RUNX1, SDHAF2, SDHB, SDHC,* and known founder mutations in additional genes). Treating physicians for eligible patients were contacted, and if they agreed, then the patients were offered participation in this study. Enrolled patients had genetic counseling and genetic testing for a multi-gene panel at no cost to the patient. **Results:** We screened 1,781 cases, and 167 patients were eligible for the study. In all, 13 patients were enrolled, but only 11 completed testing. Of these, 6 had germline mutations (54.5%) confirmed, 3 had a variant of uncertain significance (27.3%), and 2 had negative testing (18.2%). Some patients were not referred by their treating physicians based on their own assessment. Others were hesitant to enroll due to concern about the privacy of genetic information. Other confounding factors may affect our accrual, including the COVID-19 pandemic. **Conclusion:** Implementation of a somatic profiling-based screening program to identify inherited cancer predisposition syndromes is feasible; however, there are barriers to genetic counseling and testing. Our study showed only 6.6% of eligible patients underwent genetic counseling and testing even when funding removed cost as a barrier. Other barriers need to be overcome to increase the utilization of genetic counseling.

PrgmNr 3625 - Verification of an *EZH2* mutation test from formalin-fixed paraffin-embedded (FFPE) follicular lymphoma tumor tissue specimens

View session detail

Author Block: **S. Rosenthal**, A. Le, J. Yo, C. Ma, D. Sugganth, F. Lacbawan; Quest Diagnostics, San Juan Capistrano, CA
Disclosure Block: **S. Rosenthal:** None.
Background: Follicular lymphoma (FL) is the second most common non-Hodgkin lymphoma among adults in developed countries. *EZH2* mutations occur in more than 25% of FL patients, and different types of EZH2 methyltransferase inhibitors have been developed. Screening *EZH2* mutations to help select patients suitable for EZH2-target therapy is important in personalized precision therapy. This study evaluates the performance characteristics of an FDA-approved *EZH2* mutation test in a clinical setting to aid management of patients with FL eligible for treatment with tazemetostat, an inhibitor of EZH2. **Methods**: A total of 13 unique positive and 8 unique negative samples were analyzed for a total of 43 and 34 trials, respectively, by the Roche cobas *EZH2* mutation test. The cobas *EZH2* test is an FDA-approved, real-time allele-specific PCR test for qualitative detection of single-nucleotide mutations for *EZH2* (Y646N/F/H/S/C, A682G, and A692V) in DNA extracted from formalin-fixed paraffin-embedded (FFPE) human FL tumor tissue specimens. Sample pass rate, inter- and intra-assay precision, and accuracy were analyzed. For the accuracy study, results were compared to the expected mutation calls by a validated next-generation sequencing (NGS) method. **Results**: All 77 samples from 21 unique FFPE specimens were successfully analyzed by 2 different scientists in 4 independent set-ups. Variant calls were 100% concordant among intra- and inter-assay replicates for all positive and negative samples. Positive percent agreement was 100% (95% CI: 91.8%-100%), and negative percent agreement was 100% (95% CI: 90.0%-100%) in comparison to NGS result. **Conclusion**: The cobas *EZH2* mutation test demonstrated a robust and reliable assay performance for the detection of the targeted *EZH2* mutations in patients with FL in a clinical setting.

PrgmNr 3626 - A large genome-wide association study for melanoma-specific survival reveals two novel loci linked to *PSEN2,* and *ADCK3* genes

View session detail

Author Block: **M. Seviiri**[1,2], R. A. Scolyer[3,4,5], J. F. Thompson[3,5,6], G. V. Long[3,7,5], S. Macgregor[8,2], M. H. Law[8,2]; [1]Statistical Genetics, QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [2]Sch. of BioMed. Sci., Faculty of Hlth., and Ctr. for Genomics and Personalised Hlth., Queensland Univ. of Technology, Brisbane, Australia, [3]Melanoma Inst. Australia, The Univ. of Sydney, Sydney, Australia, [4]Tissue Pathology and Diagnostic Oncology, Royal Prince Alfred Hosp. and NSW Hlth.Pathology, Australia, Sydney, Australia, [5]Faculty of Med. and Hlth., The Univ. of Sydney, Sydney, Australia, [6]Dept. of Melanoma and Surgical Oncology, Royal Prince Alfred Hosp., Camperdown, Australia, [7]Dept. of Med. Oncology, Royal North Shore Hosp., Sydney, Australia, [8]QIMR Berghofer Med. Res. Inst., Brisbane, Australia

Disclosure Block: **M. Seviiri:** None.

Background: Melanoma is the deadliest skin cancer. Important prognostic factors include age, site of the primary tumour, primary tumour thickness, primary tumour ulceration, mitotic rate, and the stage of the tumour. The role or relative importance of germline genetic variation in melanoma survival is poorly understood. Objective: To identify germline genetic variants that influence melanoma-specific survival (MSS). Methods: First, we conducted two genome-wide association studies (GWAS) of melanoma-specific survival (MSS) in the Melanoma Institute Australia cohort (MIA; 5,762 patients with melanoma and 800 melanoma-specific deaths) and in the UK Biobank (5,220 melanoma patients and 241 melanoma-specific deaths) cohort. Using Cox proportional-hazard modelling, hazard ratios (HR) were computed adjusting for age, sex and the first ten ancestral principal components. Next, we conducted a GWAS-meta-analysis (N=10,982 including 1,041 melanoma-specific deaths) using a fixed-effects inverse-variance weighted model. Results: Two independent genome-wide significant (P-8) loci for MSS with lead SNPs rs41309643/G (HR=2.09, 95% CI = 1.61-2.71, P=2.08x10^{-8}, EAF=2%) on chromosome 1 (1q42.13) and rs75682113/C (HR=2.38, 95% CI = 1.77-3.21, P=1.07x10^{-8}, EAF=2%) on chr 7 (7p14.1). rs41309643/C is an intron of the *PSEN2* gene; rare mutations in this gene influence Alzheimer's disease susceptibility, and cardiomyopathy dilated type 1V risk. eQTL analysis revealed another gene *ADCK3* that is induced by *p53* in response to DNA damage; inhibition of *ADCK3* counteracts p53-induced apoptosis. The other novel variant rs75682113 is in an intron of the *SUGCT* gene; mutations in this gene have been associated with glutaric aciduria type 3 disease susceptibility. Conclusion: A large GWAS analysing MSS revealed novel loci; while needing functional confirmation, we identified potential candidate genes underlying these loci whose biology is linked to tumour progression, as well as premature deaths due to congestive heart failure.

PrgmNr 3627 - A segregation analysis of 17,425 population-based breast cancer families: Implications for breast cancer genetic susceptibility and risk prediction

View session detail

Author Block: **S. Li**[1], A. Lee[2], R. J. MacInnis[3], L. Dorling[2], S. Carvalho[2], T. Nguyen-Dumont[4,1], G. S. Dite[1], G. G. Giles[3], P. Pharoah[5], M. C. Southey[6], D. F. Easton[2], J. L. Hopper[7], A. C. Antoniou[2]; [1]The Univ. of Melbourne, Melbourne, Australia, [2]Univ. of Cambridge, Cambridge, United Kingdom, [3]Cancer Council Victoria, Melbourne, Australia, [4]Monash Univ., Clayton, Australia, [5]Univ Cambridge, Cambridge, United Kingdom, [6]Monash Univ., Melbourne, Australia, [7]Univ Melbourne, Carlton, Australia
Disclosure Block: **S. Li:** None.
Background Breast cancer risk models used in family cancer clinics rely on accurate modelling of the familial relative risks; however, rare pathogenic variants in known breast cancer susceptibility genes, together with known common genetic variants, do not fully explain the familial aggregation of breast cancer. We aimed to investigate plausible genetic models for the residual familial aggregation.
Methods We used data on 17,425 UK and Australian families ascertained through population-based sampling of women diagnosed with breast cancer (probands). 86% of probands were screened for pathogenic variants in *BRCA1*, *BRCA2*, *PALB2*, *CHEK2*, *ATM* and *TP53* using gene-panel sequencing. We conducted complex segregation analyses and fitted genetic models in which breast cancer incidence depended on the effects of pathogenic variants in the known susceptibility genes, other unidentified major genes and a normally distributed polygenic component. Maximum likelihood estimation was used to estimate the allele frequencies and breast cancer risk associated with pathogenic variants in the genes. We computed the age-specific familial relative risks (FRRs) predicted by the genetic models, defined as the ratio of the risk of a woman with an affected 1st-degree relative to the population risk.
Results 881 probands carried pathogenic variants in the six known genes. Across ages, on average, pathogenic variants in *BRCA1* and *BRCA2* explained 16% and pathogenic variants in *PALB2*, *CHEK2*, *ATM* and *TP53* explained 5% of the familial aggregation of breast cancer. After allowing for these variants, the best fitting model for the residual aggregation involved a recessively inherited allele with frequency of 13% (95% CI: 0.6-21%) and penetrance of 69% (95% CI: 43-91%) by age 80 for homozygous carriers, explaining 18% of the residual familial aggregation, and a polygenic component with an age-independent variance of 1.27 (95% CI: 0.96-1.63). A risk model based on the best fitting model predicted FRRs to be 3.4, 2.0, 1.7, 1.5 and 1.4 for a woman aged in her 30s, 40s, 50s, 60s and 70s with her mother affected at the same age, and the corresponding FRRs associated with an affected sister were 3.7, 2.3, 1.8, 1.6 and 1.4. The predicted FRRs were consistent with the FRRs estimated by epidemiological studies of the Collaborative Group in Hormonal Factors in Breast Cancer.
Conclusion In addition to the pathogenic variants in known breast cancer susceptibility genes, and polygenic risk scores, unidentified major usceptibility genes might exist which explain breast cancer familial aggregation. Our findings have implications for attempts to identify new breast cancer susceptibility genes and risk prediction.

PrgmNr 3628 - Associations between tumor inflammation, survival, and somatic mutations in colorectal cancer patients

Disclosure Block: **H. Yin:** None.

Colorectal cancer (CRC) is the third most common cancer and a leading cause of cancer-related death in the United States. The anti-tumor immune response plays a key role in tumor progression and survival. The T cell-inflamed gene expression profile (GEP) is a biomarker predicting response to checkpoint inhibitor immunotherapy. We evaluated its ability in predicting disease-specific death and associations with somatic mutations among sporadic CRC patients. This study included 84 incident CRC cases from the Seattle Colon Cancer Family Registry with formalin-fixed paraffin-embedded (FFPE) tumor tissues collected between 1997-2003. Expression profiling of 770 genes was performed using Nanostringâ□□s nCounter PanCancer IO 360 panel (NanoString Technologies, Seattle, WA). The T cell-inflamed GEP was calculated as a weighted average of housekeeping gene-normalized expression counts of 18 genes (Cristescu et al., 2018 Science). Somatic mutations were identified by targeted DNA sequencing using a custom AmpliSeq panel (Zaidi et al., 2020 Nat Commun). The Cox proportional hazard model was used for survival analyses and linear regression was used for somatic mutation association analyses. The T cell-inflamed GEP was positively associated with log-transformed tumor mutation burden (r = 0.37, P = 0.0008), hypermutation status (P = 0.001) and microsatellite instability-high status (MSI-H) ($P = 2.67 \times 10^{-6}$). Higher T cell-inflamed GEP had favorable CRC-specific survival (hazard ratio (HR) per SD unit = 0.50, 95% CIs = 0.31 - 0.80, P = 0.004) after adjusting for age at diagnosis, sex and hypermutation and/or MSI status. The result remained significant among the non-hypermutated and microsatellite stable (MSS) cases (HR = 0.53, 95% CIs = 0.33 - 0.85, P = 0.008). Analysis of recurrently mutated genes having at least 10 mutation carriers across cases, suggested T cell-inflamed GEP is positively associated with *RYR1* (16 carriers, P = 0.0025, false discovery rate (FDR) adjusted P = 0.028), and negatively associated with *APC* (44 carriers, P = 0.0097, FDR adjusted P = 0.053). However, after adjusting for hypermutation and/or MSI-H status, which act as confounders, the two associations were no longer significant. Our results show that the T cell-inflamed GEP predicts CRC prognosis independent of hypermutation and MSI status. This provides further evidence that the T cell-inflamed GEP is a measure of T cell activation in the T cell-inflamed tumor microenvironment that is distinct from tumor antigenicity. At the time of writing, we are finalizing a differential expression analysis that aims to identify genes and pathways that may modulate T cell activation and tumor immune evasion.

PrgmNr 3629 - Associations of genetically predicted blood protein biomarkers with prostate cancer risk: a study using comprehensive protein genetic prediction modes

View session detail

Author Block: **L. Wu**[1], D. H. Ghoneim[1], J. Zhu[1], X. Xu[1], Y. Sun[1], P. Surendran[2], T. Liu[3], S. Fahle[2], A. S. Butterworth[2], C. Wu[4]; [1]Univ. of Hawaii Cancer Ctr., HONOLULU, HI, [2]Univ. of Cambridge, Cambridge, United Kingdom, [3]Pacific Northwest Natl. Lab., Richland, WA, [4]Florida State Univ., Tallahassee, FL
Disclosure Block: **L. Wu:** None.
Prostate cancer (PCa) is the second most frequently diagnosed malignancy among males. Identification of biomarkers is critical for understanding the pathogenesis of this common cancer. Several blood protein markers have been linked to PCa risk in previous studies, but these studies have assessed only a small number of protein biomarkers usually in small set(s) of samples. To identify novel circulating protein biomarkers of PCa, we performed a large study in 79,194 prostate cancer cases and 61,112 controls of European ancestry included in PRACTICAL/ELLIPSE consortia by using comprehensive protein genetic prediction models as instruments. Leveraging genome and plasma proteome data of 2,841 healthy European descendants included in the INTERVAL study, we established models using four methods (best linear unbiased predictor, elastic net, LASSO, and top1) to predict protein levels based on genetic variants. For each protein, of the four sets of models developed, the model showing the highest prediction performance (R^2) was retained. We selected 2,157 built protein models with a prediction performance (R^2) of >0.01 for association analyses with PCa risk. We observed associations between predicted concentrations of 45 proteins and PCa risk at a false discovery rate of P-value-5). Twenty-one of the identified proteins showed positive associations and 24 showed inverse associations (*P*-values from 1.03 Ã 10^{-3} to 5.92 Ã 10^{-152}). Besides 24 proteins that were previously reported in our earlier study using protein quantitative trait loci as instruments, we identified 21 novel proteins in this study. Pathway enrichment analysis showed that genes encoding these proteins were significantly enriched in cancer related pathways, including STAT3 Pathway, CDK5 Signaling, p38 MAPK Signaling, and GP6 Signaling Pathway. In conclusion, we identified 45 protein biomarker candidates for PCa risk with the potential to improve our understanding of the etiology of PCa.

PrgmNr 3630 - Breast cancer polygenic risk scores and rare variants in Latinas

Introduction: Polygenic risk scores (PRS), assembled from common single nucleotide polymorphisms (SNPs), can be used to predict breast cancer risk. Individually, pathogenic variants (PVs) in high and intermediate penetrance breast cancer susceptibility genes are rare but have large effects on disease risk. Few studies have examined PRS and PVs in susceptibility genes together, and most previous breast cancer genetics studies have been conducted in European ancestry populations. Here, we report findings on the combined effects of PRS and PVs in Latinas.

Methods: We conducted a pooled case-control analysis of breast cancer in Latinas from the San Francisco Bay Area, Los Angeles, and Mexico (1,776 cases and 1,589 controls). Case ascertainment included 432 participants from high-risk studies (age below 50, family history, or bilateral breast cancer) and 1,344 from general population studies. We assembled a 180-SNP PRS from known breast cancer SNPs (P-8). We determined presence of a rare PV in 9 known breast cancer risk genes (*ATM*, *BARD1*, *BRCA1*, *BRCA2*, *CHEK2*, *PALB2*, *PTEN*, *RAD51C*, and *TP53*). We used multivariable logistic regression and area under the receiver operating characteristic curve (AUC) to examine the relationships between PRS, PV status, and breast cancer risk. All analyses were adjusted for age, study, and ancestry. Secondary analyses were stratified by age, family history, or indigenous ancestry above or below the median.

Results: Higher PRS was associated with higher risk of breast cancer, with an odds ratio of 1.6 (95% confidence interval [CI]: 1.5-1.7) per PRS standard deviation and an AUC of 0.61 (95% CI: 0.60-0.63). PVs were found in 125 case and 22 control participants. Having a PV was associated with a 5.9-fold (95% CI: 3.8-9.6) increased odds of breast cancer. The AUC for breast cancer improved to 0.64 (95% CI: 0.62-0.66) when PVs were added to the PRS model. Results were similar among 255 cases and 129 controls with family history of breast cancer and among those with indigenous ancestry above and below the median. Among 599 cases and 387 controls under age 50 years, the AUC for the PRS-rare variant model increased to 0.69 (95% CI: 0.65-0.72). Among all cases, those with a PRS below the median had a 1.9-fold (95% CI: 1.4-2.7) increased odds of having a PV.

Conclusion: We found that adding PV status to a PRS model improves prediction of breast cancer, indicating that there may be clinical utility in examining PRS and PVs together, especially among young women. The lower PRS among carriers of a PV is likely an effect of case ascertainment and could be useful in epidemiological design of new gene discovery efforts.

PrgmNr 3631 - Genetic risk of second primary cancer in breast cancer survivors: the Multiethnic Cohort Study

View session detail

Author Block: **F. Chen**[1], A. J. de Smith[2], S. L. Park[3], L. R. Wilkens[3], C. A. Haiman[4]; [1]Ctr. for Genetic Epidemiology, Dept. of Preventive Med., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA, [2]Univ. of Southern California, Los Angeles, CA, [3]Cancer Epidemiology Program, Univ. of Hawaii, Honolulu, HI, [4]Ctr. for Genetic Epidemiology, Los Angeles, CA
Disclosure Block: **F. Chen:** None.
Women who have had breast cancer in the past are at increased risk of developing second primary cancer (SPC), in particular second primary breast cancer (SPBC). Identifying risk factors for SPCs is essential for cancer prevention efforts, especially with an increasing population of breast cancer survivors. Pathogenic variants (PVs) in *BRCA1* or *BRCA2* genes are known to contribute to the excess risk of SPBC among female breast cancer survivors, but little is known regarding the genetic risk of developing any SPC, and whether this varies across populations. In a sub-cohort of 3,223 Multiethnic Cohort Study (MEC) female participants, from five racial/ethnic populations (White, African American, Japanese American, Latino and Native Hawaiian) who had incident invasive breast cancer during follow-up, we conducted a prospective analysis to investigate the associations of genetic variants with risk of SPC. Sequencing of 37 cancer predisposition genes was carried out by the CAnceR RIsk Estimates Related to Susceptibility (CARRIERS) study. Breast cancer case status was identified by linkage to the SEER registry and SPC status was determined by SEER multiple primary guidelines. Out of 3,223 MEC primary breast cancer cases, 719 (22.3%) women later developed a SPC, of which 323 (10.0%) cases were SPBC. The Cox proportional hazard model was used to assess risk. We found that PVs of four genes were significantly enriched in women with SPC: *BRCA1* (hazard ratio, HR=2.3 [95% CI:1.1-4.7], P=0.022), *CHEK2* (HR=3.1 [1.5-6.7], P=0.003), *ERCC2* (HR=3.6 [1.3-9.7], P=0.012), and *PPM1D* (HR=3.4 [1.7-6.6], $P=3.4x10^{-4}$) after adjusting for potential confounders. Women carrying a PV in any of these significant genes on average had a 3.0-fold increased risk of SPC (95% CI=2.1-4.4, $P=2.0x10^{-8}$) compared to non-carriers, and this association was consistently observed across ethnic groups. In the analysis by SPC subtypes, the significant association of *ERCC2* gene was more profound in women with SPBC (HR=5.8 [1.8-18.7], P=0.003), whereas the significant enrichment of *CHEK2* PVs was specific to women with non-breast SPC (HR=5.4 [2.4-12.4], $P=6.1x10^{-5}$). There was no evidence of effect modification by age at first breast cancer diagnosis, hormone receptor status or treatment (chemotherapy, radiotherapy, or hormonal therapy). Our multiethnic study identified four genes associated with the development of SPC in female breast cancer survivors, of which *ERCC2* and *PPM1D* have not previously been implicated in SPC or SPBC. Future studies are warranted to validate our results. These findings suggest that closer monitoring of SPC may be needed for women carrying PVs in these genes.

PrgmNr 3632 - Improving risk prediction: Validation and exploration of breast cancer PRSs in a Midwest-American population

INTRODUCTION: Breast cancer (BC) is the most common cancer among women and is classified as a complex disease. Advances in population genomics have led to the development of polygenic risk scores (PRSs) with the potential to enhance current risk models, but validation is often limited. OBJECTIVE: We set out to validate a set of high-powered BC PRSs for use in a local population using an alternate genotyping platform and to assess PRS algorithm capacity to predict other clinical variables that could improve BC screening and treatments. METHODS: Two published PRS algorithms (313 and 3,820 SNPs) were used to score female subjects in this retrospective case-control study utilizing breast cancer positive cases from the integrated Cancer Repository for Cancer Research and cancer negative controls from the Netherland Twin Register which have been shown to be genetically similar populations. Subject biospecimens were genotyped on the Illumina Global Screening Array followed by imputation, principle component analysis (PCA), and quality control. Phenotypic data was collected using patient-based questionnaires for cases and controls, with additional case electronic medical record data. 409 cases and 1,375 controls and were ultimately scored via ScoreRunner, a custom bioinformatics pipeline. PRS performance was compared using area under receiver operating characteristic curve (AUROC) analysis. Phenotypic data of interest included age at diagnosis, cancer stage at diagnosis, and histopathological variables. Age at diagnosis was evaluated using survival curve analysis with subjects binned by standard deviation. RESULTS: Mean PRS standardized residual scores were significantly different (pth percentile bin starting at approximately age 40 that persisted throughout life. Stage at diagnosis showed a non-significant positive trend with an increasing 3,820 PRS, with no trend seen for histopathological variables with either PRS. CONCLUSIONS: Our study validates the results and predictive performance of the previously published work in a Midwest-American population using an alternative genotyping platform and showed that high PRS predicts earlier BC diagnosis. Assessment of other clinical variables did not reveal significant trends, indicating the specificity and limitations of PRSs for alternate uses and the need for trait specific PRS development.

PrgmNr 3633 - Increased burden of pathogenic variants in cancer predisposition genes in minority Americans with a cancer diagnosis between age 0-26: Use of linked California health registries

View session detail

Author Block: **Q. Feng**[1], E. Nickels[2], I. S. Muskens[1], A. J. de Smith[1], W. J. Gauderman[1], A. Yee[1], S. Feurstein[3], K. McNeely[3], C. N. Ricker[4], T. Mack[1], A. D. Leavitt[5], L. A. Godley[3], J. L. Wiemels[1]; [1]USC Keck Sch. of Med., Los Angeles, CA, [2]Children's Hosp. Los Angeles, Los Angeles, CA, [3]The Univ. of Chicago, Chicago, IL, [4]USC Norris Comprehensive Cancer Ctr., Los Angeles, CA, [5]Univ. of California, San Francisco, San Francisco, CA

Disclosure Block: **Q. Feng:** None.

The causes of most early-onset cancer, including solid and hematologic cancers, are not well defined in minority Americans. While common genetic variants and environmental factors likely contribute to population prevalence of early-onset cancer, there are also rare single-gene syndromes that contribute to familial clustering of disease. The latter can be identified by evaluating family-based cancer concordance and sequencing of predisposition genes. The level of such familial concordance for early-onset cancers has not been assessed previously in non-European ancestral groups.We used the California Cancer and Vital Statistics Registries to evaluate the relative risks of cancer for first-degree relatives of patients diagnosed between ages 0-26. From 1989-2015, we identified 29249 cancer patients (29072 probands, 177 affected family members) and 62863 healthy family members. We calculated the standardized incident ratios (SIRs) of early-onset primary cancers diagnosed in siblings and mothers, compared to the expected age- and gender-specific cancer rates in California. We also performed exome sequencing on 35 sibling pairs with at least one hematologic cancer (leukemia/lymphoma) in one of the pairs. The GATK germline short variant pipeline and PeCanPIE pipeline were used to call and determine the pathogenicity of variants that were shared between the siblings. RFMix was used to analyze the local ancestry of pathogenic variants.In the full sample, there was an increased relative risk of any early-onset cancer for siblings and mothers (SIR=3.32; 95%CI: 2.85-3.85) of an affected probands. Given a proband with solid cancer, both Latinos (SIR=4.98; CI:3.82-6.39) and non-Latino Blacks (NLB) (SIR=7.35; CI:3.36-13.95) exhibited significantly higher relative risk of any cancer in siblings and mothers when compared to non-Latino White subjects (NLW) (SIR=3.02; CI:2.12-4.16). For hematologic cancers, higher familial risk was observed for non-Latino Asian/Pacific Islanders (NLAPI) (SIR=7.56; CI:3.26-14.90) compared to NLW (SIR:2.69; CI:1.62-4.20). Rare pathogenic variants shared between siblings were detected in 5 of the 35 sibling pairs. Among them, 4 were Latino pairs that shared variants in *TP53* and *ATM*; 1 was a NLB pair that shared a variant in *GATA2*. Interestingly, all pathogenic variants reported above (N=5) reside in European ancestry haplotypes despite the higher familial concordance in ethnic minority families.The data support increased risk of familial-associated early-onset cancers among Latino, NLB, NLAPI compared to NLW subjects. Most specific genetic variants that might explain this finding were discovered in Latino families.

PrgmNr 3634 - Inherited *TP53* variants are associated with an increased risk of prostate cancer

Disclosure Block: **H. Cheng:** None.

Background: Inherited germline *TP53* pathogenic and likely pathogenic mutations (g*TP53*) cause autosomal dominant multi-cancer predisposition including Li-Fraumeni Syndrome (LFS). However, there is no known association of prostate cancer with *gTP53*. In this study, we aimed to determine if gTP53 predisposes to prostate cancer. **Methods:** This multi-institutional retrospective study characterizes prostate cancer incidence in a cohort of LFS males, and g*TP53* prevalence in a prostate cancer cohort. We evaluated the spectrum of g*TP53* variants and clinical features associated with prostate cancer. **Results:** We identified 31 prostate cancer cases among 163 adult LFS males, including 26 of 54 age ≥50y. In 117 LFS males without prostate cancer at the time of genetic testing, six were diagnosed with prostate cancer over a median (IQR) of 3.0y (1.3-8.0) of follow-up, a 25.1-fold increased risk (95% CI 9.2-54.7; PTP53 in 38 of 6,850 males (0.6%) in the prostate cancer cohort, a relative risk 9.1x higher than population controls (95% CI 6.2-13.5; pTP53 prostate tumors had somatic inactivation of the second *TP53* allele. Among g*TP53* prostate cancer cases in this study, the median age at diagnosis was 56y (IQR: 51-62), 42% had Gleason â¥8 tumors, and 30% had advanced disease at diagnosis. **Conclusions:** Complementary analyses of prostate cancer incidence in LFS males, and g*TP53* prevalence in prostate cancer cohorts suggest that g*TP53* predisposes to aggressive prostate cancer. Prostate cancer should be considered as part of LFS screening protocols, and *TP53* considered in germline prostate cancer susceptibility testing.

PrgmNr 3635 - The immuno-genetics of viral antigen response influence glioma susceptibility and survival in a subtype-specific manner

View session detail

Author Block: **G. Guerra**[1], L. Kachuri[1], G. Wendt[1], H. Hansen[1], S. J. Mack[1], A. Molinaro[1], P. Bracci[1], J. Wiencke[1], T. Rice[1], J. E. Eckel-Passow[2], R. B. Jenkins[2], M. Wrensch[1], S. Francis[1]; [1]Univ. of California, San Francisco, San Francisco, CA, [2]Mayo Clinic, Rochester, MN
Disclosure Block: **G. Guerra:** None.
Infections and human leucocyte antigen (HLA) genetic variants have been independently linked to diffuse glioma risk. Recently, several clinical trials have suggested a prognostic benefit to antiviral medications in glioma treatment. In this study we use polygenic risk scores (PRS) to assess the relationship between genetic predictors of antibody response to 7 viral infections and glioma risk and survival.
We constructed PRSs for seroreactivity to each viral antigen using genome-wide significant (p-8) independent variants (linkage disequilibrium r^2 Genetically predicted stronger antigen response to Epstein-Barr virus (EBV) ZEBRA antigen was inversely associated with glioma risk overall (odds ratio (OR)=0.94, p=0.011) and in opposite directions with response to Merkel cell polyomavirus (MCV) L1 antigen in the IDH wild type (OR_{ZEBRA}=0.91, p=0.008 / OR_{MCV}=1.09, p=0.011) and TERT-only (OR_{ZEBRA}=0.89, p=0.011/ OR_{MCV}=1.11, p=0.018) subtypes. Correlation between PRS_{ZEBRA} and PRS_{MCV} (Pearsonâ□□s r =-0.354, p=3.8Ã□10^{-14}) suggests a shared underlying germline mechanism. In line with these findings, HLA-DQA1*03:01, which influences response to EBV ZEBRA (p=1.3Ã□10^{-16}), was associated with glioma overall (OR=1.18, p=3.9Ã□10^{-4}), IDH wild type (OR=1.22, p=0.0014), and TERT-only (OR=1.21, p=0.034) subtypes. PRS risk associations for the EBV EBNA antigen were seen in IDH-mutated (OR=1.09, p=0.04) subtypes, with the largest effect in the IDH-mutated/1p19q co-deleted (OR=1.14, p=0.031) group.
Considering clinical outcomes, we detected associations between PRS_{EBNA} and survival time in patients with IDH mutated/1p19q non-codeleted tumours (HR=0.86, p=0.019 / 615 patients, 222 events), and PRS_{EBNA} and PRS_{ZEBRA} being associated in opposite directions with survival in IDH-mutated/1p19q co-deleted tumours (HR_{EBNA}=0.75, p=0.019 / HR_{ZEBRA}=1.27, p=0.019 / 244 patients, 64 events).
Our study is the first to associate genetically predicted immune response to viruses with glioma risk. We demonstrate that HLA-DQA1*03:01 influences glioma risk in the same glioma subtypes, potentially suggesting a shared genetic architecture. We also provide preliminary evidence of a prognostic value for genetically programmed reactivity to two EBV antigens for patients with IDH-mutated gliomas. Further studies are required to disentangle the complex interactions between the HLA, infections and glioma risk and survival.

PrgmNr 3636 - CDH1 and CTNNA1 variants with incomplete penetrance in Hereditary Diffuse Gastric Cancer Chilean families

View session detail

Author Block: **G. Molina**[1,2], A. Estrada[1], A. Poceros[1], N. Coggins[1], C. Parra[2], O. Torres[3], E. Norero[4,5], A. CorvalÃin[5,6], L. Carvajal-Carmona[1,7]; [1]UC Davis Genome Ctr.. Univ. of California Davis., Davis, CA, [2]LINA. Facultad de Ciencias de la Salud. Univ. de Playa Ancha, Valparaiso, Chile, [3]Servicio de CirugÃa Digestiva. Hosp. Regional Guillermo Grant., ConcepciÃ³n, Chile, [4]Esophagogastric Surgery Unit, Surgery Dept., Hosp. Dr. Sotero del Rio, Santiago, Chile, [5]Advanced Ctr. for Chronic Disease (ACCDiS), Santiago, Chile, [6]Facultad de Med.. Pontificia Univ. CatÃ³lica de Chile,, Santiago, Chile, [7]Dept. of Biochemistry and Molecular Med., Sch. of Med., Univ. of California, Sacramento, USA, Sacramento, CA
Disclosure Block: **G. Molina:** None.
The purpose of this study is to describe two Chilean families presenting Hereditary Diffuse Gastric Cancer (HDGC). Variants of uncertain significance (VUS) were detected in these families. Gastric cancer is the leading cause of cancer-related death in Chile. Worldwide, only ten percent of gastric cancer have a familial aggregation. E-Cadherine 1 gene (CDH1) and CTNNA1 (alpha-1 catenin gene) are the most commonly mutated genes in HDGC. The index patient of the first family had diffuse gastric cancer at 59 years of age. His father and paternal grandfather died of gastric cancer. A germline variant c.88C>A (p.Pro30Thr, rs139866691) was found previously in the index patient. Genotypification of the family members showed that two non-affected sisters presented the same variant, indicating an incomplete penetrance. In the second family, there are eleven members affected with gastric cancer and two with breast cancer, in two following generations. The index patient was diagnosed with a diffuse gastric tumor at 51 years of age. Cancer gene panel sequencing was performed in index patient DNA and variant genotyping in her relatives. A germline variant c.293G>A (p.R98Q, rs746832629) in the CTNNA1 gene was found in the index patient. We found this variant in two non-affected brothers and it was not found in an affected sister, findings that could be explained by incomplete penetrance. Both variants are in conserved domains of the proteins. CDH1 variant codifies for a residue in a conserved loop of the E-Cadherine 1 preprotein domain that is crucial to the normal positioning of the protein at the membrane. Whereas, CTNNA1 variant codifies for a residue in the first alpha-helix of alfa-1-catenin corresponding to the beta-catenin binding domain. These residues are highly conserved in phylogenetic analysis and the variants population in the Genome Aggregation Database are 2 x 10-3 and 7,5x 10-5. Based on this data, we think that both variants classified as VUS, could be pathogenic and causative of the HDGC observed in these families, but showing an incomplete penetrance. We are performing isogenic models and functional analyses of both variants to clarify their pathogenicity. Also, we are doing WES in the samples of two discordant affected sisters from the second family.

PrgmNr 3637 - Saturation Genome Editing of *PALB2* Reveals Functionally Abnormal Missense Variants

View session detail

Author Block: **I. Hill**[1,2], A. Patoski[1,2], K. de Leon[1,2], A. Mehrotra[1,2], N. Smith[1,2], J. Shendure[1,2,3], L. Starita[1,2]; [1]Dept. of Genome Sci., Univ. of Washington, Seattle, WA, [2]Brotman Baty Inst. for Precision Med., Seattle, WA, [3]Howard Hughes Med. Inst., Seattle, WA
Disclosure Block: **I. Hill:** None.
Pathogenic variants in the *PALB2* gene are associated with an increased lifetime risk of developing breast, pancreatic, and ovarian cancer. However, the clinical utility of genetic testing for informing *PALB2*-associated cancer susceptibility is limited by a lack of evidence for interpreting individual variants. In fact, of the 3125 *PALB2* single nucleotide variants (SNVs) in ClinVar, 1850 (60%) are currently annotated as variants of uncertain significance (VUS). The situation is worse for missense variants, of which 1849 of 1874 (99%) are VUS. Multiplexed assays of variant effects can provide valuable evidence for reinterpreting VUS. For example, functional data from Saturation Genome Editing of *BRCA1* can be used as strong evidence that individual variants are pathogenic (PS3) or benign (BS3). Like *BRCA1*, *PALB2* - **P**artner and **L**ocalizer of **B**RCA**2** - which functions in the same double strand break repair pathway as *BRCA1*, is compatible with Saturation Genome Editing.
We performed Saturation Genome Editing on *PALB2* to generate functional data for all possible SNVs across the protein coding region and intron-exon junctions. Thus far, we have data for 2602 variants, spanning the coiled coil domain which is required for BRCA1 binding and the WD40 domain which is required for binding to BRCA2. Functional scores indicate that 176 of 1408 (12.5%) missense variants are indistinguishable from nonsense variants and are likely â□□functionally abnormalâ□□, loss-of-function variants. Our results are consistent with what is known about PALB2 function, with missense variants scoring as functionally abnormal falling in the coiled-coil (10.5%) or WD40 domain (15.6%), and 0% outside of those domains thus far (n.b. there is more missing data outside of the folded functional domains). Our results are also perfectly concordant for 26 variants with published orthogonal functional data. Nonetheless, it should be recognized that the relative lack of classified pathogenic or benign missense variants within *PALB2* presents a unique and challenging problem in validating these data for use in clinical variant interpretation. New strategies may be necessary before these data can be incorporated into variant interpretation frameworks. Finally, recent case-control studies suggest that *PALB2* missense variants do not appear to increase breast cancer risk, however, our data suggests grouping all missense variants for these studies, of which 87.5% are â□□functionally normalâ□□, may have obscured any signal.

PrgmNr 3638 - A scalable deep learning framework for breast cancer prediction using DNA methylation data

View session detail

Author Block: **N. Paul**[1], R. Jansen[1], R. Gomes[2], N. He[2], A. Huber[2]; [1]North Dakota State Univ., Fargo, ND, [2]Univ. of Wisconsin, Eau Claire, WI

Disclosure Block: **N. Paul:** None.

DNA methylation is a key epigenetic modification that can modulate gene expression to influence the cell functionality. This process affects tumor suppressor genes and oncogenes to lead to cancer. DNA methylation can be measured by high-throughput sequencing technology. However, these technologies cannot determine complete CpG coverage and hence prediction of missing methylation states are critical for complete genome-wide analysis. The main challenge for prediction is the high dimensionality and complexity of the methylation data. With high throughput bulk sequencing techniques being able to read over 850,000 methylation markers (CpGs) across the human genome, a need for a more hybrid and scalable approach to interpret these datasets is essential. To address this dimensionality, we propose a two-step method of feature selection and cancer prediction using state-of-the-art machine learning algorithms. The feature selection stage utilizes several classification and clustering algorithms that can select a subset of methylation markers contributing towards gene expression. In this work, we apply our method using breast cancer methylation data from the publicly available Cancer Genome Atlas Program (TCGA). In the first stage, Principal Component Analysis, Random Forest, and ANOVA F-test are applied to select the top CpG markers from an Illumina 450K array that could be the most important cancer related features. The degree of similarity between selected CpG markers is also analyzed using Correlated Feature Elimination and some of the highly correlated features would be documented and removed prior to classification. A Convolutional Neural Network (CNN) is implemented to develop a diagnostic prediction model for cancer detection from the selected CpG markers. Preliminary work on a subset of 20 samples shows promising results. The proposed CNN architecture was able to predict cancer samples with an accuracy of 100% using a subset of 77 most important CpG markers from a total of 487,177 markers. To validate the efficacy of the proposed approach, the algorithm is applied on 1188 samples. Our proposed approach consisting of Feature Selection stage would make this model scalable and faster while Deep Learning would improve accuracy of the prediction model and allow capture of non-linear relationships. Results and weights from the trained deep learning model will be shared with the cancer research community to facilitate transfer learning. This will ensure that the cancer research community gets access to a deep learning framework that already has preliminary knowledge from past experiments.

PrgmNr 3639 - Cell-type specific methylation changes from bulk whole genome bisulfite sequencing of matched primary and recurrent high grade serous ovarian cancers indicates stability of methylation landscape through tumor progression and chemoresistance

Disclosure Block: **N. Gull:** None.

The role of DNA methylation changes in high grade serous ovarian carcinoma (HGSOC) is largely unknown. We performed whole genome bisulfite sequencing (WGBS) and RNA-seq in paired primary and recurrent tumors 28 HGSOC patients (62 total). Genome wide methylation and transcriptomic features were largely preserved between primary and recurrent tumors from the same patient ($P=7.16x10^{-7}$ in *BRCA*,$1.41x10^{-3}$ in non-*BRCA*). We did not identify any differentially methylated regions (DMRs) or consistent loss/gain of methylation at partially methylated domains (PMDs) between primary and recurrent tumors across the cohort. Within-patient paired analysis of DMRs identified an average of 659 DMRs between the primary and recurrent tumors from *BRCA* carriers, which was significantly higher (P=0.004) than the 388 average DMRs identified from the paired analysis of primary and recurrent tumors from non-carriers. Tumors from *BRCA* carriers displayed high levels of heterogeneity, likely driven by homologous recombination repair deficiency and a high burden of structural variation, and may be related to poorer survival observed in *BRCA* non-carriers (P=0.0056). Comparing tumors from *BRCA* carriers with non-carriers we identified 135 significant DMRs, with a trend for hypermethylation in DMRs and PMDs in tumors from *BRCA* carriers (P=0.001). These DMRs are depleted within CpG islands near transcription start sites and active regulatory regions in related cell types. These changes were also observed in RNA-seq analysis, where we identified differentially expressed genes between *BRCA* carriers and non-carriers that include the known driver amplification CCNE1 and genes enriched in immune pathways and pathways that maintain stemness and cell differentiation. We applied an in silico single cell WGBS approach using the tool CluBCpG to identify cell types and their frequency in each tumor from bulk WGBS. Results from read grouping analysis support the stability of the methylome between primary and recurrent tumors, even at a cell-type specific level. As PMDs are cell type specific, we focused further analysis on these regions. A larger number of cell-type specific populations were estimated from read grouping in PMDs than non-PMDs ($P=1.82x10^{-9}$) supporting their cell type specific patterns of methylation. Ongoing analysis will compare specific cell type populations and their frequencies between tumors. The conservation of methylation signatures in progressive, chemoresistant HGSOC tumors has not been previously reported, and suggests that chemoresistance may be established early in tumor progression, potentially in small cell populations and via hypomethylation at PMDs.

PrgmNr 3640 - Exome-wide rare variant association study in lymphoid cancers

View session detail

Author Block: **S. Ralli**[1], S. Jones[2], S. Leach[1], A. R. Brooks-Wilson[3]; [1]Genome Sci. Ctr., Vancouver, BC, Canada, [2]BC Cancer, Vancouver, BC, Canada, [3]BritishColumbia Cancer Res Ctr, Vancouver, BC, Canada

Disclosure Block: **S. Ralli:** None.

Genome-wide association studies have revealed common genetic variants associated with diverse lymphoid cancers. However, these variants explain only a portion of the heritability of these cancers. Rare variants are likely to play a role in disease causation. We aim to identify rare germline variants associated with lymphoid cancers using exome sequencing. 39 multiple-case lymphoid cancer families with 86 cases were exome sequenced, jointly called, and filtered using variant quality score recalibration. Cases with the earliest onset or rarest type of lymphoid cancer were selected for rare variant association analysis from each family. Ethnicities for these cases were determined by PCA using KING; 38 cases had European ethnicity. Read depths filter â¥ 10 in 90% of samples were applied to the 38 cases and the genomes of 7718 controls from GnomAD of European ethnicity. Variants of cases were filtered to retain those with (1) CADD â¥ 20, (2) variant consequence of splice acceptor, splice donor, stop gained, frameshift, stop lost, and start lost variant, (3) allele frequency â¤ 0.001 or novel variant with no allele frequency in public databases and (4) genotype 0/1 or 1/1 in at least one case. Variants of controls were filtered using criteria (2) and (3). Burden analysis for rare variant association was performed using TRAPD under a dominant model using single nucleotide variants and indels. TRAPD performs a one-sided Fisher's exact test to analyze if there is a significantly higher burden of variants in cases than controls for each gene. An inflation factor of 1.9 was observed. 6811 genes were analyzed. 189 genes had nominal p-values â¤ 0.05; 159 withstood adjustment for the inflation factor. Of these, *FANCD2* (p-value 0.009) and *SYK* (p-value 0.009) are implicated in causing leukemia and peripheral T-cell lymphoma in the Cosmic cancer gene census. Case with *FANCD2* splice donor variant had another affected individual in the family who was sequenced and they both share the variant. After multiple testing corrections, however, these genes did not remain significant.

PrgmNr 3641 - Identifying non-coding drivers of ovarian cancer by converging germline variants and somatic mutations

There are numerous examples where germline and somatic variants target the same genes in specific cancers, indicating a common biology drives the development of both heritable and sporadic cancers. So far, these studies have focused on protein-coding genetic variants. Advances in whole genome sequencing (WGS) methods, have enable the identification of tens of thousands of non-coding germline and somatic variants of unknown function and significance. We hypothesize that a proportion of non-coding germline risk variants and somatic mutations co-locate with regulatory elements (REs) that regulate the expression of specific genes and/or gene regulatory networks. We have integrated germline risk variants identified from genome-wide association studies (GWAS) of ovarian cancer (up to 26,151 cases, 105,724 controls) and somatic mutation data from WGS analysis of ovarian tumors (n > 200) with disease specific epigenomic and transcriptomic data from ENCODE, Roadmap and in-house profiling studies, to identify REs where germline and somatic variants co-localize, which indicates they may be drivers of disease pathogenesis.
We observed significant enrichment of germline variants in transcription factor binding sites (TFBS) in ENCODE ($p = 0.03$) and ovarian cancer-specific active promoters ($p = 0.009$). Somatic mutations mostly occurred in super enhancers (205/8642 mutated, 2.37%) and ovarian cancer-specific active regions (26/1099 mutated, 2.37%). We also found 60 significantly mutated disease associated active REs that harbor putative causal risk variants for ovarian cancer. We predicted the target genes of these REs based on: (1) distance to promoters; (2) association between H3K27ac activity and target gene's expression; (3) long-range chromatin interactions from ovarian cancer cell lines. We identified co-localized variants within; an active enhancer at *2q14* associated with *PAX8*, a lineage-specific TF thought to regulate cell migration and metastasis in ovarian cancer; the promoter of the *TERT* gene at *5p15.33*; and an active enhancer at *1p34.3* linked to *RSPO1*. Pathway analysis mapped putative non-coding drivers to pathways involved in *TERT* activation in cancer ($p = 0.01$), *PAX8* targets in thyroid dysgenesis ($p=0.03$), and regulation of response to DNA damage stimulus ($p=0.03$). In conclusion, this study suggests that germline and somatic non-coding genetic alterations co-localize in REs to indicate novel pathways and biological drivers of ovarian cancer pathogenesis

PrgmNr 3643 - Spatial molecular profiling of Triple-Positive Ductal Carcinoma In Situ of the Breast using Visium Spatial Gene Expression for FFPE

View session detail

Author Block: **S. R. Williams**[1], M. Turkekul[1], A. Jurek[1], M. Mignardi[1], P. Mielinis[1], X. Huang[2], M. Stoeckius[1], V. Giangarra[1], N. I. Weisenfeld[1], J. Chell[1]; [1]10x Genomics, Pleasanton, CA, [2]Univ. of Washington, Seattle, WA

Disclosure Block: **S.R. Williams:** None.

Triple-positive ductal carcinoma in situ of the breast (TPDCIS) is a pre-neoplastic lesion that can give rise to invasive ductal breast carcinoma. Such lesions routinely exhibit elevated levels of HER2, ER, and PR but the underlying phenotype and survival rates vary. To investigate the tumorigenic potential of TPDCIS, we examined the tissue microenvironment of two TPDCIS samples, characterizing the tissue distribution of cellular gene expression using spatial transcriptomics

Spatial transcriptomics technology combines histological techniques with the massive throughput and discovery power of RNA sequencing, adding a powerful toolset to pathological examination. However, standard clinical workflows collect formalin-fixed paraffin-embedded (FFPE) tissue, which can significantly damage molecules such as RNA, making investigation at the transcriptomic level intractable.

We assessed the profiles of two TPDCIS samples using the10x Genomics Visium Spatial Gene Expression Solution for FFPE tissue with a new RNA Templated Ligation (RTL) approach that probes native RNA. Tissue sections on a Visium gene expression slide were H&E stained, imaged, and spatially barcoded to generate libraries. Sequencing data from the libraries were visualized for spatial and quantitative gene expression profiles.

Spatial profiles aligned with pathologist annotation demarcating the tumor, stromal, and immune compartments as well as with staining for HER2, PR, and ER. These data were paired with single nucleus RNA-seq (Chromium Single Cell 3â□□ assay), generating cell type expression profiles for estimating spot level cell type proportions and gaining insight into cell-type co-localization. New computational methods were used to infer copy number variation (CNV) at the spot level, elucidating the spatial relationship between CNVs and intra-tissue phenotypes.

These results demonstrate that gene expression profiling of FFPE tissues using the Visium platform complements traditional histopathological methods. TPDCIS gene expression profiles at both the single nucleus and spatial level provide comprehensive tissue architecture insights. This knowledge enables unprecedented understanding of tumor biology, disease progression, potential predictive biomarkers, and development of therapeutic targets.

PrgmNr 3644 - Tracing intratumoral genetic heterogeneity using genetic barcoding in small cell lung cancer

View session detail

Author Block: **H. Wollenzien**[1,2], Y. A. Tecleab[2], M. Mukherjee[2], M. S. Kareta[2]; [1]Univ. of South Dakota, Sioux Falls, SD, [2]Sanford Res., Sioux Falls, SD
Disclosure Block: **H. Wollenzien:** None.
Small Cell Lung Cancer (SCLC) is often a heterogeneous tumor, where multiple populations of phenotypically different cells exist and contribute differentially to tumor dynamics. This tumor is characterized by a very low 5- year survival rate, high metastatic rates, and rapid acquisition of chemoresistance. Beyond first-line chemotherapy, targeted treatment options are scarce, and none take in to consideration the complex genetics of the tumor. The heterogeneous nature of this tumor makes it difficult to study and to treat, as current attempts to understand tumor dynamics use a bulk approach that averages the contribution of all cells within a tumor. This work uses a novel cellular barcoding lineage tracing approach combined with single-cell RNA sequencing (scRNA-seq) to understand tumor heterogeneity and evolution of SCLC in both a xenograft model of human SCLC cell lines and an in vivo system using a genetically modified mouse model with alterations in the same driver genes as the majority of humans with SCLC. Tumors are sampled pre-growth, post growth and metastasis, and pre- and post- chemotherapy. By paring the barcode populations that exist in samples over time, in metastasis, or in chemoresistance, a clonal evolution map of growth, metastasis, and chemoresistance can be generated, based on shared barcodes and convergent or divergent transcriptomic profiles. In validation of scRNA-seq data, an emphasis will be placed on genes that may already be targetable by approved therapeutics. This work will identify the genes responsible for tumor dynamics, develop the in vivo cellular barcoding approach, and lead to the identification and investigation of therapeutic targets for human SCLC.

PrgmNr 3645 - Transcriptome-wide association study identifies novel genes associated with the immune traits in cancer

Background: Immune infiltration in solid tumors is a strong predictor of improved survival in many tumor types. We have recently demonstrated the heritability of immune infiltration components in solid tumors by using germline genetic data from The Cancer Genome Atlas (TCGA). We also identified over 20 individual loci that are associated with over 10 immune signatures including genes that are involved in autoimmune disorders and genes that are proposed targets of immunotherapy. Here, we sought to identify additional genes associated with variation in the immune microenvironment. We performed transcriptome-wide association study (TWAS) to predict immune signatures in the pan-cancer analyses of 30 non-hematological cancers in TCGA. Methods: We integrated the results from the pan-cancer genome-wide association study with large-scale expression quantitative trait loci (eQTLs) from whole blood, spleen, and EBV-transformed lymphocytes tissues in GTEx (version 8). We conducted a TWAS using the Summary-MulTiXcan approach. We used an false discovery rate of ZBTB8OS, RAB43, TNNT1, TSSK3, ZNF134, SAP30B, LRFN3, UPK3BL, EPHB6, GKAP1, NT5C, and *RP11-290F24.6*) whose genetically predicted expression was associated with different immune signatures in tumors. One of these genes, *EPHB6* was found to be inversely associated with a Th1 enrichment ($p=2.2x10^{-6}$). EphB6 plays a crucial role in T-cell activation with EphB6-deficient mice displaying reduced activation, phosphorylation and recruitment of the T cell signaling molecules. *RAB43* was found to be inversely associated with activated a signature of natural killer cells ($p=3.8x10^{-7}$). RAB proteins are involved in signal transduction pathways regulating cell invasion, cell apoptosis and innate immune response, particularly in gliomas, leading to poor clinical outcomes. Conclusion: This is the first TWAS investigating the relationship between genetically predicted gene expression and immune traits. Of these, *EPHB6,* and *RAB3* are strong candidates for a mechanistic role in modifying the immune response to tumors.

PrgmNr 3646 - Epigenome-wide association study (EWAS) for soluble CD14 level in African Americans from the Jackson Heart Study

View session detail

Author Block: **K. Ferrier**[1], N. E. Olson[2], A. Reiner[3], E. M. Lange[4], L. A. Lange[5]; [1]Univ. of Colorado Denver, Aurora, CO, [2]PerkinElmer, Seattle, WA, [3]Univ of Washington, Seattle, WA, [4]Univ North Carolina, Chapel Hill, NC, [5]Univ Colorado Denver, Aurora, CO
Disclosure Block: **K. Ferrier:** None.
The human monocyte differentiation antigen CD14 is a pro-inflammatory cytokine that has been implicated in the pathogenesis of a number of disease processes including inflammation, metabolic disease, tumor development, and atherosclerosis. In a separate analysis, we showed soluble CD14 (sCD14) is associated with incident coronary heart disease, heart failure, and all-cause mortality independently of established cardiovascular disease risk factors in African Americans (AAs) from the Jackson Heart Study (JHS). We also identified novel associated genetic variants near the *CD14* locus. To understand the epigenetic influences on CD14, we performed an EWAS for sCD14 levels in n=1613 JHS participants with available Illumina EPIC array data (n=721,757 methylation sites) measured from whole blood. Methylation values were normalized and adjusted for batch effects. Epigenome-wide association analysis was performed using a linear regression model. Analyses were adjusted for age, sex, estimated cell counts (Houseman method), smoking status and 10 genetic ancestry principal components. We observed four methylation sites that reached epigenome-wide significance (p-8) for association with sCD14 levels after multiple-testing correction: cg27161585 near *TMC06* (near the *CD14* gene), cg26470501 near *BCL3*, and cg03396765 and cg15627993 near *LDLRAD4*. Conditional analyses of cg27161585 by a previously identified sCD14-associated SNP in the *CD14* gene region (rs75652866) completely attenuated the association between the methylation site and sCD14 level, suggesting that rs75652866, or a variant in high linkage disequilibrium with it, may regulate CD14 expression. In conclusion, this study identified several novel possible regulatory regions associated with sCD14 levels in AAs previously not identified in GWAS. Methylation levels near *CD14* do not appear to provide additional predictive value for sCD14 levels beyond what is explained by identified associated genetic variants. Spontaneous coronary artery dissection (SCAD) is a cause of acute coronary syndrome that predominantly affects women. Its pathophysiology remains unclear but connective tissue disorders (CTDs), vasculopathies, and other conditions such as Fragile-X have been observed in SCAD patients. That SCAD has a genetic component is accepted, yet few genes have been robustly implicated. We sought to clarify the genetic etiology of SCAD using targeted and genome-wide methods in sporadic cases to identify both common and rare disease-associated variants.

A cohort of 91 unrelated sporadic SCAD cases were investigated for rare, likely pathogenic variants in genes associated with either SCAD, CTDs, or vasculopathies. New candidate genes were sought using rare variant collapsing analysis relative to 1127 healthy, elderly controls and through identification of novel loss-of-function variants in genes intolerant to such variation. Pathway analysis was used to investigate common themes across potential novel candidate genes. Candidate genes were validated in an independent cohort of 384 SCAD cases. The Fragile X-associated short tandem repeat (STR) was assessed. Finally, two SCAD polygenic risk scores (PRSs) were used to assess the contribution of common variants.

We identified 10 cases with at least one rare, likely disease-causing variant in CTD-associated genes, although only one had a significant CTD phenotype. No genes were significantly associated with SCAD in our genome-wide rare variant collapsing analysis, however, pathway analysis of 24 genes harboring novel loss-of-function variants implicated the TGF-Î² signaling pathway (adjusted p-value = 0.0005). Validation of these 24 genes in 384 independent SCAD cases identified one further case who carried a different novel loss-of-function variant in the gene ACACA. No expansions of the Fragile-X STR were found. Sporadic SCAD cases showed elevated SCAD risk compared to controls for both PRSs (p-value range: 1.372e-09 - 2.052e-10).

Our analysis included screening for single nucleotide variants, insertion/deletions, structural variants of all sizes, splice-altering variants including deep intronic variants, and STR expansions, making this the first study to systematically interrogate WGS data for all types of rare variation to identify potential causes of SCAD. We showed that SCAD shares some genetic overlap with CTDs, both in a targeted analysis of known CTD genes and in potential candidates identified in this study - all despite the absence of any major CTD phenotype in most of the cohort. Consistent with a complex genetic architecture, SCAD patients also have a higher burden of common SCAD variants than controls.

PrgmNr 3648 - Gene expression analysis of lipid traits in multi-ethnic population

Disclosure Block: **Z. Du:** None.

Backgrounds Blood concentration of lipids, including total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), and triglycerides (TG) are well-established risk factors for cardiovascular disease (CVD). Gene expression can offer key information for understanding the regulatory and functional mechanisms underlying phenotypic differences among individuals. In the present study, we examined associations between blood RNA-seq and lipid traits to identify genes and pathways involved in regulating blood lipid levels. **Methods** A two-stage association study was performed, with a discovery set in Women's Health Initiative (WHI) and Framingham Heart Study (FHS), including a total of 2383 European-ancestry subjects and 480 non-European subjects, and validation in a second set of 1,189 FHS participants of European-ancestry. The association between transformed RNA-seq counts of each gene with lipid traits was examined using linear regression adjusting for age, genetic PCs, surrogate variables, complete blood counts, lipid-modifying medicines, and other cohort-specific covariates (i.e, sex in FHS). Fixed-effect meta-analysis was used to combine results. Bonferroni adjustment was used to correct multiple tests. Gene and pathway enrichment analyses were performed for replicated differentially expressed genes (DEGs) using R package clusterProfiler. Sensitivity analyses were performed by adding more potential confounders, including BMI, smoking and alcohol drinking, into the model. Causal effects of the detected DEGs will be estimated using Mendelian randomization.
Results A total of 334, 14, 61 and 370 genes were identified in the discovery and replicated to be differentially expressed for blood HDL-C, LDL-C, TC and TG levels, respectively; among which 260, 10, 46 and 312 were not in previously identified GWAS risk *loci* (>250 kb). Enrichment analyses showed overrepresentation in biologic processes including regulation of lipid and cholesterol metabolic process for HDL and TC, Fc receptor signaling pathway for HDL, heart process pathway for LDL and HDL, neutrophil activation for TG, and reproductive system for TC.
Conclusion Our results identify novel genes and pathways related to blood lipids levels, providing clues for future research of biological mechanisms of population lipid diversity and potential therapeutic targets.

PrgmNr 3649 - Investigating a potential causal relationship between maternal blood pressure during pregnancy and future offspring cardiometabolic health

Disclosure Block: **G. Wang:** None.

Background: Observational epidemiological studies have reported that higher maternal blood pressure during pregnancy is associated with increased future risk of offspring cardiometabolic disease. However, it is unclear whether this association represents a causal relationship through intrauterine mechanisms.

Methods: We used a Mendelian randomization (MR) framework to examine the potential causal relationship between unweighted maternal genetic scores for systolic blood pressure (SBP) and diastolic blood pressure (DBP), and a range of cardiometabolic risk factors in the offspring of up to 29,708 genotyped mother-offspring pairs from the UK Biobank (UKB) and the TrÃ¸ndelag Health (HUNT) studies. The cardiometabolic risk factors included in our analysis were SBP, DBP, body mass index, lipid profile (i.e. apolipoprotein A, apolipoprotein B, total cholesterol, low-density lipoprotein cholesterol, lipoprotein A, high-density lipoprotein cholesterol, and triglycerides), glycaemic biomarkers (i.e. non-fasting glucose, glycated haemoglobin, and insulin-like growth factor 1) and other relevant traits (i.e. C-reactive protein and urate). We conducted similar analyses in up to 21,423 father-offspring pairs from the same cohorts as a negative control for postnatal effects. We also calculated the statistical power to detect maternal genetic effects on offspring cardiometabolic risk factors conditional on offspring genotype.

Results: We did not detect any association between maternal (or paternal) unweighted genetic scores for blood pressure and offspring cardiometabolic outcomes in the meta-analysis of UKB and HUNT analyses after adjusting for offspring genotypes at the same loci. Power calculations indicated that we had â¥80% power to detect a maternal genetic effect that explained as little as 0.035% of the variance in the offspring cardiometabolic traits with 29,708 mother-offspring pairs (two-tailed Î± = 0.05).

Conclusions: We find little evidence to support the notion that normal variation in maternal blood pressure is a major causal risk factor for adverse offspring cardiometabolic outcomes in later life. These results complement the findings from conventional epidemiological studies, and indicate that offspring genetic effects or/and other environmental factors predominantly increase offspring cardiometabolic disease risk.

PrgmNr 3650 - Investigating exposure mediated genetic scoring for coronary artery disease

Author Block: **D. Adams**[1], W. Reay[2], M. Cairns[3]; [1]Univ. of Newcastle, Callaghan, Australia, [2]Univ. of Newcastle/Hunter Med. Res. Inst., Callaghan, Australia, [3]The Univ. of Newcastle, Callaghan, Australia
Disclosure Block: **D. Adams:** None.
Coronary artery disease (CAD) is significantly heritable and remains one of the leading causes of death worldwide. Current risk prediction methods such as polygenic risk scoring (PRS) may be useful to stratify individuals at risk of CAD but do not indicate actionable interventions that could reduce disease severity. We developed two novel methods; the instrumental variable risk score (IVS) and individual Mendelian randomisation scores (IMR) to investigate the genetic heterogeneity in the manifestation of known CAD risk factors (lipids - triglycerides, low density lipoprotein and total cholesterol). The IVS sums the effect of individual SNPs as genetic instrumental variables that represent the predicted effect of exposures (lipids) on CAD using summary statistics from genome wide association studies. Thus, representing the additive effect of the genetically predicted exposure on CAD within the individual. The IMR method has a similar aim but utilises the individualâ□□s genotypes for IV SNPs as input into several Mendelian randomisation models with different underlying assumptions regarding IV validity. We investigated the relationship between these scores and CAD in the UK Biobank (UKBB) and gene expression in the GEUVADIS cohort. We found IVS and IMR that were significantly associated with the odds of CAD and remained significant for a subset of scores upon covariation for CAD PRS and a polygenic score for the lipid exposure. Interestingly, we found that approximately 22% of the UKBB cohort had a non-significant IMR estimate for the effect of triglycerides on CAD, suggesting there is heterogeneity in this relationship. The addition of IVS and IMR scores for causal exposures can improve the prediction of coronary artery disease risk from genomic information and measured traits, however, more investigation is needed to refine and investigate the broader utility of these approaches.

PrgmNr 3651 - Investigation of eQTLs in the *CELSR2/ PSRC1/SORT1* gene cluster for independent effects in the liver and skeletal muscle that influence LDL levels and energy expenditure in American Indians

American Indians (AI) living in southwestern USA have unique genetic architecture and show a heritable predisposition to obesity and type 2 diabetes. To identify genetic variants that contribute to these diseases, we conducted genome-wide association studies for various traits using genotypes derived from a custom Axiom array specific for AI (captures 92% of all variation with minor allele frequency â¥ 0.05). Analysis of fasting LDL levels measured in 5,205 AI identified rs12740374 (G/T) as robustly associated with LDL (P= 1 Ã 10Â$^{-22}$; effect (Î²)= 8% lower per copy of minor allele, T) and total cholesterol (P= 9 Ã 10Â$^{-15}$; Î²= 4% lower). An expression-QTL (eQTL) analysis in the GTEx database showed that rs12740374 associates with the expression of *CELSR2* (P= 10Â$^{-34}$) and neighboring genes *PSRC1* (P= 10Â$^{-37}$) and *SORT1* (P= 10Â$^{-54}$) in liver (N= 208). It is reported that rs12740374 alters the hepatic expression of the SORT1 gene by creating a C/EBP transcription factor binding site. However, the database also showed that rs12740374 is a very strong eQTL for *CELSR2* (P= 10Â$^{-76}$) and *PSRC1* (P= 10^{-12}) in skeletal muscle (N= 706). Therefore, we looked for additional phenotypes associated with this variant which may have a physiologic role in muscle and found that rs12740374 associates with resting metabolic rate (RMR) measured by a ventilated hood system (N= 509; P= 0.003; Î²= -0.13). A major determinant of human metabolic rate is muscle mass. We speculated rs12740374, which has a known role for LDL in liver, maybe tagging a functional variant in the muscle that underlies association with energy expenditure, and observed that rs6670347 (T/C) (r^2= 0.98) located in *CELSR2* intron is similarly associated with LDL and RMR. We did eQTL analysis in AI skeletal muscle (N= 202) and adipose tissue samples (N= 192) and noticed that rs6670347 contributes to higher *CELSR2* expression in muscle (P= 2 Ã 10Â$^{-7}$, Î²= 0.61 SD units per copy of minor allele, C). This eQTL appears to be muscle-specific as no association was detected in studied adipose tissue or other non-muscle tissues reported in the GTEx portal. Further *in-silico* analysis revealed that rs6670347 forms the core binding motif of the NR3C1 transcription factor, and the C allele enables a stronger binding. NR3C1 encodes a receptor for glucocorticoids, which are key regulators of muscle mass, and their prolonged exposure induces atrophy. Glucocorticoid resistance is shown to decrease *CELSR2* expression in human leukemia cells and its inactivation in mice reduces muscle atrophy, which could explain its role in altering RMR. Our findings indicate that different variants in *CELSR2/ PSRC1/SORT1* gene cluster may have tissue-specific effects on diverse metabolic traits.

PrgmNr 3652 - Methylome-wide association analysis identified novel CpG sites for lipid concentrations in ancestral-diverse populations from the PAGE Study

Circulating lipids are clinically associated with cardio-metabolic diseases. The phenotypic variance explained by identified genetic variants remains limited. DNA methylation has been linked to lipids in previous studies, and a total of 43 CpG sites mapped to 30 unique genes have been repeatedly linked to high-density lipoprotein cholesterol (HDL-c), low-density lipoprotein cholesterol (LDL-c), total cholesterol (TC), and triglycerides (TG) through methylome-wide association analyses. However, all these analyses were performed in European-ancestry populations with moderate sample sizes. In addition, knowledge regarding the joint potential effects of methylation patterns and non-genetic factors on lipids is extremely limited. In the Population Architecture Using Genomics and Epidemiology (PAGE) Study, a total of 7,864 participants from the Womenâ□□s Health Initiative (WHI) and the Atherosclerosis Risk in Communities (ARIC) studies with available HDL-c, LDL-c, TC, and TG concentrations were examined on the Illumina 450K array, mainly African (3,877) and European (3,079) Americans. After quality control, we performed methylome-wide association analysis on ~400,000 CpG sites and the four lipid traits with adjustment for age, sex, white blood cell proportions, technical covariates, and the first ten genetic principal components. We identified 252 novel CpG sites at 214 loci associated with at least one lipid trait (located more than 500kb away from any previously reported/known CpG sites, P

PrgmNr 3653 - Polygenic risk score analysis of congenital heart disease phenotypes: elucidating the contribution of common variants to congenital heart defects

Congenital heart disease (CHD) occurs in ~1% of live births. To date, the genetic architecture of CHD has shown that monogenic mutations are not completely penetrant and variably expressive, and that oligo- or poly-genic inheritance may be important. Polygenic risk scores (PRS) aggregate the effects of many common variants across the genome to investigate whether these variants as a group are associated with disease risk or severity. We hypothesized that PRS identify CHD cases that can be explained by the additive effects of common genetic variants and that PRS will be related to severity of the disease. Using genome-wide association study (GWAS) results from the UK Biobank (UKBB) as our base study, and whole genome sequencing data from the CHD cohort (n=711 trios) of the Gabriella Miller Kids First (GMKF) dataset as our target study, we developed a PRS for CHD. We used summary statistics from three CHD-related GWAS. GMKF whole-genome sequences underwent quality control and we narrowed our target data to 362 trios that aggregate with individuals of European genetic ancestry in principal component analysis. As the dataset is composed of trios, pseudo-controls were generated using untransmitted parental alleles. PRS were separately generated using both case-control and severity phenotypes. PRS were generated using all SNVs as well as using a subset of SNVs from top expressed fetal cardiac genes. The PRS from the â□□heart valve problem or heart murmurâ□□ GWAS gives significant results in European case-control PRS analyses using all SNVs (p=0.0081) as well as SNVs from genes expressed in fetal cardiac tissue (p=0.0082). The severity PRS using SNVs from genes expressed in fetal cardiac tissue was also significant (p=0.0077). These results can help explain the genetic basis of CHD of unknown genetic origin, as they indicate that common variants can contribute to risk and severity of CHD. In addition, by further elucidating the genetic basis of CHD this research lays the groundwork for new discoveries in treating CHD and its related health problems.

The degree to which polygenic risk scores (PRS) influence preventive health is the subject of debate, with few prospective studies completed to date. We developed a smartphone application for the prospective and automated generation, communication, and electronic capture of response to a PRS for coronary artery disease (CAD). We evaluated self-reported actions taken in response to personal CAD PRS information, with special interest in the initiation of lipid lowering therapy (NCT03277365). 19% (721 of 3,800) of valid participants provided complete responses for baseline and follow-up use of lipid lowering therapy. 20% (n = 19 of 95) of high genetic risk vs 7.9% (n = 8 of 101) of low genetic risk individuals initiated lipid lowering therapy at follow-up (p-value = 0.002). The initiation of both statin and non-statin lipid lowering therapy was associated with degree of genetic risk - 15.2% (n = 14 of 92) vs 6.0% (n = 6 of 100) for statins (p-value = 0.018) and 6.8% (n = 8 of 118) vs 1.6% (n = 2 of 123) for non-statins (p-value = 0.022) in high vs low genetic risk, respectively. Overall, degree of genetic risk was associated with use of any lipid lowering therapy at follow-up - 42.4% (n = 56 of 132) vs 28.5% (n = 37 of 130) (p-value = 0.009). We also find that CAD PRS information is perceived to be understandable, actionable, and does not induce health anxiety.

Recent studies have demonstrated the plausible extension of polygenic risk scores (PRS) to clinical settings for risk prediction and precision treatment. For the prediction of atherosclerotic cardiovascular disease (ASCVD), PRSs of known cardiovascular risk factors such as LDL, HDL, total cholesterol, and triglyceride levels can be used in addition to coronary artery disease (CAD) PRS. As most GWAS have an overrepresentation of populations of European ancestry, there is a concern about PRS generalizability across ancestries. Either ancestry-specific PRSs or trans-ancestral PRSs will be needed to predict diseases more accurately in underrepresented populations. The Global Lipids Genetics Consortium (GLGC) has developed trans-ancestral PRSs for lipid traits. Here, we apply the GLGC PRSs to the diverse Population Architecture through Genomics and Environment (PAGE) participants (17k African American, 3k Asian, 23k Hispanic, ~600 Native American, 2k Native Hawaiian, 23k European participants) for evaluation of LDL, HDL, total cholesterol, and triglyceride levels (R2~1.7% - 6%, adjusted for age, sex, self-reported race/ethnicity, use of lipid lowering medication, and 5 genetic PCs). When stratifying by ancestry, the explained variance is higher for European than for the average of the non-European populations (adjusted R2 European ~ 10%, 9.8%, 10%, 8.1%; average of the non-European~3.6%, 3.2%, 5.8%, 5.1% for HDL, LDL, total cholesterol, and triglyceride levels, respectively). The lowest correlations were observed for participants who self-identified as African American. We next examined the predictive accuracy of lipid PRSs for incident ASCVD 10-year risk in our ancestrally diverse population. Triglyceride and LDL PRSs outperformed the other two lipid PRSs and resulted in the discrimination for ASCVD C-statistic of 0.53. In comparison, non-genetic risk factors using the pooled cohort equation (PCE) score yielded an area under the receiver operating curve (AUC) of 0.71, which did not differ much by sex/race but decreased with increased age. Further, we evaluated the effects of adding lipid PRSs to the PCE score for ASCVD risk prediction. With added triglyceride and LDL PRS, the prediction performance of 10-year ASCVD risk improved among middle-aged participants (50-60 years old, increase in AUC 0.02) but not among older groups, shedding light on the potential clinical utility of lipid PRS. Overall, this study highlights the inconsistent performance of the trans-ancestral PRS for lipids traits across different ethnic groups, and pinpoints the subgroup populations that may benefit from the enhanced predictive ability of a PRS for CVD risk.

PrgmNr 3656 - Biometric trait sex heterogenous SNPs disproportionately influence predicted gene expression and diverse traits later in life

Phenotypic differences across sexes are pervasive. We previously found that common SNPs differentially contributing to female and male secondary sexual characteristics are enriched in association signals in autism and other diseases [Mitra et al., 2016; Traglia et al, 2016]. We now leverage GIANT and UK Biobank cohorts to define a set of sexually dimorphic independent SNPs across 20 biometric phenotypes, and we investigated: 1) enriched biological processes, 2) disease/trait association signal, and 3) regulatory element overlap. Using a univariate approach combining female and male summary statistics of 20 anthropometric, metabolic and lung function traits, we extracted trait-specific sex-heterogenous SNPs (*Cochran test* P_Q -8). Then, we performed a multivariate meta-analysis of *Z-heterogeneity scores*. We extracted 2,320 independent *sex-heterogenous SNPs* within and across traits (MAF > 0.1%, *P* -8). For validation with empirical *P*-values (*EmpP*), we sampled 1,000 sets of 2,320 random *sex-homogeneous SNPs* matching the allele frequency and the combined-sex marginal effect for the leading sex-heterogeneous trait. *Sex-heterogenous SNPs* map in/near 1,325 genes (distance FDR and *EmpP* We investigated pleiotropic effects of sex-heterogenous SNPs, and we found association enrichment in 12 out of 18 diseases/traits at 5% alpha, ranging between 7.2% in ASD and late-onset asthma (*EmpP* 0.04) and 13.8% in educational attainment and schizophrenia (*EmpP* ex-heterogenous SNPs significantly overlap conserved regions across mammals, *TSS, promoter, coding*, *UTR 5â□□ regions* and introns (*EmpP* EmpP > 0.5). Interestingly, s*ex-heterogenous SNPs* strongly overlap with SNPs predicting gene expression, both across 49 GTEx tissues and across brain tissues only *(EmpP* . The excess of association signal for most tested diseases was retained compared to *eQTL-matched sex homogeneous SNPs* (*EmpP*

Million Veteran Program (MVP) genetic and medical data from a large, diverse population are ideal for addressing unresolved questions about non-glycemic effects on HbA1c. We investigated variants associated with pre-diabetes and whether non-glycemic effects on HbA1c might affect detection of glycemic dysregulation in health care settings.

To identify candidate genes, we conducted a GWAS of patients with pre-diabetes versus normoglycemic controls with status determined by electronic health ICD codes, lab results and pharmacy data. A sample of 128,098 European (EUR), 30,726 African (AFR) and 12,672 Hispanic (AMR) ancestries, analyzed separately, identified 44 independent significant (PAfter tripling sample sizes by adding Type 2 diabetes (T2D) patients and recent enrollees, erythrocytic GRS (eGRS) explains 4% of HbA1c variance in AFR but Thus, non-glycemic genetic effects can lower HbA1c level enough to lead to missed detection of pre-diabetes, especially in patients with African ancestry.

Background Sphingolipids are bioactive molecules responsible for cellular responses such as cell growth, death, and membrane dynamics. Recently, ceramides, a class of sphingolipids, have gained attention as antagonists for insulin signaling and drivers of metabolic diseases, including diabetes. While most research has focused on manipulating sphingolipid pathway genes to alter ceramide levels, little is known about the genetic determinants of their regulation. Here, we investigated genetic loci associated with circulating sphingolipid levels and identified variants located in cis-regulatory regions of key members of sphingolipid biosynthetic pathways. **Methods** We performed a genome-wide association study (GWAS) on 39 serum lipid traits, including dihydroceramides and ceramides, in 293 patients from the Utah Diabetes and Diabetic Complications Study. To identify variants driving cis-regulation of sphingolipid levels, we focused our analyses on single nucleotide polymorphisms (SNPs) that i) are reported as expression quantitative trait loci (eQTLs) from the Genotype-Tissue Expression (GTEx) Project for sphingolipid pathway genes, and ii) localize to candidate cis-regulatory elements from the Encyclopedia of DNA Elements (ENCODE) Project. **Results** Top associations were identified at several novel candidate genes, including *COL4A2*, *CPPED1*, and *THSD7B,* that may influence ceramide levels. Focusing on eQTL-associated SNPs for sphingolipid pathway genes, we identified rs35237501, near *CERS4*, in a cis-regulatory element associated with Cer16:0 levels. Additionally, we identified an intronic SNP (rs11006155) in *SGMS1,* associated with Cer16:0 levels. Additional associations were identified in cis-regulatory regions near *SPTLC2* for both Cer16:0 and Cer18:0. **Conclusion** Our study has identified genetic variants that are associated with both circulating sphingolipid levels, including lipotoxic ceramides, and expression of genes involved in the sphingolipid pathway. Importantly, these variants may predispose individuals to aberrant levels of ceramides, which can further influence disease progression in metabolic disorders. Further examination into these variants is necessary to understand the extent of their influence on ceramide levels and their role in disease.

PrgmNr 3659 - Grip strength, adiposity, and genetic risk of non-alcoholic fatty liver disease: Findings from the UK Biobank study

Disclosure Block: **T.M. Schnurr:** None.

Background and Aims: Non-alcoholic fatty liver disease (NAFLD) is a major cause of morbidity and mortality with an estimated global prevalence of 25%. Obesity and a sedentary lifestyle are risk factors for NAFLD. We investigated whether the genetic predisposition to NAFLD is altered by muscular fitness (as assessed by hand grip strength) and adiposity. We hypothesized that grip strength attenuates, while adiposity accentuates, the genetic risk of NAFLD.

Methods: Elevated levels of the liver enzyme alanine aminotransferase (ALT) in the absence of excessive alcohol intake and liver-related diseases are routinely used to identify individuals with NAFLD. Using UK Biobank data, we excluded individuals with excessive alcohol intake and liver-related diseases and restricted our analysis to the White British ancestry subset with available genotype information (N= 242,524). Genetic predisposition for NAFLD was quantified using a genetic risk score (GRS) comprising 77 loci that are associated with chronically elevated ALT levels in the Million Veteran Program. We used relative instead of absolute grip strength to reduce confounding effects of body size. Relative grip strength was calculated as the average of right- and left-hand measurements divided by whole body fat-free mass. We used linear regression models to test for associations of grip strength, body-mass index (BMI), and the GRS with ALT levels. We also tested for GRS*grip strength and GRS*BMI interactions on ALT. All analyses were adjusted for age, gender, Townsend deprivation index, and UK Biobank assessment center. Analyses including the GRS were additionally adjusted for genotyping array and the first ten genome-wide principal components. Phenotypic traits were rank inverse normally transformed to approximate normal distribution, and the effect sizes are thus reported in standard deviation (SD) units of the inverse normally transformed trait.

Results: Higher grip strength is associated with decreased ALT levels (Î²=-0.090 SD, p-16), while higher BMI is associated with increased ALT levels (Î²=0.28 SD, p-16). A higher GRS is associated with increased ALT levels (Î²=0.045 SD/allele, p-16), but grip strength attenuates this effect (p=1.1Ã10^{-5} for GRS-grip strength interaction), while adiposity accentuated this effect (p-16 for GRS-BMI interaction).

Conclusions: We confirm previous reports that adiposity amplifies the genetic risk of NAFLD, and discover that hand grip strength attenuates the genetic risk of NAFLD. Our results highlight the importance of normal weight and muscular fitness in the context of genetic predisposition to NAFLD.

PrgmNr 3660 - Integration of transcriptome genetics, metabolic perturbations, and trait associations identifies high-confidence cardiometabolic risk genes

Identification of causal genes for GWAS loci of cardiometabolic traits has been extremely challenging, and our understanding of how physiological and pharmacological stimuli modulate genetic risk for these loci is limited. Moreover, insulin resistance (IR), a common feature of type 2 diabetes, obesity and dyslipidemia, lacks well-powered GWAS and therefore few causal genes have been identified for IR. Here, we perform LD-adjusted integrative colocalization analyses across nine cardiometabolic traits combined with eQTLs and sQTLs from five metabolically relevant human tissues (subcutaneous and visceral adipose, skeletal muscle, liver, and pancreas). We identify 470 colocalized loci and further prioritize 207 loci with a single colocalized gene. To elucidate upstream regulators and functional mechanisms for these genes, we measure their transcriptional responses to 21 physiological and pharmacological cardiometabolic regulators in human adipocytes, hepatocytes, and skeletal muscle cells, and map their protein-protein interactions. The combination of genetic associations from our state-of-the-art colocalization approach with transcriptional responses to a large panel of metabolic perturbations provides a knowledge-based list of likely causal genes and potential upstream regulators in the context of IR-associated cardiometabolic risk.

PrgmNr 3661 - Investigation of Rapid-onset Obesity with Hypothalamic dysfunction, Hypoventilation and Autonomic Dysregulation (ROHHAD) by comprehensive whole genome sequencing

View session detail

Author Block: **S. Barclay**[1], A. Crawford[2], R. Wang[2], C. Rand[3], R. J. Taft[2], K. Kurek[1], N. T. Bech-Hansen[1], D. E. Weese-Mayer[3]; [1]Alberta Childrenâ□□s Hosp. Res. Inst. and Cumming Sch. of Med., Univ. of Calgary, Calgary, AB, Canada, [2]Illumina Inc., San Diego, CA, [3]Ann & Robert H. Lurie Childrenâ□□s Hosp. of Chicago and Stanley Manne Children's Res. Inst. Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Disclosure Block: **S. Barclay:** None.

Rapid-onset Obesity with Hypothalamic dysfunction, Hypoventilation and Autonomic Dysregulation (ROHHAD) is an ultra-rare pediatric disorder without a clear-cut etiology. Less than 200 cases have been described globally. The hallmark characteristic of affected children is rapid weight gain of 20-30 pounds over the course of 3-6 months before the age of 10, in addition to pronounced hypoventilation and autonomic dysregulation. Identification of the genetic etiology of ROHHAD would provide a much-needed diagnostic tool and insight into its pathogenesis and might offer intervention strategies. Prior candidate gene and whole exome sequencing studies in modestly sized cohorts have failed to discover a genetic basis for ROHHAD to date. Here, we undertook whole genome sequencing of the Lurie Childrenâ□□s Hospital cohort of 40 ROHHAD families (6 quads, 3 trios, 2 duos and 29 singletons), using DNA from peripheral blood or saliva samples, in an effort to establish a genetic basis for ROHHAD. In our extensive clinical study of ROHHAD, we have not identified affected siblings or parents, suggesting *de novo* mutations as a potential disease mechanism. In addition, ROHHAD has been described in 2 sets of identical twins discordant for the ROHHAD phenotype, supporting this theory, and possibly extending it to somatic, as opposed to germline, *de novo* variants. Despite an investigation that spanned all known disease genes, included SNVs, indels, SVs, repeat expansions and CNVs, and prioritized all potentially disease-causing variants based on both heuristic and AI-prioritization, no candidate disease genes were identified among ROHHAD probands. We also examined the coding and intronic regions of previously suggested ROHHAD candidate genes but found no consistent association in our dataset. Taken together, these results suggest that the underlying pathophysiology of ROHHAD is unlikely to stem from simple Mendelian inheritance. While we have previously reported a similar conclusion from exome sequencing in a subset of this cohort, we have now extended the analysis to include non-coding genetic variants that may affect splicing or gene regulation, structural variants, and repeat expansions--all of which cannot be reliably detected by exome sequencing. Now that the whole genomes of the expanded ROHHAD cohort (n=40) have been thoroughly searched for â□□simpleâ□□ genetic explanations, the ROHHAD research community can confidently move forward in exploring other tissue sources and other etiologies including complex/multifactorial genetic inheritance, somatic genetic variants, autoimmune pathology, a paraneoplastic syndrome, and an epigenetic basis.

Sexual dimorphism has been observed for autosomal variants in genetic association studies of fat distribution, but less so for overall obesity. Although the X chromosome represents ~5% of the genome, few genome-wide association studies (GWASs) have investigated the contribution of the X chromosome to obesity. To discover new loci and gain a better understanding of the role that the X chromosome plays in the genetic architecture of obesity, we conducted trans-ancestry meta-analyses of GWASs of body mass index (BMI) and waist-to-hip ratio unadjusted for BMI (WHR). Meta-analyses included up to 655,573 individuals (307,149 males and 348,424 females) from five major ancestries (African American, East Asian, European, Hispanic American, and South Asian) and were imputed to the 1000 Genomes Phase 3 and Haplotype Reference Consortium reference panels. Each study was analyzed separately for men and women using a linear mixed model. After applying quality control measures, the results were meta-analyzed using a fixed-effects model. In the trans-ancestry meta-analysis for BMI, we identified 9 loci at a stringent genome-wide significance level of P 1 million individuals with plans to conduct further fine-mapping of identified loci within and across ancestries and bioinformatic analyses to gain further insight into the biology of these variants.

PrgmNr 3663 - Ancestry-aware polygenic risk scores identify host factors behind susceptibility and disease outcomes associated to SARS-CoV-2 infection from a nationwide longitudinal direct-to-consumer survey of 30,000 individuals

Background: Despite advances in genetic medicine, our understanding of pleiotropy and variable expressivity remains poor. This persistent knowledge gap represents a key impediment in both stratifying health care delivery and predicting risk across a range of disorders. SARS-CoV-2 has highlighted this phenomenon by virtue of the fact that infected individuals present acutely varied manifestations, ranging from asymptomatic to severe complications or even death. Although some of this variability can be attributed to the genetic variation in the viral genome, underlying host conditions, and health disparities, recent data also suggest a significant contribution of the host genome to SARS-CoV-2 sequelae. The pandemic, together with our technological capacity to systematically test for infection and to genotype large numbers of individuals offers an unprecedented opportunity to identify host factors associated with disease susceptibility and progression across different ancestries. **Methods:** We collected information regarding COVID-19 risk factors and host genetics via an online survey from research participants belonging to a large nationwide direct-to-consumer genetic testing research cohort in the USA. Age, sex, ancestry, and preexisting conditions were explored as risk factors using bivariate and multivariate logistic regression models. **Results:** From June to November 2020, we collected information from 30,169 participants. From 2,851 individuals tested for COVID-19, we identified 220 (7%) who reported a positive COVID-19 test, of which 29 (1%) reported hospitalization with COVID-19 symptoms. Of those, 21 individuals required respiratory support in the ICU. Our logistic regression models predicted that non-European ancestry and preexisting health conditions were associated with a higher risk of hospitalization with an accuracy of 0.76 and 0.92 respectively. When controlled by cofactors, non-Europeans over 45 years and participants managing high blood pressure exhibited the highest risk (OR 2.44 and 1.54 respectively). Our polygenic risk score (PRS) analysis of phenotypes related to COVID-19 diagnosis and severity will likely improve our ability to predict genetic risk and help us locate specific loci contributing to this score. **Conclusions:** Preexisting genetic cohorts offer an unprecedented opportunity to identify genetic correlates of disease onset and progression. Our ongoing online survey is poised to identify multiple genetic determinants of disease susceptibility and severity for COVID-19 and, together with our local ancestry inference algorithm, help establish how these variants differ between ancestry groups.

PrgmNr 3665 - Common and rare variant analyses combined with single-cell multiomics reveal cell-type-specific molecular mechanisms of COVID-19 severity

The determinants of severe COVID-19 in non-elderly adults are poorly understood, which limits opportunities for early intervention and treatment. Here we present novel machine learning frameworks for identifying common and rare disease-associated genetic variation, which outperform conventional approaches. By integrating single-cell multiomics profiling of human lungs to link genetic signals to cell-type-specific functions, we have discovered and validated over 1,000 risk genes underlying severe COVID-19 across 19 cell types. Identified risk genes are overexpressed in healthy lungs but relatively downregulated in severely diseased lungs. Genetic risk for severe COVID-19, within both common and rare variants, is particularly enriched in natural killer (NK) cells, which places these immune cells upstream in the pathogenesis of severe disease. Mendelian randomization indicates that failed NKG2D-mediated activation of NK cells leads to critical illness. Network analysis further links multiple pathways associated with NK cell activation, including type-I-interferon-mediated signalling, to severe COVID-19. Our rare variant model, PULSE, enables sensitive prediction of severe disease in non-elderly patients based on whole-exome sequencing; individualized predictions are accurate independent of age and sex, and are consistent across multiple populations and cohorts. Risk stratification based on exome sequencing has the potential to facilitate post-exposure prophylaxis in at-risk individuals, potentially based around augmentation of NK cell function. Overall, our study characterizes a comprehensive genetic landscape of COVID-19 severity and provides novel insights into the molecular mechanisms of severe disease, leading to new therapeutic targets and sensitive detection of at-risk individuals.

Disclosure Block: **L. Jiang:** None.

Introduction: Infectious diseases are one of the most common causes of morbidity and mortality worldwide. Susceptibility to infection is highly heritable; however, little has been done to identify the genetic determinants underlying common infectious diseases. Previous associations were sought in small candidate gene studies, and there have been few GWAS applicable to US patients. The one relevant GWAS was performed using 23andMe data, but only self-reported infections.

Methods: We leveraged the EHR-based biobank at Vanderbilt and physician-confirmed diagnosis codes (International Classification of Disease [ICD]) to identify cases for 12 infectious diseases studied in the 23andMe GWAS: urinary tract infection (UTI), pneumonia, chronic sinus infections, otitis, candidiasis, hepatitis C, streptococcal pharyngitis, herpes zoster, cold sores, hepatitis B, infectious mononucleosis, and tuberculosis (TB). The number of cases ranged from 9359 (UTI) to 102 (TB). We selected controls from patients with no ICD code for the candidate disease and matched by year of birth, gender, and calendar year at 1st and last VUMC visits. We conducted GWAS using SAIGE (covariates: age, gender, EHR length, and PCs) and transcriptome-wide analysis (TWAS) using S-PrediXcan and Genotype Tissue Expression.

Results: We replicated three 23andMe hits (p-3); rs2808290-C (OR, 1.09; 95% CI [1.02-1.16]; $p=9.6\tilde{A}\square10^{-3}$) and rs114947103-C (OR, 1.09; 95% CI [1.00-1.18]; p=0.04) associated with ear infections. We also identified 3 novel associated regions (p-8). Top hits included: rs113235453-G for otitis (OR, 1.5; 95% CI [1.3-1.7]; $p=3.04\tilde{A}\square10^{-8}$); rs10422015-T for candidiasis (OR, 1.3; 95% CI [1.2-1.4]; $p=3.11\tilde{A}\square10^{-8}$); and rs1242993-C for TB (OR, 2.5; 95% CI [1.8-3.4]; $p=5.03\tilde{A}\square10^{-8}$). In TWAS, we identified 4 gene-disease associations: SLC30A9 associated with otitis ($p=8.06\tilde{A}\square10^{-7}$); LRP3 ($p=3.91\tilde{A}\square10^{-7}$) and WDR88 associated with candidiasis ($p=1.95\tilde{A}\square10^{-6}$); and AAMDC associated with hepatitis B ($p=1.51\tilde{A}\square10^{-6}$).

Conclusion: We conducted GWAS and TWAS for 12 common infectious diseases and identified novel genetic contributors to the susceptibility of infection diseases.

PrgmNr 3667 - Mid-density Gene Expression Profiling of SARS-COV-2 infected samples using Applied Biosystems TaqMan Flexible Array Panels

View session detail

Author Block: **A. Gupta**, S. Jackson; Thermo Fisher Scientific, South San Francisco, CA
Disclosure Block: **A. Gupta:** Salary/Employment; Thermo Fisher Scientific.
The broad spectrum of clinical manifestations from SARS-COV-2 infection, as well as the observed risk factors for severe disease, highlight the importance of understanding molecular mechanisms underlying COVID-19 disease development and progression. Research studies have identified a large number of host proteins that play roles in viral entry, innate immune response, or immune signaling during infection. The ability to interrogate subsets of these genes simultaneously within SARS-COV-2 infected samples is critical to understanding how their expression contribute to phenotypic variability of COVID-19 disease. To bridge this gap, we will use flexible TaqMan array panels designed by Applied Biosystems specifically for targeting the most cited genes related to entry and restriction factors as well as cytokines, chemokines, and growth factors. Each array features a curated list of predesigned TaqMan Gene Expression Assays that can be modified according to research objectives. In this initial study, these arrays will be used to highlight gene expression patterns that exist within confirmed SARS-COV-2 positive and negative nasopharyngeal swab samples and demonstrate the utility of these panels for gene expression profiling of SARS-COV-2 infected samples at medium throughput and scale.

PrgmNr 3668 - Multi-ancestry GWAS reveals association between absolute neutrophil count and *SETD1B*

Neutrophils are key components of immune response and make up the largest portion of white blood cells. Understanding the biology of neutrophils may reveal insights into interindividual variation in immune response and susceptibility to infection. We performed GWAS on absolute neutrophil count (ANC) on participants from ten sites from the Electronic Medical Records and Genomics (eMERGE) study, adjusting for known associated loci to detect novel signals. The data set include N=37,199 unrelated participants from multiple ancestries (N= 35,306 European ancestry, N=1,256 African ancestry, N=429 Asian/Pacific Islander/Native American ancestry; self-reported) with phenotype and genotype data. Previously, genotypes from multiple arrays were aligned and then used to impute genome-wide using the Michigan Imputation Server (PMID: 30298529). After quality control, there were approximately 10M SNPs in HWE with MAF > 0.005 and imputation r^2 > 0.3 for this study. As multiple records at multiple time points were available, we used the square root mean ANC and adjusted it for mean age, sex, the first four principal components of ancestry as well as independent (r^2 ACKR1) on chromosome 1 (2 SNPs, F-test p=3E-95), HLA region on chromosome 6 (4 SNPs, F-test p=5E-5), a known eQTL, rs542000 and *CDK6* on chromosome 7 (p=1.1E-8 and 8.8E-10, respectively) and *PSMD3* on chromosome 17 (5 SNPs, F-test p=3E-49). Using a p-value cutoff of 5E-8 and adjusting for inflation factor (Î»=1.02), the resulting GWAS detected signals at rs34599082 (p=1.9E-8), a missense in exon 2 of *ACKR1*, which is common in European and South Asian ancestries (MAF=0.01), as well as other previously reported loci including *CSF3R* on chromosome 1 (rs3917932, p=4.3E-11), an intergenic region on chr3 (rs6782812, p=1.4E-8) and a locus previously reported in Asian ancestry populations on chr19 (rs144284241, p=1.3E-10). Interestingly, we found a potentially novel locus on chromosome 12 with moderate evidence of association (rs117724148, p=2.1E-8). This SNP is an intronic variant of *SETD1B*, which plays a role in trimethylation of histones and is reported to regulate hematopoiesis in mice (PMID: 29916805).

PrgmNr 3669 - Predicting host response to Covid-19

View session detail

Author Block: **R. Allman**[1], J. McDevitt[2], N. M. Murphy[1], G. S. Dite[1]; [1]Genetic Technologies Limited, Fitzroy, Australia, [2]Inifinity BiologiX LLC, Piscataway, NJ
Disclosure Block: **R. Allman:** Salary/Employment; Genetic Technologies Limited. Receipt of Intellectual Property Rights/Patent Holder; Genetic Technologies Limited.
Epidemiological analysis of clinical risk factors associated with disease severity in people with COVID-19 began appearing on pre-print sites and in the literature soon after the declaration of COVID-19 as a pandemic. The availability of genetic data associated with disease severity has been slower, despite the establishment of the COVID-19 Host Genetics Initiative. Identification of host genetic factors that predispose individuals to severe COVID-19 is important, not only for understanding the disease and guiding the development of treatments, but also for risk prediction. Using SARS-CoV-2 positive participants from the UK Biobank, we developed and validated a clinical and genetic model to predict risk of severe COVID-19. We used source of test result as a proxy for severity of disease. Inpatient results were considered cases and outpatient results were considered controls. Of the 7621 eligible participants, 2205 (28.9%) were cases and 5416 (71.7%) were controls. We used multivariable logistic regression on a 70% training dataset and used the remaining 30% for validation. The resultant model comprised age, sex, ethnicity, body mass index, haematological cancer, non-haematological cancer, respiratory disease (excluding asthma), hypertension, diabetes, kidney disease, cerebrovascular disease, and 7 single-nucleotide polymorphisms (SNPs), with each SNP being incorporated as an independent risk factor.
The model was strongly associated with severe COVID-19 (odds ratio per quintile of risk=1.77, 95% confidence interval [CI]=1.64, 1.90). Discrimination (as assessed by the area under the receiver operating characteristic curve) was 0.732, 95% CI=0.708, 0.756. Calibration was assessed using logistic regression of the log odds of the risk score, with the model showing no evidence of over- or under-estimation of risk (Î±=â□□0.08; 95% CI=â□□0.21, 0.05) and no evidence or over-or under-dispersion of risk (Î²=0.90, 95% CI=0.80, 1.00).
We also attempted to validate the SNP panels identified by Pairo-Castinera et al. and found that when combined as polygenic risk scores, their two SNP panels had no ability to distinguish severe COVID-19 from non-severe COVID-19. We suspect that our inability to replicate their findings is because they used population controls instead of non-severe cases of COVID-19 and have identified SNPs associated with propensity to become infected rather than SNPs associated with severe COVID-19. Relying on population controls may not just attenuate results as Pairo-Castinera et al. claim. We propose that results from studies that use population controls to study severe COVID-19 should be interpreted with care.

PrgmNr 3670 - Identification of Gene Expression Patterns Associated With Polycystic Ovary Syndrome

View session detail

Author Block: **S. Lyle**, B. Drogemoller; Univ. of Manitoba, Winnipeg, MB, Canada
Disclosure Block: **S. Lyle:** None.
Background: Polycystic ovary syndrome (PCOS) is a common endocrine disorder, which is accompanied by a variety of comorbidities including metabolic, reproductive, and psychiatric disorders. PCOS is significantly influenced by genetics both in terms of germline genetic variants and epigenetic influences. While there are a number of treatment options for patients with PCOS, the administration of these therapeutics is done using a trial-and-error-based approach, which fails to provide optimal treatment outcomes for many patients.**Methods:** We performed a transcriptome-wide association study (TWAS) to uncover heritable gene expression profiles that are associated with PCOS. After colocalization analyses, the lead variants associated with both gene expression and PCOS were included in a Phenome-wide association study (PheWAS) using the UK Biobank (UKBB) and Finngen data. Drug repurposing using the data housed in CMap were performed to identify small molecules with significant similarity and dissimilarity to the PCOS gene expression profiles identified via the TWAS.**Results**: The TWAS analyses revealed that increased expression of *ARL14EP* was significantly associated with PCOS (P=1.6x10^{-6}), with increased expression of this gene shown to be of particular relevance to the female reproductive organs i.e. ovaries, uterus and vagina. Upon colocalization evaluation, rs4071559 was shown to be associated with both an increase in PCOS risk and *ARL14EP* expression. PheWAS analyses revealed that this variant was associated with a number of traits of relevance to PCOS, including increased length of menstrual cycles (P=8.5x10^{-34}), which is a key clinical feature of PCOS. The CMap analysis revealed a number of possible therapeutic candidates, including prednisone, which induces ovulation in patients with PCOS by directly reducing adrenal androgen production.**Discussion**: This TWAS of PCOS, being the first of its kind, has provided evidence for the role of *ARL14EP* in PCOS disease mechanisms. The drug repurposing analyses have opened avenues for the exploration of redirecting therapeutics to target the various physiology ailments associated with PCOS. By uncovering a genetic candidate of PCOS, this study has contributed to generating knowledge that can be used to guide strategies to improve the efficiency, accuracy, timing and safety of therapeutics used in the treatment of PCOS.

PrgmNr 3671 - Mendelian randomization analyses reveal no evidence of causal relationships between chronic health conditions and sporadic and recurrent miscarriage

View session detail

Author Block: **J. Painter**[1,2,3], T. Laisk[4], C. Lindgren[5], S. E. Medland[6,2,3]; [1]QIMR Berghofer Med. Res. Inst., Herston, Australia, [2]Univ. of Queensland, Brisbane, Australia, [3]Queensland Univ. of Technology, Brisbane, Australia, [4]Inst. of Genomics, Univ. of Tartu, Tartu, Estonia, [5]Big Data Inst., Oxford Univ., Oxford, Oxfordshire, United Kingdom, [6]QIMR Berghofer, Brisbane, Australia
Disclosure Block: **J. Painter:** None.
Miscarriage is estimated to end between 10-25% of clinically confirmed pregnancies. Observational studies have suggested that risk of miscarriage is increased by numerous chronic health conditions in mothers, such as uncontrolled type 2 diabetes, endometriosis, polycystic ovarian syndrome, hyper- and hypothyroidism, and various inflammatory conditions. However, definitive causal relationships between these potential risk factors and either sporadic or recurrent miscarriage have not yet been demonstrated. Using summary results from large-scale genome-wide association studies (GWAS) we have conducted two-sample Mendelian randomization association and sensitivity analyses to investigate relationships between miscarriage and chronic health conditions. Instrumental variables were constructed using 6-46 genetic variants significantly associated with type 2 diabetes, fasting glucose, fasting insulin, endometriosis, polycystic ovarian syndrome, FT4 and thyroid stimulating hormone (as measures of thyroid status), and C-reactive protein (as an inflammation marker). Associations of the instrumental variables with miscarriage were investigated using summary association data from women of European ancestry included in our miscarriage GWAS, including 49,996 sporadic miscarriage cases and 174,109 female controls, and 750 recurrent miscarriage cases and 150,215 female controls. We found no significant relationships between either sporadic or recurrent miscarriage and any of the listed chronic health conditions or status-measures. Endometriosis was nominally associated with recurrent miscarriage (Inverse variance weighted odds ratio= 1.03, 95% confidence intervals 1.00-1.07, Pvalue=$2.9x10^{-2}$), but this association did not reach the threshold for multiple testing (Pvalue=$6.25x10^{-3}$). In summary, we find no evidence of a causal link between any of the chronic health conditions tested to date and miscarriage. While data utilised here come from large-scale GWAS including 1000s of individuals, genetic variants significantly associated with each risk factor currently explain small percentages (0.02-5%) of the variance in each trait. Larger GWAS for specific risk factors, and for sporadic and recurrent miscarriage, will be required to clarify some of these potential risk relationships.

PrgmNr 3672 - Development of a discovery pipeline for structural variation contributing to the cause of amyotrophic lateral sclerosis

View session detail

Author Block: **E. McCann**[1], S. Chan Moi Fat[1], L. Henden[1], K. L. Williams[1], G. A. Nicholson[2], D. B. Rowe[1], J. A. Fifita[1], I. P. Blair[1]; [1]Macquarie Univ. Ctr. for MND Res., Sydney, Australia, [2]Northcott NeuroSci. Lab., ANZAC Res. Inst., Sydney, Australia
Disclosure Block: **E. McCann:** None.
Amyotrophic lateral sclerosis (ALS; also known as Lou Gehrigâ□□s disease) is a fatal neurodegenerative disease. Death of the upper and lower motor neurons causes progressive muscle weakness and eventual paralysis, culminating in death from associated respiratory failure. Approximately 10% of ALS cases are familial, while the remainder occur apparently sporadically. Gene mutations are the only known cause of ALS, and with over 30 ALS genes identified, ALS is genetically heterogeneous. Despite heritability estimates of 40-60% for all forms of ALS, only ~40% of familial and ~10% of sporadic ALS can be explained by known ALS gene mutations. As such, almost 90% of ALS cases remain with no known genetic predisposition.

Though almost all ALS gene mutations identified to-date have been small nucleotide level changes, the most common known cause of ALS is a more complex pathogenic expansion of a short tandem repeat within the *C9orf72* gene. This mutation spans thousands of nucleotides, and is therefore comparable in size to large structural variants (SVs). Coupled with the implication of SVs in other neurodegenerative conditions such as Parkinsonâ□□s disease and spinocerebellar ataxia, this suggests that novel SVs are likely to account for a percentage of ALS cases. The study of SVs in ALS has so far been precluded due to various technical hindrances but is now feasible with the advent of sophisticated tools and technologies.

Using whole genome sequencing data from 650 ALS cases, we have developed a discovery pipeline for ALS relevant SVs. This involves the application of several bioinformatics tools including Lumpy, Manta, MetaSV, Duphold, ReciprocalOverlapAnnotator, AnnotSV and Samplot to generate a high confidence SV call set in each individual. This is followed by customised R filtering strategies to remove population-based SVs and perform cohort specific analyses. We have successfully applied this pipeline to a small ALS family to identify just seven candidate SVs from an initial >7000, one of which is potentially acting as the cause of ALS within this family, following the exclusion of all SNP/indel variants. Using these candidate SVs, we are currently optimising our wet-lab SV validation strategy employing a combination of traditional PCR, repeat-primed PCR, TaqMan assays and Bionano Genomics optical genome mapping.

The identification of novel SVs in ALS will not only implicate novel ALS genes, but also highlight SV as an important contributor to ALS pathogenesis. ALS relevant SVs will be prime targets for much needed therapeutic development, particularly given their effects on gene expression and the recent promise shown by gene silencing therapies in ALS clinical trials.

PrgmNr 3673 - First joint exome and metabolome analysis in dyslexia implicates immune system deficits and dysregulated sensory perception

View session detail

Author Block: **R. Nandakumar**[1], V. Dinu[1], X. Shi[1], H. Gu[1], Y. Kim[2], W. H. Raskind[3], B. Peter[4]; [1]Arizona State Univ., Tempe, AZ, [2]Arizona State Univ., tempe, AZ, [3]Univ of Washington, Seattle, WA, [4]Arizona State Univ, Tempe, AZ

Disclosure Block: **R. Nandakumar:** None.

Dyslexia is a common learning disability affecting children's reading and spelling development[1-3]. Dyslexia is thought to be under genetic influence, but despite decades of research, the mechanisms of genetic disruptions are not yet well understood. Similarly unclear is the role of associated health impairments, such as immunodeficiency[4,5] and sensory dysregulation (neural noise hypothesis)[6] Findings are mixed, with some studies showing evidence for immune system disorders [4,7] while others do not [5]. DNA is not the only biological agent that may influence dyslexia. Metabolomics, which is a rapidly evolving field of measuring endogenous metabolites in a cell or body fluid, may contribute new insights into the biology of dyslexia [8]. A few recent studies have examined neurometabolite concentrations in children[9], adults[10], and both[11] with dyslexia. They found a correlation between a wide range of reading skills and neurometabolites concentration (e.g., choline) in medial occipital and left temporoparietal cortices. Here, we report the first experimental joint exome and metabolome study in adults and children with dyslexia and some of their family members. Exomes of 38 individuals (29 with dyslexia) and metabolomes of 26 individuals (17 with dyslexia) were available; both data types of were available for 21 of these individuals. Two metabolites, pyridoxine and kynurenic acid, were found in significantly lower concentrations ($p = .0076, .0258$, respectively) in the individuals with dyslexia, compared to the controls. Pyridoxine plays a role in Vitamin B6 metabolism, which is implicated in autism spectrum disorder (ASD). Kynurenic acid has been implicated in sensory signal/noise filtering in schizophrenia and ASD. A gene ontology analysis based on the output of an allelic association analysis showed significant (p

Disclosure Block: **M.K. Lupton:** None.

Neuronal iron is likely to be the major source of contrast captured by MRI using quantitative susceptibility mapping (QMS), which quantifies magnetic susceptibility, a fundamental electromagnetic property. Iron accumulation in the brain, as measured by QSM is associated with normal aging and neurodegenerative processes where it has been shown to associate with cognitive decline and implicated in Alzheimerâ□□s disease and Parkinsonâ□□s disease pathogenesis.

Using brain MRI data from the UK Biobank we computed QSM images by combining multi-channel phase and magnitude data from a T2*-weighted sequence with 19.7 ms Echo-time. Anatomical MRI images were automatically segmented to identify corresponding cortical and subcortical regions on QSM.

We carried out a Genome Wide Association Study (GWAS) of neuronal iron measured using QSM in each brain region with a sample size of approximately 35,000 individuals. We identify novel genetic risk variants for iron accumulation in the brain, highlighting key pathways. In addition, we examine genetic relationships of iron accumulation in the brain with peripheral iron measures and neurodegenerative diseases using LD score regression. We investigate causal relationship between iron accumulation and Neurodegenerative diseases using Mendelian Randomization (MR) methods. This is the largest GWAS study to date for neuronal iron measured using QSM. Our findings support the utility of QSM as a proxy for brain iron and increase our understanding of the biological pathways leading to iron accumulation. Previous work has shown a clear association of brain iron accumulation with neurodegenerative disease, but this analysis allows for the investigation of the causal relationship, without confounding from reverse causation.

PrgmNr 3675 - Integrated gene analyses of *de novo* mutations from 46,612 trios with autism and developmental delay

Coding *de novo* mutations (DNMs) have identified hundreds risk genes for neurodevelopmental disorder (NDD); however, most studies have considered autism spectrum disorder (ASD) and developmental delay (DD) separately despite the overwhelming comorbidity and shared DNM genetic etiology. To increase power, we integrated DNMs from 15,560 ASD and 31,052 DD trios and performed comprehensive enrichment analyses using three models. We considered diagnostic overlap, mutation class, sex differences, and functional enrichments of risk genes. In total, we identified 615 NDD candidate risk genes predicted by one or multiple models (FDR 5%, 189 potentially novel), which including 138 genes reaching exome-wide significance supported by all models (*P* GATAD2B and *KIF1A*) are exclusive to have DNM only in DD. In contrast, no ASD-specific genes were identified. Considering the mutation class, we identify 12 genes enriched for likely gene-disruptive DNM compared to 41 genes that incur predominantly missense DNM. By treating males and females separately, we identify 22 genes show sex-specific bias (*P* DDX3X, *MECP2*, *SMC1A*, *WDR45*, and *HDAC8*) also show significant DNM burden in females when compared to males. NDD risk genes grouping into five main protein-protein interaction networks, which tend to associate with distinct cellular lineages based on single-nucleus transcriptomic data. Our results identify new candidate genes as well as functional networks, defining both gene-, mutation class, and sex-specific differences among DNM, which are important for future clinical diagnosis and functional studies.

PrgmNr 3676 - Multivariate genomewide associations on microstructural compartments of human brain highlight the consistent neurodevelopmental molecular pathways from adolescent to late adulthood

View session detail

Author Block: **C. Fan**; Univ California San Diego, La Jolla, CA
Disclosure Block: **C. Fan:** None.
Background: It is important to understand the molecular determinants for microstructures of human brain. Here, we adopt novel imaging processing methods and multivariate GWAS on two large scale imaging genetic datasets to identify key genetic association signals**Study Methods:** UK Biobank participants who have received MRI scans before 2019 as discovery set (n = 23666) and who received MRI scans between 2019 and 2020 were replication set (n = 6396). Furthermore, we used Adolescent Brain Cognitive Development study (ABCD) for further replication (n = 8189). The tissue compartments were inferred based on the mixture modeling [White et al., 2013, 2014]. Three metrics for the tissue compartments were derived. ND as normalized directional signals represents the tissue properties within a tubular structure, such as axonal bodies. N0 as normalized zeroth order signals represents the tissue properties within a cell body, such as neurons. NF as normalized free diffusions represents free water elements outside of the cell body, such as CSF. We applied the combined principal component analyses proposed by Aschard et al., 2014, for discovery. In the replication stage, the loci effects across voxels from the discovery samples were projected onto replication samples. The gene enrichment analyses were performed using MAGMA [de Leeuw et al., 2015] and ShinyGO [Ge et al., 2020]. The anatomical enrichment analyses is by contrasting the observed average effect size per ROI over the null distribution of the average effect size per ROI, sampled from none-significant SNPs (p Results: We found 372, 599, and 471 unique loci for NF, N0, and ND, respectively. Among those discovered loci, 292 (78%), 461 (77%), and 383 (81%) can be replicated in the independent UKBiobank replication set for NF, N0, and ND. Furthermore, 97 of the NF loci (26%), 118 of the N0 loci (20%), and 180 of the ND loci (38%) can be replicated in the ABCD study. The effects of the loci replicated in both datasets are enriched in the cerebellum for NF, corpus callosum for N0, and motor related pathways for ND. Gene-set enrichment analysis shows evident enrichment in neurogenesis and nervous system development across all tissue compartments (Enrichment FDR Conclusion: We found consistent neurodevelopmental molecular pathways from adolescent to late adulthood in microstructures of human brain.

PrgmNr 3677 - Pairwise contributions of 16p11.2 CNV genes to brain-related traits

View session detail

Author Block: **M. Vysotskiy**[1], L. A. Weiss[2]; [1]Dept Psychiatry, Univ California San Francisco, San Francisco, CA, [2]Univ California San Francisco, San Francisco, CA
Disclosure Block: **M. Vysotskiy:** None.
Deletions and duplications of the 16p11.2 copy number variant (CNV) region are associated with a variety of brain-related disorders, including schizophrenia, obesity, autism spectrum disorder, bipolar disorder, and intellectual disability. The region contains approximately 30 coding and 30 noncoding genes, and the relationship between genes at the locus and the associated brain-related traits is not yet understood. We expect deletions and duplications to affect gene expression. To impute gene expression in large (non CNV-carrier) GWAS datasets, and measure association between individual CNV gene expression and trait, we can use PrediXcan. Previously, we have used this methodology to identify individual 16p11.2 genes driving schizophrenia, BMI (measuring obesity), and IQ (measuring intellectual disability), but we could not find single-gene drivers of autism or bipolar disorder. Given that there may be multiple 16p11.2 genes affecting each trait, it may be advantageous to analyze the effects of multiple 16p11.2 genes acting together. To systematically consider pairwise effects of two 16p11.2 genes expressed in the same direction (as would be the case in CNV carriers), we extended the PrediXcan model training and association approach to consider pairs of genes. We tested over 1,500 expression-imputed pairs of 16p11.2 genes for association with autism, BMI, and IQ using publicly available summary statistics across 49 GTEx tissues. We found a contribution of pairs of 16p11.2 genes to BMI larger than that of control genomic regions matched on gene count, length, and coding to noncoding gene ratio. Top associated pairs include those where neither gene had an independent main effect, and those including non-coding genes. Our study provides in-silico evidence that pairwise effects of genes within the 16p11.2 CNV drive one or more brain related traits.

PrgmNr 3678 - Association between complement component 4 variation and childhood brain and behavioral phenotypes: Multiethnic PheWAS in the Adolescent Brain and Cognitive Development (ABCD) Study

View session detail

Author Block: **L. Hernandez**[1], M. Kim[2], G. Hoftman[1], R. Bethlehem[3], W. K. Thompson[4], M. Gandal[5]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]David Geffen Sch. of Med. at UCLA, Los Angeles, CA, [3]Univ. of Cambridge, Cambridge, United Kingdom, [4]Univ. of California, San Diego, La Jolla, CA, [5]UCLA, los angeles, CA

Disclosure Block: **L. Hernandez:** None.

Background: The most significant common variant association for schizophrenia (SZ) reflects increased expression of the complement component 4A (*C4A*) gene. However, it remains unknown whether *C4A* expression affects childhood brain development and is associated with prodromal psychosis. To address these questions, we performed a multiethnic phenome-wide association study in 7,792 youth ages 9-10 to examine how individual variability in genetically predicted *C4A* expression is related to the number and severity of psychosis-like events (PLEs), psychiatric/behavioral traits, and brain structure (volume, cortical thickness, surface area [SA]).

Methods: Data were obtained from the ABCD Study. *C4* haplotypes were imputed using a multiethnic reference panel (Kamitaki, 2020) and predicted *C4A* gene expression was computed using previously published weights (Sekar, 2016). PLEs were measured with the Prodromal Psychosis Scale and the Kiddie Schedule for Affective Disorders and Schizophrenia. Polygenic risk scores (PRS) for SZ were computed using PRS-CS. As previous work suggests that smoking also affects *C4A* expression in the brain (Kim, 2021), we tested how parentâ□□s self-reported smoking may interact with *C4A* to affect childrenâ□□s brain structure. Results were FDR corrected at p**Results**: Predicted *C4A* expression was unrelated to childhood PLEs, psychiatric symptomatology, or global brain size. However, predicted *C4A* expression was associated with reduced SA of the entorhinal cortex (ENT), demonstrating a sex-biased effect such that *C4A* expression had a significantly greater impact on ENT SA in male relative to female youth. Further, smaller ENT SA at 9-10 years predicted, in both males and females, greater number and severity of PLEs 1-year later. SZ PRS was unrelated to ENT SA. The C4A x smoking interaction was significant; youth whose parents smoked more had smaller ENT SA regardless of predicted *C4A* expression levels, while youth whose parents smoked less had smaller ENT SA only in the context of high predicted *C4A* expression.

Discussion: This characterization of the neurodevelopmental effects of *C4A* suggests sex-differences in the effects of *C4A* on regional temporal lobe structure, which is independent of polygenic risk for SZ. Further, we find that the effects of inferred exposure to second-hand smoke on ENT SA mirrors the effects of genetic risk for schizophrenia on the C4 locus. Overall, these data indicate that reduced ENT SA in childhood may serve as a biomarker for schizophrenia risk prior to symptom onset and highlight the importance of large-scale genetic investigations into the predictors of psychiatric disorder in pediatric populations.

PrgmNr 3679 - Polygenic risk and causal inference of psychiatric comorbidity in inflammatory bowel disease

View session detail

Author Block: **P. Hu**[1], Y. Li[2], C. Bernstein[1], W. Xu[2]; [1]Univ. of Manitoba, Winnipeg, MB, Canada, [2]Univ. of Toronto, Toronto, ON, Canada
Disclosure Block: **P. Hu:** None.
Approximately, 40% of patients with inflammatory bowel disease (IBD) experience psychiatric comorbidities (PC). Previous studies demonstrated the polygenetic effect on both IBD and PC. In this study, we evaluated the contribution of the genetic variants to the PC susceptibility among the IBD population, and whether this effect is mediated by the expression levels of *RBPMS*, which is a potential risk factor of PC in IBD patients identified in our previous studies. The polygenic risk score (PRS) was estimated among IBD patients (n=240) from the Manitoba IBD cohort study by using external Genome-Wide Association Studies. The association and prediction performance were examined between the estimated PRS and the PC status in IBD patients. Finally, regression-based models were applied to explore whether the expression levels of the *RBPMS* gene are a mediator between estimated PRS and PC status in IBD. The estimated PRS had a significantly positive association with PC status (for the highest effect: P-value threshold=$5*10^{-3}$, odds ratio=2.3, P-value= $4.1*10^{-7}$). Around 10**%** of the causal effect between the PRS and PC status in IBD was mediated by the expression levels of the *RBPMS* gene. The area under the curve of the PRS-based PC prediction model is around 0.7 at the threshold of $5*10^{-4}$. In conclusion, the PC status in IBD depends on its genetic influences. Around 10% of this genetic influence could be explained by the expression levels of the *RBPMS* gene.

PrgmNr 3680 - Polygenic risk scores for Bipolar Disorder predict age of diagnosis and the number of lifetime psychiatric diagnoses experienced by participants in the Australian Genetics of Bipolar Disorder Study

View session detail

Author Block: **P. A. Lind**[1], I. B. Hickie[2], D. J. Siskind[3], C. M. Olsen[4], D. C. Whiteman[4], N. G. Martin[5], S. E. Medland[5]; [1]Psychiatric Genetics, QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [5]QIMR Berghofer Med. Res. Inst., Brisbane, Australia

Disclosure Block: **P.A. Lind:** None.

Bipolar Disorder (BD) is a severe mental illness which can result in a high degree of disability. The 2021 Psychiatric Genomics Consortium (PGC) BD genome wide association study (GWAS) identified 64 associated genomic loci (Mullins et al, 2021) and the polygenic risk scores (PRSs) for BD explained ~4.6% of phenotypic variance. Herein we examined whether increased genetic risk (indexed by PRSs derived from the 2021 PGC study) would be associated with earlier age of diagnosis and a higher number of lifetime psychiatric diagnoses in individuals living with BD from a nationally recruited cohort. Genetic and phenotypic data were available for 3,570 unrelated BD cases and 12,591 unrelated controls. Participants with lived experience of BD (68.7% female, aged 44.7Â±13.5, n=3,570) were recruited to the Australian Genetics of Bipolar Disorder study from electronic prescription records and a national media campaign. BD diagnosis was determined using the self-report Mood Disorder Questionnaire (Hirschfield, 2002) and items derived from the DSM-5 criteria for BD. Age of diagnosis (AOD; N=2868) and number of lifetime psychiatric diagnoses (DIAGNOSES; N=3462) were self-reported. Controls were drawn from the Australian QSkin Sun and Health Study (50.9% female, aged 61.3Â±7.9, N=12,591). PRSs were calculated in PLINK using the clumping and thresholding approach. Linear and logistic regressions were performed, controlling for relatedness, ancestry, sex, age and age2 at survey time, and sex*age. The PRS significantly explained 2.8% of the phenotypic variance in BD on the liability scale (P=5.9E-62), 0.07% of AOD (P=8.13E-05), and 0.3% of DIAGNOSES (P=5.9E-04). Compared to individuals in the lowest 10% of the GWAS P-value threshold

PrgmNr 3681 - A GWAS of atopic dermatitis in African American individuals

View session detail

Author Block: **M. Boorgula**[1], M. Daya[1], N. Rafaels[1], M. Campbell[1], S. Chavan[1], C. H. Arehart[1], T. M. Brunetti[1], C. Cox[1], R. A. Mathias[2], K. C. Barnes[1]; [1]Univ Colorado, Aurora, CO, [2]Johns Hopkins Univ, Baltimore, MD

Disclosure Block: **M. Boorgula:** None.

Atopic dermatitis (AD) is a complex chronic skin disease affecting up to 30% of children, often persisting into adulthood. Despite an increased burden of AD in African ancestry populations in the USA, to date, most GWAS of AD were performed in subjects of Asian and European ancestry. The largest GWAS of AD published by the EArly Genetics & Lifecourse Epidemiology (EAGLE) eczema, also included only 1% African ancestry populations. To reduce this paucity of information from GWAS of AD in African ancestry populations, we performed and report the results of a GWAS in 1,113 African American AD cases & controls using Illuminaâ□□s multiethnic global array (MEGA). SNPs that failed on hardy-weinberg, missingness thresholds and that showed significant differences in cases between batches, were excluded. PCA analysis was performed using Genesis PC-AiR and two outliers identified on PC1 (6 standard deviations away from the estimated mean) were excluded. A final data set with 1,111 individuals and 914,377 SNPs was imputed against the TOPMed reference panel and 14,721,903 SNPs with Rsq >= 0.7, MAF>=1% were retained for association analysis. Logistic mixed effects models were used to test for association between allelic dosage and case-control status using the GENESIS R â□¯Bioconductor package. 54 SNPs were suggestive (P-6), from which 13 independent sentinel SNPs were identified. Three SNPs (rs72745472 on chromosome 1, rs12350801 and rs369559451 on chromosome 9) reached genome-wide significance (P-8). SNP rs116000308 (in chromosome 15q22) maps to the *SNX1* gene, which encodes an endosomal protein that regulates the cell-surface expression of epidermal growth factor receptor (EGFR). EGFR plays a crucial role in skin development ,homeostasis and EGFR ligands have been found to be upregulated in chronic inflammatory skin disorders, such as psoriasis, AD, allergic contact dermatitis. All 54 significant SNPs were tested for replication in UKbiobank, EAGLE, BioMe, AD GWAS in Afro-brazilian cohort and imputed data from Colorado Center for Personalized Medicine biobank. Unfortunately, none of the SNPs showed replication in any of these data sets. We identified novel associations in atopic dermatitis individuals from African ancestry in loci on chromosome 15 and chromosome 9 that reached genome level significance. Lack of replication in multiple data sets tested might explain the potential challenge related to power and the definition of the phenotype used in different studies. For future work, we plan to perform integrative omics analyses which will help overcome the power issue and help understand and support novel genetic associations identified from this analysis.

PrgmNr 3683 - A repetitive request: for the genome wide study of short tandem repeats in human phenotypic variation

View session detail

Author Block: **J. Margoliash**[1], S. Saini[2], A. Goren[3], M. Gymrek[2]; [1]Univ. of California, San Diego, CA, [2]Univ California San Diego, La Jolla, CA, [3]UCSD, San Diego, CA
Disclosure Block: **J. Margoliash:** None.
Genome wide association studies (GWAS) have allowed the scientific community to identify the genetic basis of human phenotypes faster than ever before. GWAS findings motivate follow-up mechanistic and medical studies and thus drive our understanding of and ability to treat disease. GWAS traditionally have focused on single nucleotide polymorphisms and short indels (collectively known as SNPs) as they are relatively easy to call from cheap whole genome sequencing (WGS) assays. However, SNPs fail to explain much of the heritability of many complex traits, and detailed analysis of GWAS hits often reveals nearby, more complex, variants to be causal.
Here we produce the first GWAS in a population-scale dataset that studies short tandem repeat (STR) as well as SNPs. STRs are a highly polymorphic class of genetic variants that have been implicated in many diseases and have been estimated to account for 10-15% of *cis* heritability of gene expression. Preliminary evidence suggests noncoding STRs regulate gene expression in a variety of manners - disrupting methylation and repositioning nucleosomes among others. However, until now STRs have largely been excluded from GWAS due to the difficulty of calling them in cheap WGS assays and the lower power inherent in analyzing polymorphic variants, and this has constrained our ability to broadly delineate the role of STRs in human phenotypic expression.
We overcome these limitations by imputing the genotypes from our 2,500 person SNP-STR reference haplotype panel into the SNP callsets of the 500,000 UK Biobank participants. We perform association tests of the imputed STRs against a variety of human phenotypes such as height and white blood cell count. We apply fine-mapping techniques to identify signals previously published by SNP-only GWAS that we predict to be causally driven by a nearby STR, and examine the potential mechanisms by which those STRs act. Lastly, we quantify the additional heritability of each trait explained when also considering STRs.
Our preliminary results suggest that 9% of the genomic signal for height is causally driven by STRs, and that 20% of the genomic regions which are correlated with height contain an STR that has a posterior probability of causality of at least 50%. These data demonstrate that conclusions drawn from GWAS and fine-mapping studies run only on SNPs may frequently be misleading. We hope these data and the analysis pipeline we provide will encourage other researchers to incorporate STRs into their GWAS so as to strengthen the validity of their results, increase their odds of finding medically relevant associations, and provide further insight into the biology of STRs.

PrgmNr 3684 - Enabling biobank-scale GWAS data sharing with efficient compression and indexing

View session detail

Author Block: **K. Schneider**[1], C. R. Gignoux[2], R. Layer[3]; [1]Univ. of Colorado Boulder, Boulder, CO, [2]Univ of Colorado Denver, Anschutz Med. Campus, Aurora, CO, [3]Univ. of Colorado, Boulder, CO
Disclosure Block: **K. Schneider:** None.
A global surge in biobanksâ□□large-scale biomedical databases which match electronic health records to genetic dataâ□□have offered the unprecedented ability to investigate links between phenotype traits and their possible genotypic causes. The ability to use data from these biobanks to uncover important information regarding risk factors and prognosis for a wide range of traits has led to an increase in genome wide association studies (GWAS). Projects such as UK Biobank have done GWAS for hundreds of thousands of individuals across thousands of traits, and we are likely to see similarly sized experiments performed by other biobanks. With current technologies, the summary statistics alone from each GWAS require up to 2GB of storage space, which amounts to over 700TB for the UK Biobank alone. The already large and growing number of GWAS ensures interest in sharing summary statistics data for greater population-wide discovery; but the sizes of these files creates a bottleneck which limits our ability to perform this large-scale sharing and analyses. Current tools like bgzip and tabix are effective for compressing and indexing files of this size, but are general solutions that are not optimized for GWAS data (e.g., summary statistics). For this reason, there is an immediate demand for new methods which allow for especially efficient storage, compute, and sharing ability for GWAS files. We propose a method which achieves more efficient storage with better compression ratio and faster decompression times by use of fast integer-based codecs, which outperform standard codecs (gzip, zlib, or LZ4). Furthermore, we include the addition of summary statistic indexing, which complements traditional genomic position indexing to drastically improve retrieval times of many GWAS queries. This strategy can, for example, quickly identify significant SNPs in a target gene across thousands of traits. Our new file format for compressed GWAS data can be stored, shared, and indexed more efficiently than files compressed with the current standard compression tools, and is freely available at https://github.com/kristen-schneider/gwas-compress.

PrgmNr 3685 - Genetic burden of cardio-metabolic diseases on womenâ□□s health outcomes from a study of multi-ancestry population

View session detail

Author Block: **B. Xiao**[1], A. Lucas[1], T. Drivas[2], M. D. Ritchie[1], S. S. Verma[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Children's Hosp. of Philadelphia, Philadelphia, PA
Disclosure Block: **B. Xiao:** None.
Cardio-metabolic diseases are generally comorbid with other conditions and are associated with poor health outcomes. However, the investigation of the genetic burden of cardio-metabolic diseases with womenâ□□s health phenotypes such as ovarian cancer and many pregnancy-related complications is highly understudied in large populations. Polygenic risk scores (PRS) can be used to characterize shared genetic effects that could estimate disease risk, and the Penn Medicine Biobank (PMBB) is an electronic health record-based academic biobank consisting of genomic data on many women from multiple ancestries. To analyze the shared genetic effect of PRS from common cardio-metabolic diseases on phenotypes of womenâ□□s health, we calculated PRS for women in PMBB using PRS-CS with an external trans-ancestry LD reference panel and the largest trans-ancestry summary statistics available for seven phenotypes (body mass index (BMI), coronary artery disease, chronic kidney disease, myocardial infarction, type 2 diabetes (T2D), hypertension, and lipid measurements such as high-density lipoprotein (HDL) and triglycerides (TG)). We then tested the association of PRS with clinical lab measurements and case/control phenotypes for all participants and stratified by European and African ancestry. Our analysis identified >30 significant associations reflecting shared biology among common cardio-metabolic phenotypes and diseases such as ovarian cancer, polycystic ovarian syndrome (PCOS), and pregnancy related complications such as postpartum hemorrhage. We replicated known associations such as association of BMI PRS with median overall BMI in women and median BMI during pregnancy. We also identified shared etiology between ovarian cancer and coronary artery disease ($p = 0.0067$) and associations of T2D PRS with PCOS ($p = 0.0064$) and gestational diabetes ($p = 0.0047$) among African ancestry individuals. Additionally, PRS for HDL and TG were significantly associated with excessive fetal growth ($p = 0.0096$) and intrauterine death ($p = 0.0045$) respectively. T2D PRS was also associated with postpartum hemorrhage ($p = 0.002$) when analyzing all participants. Our findings indicate that comorbid womenâ□□s health disorders and cardio-metabolic diseases reflect a dual burden of cardio-metabolic and female-specific genes; the latter may also contribute to pregnancy-related outcomes. Since the strength of association for many phenotypes varied greatly among European and African ancestry groups, our results also highlight that clinical care recognizing racial differences among this dual burden may help improve health outcomes in women living with comorbid disorders.

PrgmNr 3686 - Genetic variants affecting the expression of two Mendelian deafness genes are associated with age-related hearing impairment

View session detail

Author Block: **M. Wilke**[1], B. Drogemoller[1,2,3]; [1]Dept. of Biochemistry and Med. Genetics, Univ. of Manitoba, Winnipeg, MB, Canada, [2]The Childrenâ□□s Hosp. Fndn. of Manitoba, Winnipeg, MB, Canada, [3]CancerCare Manitoba Res. Inst., Winnipeg, MB, Canada
Disclosure Block: **M. Wilke:** None.
Introduction: Age-related hearing impairment (ARHI) is one of the most common sensory impairments in the aging population. ARHI has been shown to be genetically heterogeneous and has genetic mechanisms which are largely unknown. As past genome-wide association studies performed for ARHI have shown that regulatory variants play an important role in ARHI, transcriptome-wide association studies (TWAS) can provide an excellent framework to shed light on the genetic etiology of this complex trait. **Methods:** TWAS were performed on two independent hearing loss cohorts (discovery (n=330,759) and replication (n=52,409)), to determine which hearing loss associated variants have an effect on gene expression levels across various tissues. Both hearing loss genome-wide association summary statistics and expression reference panels from the Genotype-Tissue Expression database were used as input for TWAS analyses performed with S-PrediXcan. Genes that were significantly associated (*P*-6) with hearing loss in the discovery cohort were investigated in the replication cohort. The role of these genes in hearing loss was validated using murine inner ear gene expression databases (gEAR and Shared-Harvard Inner Ear Laboratory Database), gene set overrepresentation analysis (Enrichr) and annotation platforms (FUMA:Gene2Func). **Results:** TWAS analyses in the discovery cohort identified significant associations between hearing loss and thirty-five genes. Two of these genes were replicated in the independent cohort: *TRIOBP* (discovery cohort: $P=4.6x10^{-8}$, z-score=0.67; replication cohort: $P=7.8x10^{-8}$, z-score=1.2) and *ILDR1* (discovery cohort: $P=2x10^{-7}$, z-score=-0.002; replication cohort: $P=4.4x10^{-4}$, z-score=-0.48). Further investigation of these genes revealed that both genes were enriched for abnormal hair cell functions, had high expression in inner and outer ear hair cells, and were associated with hearing loss phenotypes in both mice and humans. **Conclusion:** To the best of our knowledge, this is the first study to perform a TWAS of hearing loss. This TWAS identified two genes, *TRIOBP* and *ILDR1*, that were associated with age-related hearing impairment in two independent hearing loss cohorts. Several lines of evidence have supported the role that these Mendelian deafness genes play in hearing loss. As past research has shown that variants affecting the expression of Mendelian deafness genes play a role in non-Mendelian forms of hearing loss, future research should examine the relevance of these findings to other hearing loss traits.

PrgmNr 3687 - Low-Coverage Whole Genome Sequence Genotyping Pipeline on Heterogeneous Stock Rats

View session detail

Author Block: **D. Chen**, R. Cheng, A. S. Chitre, O. Polesskaya, A. A. Palmer; Univ. of California San Diego, La Jolla, CA
Disclosure Block: **D. Chen:** None.
Both mice and rats are widely used mammalian model organisms; however, for certain phenotypes, rats are preferred over mice. For example, complex behavioral paradigms such as those used to study drug abuse-related phenotypes, are more easily studied in rats. Our laboratory has focused on the use of outbred heterogeneous stock (HS) rats, which were derived in 1984 by intercrossing 8 inbred rat strains, which have now been deeply sequenced. HS rats have been maintained as an outbred population for more than 90 generations and provide both genetic diversity and excellent mapping resolution. In order to perform Genome-Wide Association Studies (GWAS) for drug-abuse related traits, we have developed a cost-effective and high-throughput genotyping pipeline based on low-coverage whole-genome sequencing (LC-WGS). The low-coverage (~0.25x) sequence data are sequenced on Illumina NovaSeq 6000 with Riptide (iGenomX) library preparation, a low-cost whole-genome library preparation kit. Our genotyping pipeline uses BWA for alignment, follows GATKâ□□s best practice for variant calling, and then uses STITCH for genotype imputation. With this LC-WGS genotyping pipeline, we are able to call 8 million SNPs with 99% concordance rate. Moreover, this approach has allowed us to discover tens of thousands of novel SNPs that are not present among the 8 founders. Our laboratory has produced extensive genotype and phenotype data related to drug abuse and other biomedically important traits using these methods.

Accelerated aging is a hallmark of Down syndrome (DS), with adults experiencing early-onset Alzheimerâ□□s disease and premature aging of skin, hair, and immune and endocrine systems. Accelerated epigenetic aging was found in blood and brain tissue of adults with DS, but when this premature aging begins is unknown. We investigated whether accelerated aging in DS is already detectable in blood at birth.

Dried bloodspots were obtained from 347 newborns with DS and 567 newborns without DS from California or Washington. DNA was isolated, bisulfite-converted, and assayed on Illumina MethylationEPIC DNA methylation (DNAm) arrays. We calculated epigenetic age (DNAmAge) using a published epigenetic clock (391 CpGs) and performed reference-based deconvolution of blood cell proportions using the â□□Identifying Optimal Librariesâ□□ algorithm. *GATA1* was sequenced in a subset of 184 newborns with DS to identify somatic mutations associated with transient abnormal myelopoiesis. We compared DNAmAge between DS and non-DS newborns using linear regression adjusting for chronological age from conception (gestational age plus age at blood sampling), sex, batch, blood cell proportions, and genetic ancestry using EPISTRUCTURE. Age acceleration was calculated as the deviation from expected DNAmAge based on its linear association with chronological age in non-DS newborns. We repeated analyses excluding 61 newborns (60 DS) exceeding mean+1SD for nucleated red blood cell (nRBC) proportions and 30 *GATA1*-positive DS newborns to address potential confounding. We tested for association between *GATA1* mutation variant allele frequency (VAF) and DNAmAge in DS newborns.

Mean chronological age from conception was 269 days in DS and 276 in non-DS newborns. Chronological age was more strongly positively correlated with DNAmAge in non-DS (r=0.17, $P=9.9x10^{-5}$) than DS newborns (r=0.15, P=0.051). Blood cell proportions were significantly associated with DS status and DNAmAge, including strong correlation between nRBCs and DNAmAge (r=0.30, $P=5.8x10^{-19}$). Adjusting for cell proportions, DS was significantly associated with increased DNAmAge (beta=0.2641, $P=8.43x10^{-19}$), with an age acceleration of 245 days. This association remained after excluding high nRBC newborns and *GATA1*-positive DS newborns (beta=0.1865, $P=1.07x10^{-17}$, age acceleration=179 days). Among newborns with DS, *GATA1* mutations were associated with increased DNAmAge ($P=6.65x10^{-12}$), with age acceleration of 110 days per 10% increase in VAF.

Our results support that accelerated aging in blood in DS begins prenatally, with implications for the pathophysiology of immunosenescence and other aging-related traits in DS.

PrgmNr 3690 - Characterizing molecular mechanisms of the oncogene transcription factor FOXM1 in lung and breast cancer to suppress cell proliferation

View session detail

Author Block: **S. Yang**, S. Schreiner, L. Zhu, S. K. Rhie; Dept. of Biochemistry and Molecular Med., Keck Sch. of Med. of Univ. of Southern California, Los Angeles, CA, United States, Los Angeles, CA
Disclosure Block: **S. Yang:** None.
Transcription factors are proteins that bind to DNA to control the rate of transcription. Transcription factors bind to regulatory elements such as promoters and enhancers to control expression of numerous genes. Changes in transcription factor activity could lead to either the inactivation of tumor-suppressor genes, or the activation of oncogenes in cancer. Therefore, characterizing molecular mechanisms of transcription factors dysregulated in cancer and developing specific inhibitors of those transcription factors can provide potential therapeutic candidates.
Using an in-house developed bioinformatic tool called Tracing Enhancer Networks using Epigenetic Traits (TENET), which identifies key transcription factors linked to cell-type specific enhancers with multi-omic datasets generated in tumor tissues, we have identified that the transcription factor FOXM1 is involved in oncogenic networks of tumor-specific enhancers for breast and lung cancer. Moreover, we found that more enhancers linked to FOXM1 are activated in the basal subtype of breast cancer as well as the lung cancer subtype that is associated with worse prognosis.
In this study, we have investigated molecular mechanisms of FOXM1 in both the A549 lung cancer cell line and MDAMB231 basal breast cancer cell line. To identify FOXM1 binding sites, chromatin immunoprecipitation coupled with sequencing (ChIP-seq) experiments were performed. Moreover, we have performed siRNA knockdown followed by RNA-seq experiments to discover genes regulated by FOXM1. We have integrated ChIP-seq data with RNA-seq data to identify target genes of FOXM1 specifically in lung and breast cancer, and identified potential genes directly regulated by FOXM1 in each cancer type. Furthermore, to suppress the activity of dysregulated FOXM1 and to better understand the molecular mechanisms of FOXM1 inhibition, we have treated cancer cells with FOXM1 inhibitors and then performed western blot, RNA-seq, and functional assays that measure cell proliferation rates. We have characterized the effect of FOXM1 inhibitors on the protein expression of FOXM1 as well as the expression of genes that are regulated by FOXM1.
In conclusion, we found that abnormally high expression of FOXM1 alters cancer-type specific enhancer networks in lung and breast cancer, and we are investigating ways to suppress FOXM1 activities in a cancer-type specific manner. Our findings will provide useful information for future development of improved therapeutics as well as diagnostics.

PrgmNr 3691 - Comparative analysis of bulk RNA versus single-cell RNA sequencing to profile gene expression in cellular subgroups within peripheral blood mononuclear cells

Background: The identification of differentially expressed genes between viral- and alcohol-associated hepatitis is critical to understanding the biological mechanisms underlying these two diseases. Recent work from our group has demonstrated that alcohol-associated hepatitis (AH) and chronic hepatitis C viral infection (HCV) can be distinguished by bulk RNA-seq from peripheral blood mononuclear cells (PBMCs). The goal of the current study was to compare expression profiles from single-cell (scRNA) and bulk RNA-seq of PBMCs from the same participants, to determine if there were different cell types driving the gene expression in the PBMCs between these disease groups. **Methods**: Biospecimens from an IRB-approved study by the Southern California Alcoholic Hepatitis Consortium (SCAHC) were collected at baseline with consent by the patients from AH (n=1), HCV (n=1), and healthy control (n=1). ScRNA-seq was performed using the 10x Genomics Chromium Single Cell 3â technology and Illumina sequencing. Sequence data was mapped to the human genome (hg19) and integrated using cellranger 3.1.0 version. We then performed downstream analysis using Seurat (version 4.0.1). Bulk-RNA data was aligned and mapped to the human genome (hg19) using Bowtie2 release 2.3.4.1 and Tophat2 release 2.1.1. Differential expression was then performed using cuffquant and upper quartile normalization by cuffdiff in the Tuxedo suite 2.2.1. Differential expressed genes (DEGs) between the samples were filtered to retain only those with abs(log_2(fold change)) â¥1, FPKM â¥ 5, and significance at FDR-adjusted p-value â¤0.01. **Results**: We compared DEGs across conditions within each of the 9 cell types in the scRNA-seq against the unique significant DEGs between the disease conditions from bulk RNA-seq. Significant DEGs were identified in both bulk and scRNA sequencing. Using scRNA-seq, we were able to detect genes expressed in certain subtypes of cells. For example, interferon-induced gene *IFITM3* was highly expressed in HCV bulk RNA, and was specifically expressed in monocytes and natural killer (NK) cells. The *RETN* gene, which is related to the innate immune system, is highly expressed in AH bulk RNA and was also found to be highly expressed in monocytes. **Conclusion**: This exploratory study assessed the performance of scRNA-seq against bulk RNA using samples of PBMCs from the same participants, so that we could directly compare these two sequencing platforms. Our results provided evidence of transcriptional heterogeneity of cellular subtypes in viral- and alcohol-associated hepatitis.

PrgmNr 3692 - Genome-wide effects of sex chromosome aneuploidy on gene expression and DNA methylation in isogenic neural precursor lines

View session detail

Author Block: **J. Berletch**[1], G. Filippova[1], A. SkakkebÃ¦k[2], W. Ma[3], C. Groneck[1], H. Fang[1], X. Deng[1], C. Gravholt[2], C. M. Disteche[1,4]; [1]Dept. of Lab. Med. and Pathology, Univ. of Washington, Seattle, WA, [2]Aarhus Univ. Hosp., Aarhus, Denmark, [3]Dept. of Statistics, Univ. of California, Riverside, Riverside, CA, [4]Dept. of Med., Univ. of Washington, Seattle, WA
Disclosure Block: **J. Berletch:** None.

Sex chromosome aneuploidy leads to phenotypic abnormalities that often affect brain structure and function. These malfunctions are due to a combination of sex-linked gene imbalance and hormonal dysregulation. For example, in Klinefelter syndrome (XXY), hypogonadism during adolescence and adulthood only partly explain phenotypic abnormalities since many of the co-morbidities are already present at an earlier age, suggesting an important contribution of abnormal gene dosage. Previous studies of sex chromosome aneuploidy done on a limited number of cell types (mainly blood) have detected changes in gene expression and epigenetic features throughout the genome, suggesting widespread effects of aneuploidy. To investigate gene expression and epigenetic changes associated with aneuploidy specifically in neuronal cells, we derived isogenic pairs of human induced pluripotent stem cells (hiPSCs) with a different number of sex chromosomes on the same genetic background. We derived XXY/XY and XXX/X pairs either by reprogramming blood cells from mosaic individuals (XXY/XY and XXX/X) or by removal of the inactive X chromosome in X aneuploid hiPSCs using a selectable marker (thymidine kinase) inserted in the *XIST* gene and selection in ganciclovir. These new isogenic hiPSC lines uniquely position us to address the effects of sex chromosome dosage (SCD), while minimizing variability between individuals as well as environmental or hormonal confounders. We differentiated the isogenic pairs into neural precursor cells (NPCs) to assess epigenetic and transcriptomic consequences of SCD (XXY, XXX, and X). Increased dosage of the sex chromosomes resulted in changes in expression of sex-linked genes, as well as in autosomal genes independent of the sex of the individual, as well as distinct DNA methylation signatures dependent on SCD. Changes were noticeably less prominent between isogenic samples than between independent samples, resulting in identification of critical genes. Together, these data point to trans-acting effects of SCD on autosomal gene regulation in neuronal cells.

PrgmNr 3693 - Interrogation of allergy associated regulatory variants for *GATA3* in human T cells

View session detail

Author Block: **H. Chen**[1], P. C. Fiaux[2], A. Chen[1], G. McVicker[1]; [1]Salk Inst. for Biological Studies, La Jolla, CA, [2]San Diego, CA
Disclosure Block: **H. Chen:** None.
Recent studies suggest allergic diseases may share a common genetic etiology. To characterize the potential common genetic etiology, we analyzed the 38 significant loci from cross-trait analysis on allergic diseases from UK Biobank. GO analysis on all the genes in the 38 loci showed the genes are most enriched in T helper cell differentiation. T helper 2 (Th2) cells are one of the T helper cells that induce allergic inflammation. The differentiation of Th2 cells is regulated by the gene *GATA3*. Carefully examining all 38 loci, we found 2 loci located 1 and 0.6 Mb downstream of *GATA3*, named Risk Region 1 and 2 (RR1 and RR2) respectively. Fine-mapping of the two loci identified the candidate SNPs for the causal variants. Notably, the risk alleles of the causal variants in RR1 have high allele frequency of 0.94. The protective alleles occur more recently and arise after human-chimpanzee split. With the lack of eQTL studies of activated Th2 cells, we inspected all available eQTL studies with relevant cell types. We discovered those variants are associated with changes in *GATA3* expression in naÃ¯ve CD4 T cells, although with much weaker evidence. To uncover all regulatory sequences within 2 Mb region around *GATA3*, we conducted a CRISPR/Cas9 tiling deletion screen in Jurkat T cells. The results analyzed by RELICS discover 36 functional sequences (FSs), most of which are enriched in the *GATA3* TAD. One of the FSs, FS28, marked by strong H3K27ac was found to be a conserved strong enhancer for *GATA3* in mouse T cells. Surprisingly, while some FSs overlap with canonical enhancer signatures, the other FSs are devoid of those signatures in Jurkat cells. FS10, located in RR1, overlaps with the potential causal variants and is one of the unmarked FSs. We validated the screen results by introducing Cas9 RNPs with dual sgRNAs to delete FS28 or FS10 and observe *GATA3* expression. To further characterize the role of FS28 and FS10 for *GATA3* in primary Th2 cells, we intersected the H3K27ac ChIP-seq datasets with the 36 FSs during different T helper cell differentiation. We found both FS28 and FS10 are marked by strong H3K27ac specifically in Th2 cell differentiation. To test whether the loss of FS28 or FS10 affect *GATA3* expression in Th2 cells, we deleted FS28 or FS10 and found decreased *GATA3* expression. Importantly, the deletions of FS28 or FS10 may potentially affect Th2 cell differentiation and maintenance, ultimately leading to loss of Th2 cells. Our results uncover two strong Th2 specific enhancers for *GATA3* and provide Th2 cell specific therapeutic targets. Also, the variants in the enhancers could contribute to the common genetic etiology by altering the activities of the enhancers.

PrgmNr 3694 - Novel insight into the etiology of ischemic stroke gained by integrating human transcriptome wide association study with rodent expression data

View session detail

Stroke, characterized by sudden neurological deficits, is the second leading cause of death worldwide. The main cause of stroke is ischemic stroke (IS) due to cerebral infarction. Although genome-wide association studies (GWAS) have successfully identified many genomic regions associated with IS, the genes underlying risk and their regulatory mechanisms remain elusive. In contrast, the transcriptome-wide association study (TWAS) approach has allowed for more interpretable biologically relevant results by integrating GWAS associations and functional genomic data. Previous work has identified putative susceptibility genes underlying IS risk through TWAS, however transcriptomic data was limited to whole blood and adipose tissue, which may miss possible disease mechanisms in other disease-relevant tissues.
Here, we sought to identify susceptibility genes for IS risk by integrating large-scale IS GWAS summary statistics (N=440,328) together with expression quantitative trait loci data in 48 tissues from GTEx v7 (median N=166) and CommonMind (N=452), and protein quantitative trait loci data in plasma from the INTERVAL study (N=3,301). We performed TWAS and identified 11 genes in 5 genomic regions (PNext, we performed a proteome-wide association study (PWAS) and identified 3 genes in 3 independent genomic regions (PTo validate our findings, we constructed co-expression networks using a cortex gene expression from IS patients (N=12) together with cortex expression datasets obtained from mouse (N=8) and rat IS models (N=8). We identified a co-expressed gene set consistently expressed in mouse, rat, and human brain cortex linked with the chemical synaptic transmission which is significantly enriched (FDR

PrgmNr 3695 - Prediction of genetically regulated expression of asthma target tissues for African-ancestry populations

Integration of genetics with transcriptomics has improved our ability to identify genes associated with phenotypes. CD4+ T cells play a central role in modulating allergic disease and asthma. However, this tissue is not well-represented in public repositories such as GTEx, particularly for populations of African ancestry that are disproportionately affected by allergic disease and may have distinct genetic risk factors. From 260 subjects of Afro-Caribbean ancestry participating in the Barbados Asthma Genetics Study (BAGS), we quantified gene expression using RNA-seq from isolated, unstimulated CD4+ T cells. DNA was extracted for genotyping on Illuminaâ□□s Multi Ethnic Global Array and imputed to the TOPMed Freeze5 reference panel. Reproducible workflows/tools implementing the Predixcan family of tools were created on the NHLBI BioData Catalyst Ecosystem powered by Seven Bridges and used to build prediction models for gene expression from genotyping data using nested cross-validated elastic net linear models. We limited potential predictors to cis-acting SNPs within 1Mb up or downstream of the gene location for each gene quantified. Models were fit on gene expression residuals after adjustment for sex, asthma status, genetic PC1, and 45 PEER factors. We achieved significant prediction for 4,072 of 16,692 genes tested, defined as R2>0.01 for predicted versus observed gene expression during nested cross-validation and p

PrgmNr 3696 - Regulatory landscape of CD4+ T cells with implications for asthma

View session detail

Disclosure Block: **C.H. Arehart:** None.

Asthmatics of African ancestry tend to have more severe asthma than those of European ancestry, but relatively few studies have focused on this underrepresented minority group. In the U.S., childhood asthma prevalence is almost twice as high in African Americans (14.6%) compared to European Americans (8.2%) and in Barbados, prevalence is even higher (~20%) due to the elevated exposure to relevant antigens (house dust mite, domestic endotoxin). The Barbados Asthma Genetics Study (BAGS) provides an opportunity to study the complex genetics underlying asthma susceptibility among individuals of Afro-Caribbean ancestry. Since manifestations of asthma depend on T cell activities, particularly the CD4+ Th2 subset of T cells, we test if genetic variants regulate gene transcription in a cell-specific manner by characterizing the transcriptome of CD4+ T cells from atopic asthmatics and non-asthmatics using RNA-Seq.

We performed expression quantitative trait locus (eQTL) analysis on 190 samples (117 asthmatic cases, 73 controls) genotyped with the Multi Ethnic Global array (MEGA) imputed to the TOPMed Freeze5 reference panel and RNA-Seq on CD4+ T cells. Post quality control and alignment we used MatrixEQTL and eigenMT to select the most significant variant-per-gene. We discovered 3,205 eQTLs, 657 of which were validated in an independent sample drawn from the same population (N = 70; 48 cases, 22 controls) also with RNA-Seq on CD4+ T cells. Comparing the 657 replicated CD4+ T cell eQTLs to 49 Genotype-Tissue Expression (GTEx) v8 tissue types, 66 eQTLs were untested in any GTEx tissue, 60 were tested for and novel to our dataset, 531 showed concordant significance with at least one GTEx tissue, and the overall regulatory landscape was most similar to whole blood. Among known genome wide association study (GWAS) & candidate identified asthma genes, we found eQTLs for *HLAâ□□DQA1*, *HLAâ□□DQB1*, *HLAâ□□DRB1*, *HLAâ□□DPB1*, and *ORMDL3*. Gene ontology analysis for the 657 eQTLs confirmed this cell typeâ□□s relevance to asthma through enrichment for antigen processing/presentation and adaptive immune response biological processes. Analysis of differential expression by asthma status highlighted 338 genes, 6 of which overlapped with replicated eQTLs (*AC015712.6*, *PLEKHH2*, *AC067930.4*, *RBM11*, *TXNRD3*, and *RPL23AP7*).

The present study details the regulatory landscape for CD4+ T cells among African ancestry individuals within the context of asthma. This set of immune-related eQTLs will form a strong basis for our further analyses in tissue types implicated in the biology of asthma such as nasal epithelium.

PrgmNr 3697 - Single-cell RNA sequencing of lung identifies disease-associated cell type-specific eQTLs

View session detail

Author Block: **H. M. Natri**[1], C. B. Azodi[2,3], A. J. Gutierrez[1], L. E. Bui[1], L. Peter[1], R. P. Kendle[1], D. J. McCarthy[2,3], N. E. Banovich[1]; [1]The Translational Genomics Res. Genome-wide association studies and functional genomics approaches have identified regulatory loci that contribute to complex traits and disease. However, the effects of expression quantitative trait loci (eQTL) can be both cell-type and context-specific. Single-cell RNA-sequencing (sc-RNAseq) facilitates the mapping of eQTLs across different cell types, allowing the identification of cell type-specific eQTLs that would go undetected by bulk methods. Here we use sc-RNAseq to examine primary human tissue from the lungs of healthy individuals and those with interstitial lung disease (ILD). ILD is a chronic, progressive lung disease characterized by the scarring of lung tissue through epithelial remodeling and accumulation of extracellular matrix (ECM). Pulmonary Fibrosis (PF) is a clinical phenotype that exhibits the end stage of ILD. In general, progression of fibrosis occurs in a gradient resulting in some regions of extreme remodeling and some regions that appear largely normal. For the most common and severe form of ILD, idiopathic PF (IPF), lung transplantation is the only treatment option.
In the current study, we have used sc-RNAseq to generate expression profiles of 532,488 cells derived from 170 lung tissue samples from 52 healthy and 68 ILD donors, including 39 donors with IPF. To identify cell type-specific expression changes associated with genetic variation, we have used Whole Genome Sequencing (WGS) to genotype 97 individuals with available sc-RNAseq profiles. In an effort to map cis-eQTLs across lung cell types, we have used a pseudo-bulk approach aggregating the expression levels of cells for each of the study individuals. To identify shared and cell type-specific signatures, we have performed stratified analyses as well a joint analysis of all cell types to assess cis-eQTL effect size heterogeneity between cell types. Using this approach, we detect clear cell population, lineage, and cell type-specific signals Further integration with GWAS allows connecting PF risk variants to molecular functions in disease-relevant cell types.
These analyses aid in determining the cell types and states in which PF-associated genetic variants function, and highlight the importance of cellular context in gene regulation in health and disease.

PrgmNr 3698 - Association between the tobacco-specific carcinogen metabolite NNAL and DNA methylation in a multiethnic population

View session detail

Park[3]; [1]Keck Sch. of Med. of USC, Los Angeles, CA, [2]Univ. of Minnesota, Minneapolis, MN, [3]Univ. of Hawaii Cancer Ctr., Honolulu, HI, [4]Univ of Southern California, Los Angeles, CA

Disclosure Block: **B. Huang:** None.

Introduction: Prior epigenome-wide association studies (EWAS) have found that smoking is associated with differential DNA methylation at numerous CpG loci across the epigenome. To investigate whether these changes are attributable to specific smoking-related constituents, we performed the first EWAS of the tobacco carcinogen metabolite 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL) in a multiethnic population of smokers. We aimed to explore whether these associations differed by race/ethnicity and whether they were independent of smoking dose as measured by total nicotine equivalents (TNE). **Methods:** This study was conducted in a subcohort of participants from the Multiethnic Cohort who were current smokers at time of biospecimen collection, had urinary smoking biomarker data, and never had lung cancer. Total NNAL (sum of NNAL plus its glucuronides) was measured in urine using a validated liquid chromatography-tandem mass spectrometry assay. DNA methylation profiling was performed on serum using the Illumina MethylationEPIC BeadChip assay. We used linear regression to investigate the association between a standard deviation (SD) increase in the natural log-transformed NNAL concentration and DNA methylation beta value in all participants and by race/ethnicity. Additional models adjusting for TNE were run to evaluate the associations of NNAL independent of smoking dose. **Results:** A total of 1,996 current smokers (average age 63.9, 55% female) were included in the analysis. The mean total NNAL concentration was 1.71 pmol/mL and was highest in African Americans (2.44) and lowest in Japanese Americans (1.22). Total NNAL was associated with 88 differentially methylated CpG sites (pâ□□8), many of which were identified in prior smoking-related EWAS. Each SD (0.84) increase in the natural log-transformed total NNAL was associated with decreased methylation at the top significant CpG loci located on *GPR15* (cg19859270), *AHRR* (cg23576855, cg05575921, cg21161138), *PRSS23* (cg14391737), *RARA* (cg17739917), *F2RL3* (cg03636183), *MGAT3* (cg05086879), and an unmapped region on chromosome 2 (cg21566642, cg01940273) (coefficient estimates ranging from -0.004 to -0.032). There was no statistically significant heterogeneity across race/ethnicity. After adjusting for TNE, estimates were attenuated and only two loci on *AHRR* (cg05575921) and *MGAT3* **(**cg05086879) remained statistically significant. **Conclusions:** NNAL is associated with differential methylation at several previously identified smoking-related CpG loci. Further research is needed to establish a causal relationship between NNAL and decreased methylation at *AHRR* and *MGAT3*.

PrgmNr 3699 - Automated High-throughput IP Workflows using Covaris Adaptive Focused Acoustics (AFA) System for Accelerated Epigenomic Mapping

View session detail

Author Block: **A. Goren**[1], G. Heitmann[1], Y. Cau[1], J. Young[1], T. Xu[1], E. Daviso[2], J. Laugharn[2], H. Khoja[3]; [1]UCSD, San Diego, CA, [2]Covaris, Woburn, MA, [3]Covaris Inc,, Woburn, MA
Disclosure Block: **A. Goren:** None.
Mapping the epigenomic landscape is essential for understanding gene regulatory mechanisms along cell fate changes, disease onset and treatment response. Such epigenomic mapping holds high potential for identification of biomarkers and targets for therapy in general, and epigenetic targets in particular (e.g., DNA binding proteins or DNA methylation). Several key methods for studying of the localization cellular biomolecules use Immunoprecipitation (IP) to capture the specific targets. IP builds on the precipitation of a biomolecule such as a protein, modified protein or a modified DNA fragment, by using an antibody that specifically recognizes the target biomolecule.
Yet, existing next generation sequencing (NGS) approaches - such as chromatin immunoprecipitation (ChIP-seq) and methylated DNA immunoprecipitation (meDIP-seq) - require time-consuming multiple-day workflows. They involve many manual steps and are difficult to optimize and standardize for different input material and across laboratories. These limitations hamper the use of such tools for applications that require high robustness, reproducibility, and automatability such as high throughput screening of small molecules in drug development or biomarkers in diagnostics.
To overcome these challenges, we combined our automated ChIP-seq (Busby *et al.*, 2016) with the Covaris Adaptive Focused Acoustics (AFA) technology to enhance and improve the IP process. Our preliminary results provide supporting evidence that micromixing and fluid streaming generated by AFA can highly accelerate the time required to achieve antibody binding while improving stringency and specificity (minimizing non-specific binding).
We tested the ability of AFA to enhance the binding kinetics of antibody-epitope association, improve signal-to-noise ratios, and decrease total processing time. We evaluated both ChIP-seq for a range of epitopes (e.g., H3K4me3, H3K27me3, H3K27ac and CTCF) and meDIP-seq. Our preliminary results show that AFA highly expedites the IP process (Together, we developed a novel use of AFA for accelerated IP that allows enhancing and simplifying IP-based methods such as ChIP-seq and meDIP-seq. The sample preparation, shearing, and IP can be performed in the same 96 well Covaris AFA-TUBE plate and integrated with automated library preparation thus enabling same day sample-to-sequencer workflows. We expect this key advancement to be highly useful for both research, clinical diagnostic applications and discovery pipelines for epigenetics drugs.

PrgmNr 3700 - Black Representation in Genomics Research (BRGR) Study of eQTLs in venous blood of 23andMe research participants with African ancestry

View session detail

Author Block: **K. Fletez-Brant**[1], K. Kukar[2], E. Bullis[2], C. D. Wong[2], J. O'Connell[2], B. Hicks[2], N. Batada[1], A. Petrakovitz[2], 23andMe Research Team, S. J. Pitts[1], M. Moreno[2], V. Vacic[1]; [1]23andMe Therapeutics, South San Francisco, CA, [2]23andMe, Inc, Sunnyvale, CA
Disclosure Block: **K. Fletez-Brant:** Salary/Employment; 23andMe Therapeutics.
African Americans make up about 14% of the US population, but are disproportionately underrepresented in clinical trials. Genomics studies are similarly biased, with the vast majority of gene expression studies having been conducted in European and, to a lesser extent, East Asian cohorts. This underrepresentation hampers research on conditions with high prevalence in African Americans, restricts interpretation of clinical findings, and limits our understanding of variation in human gene regulation, both in a population-specific manner and in general. These limitations reinforce each other in the interpretation of GWAS in African Americans, where the relative increase in genetic heterogeneity makes the use of European functional data suboptimal. This dearth of functional data in African Americans in turn means that GWAS findings unique to African Americans do not receive appropriate follow-up, thereby further increasing health disparities as compared to Europeans. To help remedy this situation, 23andMe, Inc. initiated the Black Representation in Genomics Research (BRGR) eQTL Study, which surveys gene expression and genetic variation in a large cohort of 23andMe research participants with African ancestry. 23andMe contacted research participants (a) who have >50% genetic African ancestry (as determined by our ancestry inference algorithms), (b) reside in the continental US, and (c) are between 20 and 60 years of age. Approximately 1,000 23andMe research participants consented to participate in the study, with over 40% from the South of the United States. Nearly 75% of enrollees were female, and the median age was 37. Saliva-based DNA samples obtained from these participants were subject to whole genome sequencing (WGS), to an average read depth of 20x. Using a mobile door-to-door phlebotomy service, we collected venous blood samples from approximately 800 research participants, which are undergoing RNA-seq at an average 60M reads/sample. To maximize the utility of this study for the advancement of research on health conditions affecting African Americans and better encourage the development of therapeutics that serve to benefit the Black community, 23andMe will make these de-identified RNA-seq and WGS data publicly available to all qualified researchers via dbGaP. We also plan to host a webinar with study participants to share study outcomes and the impact of their contribution. We hopewith this study to both reduce disparities in research with African Americans and to further our understanding of the genetic contribution to gene regulation in humans broadly.

PrgmNr 3701 - Circular RNAs preferentially localize to synapses in the human brain implying critical functions for synaptic plasticity and may be important components of neurodegeneration

View session detail

Author Block: **S. Smukowski**[1], C. Danyko[1], M. Course[2], K. Gudsnuk[1], N. Postupna[1], C. D. Keene[1], P. N. Valdmanis[3]; [1]Univ. of Washington, Seattle, WA, [2]Seattle, WA, [3]Univ of Washington, Seattle, WA
Disclosure Block: **S. Smukowski:** None.
Circular RNAs (circRNAs) are unique transcript isoforms that may play critical regulatory roles in the human brain which could have implications in the progression of neurodegenerative disorders such as Alzheimerâ□□s Disease (AD). CircRNAs are produced by back-splicing a later exon to a preceding exon creating a closed-loop structure. For example, splicing exon 5 in a gene to exon 3, instead of continuing to exon 6, making a loop consisting of exons 3, 4, and 5. CircRNAs can perform a variety of functions, in addition to being translated, including acting as microRNA â□□spongesâ□□ and sequestering RNA binding proteins. They also persist in the cytoplasm due to resistance to exonucleases. It has been previously demonstrated that circRNAs are differentially expressed in postmortem brains of AD patients which suggests that circRNAs could be involved in important regulatory functions that become perturbed during synaptic and neuron degeneration in AD.
As part of our current investigation into synaptic localized translation, we discovered an enrichment of circRNAs located at the synapse. We were able to identify and quantify synaptic-localized RNA via subcellular fractionation of â□□synaptosomesâ□□ from frontal cortex postmortem brain samples of both AD and control patients using a sucrose gradient ultracentrifugation technique and subsequent total RNA sequencing. Not only did we discover localization differences of linear RNAs, but remarkably, we discovered an overwhelming abundance of circRNAs in synaptosomes. Given that there were also significant quantitative differences of these circRNAs between AD and control, we postulate that circRNAs serve important roles in the regulation of synapses that become disrupted during neurodegenerative disease progression. For example, it could be that the presence of circRNAs at the synapse modulates the presence of other transcripts by interacting with microRNA degradation machinery. Critically, several of these candidate genes already have established associations with AD such as *GSK3B* and *AKT3*. Here, we present our work to uncover the significance of these findings which represents a novel investigation into this class of understudied molecules.

PrgmNr 3702 - Dissecting the evolutionary and functional architecture of human enhancer sequences with multiple ancestral origins

View session detail

Author Block: **S. L. Fong**[1], J. A. Capra[2]; [1]Vanderbilt Univ., Nashville, TN, [2]Univ. of California San Francisco, San Francisco, CA
Disclosure Block: **S.L. Fong:** None.
Motivation: Functional divergence of cis-regulatory enhancer sequences is a major driver of vertebrate speciation. However, the relationship between the evolutionary histories of enhancer sequences and their functional constraint is unclear. To address this question, we traced the evolutionary origins of transcribed human enhancer sequences active across diverse cellular contexts. *Results*: While most human transcribed enhancer DNA can be traced to a single evolutionary origin, we estimate that 40% of enhancers are composed of DNA from multiple ancestral origins (i.e. of multiple ages). These â□□multi-originâ□□ enhancers have evolutionary architectures consisting of older â□□coreâ□□ sequences flanked by younger â□□derivedâ□□ sequences. Within multi-origin enhancers, we find that both the derived and core sequences show evidence of independent biochemical enhancer activity. However, specific transcription factors (TFs) have stable preferences for binding core and derived regions that span sequence origins. Despite the evidence for activity and TF binding in both core and derived sequences, derived regions are under lower purifying selection pressures than adjacent cores. As a result, derived regions tolerate more common genetic variation and are enriched for eQTL associated with gene expression variability in human populations. *Conclusions*: We propose that the integration of younger, derived sequences with conserved core sequences generates regulatory substrates with robust enhancer activity across both core and derived regions and the potential for functional variation enriched in younger derived regions. Our analyses demonstrate that considering enhancer evolutionary architectures can aid interpretation of evolutionary forces acting on enhancer sequences and functional variation across human populations.

PrgmNr 3703 - Enhancer enhancer interaction networks involved in long-distance genome regulation link multiple non-coding variants to function

View session detail

Author Block: **X. Lin**; Stanford Univ., Belmont, CA
Disclosure Block: **X. Lin:** None.
Mammalian genomes often use multiple enhancers spanning an ultra long-distance (>Mb) to modulate genes, yet it is not clear how multiple enhancers may coordinate to achieve this task. In addition, Genome-Wide Association Studies (GWAS) reveal that variants in the non-coding regulatory elements, including enhancers, are estimated to account for >90% of the variants in disease. While individual enhancer variants mostly present small-to-modest clinical risks, a combination of multiple genetic variants among various enhancers can greatly amplify the effects of individual low-penetrance variants in complex diseases and traits, suggesting the importance of an enhancer-enhancer interaction network in controlling disease relevant genes and connecting multiple non-coding variants association to function. Recent progress in genomic mapping approaches and CRISPR perturbation technologies have accelerated the identification of enhancer and their roles in gene regulation. However, it remains unclear why multiple enhancers are needed, as well as a quantitative understanding of the underlying enhancer epistasis network, wherein the activity of an enhancer can functionally interact with others.
we used multiplexed CRISPR-based screening with a pooled library consisting of 87,025 sgRNA combinations to combinatorially probe enhancer-enhancer interactions. We discovered a previously uncharacterized two-layer enhancer-enhancer epistasis network across multiple oncogenes. In this network, we defined a class of synergistic regulatory elements (SREs) which are theorized to maintain both expression level and robustness of genes and provide buffering effects against genome instability over long distances. A suite of quantitative experimental and computational approaches, including chromatin interaction assays (Trac-looping), cellular imaging (multicolor 3-dimensional FISH), and machine learning (elastic-net regularized generalized linear model), unveiled mechanisms associated with this enhancer epistasis. We used this information to create a computational model to predict SREs and provided a strategy to link multiple non-coding variants to reveal their epistasis influence in clinical risk. In the genetic association analysis, we found that the SRE variants could cooperatively impact gene expression and alter clinical risk in cancer and autoimmune disorder. Our work unveiled new mechanisms underlying enhancer-mediated control of gene expression in ultra-long genomic distance, with implications for annotation of enhancer function within cells and interpretation of epistasis contribution of non-coding variants in human disease.

PrgmNr 3704 - Human-specific structural variants alter *cis*-regulation and chromatin structure

View session detail

Author Block: **C. Shew**[1,2], G. Kaya[1,2], M. Y. Dennis[1,2]; [1]Univ. of California, Davis, Davis, CA, [2]Genome Ctr., Univ. of California Davis, Davis, CA
Disclosure Block: **C. Shew:** None.
Segmental duplications (SDs) and other structural variants (SVs) comprise most of the variable base pairs within and between primate genomes. Notably, genes within human-specific SDs (HSDs) have known roles in regulating neuronal proliferation and autoimmune response, and SD-mediated rearrangements are associated with a wide variety of neurodevelopmental disorders. We have previously shown that HSD genes exhibit paralog-specific expression patterns across diverse cell and tissue types in spite of their high sequence similarity (>98.5%), likely as a result of *cis*-regulatory divergence following duplication. However, the regulatory landscape of HSDs and other human-specific SVs has yet to be systematically characterized. We have designed a massively parallel reporter assay (MPRA) to quantify *cis*-regulatory activity of 5701 paralogous sequence variants and 2444 chimpanzee orthologs of candidate regulatory elements within HSDs. The MPRA will be performed in human lymphoblastoid cell lines (LCLs) and SH-SY5Y neuroblastoma cells to identify differentially active sequences in those cell types. We have also designed a complementary capture Hi-C assay targeting 2401 promoters within and adjacent to human- and chimpanzee-specific SVs, which will identify candidate enhancers associated with SV promoters as well as changes to promoter-enhancer connectivity across breakpoints. Preliminary analysis of capture Hi-C in human and chimpanzee LCLs has identified human-specific contacts associated with the insertion of *DUSP22B* on chromosome 16. Together, these assays will identify differences in the connectivity and activity of a comprehensive set of regulatory elements associated with HSDs and other SVs in humans. We hypothesize that changes to the expression of recently duplicated and rearranged genes can be modeled with a more complete picture of their regulatory environment. This work will inform how human-specific SVs alter gene expression, with potential insight into neurological and immunological traits unique to our species.

PrgmNr 3705 - Integrative single cell analysis of cardiogenesis identifies developmental cellular trajectories and prioritizes noncoding mutations in congenital heart disease

View session detail

Author Block: **L. Sundaram**[1], M. Ameen[1], K. Wang[1], T. Quertermous[2], A. Kundaje[1], W. Greenleaf[1]; [1]Stanford Univ., Stanford, CA, [2]Stanford Cardiology, Stanford, CA
Disclosure Block: **L. Sundaram:** None.
Congenital heart disease (CHD) is the most common birth defect. CHD is caused by genetic dysregulation of heart development, which involves intricate cell state transitions across numerous precursor cell lineages. However, deciphering causal, de-novo, non-coding CHD mutations has been challenging due to a limited understanding of the dynamic regulatory landscape of developmental trajectories in cardiogenesis. Hence, we profiled the single cell chromatin landscape of human fetal hearts from three early development stages to comprehensively map the cis-regulatory landscape of dynamic regulatory elements and their target genes that manifest all major cardiac cell types across 8 major differentiation trajectories. We trained and interpreted base-pair resolved interpretable deep learning models of cell state specific chromatin landscapes, to systematically infer cis-regulatory motif syntax of cooperative TF binding driving cell state transitions. We used the models to predict and interpret the cell-state specific regulatory impact of non-coding mutations in CHD case and control cohorts. We observed a strong enrichment for deleterious *de novo* mutations from CHD in arterial and capillary endothelium cell, identifying for the first time the relevant cell types causing structural changes to the developing fetal heart. Furthermore, we used iPS derived endothelium cells to validate the regulatory impact of several predicted *de novo* non coding causal mutations, highlighting a viable approach in mapping deleterious mutations disrupting cell-type specific regulatory mechanisms even at the early intractable timepoints of fetal development.

PrgmNr 3706 - Investigating conservation of chromatin accessibility signatures during iPSC reprogramming across human and mouse ATAC-seq data

View session detail

Author Block: **C. Thangavelu**[1], T. M. Norden-Krichmar[2]; [1]Univ. of California Irvine, Irvine, CA, [2]Univ of California Irvine, Irvine, CA
Disclosure Block: **C. Thangavelu:** None.
Background: Induced pluripotent stem cells (iPSCs) can be generated from somatic cells, such as fibroblasts, through a process known as iPSC reprogramming. During reprogramming, dynamic changes occur in chromatin accessibility, which are essential for the conversion of fibroblast cells into iPSCs. iPSCs can be used to generate a wide variety of cells with potential for therapeutic purposes. However, efficiently reprogramming cells to a pluripotent state remains a current challenge, particularly in human cells. To further investigate the differences that underlie species-specific differences in reprogramming efficiency and to identify conserved regulatory patterns between species, we conducted a cross-species meta-analysis of mouse and human ATAC-seq data. **Methods**: In this study, a meta-analysis was conducted using ATAC-sequencing data that was generated as mouse and human fibroblasts transitioned to iPSCs. The data was obtained from the publicly available GEO database (mouse: GSE113431, GSE101905, GSE93029; and human: GSE14764). We followed a similar pipeline with the processed ATAC-seq peak data for each species. Replicates were merged using bedtools intersect, and differential accessibility analysis was conducted to filter out peaks associated with housekeeping genes. Peaks from each timepoint were compared across experiments using the bedtools intersect function. HOMER was used to determine what genes and associated pathways were enriched in these regions. Finally, we compared the results obtained for human versus mouse at the nearest equivalent timepoints for evidence of conservation between these species. **Results**: There were noticeable similarities and differences in the chromatin accessibility signatures as the cells transitioned from fibroblasts into iPSCs in mouse versus human data sets. Accessible peaks were located near genes associated with similar developmental and differentiation-related gene ontology terms during the later human and mouse timepoints. However, there were more differences in the levels of motif enrichment at the later timepoints between the species. **Conclusions**: This study demonstrated that there were consistent trends between the species that point to increased areas of accessibility near genes and motifs associated with pluripotency. However, variation in motif enrichment and reprogramming kinetics were also observed. Taken together, these results and methodology may aid in elucidating species-specific differences in iPSC reprogramming.

PrgmNr 3707 - Systematic reconstruction of the cellular trajectories of mammalian embryogenesis

Mammalian embryogenesis is characterized by rapid cellular proliferation and diversification. Within a few weeks, a single cell zygote gives rise to millions of cells expressing a panoply of molecular programs, including much of the diversity that will subsequently be present in adult tissues. Although intensively studied, a comprehensive delineation of the major cellular trajectories that comprise mammalian development in vivo remains elusive. Here we set out to integrate several single cell RNA-seq datasets (scRNA-seq) that collectively span mouse gastrulation and organogenesis. We define cell states at each of 19 successive stages spanning E3.5 to E13.5, heuristically connect them with their pseudo-ancestors and pseudo-descendants, and for a subset of stages, deconvolve their approximate spatial distributions. Despite being constructed through automated procedures, the resulting trajectories of mammalian embryogenesis (TOME) are largely consistent with our contemporary understanding of mammalian development. We leverage TOME to nominate transcription factors (TF) and TF motifs as key regulators of each branch point at which a new cell type emerges. Finally, to facilitate comparisons across vertebrates, we apply the same procedures to single cell datasets of zebrafish and frog embryogenesis, and nominate â□□cell type homologsâ□□ based on shared regulators and transcriptional states.

PrgmNr 3708 - Telomere-to-telomere map of a human epigenome

View session detail

Author Block: **A. B. Stergachis**[1,2], D. Dubocanin[1], A. Sedeno Cortes[1], T. Real[1], J. Ranchalis[1], B. Mallory[1]; [1]Univ. of Washington, Seattle, WA, [2]Brotman Baty Inst. for Precision Med., Seattle, WA
Disclosure Block: **A.B. Stergachis:** None.
Chromatin plays a central role in the regulation of the human genome by modulating the occupancy of DNA-binding proteins, and constructing both repressive and permissive environments for gene regulation. However, our understanding of the chromatin architecture for some of the most structurally important and fastest evolving portions of the human genome remains largely unknown. The completion of a telomere-to-telomere human genome for the CHM13 cell line provides an opportunity for exploring the epigenome within these previously poorly resolved regions. To construct a telomere-to-telomere map of a human epigenome, we leveraged long-read single-molecule chromatin fiber-sequencing (Fiber-seq), which permits the near single-nucleotide mapping of chromatin accessibility, nucleosome positioning, and transcription factor occupancy patterns within portions of the genome previously impervious to short-read epigenomic methods. Specifically, Fiber-seq uses non-specific DNA N^6-adenine methyltransferases to precisely stencil the structure of individual chromatin fibers onto their underlying DNA templates, which are read using PacBio single-molecule long-read sequencing. Application of Fiber-seq to CHM13 cells resulted in chromatin architectures for 1.7 million individual intact chromatin fibers with an average length of 16 kb. The high sequencing quality and long-read nature of these chromatin fibers permitted us to uniquely map the chromatin architecture for 97% of the human genome, including 96% of telomeric, 82% of segmentally duplicated, and 70% of centromeric sequence. Single-molecule telomere stencils precisely reveal the transition between nucleosome-bound DNA and the telomere cap, exposing that the terminal several kilobases of each telomere are devoid of nucleosomes, and that the transition from nucleosome-bound DNA is variably positioned across individual fibers. Although centromeres are predominantly comprised of regularly spaced and highly compacted nucleosome arrays, the kinetochore contains a highly unusual chromatin structure consisting of extremely compacted nucleosomes juxtaposed next to large accessible patches of chromatin mirroring those seen at accessible regulatory DNA. Finally, we expose regulatory elements with divergent regulatory activity across paralogous copies of segmental duplications, revealing segmental duplications as a mechanism for the rewiring of the gene regulatory landscape. Overall, this telomere-to-telomere map of a human epigenome provides a foundation for studying the human epigenome in its entirety.

PrgmNr 3709 - The landscape of alternative polyadenylation in single cells of the developing mouse embryo

View session detail

Author Block: **V. Agarwal**[1], S. Lopez-Darwin[2], D. Kelley[1], J. Shendure[2]; [1]Calico Life Sci., South San Francisco, CA, [2]Univ. of Washington, Seattle, WA
Disclosure Block: **V. Agarwal:** Salary/Employment; Calico Life Sciences.
3â□² untranslated regions (3â□² UTRs) post-transcriptionally regulate mRNA stability, localization, and translation rate. While 3â□²-UTR isoforms have been globally quantified in limited cell types using bulk measurements, their differential usage among cell types during mammalian development remains poorly characterized. In this study, we examined a dataset comprising ~2 million cells spanning E9.5-E13.5 of mouse embryonic development to quantify transcriptome-wide changes in alternative polyadenylation (APA). We observe a global lengthening of 3â□² UTRs across embryonic stages in all cell types, although we detect shorter 3â□² UTRs in hematopoietic lineages and longer 3â□² UTRs in neuronal cell types within each stage. An analysis of RNA-binding protein (RBP) dynamics identifies ELAV-like family members, which are concomitantly induced in neuronal lineages and developmental stages experiencing 3â□²-UTR lengthening, as putative regulators of APA. By measuring 3â□²-UTR isoforms in an expansive single cell dataset, our work provides a transcriptome-wide and organism-wide map of the dynamic landscape of alternative polyadenylation during mammalian organogenesis.

PrgmNr 3710 - Universal DNA methylation age across mammalian tissues

Disclosure Block: **A.T. Lu:** None.
Aging is often perceived as a degenerative process caused by random accrual of cellular damage over time. In spite of this, age can be accurately estimated by epigenetic clocks based on DNA methylation profiles from almost any tissue of the body. Since such pan-tissue epigenetic clocks have been successfully developed for several different species, it is difficult to ignore the likelihood that a defined and shared mechanism underlies the aging process. To address this, we generated data using 10,528 methylation arrays, each profiling up to 36 thousand cytosines in highly-conserved stretches of DNA, from over 57 tissue-types derived from 142 mammalian species. From these, we identified and characterized specific cytosines, whose methylation levels change with age across mammalian species. Genes associated with these cytosines are greatly enriched in polycomb repressive complex 2-binding sites, encode proteins known to participate in mammalian developmental processes and are implicated in age-related diseases. From the methylation profiles, we constructed three universal clocks that are similarly accurate for estimating ages (r>0.96) of any mammalian species and tissue each with a single mathematical formula. Collectively, these new observations support the notion that aging is indeed evolutionarily conserved and coupled to developmental processes across all mammalian species - a notion that was long-debated without the benefit of this new and compelling evidence.

PrgmNr 3711 - Using Taqman assays to analyze eQTL loci arising from GWAS Studies

View session detail

Author Block: **S. Jackson**, H. Veereshlingham, K. Varma; Thermo Fisher Scientific, South San Francisco, CA
Disclosure Block: **S. Jackson:** Salary/Employment; Thermo Fisher Scientific.
Tremendous progress has been made using genome-wide association studies (GWAS) to link genetic variation with phenotypes and pathologies. In spite of these success, it has been estimated that as many as 90% of SNPs identified in GWAS studies map to non-coding regions, complicating the mechanistic interpretation of the results. It is thought that these non-coding SNPs fall into regulatory regions and influence the expression of a gene or genes. The study of expression quantitative trait loci (eQTLs) provides a method for understanding the link between genetic variants and altered gene expression, and could potentially provide new insights connecting GWAS results to molecular mechanisms. To illustrate how eQTLs can be found and verified, we generated transcriptomic information from various tumor samples using Applied Biosystemsâ□¢â□□ Clariomâ□¢ D microarrays. To find putative eQTLs, we compared the SNPs genotypes and the gene expression levels in these samples to the GTEx database. Potential eQTLs in this set of samples were verified using Applied Biosystemsâ□□ Taqmanâ□¢ SNP Genotyping and Taqman Gene Expression assays. We therefore illustrate a workflow where candidate eQTLs can be confirmed and screened in larger cohorts using the more economical qPCR reagents available from Applied Biosystems.

PrgmNr 3712 - A statistical framework for single-molecule transcription factor footprinting

View session detail

Author Block: **D. Dubocanin**[1], D. M. Witten[2,3], A. B. Stergachis[1,4]; [1]Div. of Med. Genetics, Dept. of Med., Univ. of Washington, Seattle, WA, [2]Dept. of Statistics, Univ. of Washington, Seattle, WA, [3]Dept. of Biostatistics, Univ. of Washington, Seattle, WA, [4]Brotman Baty Inst., Seattle, WA
Disclosure Block: **D. Dubocanin:** None.
Transcription Factor (TF) binding and the regulatory networks they compose form the foundations of gene regulation. Currently, our knowledge on TF binding is based on short-read data, which is unable to delineate TF-DNA interactions in hard-to-map genomic regions, and cannot expose combinatorial dynamics of TF binding along individual chromatin fibers. Here we demonstrate an approach for footprinting individual TF binding events along multi-kilobase single-molecule chromatin fibers. We use a non-specific N6-methyladenine-methyltransferase (m6A-MTase) to methylate all adenine residues in DNA that are not protein-bound, and then perform PacBio sequencing. m6A-modified bases are identified using a Gaussian Mixture Model trained on polymerase kinetics obtained during single-molecule sequencing, and single-molecule nucleosome footprints are identified using a Hidden Markov Model. To identify individual single-molecule TF binding events within nucleosome free regions (NFRs), we developed a statistical framework that adjusts for the intrinsic methylation preferences of the m6A-MTase, as well as the local density of m6A-modified bases. We applied this for the de novo discovery of single-molecule TF footprints, as well as for the identification of single-molecule TF binding events at a priori defined TF elements. This method delineates the combinatorial dynamics of TF binding along multi-kilobase single-molecule DNA fibers at unprecedented resolutions.

PrgmNr 3713 - Analyzing the Effects of GWAS Fine-Mapping on PGS Analyses for Type 2 Diabetes

View session detail

Author Block: **P. Nguyen**, R. Gupta, J. Chin; DNAnexus, Mountain View, CA
Disclosure Block: **P. Nguyen:** Salary/Employment; DNAnexus.

A fundamental goal in precision medicine is to accurately quantify a person's disease risk based on their genomic information. This is important because it can have implications in both medical diagnostics and therapeutic development. For years, researchers have conducted genome-wide association studies (GWAS) to identify variations that are associated with diseases and polygenic score (PGS) analyses to summarize the GWAS information into risk for individuals. However, predictive power can be low, especially for complex diseases with a small number of individuals. Explainability can also be challenging, oftentimes because GWAS variations are not causal variations. Moreover, PGS models are not generalizable across ancestries, limiting their contributions to individuals with well-studied ancestries. Here, we analyze the effects of GWAS fine-mapping in terms of mitigating these issues.

For illustration, we focus on quantifying risk for type 2 diabetes (T2D), a disease that affects millions of people in the USA, with 200,000 reported cases per year. We build on top of a scalable framework backed by Apache Spark (which we presented last year) in order to conduct GWAS and PGS analyses at scale for 500,000 participants and 90,000,000 variations from the UK Biobank. We leverage EpiMap, a curated epigenomic dataset consisting of 10,000 epigenomic profiles covering 800 tissues and a number of histone modifications, in order to perform GWAS fine-mapping. We show that GWAS fine-mapping can improve predictive power and generalizability across ancestries. Furthermore, we demonstrate that it can suggest possible pathways that contribute to T2D, which can improve explainability.

All of our analyses are powered by the UK Biobank Research Analysis Platform, a cloud platform for genomics research and translational informatics. Each step is packaged as a workflow or notebook and can be made available upon request. Our analyses are generalized and can be applied to other phenotypic traits at will. We hope our analyses would enable not only more accurate and explainable risk quantification, but also in a way that is generalized and can be useful for more individuals across different ancestries.

PrgmNr 3714 - ChromBPNet: Deep learning models of base-resolution chromatin profiles reveal cis-regulatory syntax and regulatory variation

View session detail

Author Block: **A. Pampari**[1], A. Shcherbina[2], A. Kundaje[3]; [1]Computer Sci., Stanford Univ., Stanford, CA, [2]BioMed. Data Sci., Stanford Univ., Stanford, CA, [3]Stanford Univ., Stanford, CA
Disclosure Block: **A. Pampari:** None.

Chromatin profiling experiments such as DNase-seq, ATAC-seq, and histone ChIP-seq decorate cis-regulatory elements (cREs) with intricate read coverage profiles, whose magnitude, shape and span is regulated by cooperative binding of transcription factors (TFs). Here, we introduce ChromBPNet, the first end-to-end deep learning framework to map DNA sequence to base-resolution chromatin profiles, decipher predictive cis-regulatory sequence syntax of individual cREs and predict the impact of regulatory genetic variants on the strength and shape of different types of chromatin profiles across multiple cell types.

ChromBPNet is an optimized convolutional neural network architecture that models the influence of wide genomic sequence contexts (2-75 kbp) on quantitative base-resolution regulatory profiles from DNase-seq, ATAC-seq and histone ChIP-seq experiments. ChromBPNet trained on five ENCODE canonical cell lines achieved unprecedented predictive performance in held-out chromosomes, while automatically and optimally regressing out assay biases (DNase, Tn5 enzyme bias and input control for ChIP-seq). The models are highly performant over a range of sequencing depths and are able to de-noise and de-sparsify low coverage signal profiles at individual cREs.

We improved interpretation methods for de-novo inference of contribution of individual nucleotides across all putative cREs in the genome, thereby revealing predictive motif instances and their combinatorial interaction effects on base-resolution profiles. We deciphered syntactic sequence heterogeneity of all cREs in each cell-line and benchmarked these predictions against footprinting methods and TF ChIP-seq data. We found remarkable consistency between syntax derived from DNase-seq and ATAC-seq experiments. However, we also found intriguing differences in the influence of motif syntax and their associated cooperative TF complexes on different layers of regulatory activity (TF binding, chromatin accessibility, different types of histone marks) of individual cREs.

Finally, we developed a new variant effect score which predicts the impact of non-coding variants on the strength and shape of base-resolution chromatin profiles, thereby revealing a range of 'blast radii' of variants disrupting different types of TF motifs and syntax. Our models accurately predict quantitative trait loci associated with binding, accessibility and histone marks in lymphoblastoid cell-lines.

Our framework will enable high-resolution annotation of sequence syntax and regulatory variants in 100s of cell types that have been profiled with DNase-seq, ATAC-seq, and histone ChIP-seq experiments.

PrgmNr 3715 - Deep Learning Modeling of Transcription Factor Binding Specificity Using DNA Biophysical Properties

View session detail

Author Block: **B. Alexandrov**[1], M. Bhattarai[1], R. Vangara[1], S. Qian[2], T-P. Chiu[3], K. Rasmussen[1], A. R. Bishop[1], R. Rohs[3], J. Duan[4], X. He[5]; [1]Los Alamos Natl. Lab., Los Alamos, NM, [2]Univ. of Chicago, Chicago, IL, [3]Univ. of Southern California, Los Angeles, CA, [4]Northshore Univ Hlth.system/Univ of Chicago, Evanston, IL, [5]Univ Chicago, Chicago, IL

Disclosure Block: **B. Alexandrov:** None.

Active transcription is initiated and assisted by transcription factors (TF) binding to DNA, a process influenced by various epigenomic mechanisms. Local biophysical properties of DNA, such as local thermodynamic stability, shape, and flexibility, are important for TF-DNA binding. The structural stability of DNA is primarily governed by hydrogen bonds. Because hydrogen bonds are much weaker than covalent bonds, DNA at physiological temperature experiences conformational motions resulting from inherent thermal fluctuations. Such thermal motions of double-stranded DNA spontaneously induce local opening and closing of the double helix, i.e., â□□DNA breathing dynamicsâ□□ or â□□DNA bubblesâ□□ and their propensities are interrelated with DNA local flexibility. The effects of DNA breathing features, such as base-pair flipping propensity and typical bubble length and height on TF binding and gene expression have been shown by multiple studies. DNA shape (i.e., the local 3D structure of the double helix) is also important for TF binding. Many TFs not only recognize DNA sequence but also local DNA shape features, such as DNA bending and minor groove width. Many of the breathing and shape features can be influenced by nucleotides outside the TF motif, which has the potential to shed light on mechanisms of functional noncoding variants associated with disease risk, found in numerous genome-wide association studies. In this work, we integrate biophysical properties of DNA, derived in a high-throughput manner with DNA sequence into the modeling of TF binding specificity in a deep attention DNA machine learning model (DADm). We trained our DADm on TF binding specificity using protein binding microarray data for 203 mammalian TFs. We demonstrate that DADm, based only on DNA sequence, outperforms other state-of-the-art methods. Further, we encode in DADm DNA breathing dynamics and shape together with the sequence. Thus, DADm convolution layer captures the sequence along with DNA biophysical characteristics, the attention layer captures their significant importance and the recurrent layer captures long-term dependencies between the sequence and physicochemical characteristics to learn a new regulatory 'grammar' and improve DADmâ□□s predictions. Our results show that DNA breathing and shape characteristics-augmented models compared favorably to sequence-based models, which we also verified with attention maps of the trained model.

PrgmNr 3716 - DMRscaler: A scale-aware method to identify regions of differential DNA methylation spanning basepair to multi megabase features

View session detail

Author Block: **L. Bondhus**[1], A. Wei[1], V. A. Arboleda[2]; [1]UCLA, Los Angeles, CA, [2]Univ California los Angeles, Los Angeles, CA
Disclosure Block: **L. Bondhus:** None.
Pathogenic mutations in genes that control chromatin function cause epigenetic aberrations resulting in rare genetic syndromes. These chromatin modifiers exhibit extraordinary diversity in the scale of the epigenetic changes they affect, from single basepair modifications by DNMT1 to whole genome structural changes by PRM1/2. Patterns of DNA methylation are related to a diverse set of epigenetic features across this full range of epigenetic scale, making DNA methylation valuable for mapping regions of general epigenetic dysregulation. However, no existing methods make use of these relations to accurately identify the scale of epigenetic changes directly from DNA methylation data. To address this, we developed DMRscaler, a novel method that uses an iterative windowing procedure to capture regions of differential DNA methylation (DMRs) ranging in size from single basepairs to whole chromosomes. We benchmarked DMRscaler against several DMR callers in simulated and natural data comparing XX and XY peripheral blood samples. DMRscaler was the only method that accurately called DMRs ranging in size from 100 bp to 1 Mb (pearson's r = 0.92) and up to 152Mb on the X-chromosome. We then analyzed methylation data from rare-disease cohorts that harbor chromatin modifier gene mutations in NSD1, EZH2, and KAT6A. DMRscaler identified novel DMRs spanning PCDHA, PCDHB and PCDHGB gene clusters across these three groups suggesting these are common mechanisms driving their epigenetic dysregulation. Taken together, our results show DMRscaler is uniquely able to capture the scale of DMR features and identify novel, co-regulated regions that drive epigenetic dysregulation in human disease.

PrgmNr 3717 - Outlier gene detection to improve biological validation and classification performance in RNA sequencing

View session detail

Author Block: **S. Listopad**, T. M. Norden-Krichmar; Univ. of California, Irvine, Irvine, CA
Disclosure Block: **S. Listopad:** None.
Background: RNA sequencing (RNA-seq) serves as a proxy for the level of gene expression in a biological sample. One challenge with interpretation of RNA-seq output, however, involves expression of non-coding genes that were presumed to be removed via poly(A)-selection. It is also common to observe genes with aberrant expression that poorly distinguish between the study conditions, thereby hindering classification performance. The removal of such genes may also improve biological validation of identified gene signatures, since protein coding genes are more extensively annotated than non-coding ones. **Methods:** For this study, we used RNA-seq data obtained from 38 individuals with alcohol-associated hepatitis and 20 healthy controls. The RNA-seq data was aligned to the human genome hg38 using the STAR software and ENSEMBL gene annotation. We generated distribution normalized counts using Cuffnorm for every sample. A gene was labeled as an outlier if it was both non-coding and aberrantly expressed. The non-coding status was determined using ENSEMBL database. A gene was categorized as aberrant if the counts for at least one sample were further than a standard deviation threshold from the mean. We then developed a feature selection and classification pipeline that accepts RNA-seq counts as input, and outputs gene signatures along with corresponding classification performances. We estimated the biological validity of the resultant gene signatures using Enricher. We executed the pipeline with and without outlier gene removal, and then compared the resulting biological validation and classification accuracies. **Results:** Detection and removal of outlier genes had minor effects on classification performance. The classification accuracy varied by Â± 2% depending on the underlying feature selection architecture and choice of the machine learning classifier. The biological validation, however, improved notably with outlier removal. Typically, the number of relevant Enricher hits increased by a factor of 1.4. **Conclusion:** While the outlier removal procedure had negligible effect on classification performance it significantly improved the biological relevance of resulting gene signatures. It is likely that the classification performance did not consistently improve because some aberrant genes are still effective at distinguishing between the conditions. The effect on biological relevance, on other hand, benefited from protein-coding gene bias in existing literature.

PrgmNr 3718 - A Genealogical Estimate of Genetic Relationships to Improve Detection of Population Structure Over Time

Author Block: **C. W. Chiang**, C. Fan, N. Mancuso; Univ. of Southern California, Los Angeles, CA
Disclosure Block: **C.W. Chiang:** None.

The application of genetic relationships among individuals, characterized by a genetic relationship matrix (GRM), has far-reaching effects in genetic epidemiology. However, the current standard to calculate the GRM does not take advantage of linkage information and does not reflect the underlying genealogical history of the study sample. Here, we propose a coalescent-informed framework to infer the expected relatedness between pairs of individuals given an ancestral recombination graph (ARG) of the sample. This expected GRM (eGRM) is an unbiased and highly correlated estimate ($r^2 > 0.97$) of the latent pairwise genome-wide relatedness and maintains the mathematical properties of canonical GRMs. Through extensive simulations we show that the eGRM is robust when using genealogies inferred from incomplete genetic data, and can reveal the time-varying nature of population structure in a spatial sample. When applied to genotyping data from a population sample from Northern and Eastern Finland (N=2,644), we found that clustering analysis using the eGRM more accurately delineates population structure than would be possible using the standard GRM, and the temporal pattern of population structure in this sample is consistent with that of a recently diverged and expanded population. Taken together, our proposed estimator drastically shifts the notion of genetic relatedness from a variant-centric to a tree-centric world view, and will be widely applicable to genetic studies in understudied human or ecological samples where whole genome sequencing data or references might not be readily available.

PrgmNr 3719 - Causal variant effect sizes of complex traits differ between populations

Disclosure Block: **S. Musharoff:** None.

Despite the growing number of genome-wide association studies for complex traits, it remains unclear whether effect sizes of causal genetic variants differ between populations. Effect sizes of causal variants can differ between populations due to gene-by-gene or gene-by-environment interactions, which have important implications for the study of complex traits and for the use of polygenic scores. However, comparing causal variant effect sizes is challenging: causal variants are hard to identify, and comparisons of their tag SNPsâ effect sizes are confounded by differences in linkage disequilibrium (LD) patterns and allele frequencies between ancestries. Here, we develop a method to assess causal variant effect size differences that does not require identifying the causal variants themselves. Specifically, we leverage the fact that segments of European ancestry shared between European-American and admixed African-American individuals have the same LD patterns and allele frequencies, such that comparisons of tag SNP effect sizes in European ancestry segments are not confounded by these factors. We apply our method to two traits, gene expression of 499 European-Americans and 319 African-Americans in the Multi-Ethnic Study of Atherosclerosis (MESA) and blood lipid levels (statin-adjusted maximum low-density lipoprotein cholesterol, or LDL-C) of ~273K European-Americans and ~72K African-Americans in the Million Veteran Program (MVP). First, we find that global ancestry, local ancestry, and genotype-by-local-ancestry interactions all significantly contribute to the phenotypic variance of both traits, demonstrating the complex association between ancestry and trait architecture. Next, we find that effect sizes of causal variants differ between European-Americans and African-Americans for gene expression and blood lipid levels, likely due to gene-by-gene or gene-by-environment interactions. For gene expression, we find that differences in causal variant effect sizes explain 14% of the decrease in the cross-population genetic correlation. These differences highlight the role of genetic interactions in trait architecture and may contribute to the poor portability of polygenic scores across populations, reinforcing the importance of conducting GWAS on individuals of diverse ancestries and environments.

PrgmNr 3720 - Codon bias analysis of wildtype SARS-CoV-2 and prevalent variants indicates a mutational trajectory independent of human pulmonary tissue and genomic bias

View session detail

Author Block: **S. Brugger**, M. Grose, J. Grose, M. Davis; Brigham Young Univ., Provo, UT
Disclosure Block: **S. Brugger:** None.
Codon bias is a genomic phenomenon in which an organismâ□□s DNA coding regions exhibit a clear usage bias among synonymous codons. Every organism possesses a unique bias, and variation in this bias has even been observed between an organismâ□□s tissue systems. The aim of this study was to determine whether prominent variants of SARS-CoV-2 present evidence of mutational pressure to align their codon biases with those observed both within pulmonary tissue and throughout the human genome. To establish a baseline for analysis, the codon bias of the SARS-CoV-2 reference sequence (WT) was calculated and cross-referenced with the two aforementioned human biases. Despite a common bias for codon AAT (N) between WT and the human genome, no other biases were shared. In order to track the potential development of shared bias, three analyses were performed evaluating a) human genomic and pulmonary bias against prevalent SARS-CoV-2 variants, b) changes in the bias of said variants over time, and c) WT and human biases against the most recently sequenced variants globally. Results of the first analysis revealed modest shifting toward human biases, most notably within B.1.429 and B.1.351 when compared to pulmonary bias. Results of the second analysis showed little shifting from month to month across all tested variants; despite several instances in which samples did demonstrate a shift in bias to align with the human biases, those shifts were not sustained. Variant B.1.429 experienced a significant shift in bias from GTG (V) to GTT (V) from 10/2020 to 12/2020 and again from 02/2021 to 04/2021; similarly, a shift from GAC (D) to GAT (D) was observed over the same time period. Bias for the pre-shift codons was shared between B.1.429 and the two human biases, and the observed shift realigned B.1.429â□□s bias with that of WT. Despite marked preference shifts in several countries and codons, the results of the third analysis did not reveal any long-term changes to codon preference in comparison to WT. Of note, the WT bias for GTT (V) over GTG (V) was generally sustained in this analysis, but that shift was reversed in four samples and a trend toward reversal was observed in an additional five samples. Overall our results indicate that over time, and across several prominent and novel variants, SARS-CoV-2 does not appear to have significantly shifted its codon bias to align with those of the human genome or pulmonary tissue, indicating that such mutations are unnecessary for effective replication and transmission. Research into anomalous codon shifts, such as those observed in valine, may illuminate genomic mechanisms that influence the success or failure of the virus and warrant further investigation.

PrgmNr 3721 - Coevolution is pervasive between unrelated glycosylation pathways and points to potential disease modifiers

View session detail

Author Block: **H. Thorpe**, N. Clark, C. Y. Chow; Univ. of Utah, Salt Lake City, UT
Disclosure Block: **H. Thorpe:** None.
Protein glycosylation is the most common post-translational modification, including N-linked glycosylation, O-linked glycosylation, and GPI anchor biosynthesis. These pathways are separate with nearly no overlapping components. Because of the ubiquity of protein glycosylation, mutations in these pathways lead to a variety of multisystemic metabolic disorders broadly classified as Congenital Disorders of Glycosylation (CDG). CDGs are inherited defects in one of the >150 genes involved in the glycosylation pathways. CDGs can present with a range of symptoms, but the most consistent are seizures, hypotonia, and developmental delays. Glycosylation is ubiquitous throughout the body and affects many proteins making it difficult to identify effective treatments. As with all Mendelian diseases, clinical variability between CDG patients, even with the same mutation, is common and suggests that modifier genes are affecting the phenotypes. I am employing evolutionary approaches to identify modifier genes of CDGs. Evolutionary Rate Covariation (ERC) relies on the premise that proteins that interact physically or genetically or are functionally related coevolve at similar rates. ERC values are calculated using the correlation coefficient of evolutionary rates of gene pairs in a species tree. I pulled pairwise ERC values for 224 genes involved in protein glycosylation calculated from a species tree with evolutionary rates from vertebrates, worms, *Drosophila*, and yeast. As expected, I found enrichment for high ERC values within each glycosylation pathway. Surprisingly, I also identified several components of each pathway that showed high ERC with unrelated glycosylation pathways. For example, MAN2A2, a component of N-glycosylation localized to the Golgi, shows strong ERC with most components of the GPI anchor pathway in the ER. These types of coevolution signatures tell us that there are unappreciated connections between these unrelated pathways. I have also used ERC to look genome wide for coevolution with CDG genes. For example, I pulled ERC values for each GPI anchor synthesis gene across the genome. Gene Ontology analysis of genes that coevolve with GPI anchor synthesis genes showed enrichment of genes involved in RNA modification and mitochondrial gene expression. This enrichment indicates there may be interactions between these processes and GPI anchor synthesis. There was also an enrichment of genes involved in N-linked glycosylation, supporting the connections found previously between GPI anchor synthesis and N-linked glycosylation. These connections could lead to better understanding of the pathways and potential treatments for CDGs.

PrgmNr 3722 - DNA methylation patterns underlying lifespan differences in mammals

View session detail

Author Block: **A. Haghani**, S. Horvath; Univ. of California Los Angeles, Los Angeles, CA
Disclosure Block: **A. Haghani:** None.
The comparative cross-species analysis is a powerful tool to resolve the mysteries of evolution and phenotypic disparities among animals. This study describes the largest multi-species DNAm dataset that was collected by over 100 collaborators from Mammalian Methylation Consortium. This dataset includes over 10,000 DNA methylome data from multiple tissues of different age ranges of over 190 mammalian species. The network analysis of this dataset allowed us to identify co-methylation modules that relate to the individual (age, sex, tissue type) and species characteristics (e.g., phylogenetic order, maximum lifespan, adult weight). The unexpected correlation between DNA methylation and species was sufficiently strong to construct *phyloepigenetic* trees that parallel the phylogenetic tree. The analysis identified the epigenetic marks and the associated genes that relate to the maximum lifespan of mammals. Moreover, we could define novel epigenetic biomarkers of longevity that responded to gold standard anti-aging interventions in mice such as caloric restriction or growth hormone receptor knock outs. Our novel cross-species epigenetic analysis is a rich source of targets for future experimental studies of aging and longevity.

PrgmNr 3723 - Gnomix: local ancestry inference for whole genome sequences and large datasets

View session detail

Author Block: **A. Kumar**[1], H. Hilmarsson[1], R. Rastogi[2], D. Mas Montserrat[1], C. D. Bustamante[3], A. Ioannidis[1]; [1]Stanford Univ., Stanford, CA, [2]Cornell Univ., Ithaca, NY, [3]Stanford Univ. Sch. of Med., Stanford, CA

Disclosure Block: **A. Kumar:** None.

Local ancestry inference is becoming an increasingly important tool as genetic studies become more inclusive. In particular it is now used as a pre-processing step, when running genome wide association studies on diverse cohorts. We introduce Gnomix, a faster, more accurate, high resolution local ancestry inference algorithm designed for the challenges of modern biobank-scale datasets and whole genome sequences. Gnomix has a modular approach allowing the user to choose from a host of base learners and smoothers to optimize the tradeoff of performance vs. accuracy for any particular application. Because the Gnomix model, once trained, can be saved and re-deployed, Gnomix allows for training once with future inference able to be performed rapidly without the need for re-training. Since the trained models are portable, Gnomix allows collaborators to share compact inference algorithms, pretrained on large datasets comprised of samples that may themselves not be easy to share either due to the difficulties of moving data or due to restrictions on the transfer or release of the raw individual sequences in the datasets. This permits highly accurate models to be trained on large volumes of training data held in one location and then applied across multiple independent studies, saving time while increasing accuracy and reproducibility. We demonstrate Gnomix on worldwide datasets of whole genome human sequences, exhibiting its performance metrics on human sequences from the NHGRI Genome Sequencing Program (GSP), as well as on other species. In all cases we show robust improvements of both accuracy and speed (more than an order of magnitude), when compared to a panel consisting of currently popular methods.

PrgmNr 3724 - Human-specific evolution at multiple scales and dimensions

View session detail

Author Block: **K. Keough**, K. S. Pollard; Gladstone Inst.s, San Francisco, CA
Disclosure Block: **K. Keough:** None.
Human Accelerated Regions (HARs), conserved genomic loci that evolved at an accelerated rate in the human lineage, are of intense interest based on their potential to underlie human-specific traits. We optimized an open-source Nextflow pipeline to identify lineage-specific accelerated regions in alignments of hundreds of species and used it to identify an updated set of HARs and chimpanzee accelerated regions. We observed a striking enrichment of human lineage-specific structural variants in topological associating domains containing HARs. Combining machine-learning predictions with chromatin capture experiments in human and chimpanzee neural progenitor cells, we discovered human-specific changes to three-dimensional genome organization around HARs, potentially rewiring regulatory interactions with neurodevelopmental genes. Thus, comparative genomics together with 3D genome organization data revealed enhancer hijacking as a mechanism that may explain the surprisingly rapid evolution of HARs.

PrgmNr 3725 - Identification of ancestry specific health risks in a large cosmopolitan biobank

Zaitlen[1]; [1]Dept. of Neurology, Univ. of California Los Angeles, Los Angeles, CA, [2]USC-ISI, Marina del Rey, CA, [3]Univ. of California Los Angeles, Los Angeles, [4]Dept. of Computer Sci., Univ. of California Los Angeles, Los Angeles, CA, [5]Univ California los Angeles, Los Angeles, CA, [6]Icahn Sch. of Med. at Mount Sinai, New York, NY
Disclosure Block: **C. Caggiano:** None.
INTRODUCTION: Genetic ancestry is a key factor that affects an individualâ□□s risk for disease. In clinical settings, however, genetic ancestry is underutilized. Instead, race and ethnicity are used as noisy proxies for ancestry, reducing the ability to identify any health disparities that may exist in genetic ancestry communities.
OBJECTIVES: In this work, we studied genetic ancestry in the context of a large cosmopolitan biobank, with the goal of identifying illnesses that may exist at an elevated prevalence in fine-scale ancestry groups. To do this, we used genotype and electronic health record (EHR) data from 28,000 individuals across the Los Angeles area.
METHODS: To assess genetic ancestry, we identified identical-by-descent (IBD) segments of biobank participants via iLASH. Using these IBD segments, we identified 180 genetic communities using the InfoMap community detection algorithm. Many of these communities are populations not well-studied in clinical human genetics, including groups characterized by the presence of Persian Jews, Armenians, and Ethiopians. After identifying these groups, we used deidentified EHR data to estimate population-specific disease risks.
RESULTS: In this analysis, we observed several well-known disease-ancestry associations, including an elevated risk for Crohnâ□□s Disease in Ashkenazi Jews versus non-Jewish Europeans (logistic regression p=3.82 x 10-8, odds-ratio: 2.0 95% CI: 0.60-3.40), along with novel associations in many non-European communities, such as an increased risk for sleep apnea in Persians (logistic regression p=8.43 x 10-4; odds-ratio: 2.5, 95% CI: 0.80-4.2).
CONCLUSIONS: These results demonstrate the value of using genetic ancestry in precision medicine initiatives, especially for understudied populations.

PrgmNr 3726 - Inferring negative natural selection at short tandem repeats in the human genome

View session detail

Author Block: **B. Huang**[1], K. E. Lohmueller[2,3], M. Gymrek[4,5]; [1]Dept. of Bioengineering, Univ. of California San Diego, La Jolla, CA, [2]Univ. of California Los Angeles, Los Angeles, CA, [3]Dept. of Human Genetics, David Geffen Sch. of Med., Univ. of California Los Angeles, Los Angeles, CA, [4]Dept. of Computer Sci. and Engineering, Univ. of California San Diego, La Jolla, CA, [5]Dept. of Med., Univ. of California San Diego, La Jolla, CA

Disclosure Block: **B. Huang:** None.

Short tandem repeats (STRs) are DNA sequences consisting of repeated 1-6 base pair motifs that represent about 1.6 million loci in the human genome. Due to their high prevalence in the genome and rapid mutation rates, variation in copy number at STRs represents a large portion of human genetic variation. Since STRs play an important role in gene expression and contribute to a wide range of human traits and disorders ranging from height and intelligence to cancer and Mendelian diseases, mutations at some STRs are likely to experience natural selection. Understanding these fitness effects can provide insights into the functional importance of particular classes of repeats. Recently, we introduced SISTR (Selection Inference at Short Tandem Repeats), a population genetics framework that estimates selection coefficients (*s*) at individual STRs. Although SISTR performs well on STRs with rapid mutation rates, the method is underpowered to detect selection at loci with low mutation rates or loci under modest selection. To overcome these limitations, we present SISTR2, an extension of SISTR that jointly estimates the distribution of *s* across a set of loci. SISTR2 assumes *s* for each STR is drawn from a gamma distribution and infers the parameters of this distribution, using approximate Bayesian computation and the set of allele frequency distributions for each locus. After validating SISTR2 on simulated datasets, we estimated the distribution of selection coefficients for different STR classes. As inputs, we used STR allele frequencies obtained from European individuals from the 1000 Genomes Project. We found that coding loci are under stronger negative selection than non-coding loci as expected. Furthermore, we performed a motif analysis and found that even among STRs with the same repeat unit length, there is notable variation in negative selection across different repeat unit sequences. For example, for dinucleotides, AT repeats (which are enriched in common human transposable element sequences and thus may be under decreased negative selection) appear more neutral than AC or AG repeats. For both trinucleotides and tetranucleotides, A_nG_n type repeats (e.g. AAG/AAAG/AAGG) generally appear under less selection. This is consistent with a previous observation that these repeats are most likely to expand in healthy controls, which may be caused by unstable base-stacking interactions at these STRs. Overall, a more accurate and nuanced understanding of selection coefficients at STRs of different repeat classes will be important for future studies of variation at STRs and their role in evolution and disease.

PrgmNr 3727 - Inferring population structure in biobank-scale genomic data

View session detail

Author Block: **A. M. Chiu**[1], E. K. Molloy[1,2], Z. Tan[3], A. Talwalkar[4], S. Sankararaman[1]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]Univ. of Maryland, Coll. Park, College Park, MD, [3]Facebook, Inc., Menlo Park, CA, [4]Carnegie Mellon Univ., Pittsburgh, CA
Disclosure Block: **A.M. Chiu:** None.
Inference of population structure is a central problem in human genetics with applications ranging from understanding of human history to population stratification correction in genome-wide association studies. Approaches to population structure inference typically formalize the problem as one of estimating admixture proportions of each individual and ancestral population allele frequencies given genetic variation data. The growth of repositories of genetic variation data over large numbers of individuals has opened up the possibility of inferring population structure at increasingly finer resolution. This development has necessitated methods that can be applied to large-scale datasets with reasonable computational requirements. Thus, we developed SCOPE (SCalable pOPulation structure inferencE) - a scalable method capable of inferring population structure on biobank-scale data. SCOPE utilizes a previously proposed likelihood-free framework that estimates the individual allele frequency matrix through a statistical technique known as latent subspace estimation followed before decomposing it into ancestral allele frequencies and admixture proportions. SCOPE uses two ideas to substantially improve the scalability of this approach. First, SCOPE uses randomized eigendecomposition to efficiently estimate the latent subspace. Specifically, SCOPE avoids the need to form matrices that are expensive to compute or require substantial memory, instead working directly with the input genotypes. Second, SCOPE leverages the repeated multiplications of the genotype matrix and uses the Mailman algorithm for fast multiplication of the genotype matrix. We benchmarked the accuracy and efficiency of SCOPE on simulated and real datasets. In simulations, SCOPE obtains accuracy comparable to existing methods while being 3 to 1,800 times faster. Relative to the previous state-of-the-art scalable method (TeraStructure), SCOPE is 3 to 144 times faster. SCOPE can estimate population structure in about a day for a dataset consisting of one million individuals and SNPs whereas TeraStructure, is extrapolated to require approximately 20 days. We used SCOPE to infer continental ancestry proportions (four ancestry groups) on the UK Biobank dataset (488,363 individuals and 569,346 SNPs) in about a day. We find that the inferred continental ancestry proportions are highly concordant with self-reported race and ethnicity. SCOPE additionally can be applied in a supervised setting. Given allele frequencies from reference populations, SCOPE can estimate admixture proportions corresponding to the reference populations, to enable greater interpretability.

PrgmNr 3728 - Population level study of tandem repeats using an ensemble call-set

View session detail

Author Block: **N. Mousavi**, N. Ma, H. Ziaei Jam, B. Huang, M. Gymrek; UC San Diego, San Diego, CA
Disclosure Block: **N. Mousavi:** None.
Tandem repeats (TRs) are a class of highly variant genetic mutations characterized by motifs of 1-20 base pairs repeating in tandem. TRs form more than 3% of the human genome and have been associated with Mendelian disorders such as Huntingtonâ□□s disease and Fragile X syndrome. Furthermore, studies have linked TRs to complex traits such as gene expression. However, due to complexities in sequencing, assembly, and genotyping, TRs have been a relatively understudied class of genetic variants. Recently several tools (GangSTR, HipSTR, ExpansionHunter, AdVNTR, and others) have been developed for genome-wide and targeted genotyping of TRs from short-read sequencing data. While these methods open the doors to large-scale studies of these complex genetic variants, each method has different design principles that can lead to biased call sets. To address this issue, we have developed a graph-based method to create an ensemble TR call-set from the outputs of TR variant calling tools. Our method utilizes statistical measures of accuracy at each locus alongside knowledge on biases of each method to create a unified and unbiased output call-set. We applied this approach to the 2504 samples from the 1000 Genomes project and created a population-level unified ensemble TR call-set. We experimentally validate our ensemble call-set via fragment analysis at a subset of loci and samples and measure Mendelian error rate using 698 additional related samples. We calculate allele frequencies of TRs across different populations and find TRs with highly population-specific alleles. We further measure negative selection at different TR loci using SISTR and identify specific loci that are likely to be under selection pressure. Finally, we identify and characterize TR expansions polymorphic throughout different populations. Our results create an unbiased TR call-set on a large-scale dataset and shed light on the population-level variability of TRs.

PrgmNr 3729 - Reconstructing spatio-temporal patterns of admixture in human history using present-day and ancient genomes

View session detail

Author Block: **M. Chintalapati**[1], N. J. Patterson[2], N. Alex[1], P. Moorjani[1]; [1]Univ. of California, Berkeley, CA, [2]Broad Inst MIT & Harvard, Cambridge, MA
Disclosure Block: **M. Chintalapati:** None.
Recent studies of contemporary and ancient human populations has shown that gene flow or admixture has been pervasive throughout human history. Understanding the timing and signatures of admixture is important for studying the evolutionary and functional impact of admixture, as well as uncovering the historical context of the mixture. With the availability of a large number of present-day and ancient genomes, it is now possible to characterize the timing of demographic changes with unprecedented resolution. While a number of methods exist for characterizing population mixture in contemporary populations, they are not applicable to sparse data available from ancient DNA specimens (with low coverage and large proportions of missing genotypes). To address this need, we developed *DATES* (Distribution of Ancestry Tracts of Evolutionary Signals) that leverages ancestry covariance patterns in a single diploid genome to infer timing of admixture. By simulations, we show that *DATES* provides reliable results under a range of scenarios, including for cases with only a single admixed individual, admixed genomes with low coverage and admixed genomes with large amounts of missing data. We applied *DATES* to reconstruct the timing of population admixture using Human Origins dataset with over 7,000 present-day and 5,000 ancient human genomes, including the spread of Mongol Empire expansion and formation of present-day Japanese ancestry. Using time-transect data from diverse geographic regions and cultures in Europe, we perform a fine-scale reconstruction of the mixture of ancient hunter-gatherers, Neolithic farmers and Steppe-pastoralists uncovering the dynamics of Neolithic farming and the spread of Indo-European languages in Europe. Our analyses highlight the power of genomic dating methods to elucidate the legacy of human migrations and provide complementary insights to archaeological and linguistic evidence.

PrgmNr 3730 - Reconstructing the 3D chromatin organization of archaic hominins reveals that genome folding shaped human-Neanderthal phenotypic divergence and introgression

View session detail

Author Block: **J. A. Capra**[1], E. McArthur[2], D. C. Rinker[2], E. Gilbertson[1], G. Fudenberg[1], M. Pittman[1], K. Keough[3], K. S. Pollard[4]; [1]Univ. of California San Francisco, San Francisco, CA, [2]Vanderbilt Univ., Nashville, TN, [3]Gladstone Inst.s, San Francisco, CA, [4]Univ California San Francisco, San Francisco, CA
Disclosure Block: **J.A. Capra:** None.
Introduction: Modification of gene regulation was a driving force in the divergence of modern humans and archaic hominins. While previous investigation has focused on changes in cis-regulatory elements, the three-dimensional (3D) organization of the genome plays a critical role in regulating gene expression by facilitating and insulating enhancer-promoter interactions. However, the role of 3D genome organization changes in recent human evolution has not been explored because the degradation of ancient samples does not permit experimental interrogation of archaic hominin 3D genome folding.
Results: We address this gap by applying novel deep learning methods for inferring 3D genome organization from DNA sequence patterns to Neanderthal, Denisovan, and diverse modern human genomes. Using the resulting genome-wide 3D genome folding maps, we find that Neanderthals have more predicted 3D genome similarity to humans than expected based on sequence similarity. This suggests that pressure to maintain 3D conformation has constrained sequence divergence in recent hominin evolution. Although humans and Neanderthals have broadly similar 3D genome structures, we identify many archaic-specific and modern human-specific 3D patterns (e.g. chromatin loops). Thus, Neanderthal introgression had the potential to impart divergent 3D genome folding to Eurasians. Evaluating the legacy of introgression on human 3D genome organization, we identify substantial changes in 3D folding patterns caused by introgressed variants that also associate with traits relevant to human-Neanderthal differences, including height, fat distribution, and blood pressure. Additionally, we discover that tolerance to 3D genome variation in humans constrained Neanderthal introgression: regions more tolerant of 3D variation in modern Africans are enriched for introgression in modern Eurasians.
Conclusion: In summary, our approach opens a window into previously unobservable molecular mechanisms underlying how genetic differences lead to phenotypic divergence between modern and archaic hominins by applying deep learning to predict archaic 3D genome folding.

PrgmNr 3731 - The mutational dynamics of short tandem repeats in large, multigenerational families

View session detail

Author Block: **C. Steely**[1], W. Watkins[2], L. M. Baird[1], L. B. Jorde[3]; [1]Univ. of Utah, Sch. of Med., Salt Lake City, UT, [2]Univ. of Utah, Salt Lake City, UT, [3]Univ of Utah, Salt Lake City, UT
Disclosure Block: **C. Steely:** None.
Short tandem repeats (STRs) are tandemly repeated sequences of 1-6 bp motifs. These sequences compose approximately 3% of the genome, and mutations at STR loci have been linked to dozens of human diseases including amyotrophic lateral sclerosis, Friedreich ataxia, Huntington disease, and fragile X syndrome. Improving our understanding of these mutations would increase our knowledge of the mutational dynamics of the genome and may uncover additional loci that have a role in causing disease. Here, to estimate the genome-wide pattern of mutations at STR loci, we examined blood-derived whole-genome sequencing data for 544 individuals from 29 three-generation CEPH pedigrees. These pedigrees contain both sets of grandparents (generation 1), the parents (generation 2), and an average of 9 grandchildren (generation 3) per family. We use HipSTR to identify *de novo* STR mutations in the 2nd generation of these pedigrees. Analyzing approximately 1.6 million STR loci, we find an average *de novo* STR mutation rate of 5.24*10-5 mutations per locus per generation. We find that perfect repeats mutate ~3x more quickly than imperfect repeats and *de novo* STRs intersect with transposable elements. Approximately 30% of these *de novo* STRs are found in *Alu* elements, even though these elements compose only 11% of the genome. Another ~10% are found in LINE-1 insertions, which compose 17% of the genome. Phasing these *de novo* mutations to the parent of origin shows parental transmission biases that vary among families. We estimate the average number of *de novo* genome-wide STR mutations per individual to be ~85, which is coincidentally similar to the average number of observed *de novo* single nucleotide variants.

PrgmNr 3732 - The waiting distance distribution in ancestral recombination graphs

View session detail

Author Block: **Y. Deng**; UC Berkeley, Berkeley, CA
Disclosure Block: **Y. Deng:** None.
The ancestral recombination graph (ARG) contains the full genealogical information of the sample, and many population genetic inference problems can be solved using inferred or sampled ARGs. In particular, the waiting distance between tree changes along the genome can be used to make inference about the distribution and evolution of recombination rates. To this end, we here derive an analytic expression for the distribution of waiting distances between tree changes under the sequentially Markovian coalescent model and obtain an accurate approximation to the distribution of waiting distances for topology changes. We use these results to show that some of the recently proposed methods for inferring sequences of trees along the genome provide strongly biased distributions of waiting distances. In addition, we provide a correction to an undercounting problem facing all available ARG inference methods, thereby facilitating the use of ARG inference methods to estimate temporal changes in the recombination rate.

PrgmNr 3733 - A retrospective study of health issues being discussed in a prenatal setting with female carriers of fragile X syndrome

View session detail

Author Block: **F. Ellahy**[1], S. Chen[2], T. Giordonello[2], M. Zak[1]; [1]Long Island Univ. Post, Brookville, NY, [2]Northwell Hlth., Great Neck, NY
Disclosure Block: **F. Ellahy:** None.
Fragile X syndrome is a complex genetic condition that has health implications for carriers as well as affected individuals. Over the past decade, a multitude of scientific literature has been published demonstrating a correlation between the premutation allele and increased incidences of various physical and mental issues beyond fragile X-associated tremor and ataxia syndrome (FXTAS) and premature ovarian failure (POF). Clinicians counseling these patients should be updated about this recent literature to provide patients with the most accurate information to make informed choices about their health and reproduction. As there is no literature published regarding what health issues are being discussed with fragile X carriers in genetic counseling sessions, one of this studyâ□□s goals is to shed light on this area. Furthermore, by analyzing the trends over the years, this study also aims to determine if the number of topics discussed with these patients has changed. In this retrospective chart review, 107 patient records spanning the years 2012 to 2020 were obtained. Since fragile X carrier screening is usually performed in a prenatal setting, this study obtained its patient population from four prenatal clinics. The study population included female intermediate or premutation carriers between the ages of 18 to 50 years. This study found that health issues strongly associated with premutation alleles, such as FXTAS and POF, were the most frequently discussed topics (44.9% of N). Other conditions with less conclusive evidence regarding association with the premutation allele, such as learning disabilities and psychological disorders (autism, anxiety, and depression), were less frequently discussed (~3% of N) but are starting to be included in the discussion. This study found an overall increase in the average number of topics discussed with carriers over the years 2012-2020 (premutation carriers: 3.00 to 4.86, intermediate carriers: 0 to 2.25). The findings from this study demonstrate that conversation regarding emerging health problems associated with premutation carriers is starting to take place. The results also suggest that clinicians are staying updated with the literature and adapting their counseling to include this new research in their discussions. This studyâ□□s findings can be used as a resource by clinicians and genetic counseling programs to inform their practices by identifying the topics currently being discussed with this patient population and to foster a discussion about improving the quality and content of counseling this patient cohort.

PrgmNr 3734 - Analysis of Financial Barriers Experienced by Prospective Genetic Counseling Students

View session detail

Author Block: **D. Lee**[1], J. Platt[2,3], P. Flodman[1], K. Singh[1], F. Quintero-Rivera[1,4]; [1]Div. of Genetic and Genomic Med., Dept. of Pediatrics, Univ. of California, Irvine, Irvine, CA, [2]Stanford Ctr. for Inherited Cardiovascular Disease, Stanford Hlth., Palo Alto, CA, [3]Div. of Med. Genetics, Dept. of Pediatrics, Stanford Univ. Sch. of Med., Palo Alto, CA, [4]Dept. of Pathology and Lab. Med., Univ. of California Irvine, Irvine, CA

Disclosure Block: **D. Lee:** None.

Background: Genetic counseling (GC) graduate program applicants are burdened with application fees and the â□□hidden costsâ□□ of applying, including graduate exam fees, prerequisite coursework, travel expenses for interviews, and time off from work to obtain relevant volunteer experiences. These costs can become prohibitively expensive for many applicants, especially those with fewer resources. Furthermore, the high costs of applying can become a barrier to diversify the workforce.

Objectives: This study aimed to address the following: 1) What were the median application costs for prospective students applying to GC programs in the United States? 2) What aspects of the application process were most expensive? 3) Were there differences between individuals of historically underrepresented racial and ethnic backgrounds in medicine (hURM) and non-underrepresented applicants with respect to total application costs, accrued volunteer hours, parental education, and familial financial assistance?

Methods: A survey was developed to capture demographic information, application history, application and preparation expenses, time volunteering, and financial resources. A total of 383 responses were analyzed.

Results: Median total application costs for respondents who attempted one application cycle were $2,634 (n = 264, range: $202 - $25,693). For those who attempted twice, median total costs were $4,762 (n = 84, range: $909 - $24,206). Interview-related items had the highest median cost (one application cycle: $879, range: $0 - $6,007; two or more application cycles: $1,310, range: $0 - $7,307). Among those who applied to more than one cycle, hURM respondents (n=19) had higher median total costs ($6,713 versus $4,762, p = 0.03) and lower median total volunteer hours (246 versus 381 hours, p =0.03) than those of non-underrepresented individuals (n = 100). Additionally, parental education level differed (p = 0.04) between the two groups. Higher parental education level was correlated with a higher percentage of familial financial support (2% median financial contribution from parents with a high school diploma or associate degree versus 60% from parents who both have advanced degrees, p = 0.0009).

Conclusion: This study demonstrates the significant costs associated with the GC application process. Differences in costs and resources were also observed between applicants of differing socioeconomic status. Stakeholders within the profession should implement strategies to reduce financial barriers and the resulting inequities in the application process, which will improve access to GC graduate programs and enhance efforts to diversify the workforce.

PrgmNr 3735 - Attitudes towards polygenic risk testing for glaucoma in an Australian population

View session detail

Author Block: **G. Hollitt**[1], O. M. Siggs[1], B. Ridge[1], M. C. Keane[1], D. A. Mackey[2], S. Macgregor[3], A. W. Hewitt[4], J. E. Craig[1]; [1]Dept. of Ophthalmology Flinders Univ., BEDFORD PARK, Australia, [2]Lions Eye Inst., Nedlands, Australia, [3]QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [4]Ctr Eye Res Aust, Brunswick, Australia

Disclosure Block: **G. Hollitt:** Major Stockholder/Ownership Interest; S MacGregor, AW Hewitt and JE Craig are listed as co-inventors on a patent application for the use of genetic risk scores to determine risk and guide treatment for glaucoma.

Despite the significant progress made in genetic risk prediction, critical gaps in knowledge pertinent to understanding barriers to the implementation of polygenic risk scores (PRS) testing persist. We performed a cross-sectional, questionnaire-based study to better understand the attitudes of individuals with and without glaucoma toward PRS for glaucoma. As the leading cause of irreversible vision loss in the world, with recognised complex heritability, few environmental risk factors, and high treatability to prevent blindness, PRS testing has strong clinical utility for glaucoma. We surveyed 1169 individuals with glaucoma and 418 individuals without glaucoma to evaluate their attitude toward polygenic risk testing for glaucoma. Those without glaucoma included those with a first-degree relative with diagnosed glaucoma, those attending an optometrist without glaucomatous features, and unselected members of the community. We assessed several factors affecting interest in testing using multivariate regression analysis. Our results showed strong interest in the test, with 69.4% of individuals with glaucoma and 71.3% of individuals without glaucoma indicating a keenness in testing. Among individuals with glaucoma, interest was seen in those from an urban area (OR 1.696, 95% CI (1.154-2.494), p=0.007), those who perceived their risk of developing glaucoma as higher (OR 2.053, 95% CI (1.280-3.293), p=0.003), and those who were worried about developing glaucoma (OR 2.068, 95% CI (1.270-3.369), p=0.004). In individuals without glaucoma, interest was seen in those who perceived their risk of developing glaucoma was higher (OR 14.579, 95% CI (1.146-185.5), p=0.039), those who were worried about developing glaucoma (OR 4.371, 95% CI (2.317-8.246), p

PrgmNr 3736 - Authorship Guidelines and Implementation: Promoting Equity and Inclusion

View session detail

Author Block: **H. Lewis**[1], S. S. Lee[2], K. A. Goddard[3], B. S. Wilfond[4], B. B. Biesecker[5]; [1]Seattle Children's Hosp., Seattle, WA, [2]Columbia Univ., New York, NY, [3]Kaiser Permanente Northwest, Portland, OR, [4]Seattle Children's Res. Inst., Seattle, WA, [5]RTI Intl., Washington, DC
Disclosure Block: **H. Lewis:** None.
Prioritizing equity in authorship is a challenge for large research teams. Navigating across institutions, disciplines, career stage, and team size contributes to the complexities. The Cancer Health Assessments Reaching Many (CHARM) study is exemplary of this layered challenge. CHARM integrates a focus on Team Science that aims to elevate the effectiveness of research teams by prioritizing diversity and inclusion through collaboration, conflict resolution, and effective communication. This approach facilitated a process to gather reflections and feedback from all CHARM investigators on prior or existing experiences with authorship that identified a need for a more equitable process. Using a Team Science approach, standard authorship guidelines for CHARM were developed to strive for better equity and inclusion. CHARM also developed an electronic matrix to track the number of manuscripts, team member authors, and distribution of authorship opportunities. Using this matrix, the CHARM team can further its goal of inclusion by identifying opportunities for those who have had fewer authorship opportunities, through mentorship of junior researchers as first authors by experienced senior authors. By clarifying authorship and writing group roles in guidelines, expectations of the level of involvement in a manuscript can be clarified and differing views on authorship position can be avoided. While CHARM authorship guidelines are specific to the team, the development process can be appropriated within other large research teams. The process included assessing authorship expectations and norms to reveal existing assumptions; soliciting specific issues and concerns with existing or prior authorship experiences; using facilitated small group discussions to illuminate optimal outcomes; and deliberating on guideline priorities within a small working group that can be taken to the team for consensus. Team leaders can configure these priorities into a fair and equitable process to be implemented across the team following final discussions and input from all team members.

PrgmNr 3737 - Clinical Sequencing Evidence-Generating Research (CSER) consortium Diversity and Inclusion Statement: development, revision, and adoption

View session detail

Author Block: **S. M. Fullerton**[1], S. J. Knight[2], A. M. Gutierrez[3], B. B. Biesecker[4], K. A. Goddard[5], G. LaMoure[6], M. A. Majumder[3], P. Murali[1], S. Outram[7], A. B. Popejoy[8,9], K. Renna[6], D. J. Kaufman[6], L. A. Hindorff[10]; [1]Univ. of Washington, Seattle, WA, [2]Univ. of Utah, Salt Lake City, UT, [3]Baylor Coll. of Med., Houston, TX, [4]RTI Intl., Washington, DC, [5]Kaiser Permanente Northwest, Portland, OR, [6]Natl. Human Genome Res. Inst., Bethesda, MD, [7]UCSF, San Francisco, CA, [8]Stanford Univ., Stanford, CA, [9]Univ. of California, Davis Sch. of Med., Davis, CA, [10]NIH, Bethesda, MD
Disclosure Block: **S.M. Fullerton:** None.
Background: The Clinical Sequencing Evidence-Generating Research (CSER) Consortium was initiated in 2017 with the aim of investigating the effectiveness of integrating genomic (exome or genome) sequencing into the clinical care of medically underserved individuals across diverse health care settings and disease states. At the recommendation of participant stakeholders, and in the wake of broader discussion about the impact of systemic racism and other forms of discrimination in many contexts including biomedical research, the consortium agreed to adopt a formal Diversity and Inclusion Statement. Here we describe the final statement ratified by CSER and the process by which the statement was developed, reviewed, revised, and adopted for use in consortium publications and presentations. **Methods**: The suggestion to adopt a consortium-wide Diversity and Inclusion statement was brought to a Steering Committee meeting in the summer of 2020. Following discussion with CSER principal investigators and workgroup chairs, an *ad hoc* group of interested CSER investigators, with representation from all eight CSER sites and the NHGRI, was convened to draft a statement for adoption and use by the consortium. A preliminary draft was presented to scientific investigators and a group of patient-participant stakeholders for feedback. The statement was revised further and circulated to CSER sites for final review before formal ratification at a Steering Committee meeting. The statement was also translated into Spanish to make it accessible to Spanish-preferring stakeholders. **Results**: The iterative drafting, review, and revision process resulted in a brief (approximately 100 word) plain language statement that describes CSERâ□□s commitment to understanding how genes impact disease and reducing barriers to genetic services among people who are discriminated against, marginalized, and medically underserved. The statement addresses stakeholder engagement and workforce diversity, as well as responsible analysis and reporting. While acknowledging that much work needs to be done to achieve a just and equitable health care future, the statement emphasizes CSERâ□□s commitment to creating genomic knowledge that will benefit people of all backgrounds. **Conclusions**: Although intended primarily to guide CSER investigators and stakeholders in the final stage of their collective work together, we hope that the statement can inform the work of the clinical translational genomics research community moving forward.

PrgmNr 3738 - Cloud-based biomedical data storage and analysis for genomic research: landscape analysis of data governance in emerging NIH-supported platforms

View session detail

Author Block: **S. C. Nelson**[1], J. Dahlquist[2], S. M. Fullerton[2]; [1]Biostatistics, Univ. of Washington, Seattle, WA, [2]Bioethics & Humanities, Univ. of Washington, Seattle, WA
Disclosure Block: **S.C. Nelson:** None.
Background: Genomic research initiatives and consortia are generating individual-level genomic, environmental, and linked phenotypic and/or health outcome data at an unprecedented pace and scale, driving innovation in the storage, sharing, and analysis of such data. At the forefront of new data sharing mechanisms are institutional and, increasingly national, cloud-based computing and storage platforms designed to support efficient and scalable data processing, analysis, and sharing. In parallel, efforts to streamline and even partially automate data access are being pursued. These new data sharing platforms and procedures are designed to facilitate collaboration and maximize the scientific utility of costly-to-generate genomic and linked clinical data. Yet the implications of current access procedures and data protections standards for trustworthy stewardship remain underexamined by ethicists and policymakers. **Methods**: To inform policy development for the responsible governance of cloud-based biomedical data and analysis, we conducted a landscape analysis of data governance practices in three newly developed NIH-supported cloud platforms, the NHLBI BioData Catalyst, the NHGRI AnVIL (Analysis, Visualization, and Informatics Lab-space), and the All of Us Research Hub, as well as two predecessor data sharing platforms, the NCBI Database of Genotypes and Phenotypes (dbGaP) and the NCI Genomic Data Commons. **Results**: In this presentation we report key initial findings from that analysis, based in a content analysis of platform documentation, participant observation of platform developer discussions, and key informant interviews with platform developers and related leadership. **Conclusions**: Our review of current platform governance policies and procedures identifies numerous tradeoffs with potential implications for both participant and public trust in precision medicine research.

PrgmNr 3739 - Conducting clinical genomic medicine research during the COVID-19 pandemic: Lessons learned from the CSER consortium experience

Disclosure Block: **S. Kraft:** None.

The COVID-19 pandemic has led to significant changes in healthcare practices and priorities and therefore has had a major impact on genomic medicine research. Research studies have faced challenges stemming from a wide range of clinical and research factors including new procedures and policies for in-person visits, the rapid implementation of telehealth and other remote procedures, and changing priorities for participants, clinicians, and research team members. Further, multi-site projects and research consortia have had to navigate variation between institutional approaches. These challenges have affected all stages of genomic medicine researchâ□□from recruitment and consent through results disclosure and clinical follow-up. These challenges to research participation may be particularly burdensome to participants from historically marginalized racial, ethnic, and socioeconomic groups who been disproportionately impacted by COVID-19, continuing the pattern of long-standing barriers to participation in genomic research.

This presentation will describe the experience of six genomic medicine studies across ten states within the Clinical Sequencing Evidence-Generating Research (CSER) consortium as they navigated the COVID-19 pandemic, highlighting challenges faced, strategies for overcoming these challenges, and lessons learned that may inform future research operations. CSER is an NIH-funded research consortium studying the integration of genome sequencing into clinical care for diverse and medically underserved individuals. We interviewed and surveyed representatives of the six extramural CSER projects at multiple time points during 2020 and 2021. Using a descriptive content analysis approach, we identified two overarching areas in which projects faced particularly impactful challenges and saw opportunities for future improvement: (1) participant recruitment, enrollment, and engagement; and (2) the transition to telehealth and other remote research procedures. In this presentation, we will describe how projects navigated these challenges throughout the COVID-19 pandemic, with a focus on ethical considerations related to the evolving clinical-research boundary and access to genomic services for medically underserved patients. We will discuss key lessons learned to advance equitable genomic medicine research moving forward.

PrgmNr 3741 - Designing and launching a pilot race and genetics seminar series for public health genetics students

View session detail

Author Block: **P. Murali**, A. Khan; Univ. of Washington, Seattle, WA
Disclosure Block: **P. Murali:** None.
The field of genetics continues to grapple with issues of race and racism, but adequate exposure to these issues in graduate training programs is lacking. Concepts of race, ethnicity, and ancestry are discussed in human genetics coursework, but little attention is given to understanding the relevance, purpose, and context of their use. Awareness of these concepts is important to avoid reinforcing notions of racial essentialism. To address this, we designed a ten-week race and genetics seminar series for the Public Health Genetics (PHG) department at the University of Washington in order to provide a space for PHG students to engage with these complex topics.
In this seminar series, we examined historical and current perspectives on race, and its role in genetic and biomedical research, as well as in health inequities. We developed a framework for reflecting on PHG core coursework and making suggestions for areas of anti-racist intervention. Examples include addressing race, ethnicity, and ancestry in (1) genetic association methods for analysis of diverse populations in the field of genetic epidemiology; (2) policy and legal cases in the intersection of genetics and the law; and (3) methods of analysis and inference for drug development in different populations in the area of pharmacogenetics. Finally, we administered an exit survey to gain feedback on the utility of the seminar. Responses from the survey illustrated that participantsâ□□ perceptions about race, racism, and genetics changed as a result of participation in the seminar, and that they gained knowledge about these topic areas. Respondents also provided suggestions for how to incorporate concepts learned in the seminar into the broader PHG training program. Ultimately, this student-driven seminar series provided opportunities for participants to wrestle with complex and challenging concepts of race and genetics. Furthermore, this seminar can be incorporated into other genetics graduate programs, such as genetic counseling and medical genetics residency programs. Genetics researchers and professionals play a pivotal role in influencing the way concepts of race, genetics, and health are interpreted in research, medical care, and policy. Therefore, exposure to these concepts with an interdisciplinary approach during graduate training is an important step towards eliminating notions of racial essentialism and improving research methods, interpretation, and application.

PrgmNr 3742 - Ethnic Differences in the Frequency of Cancer Reported from Family Pedigrees in the Prenatal Genetic Counseling Setting

View session detail

Author Block: **A. Palacios**[1], P. Flodman[2], K. French[3], M. Smith[4]; [1]Dept Pediatrics, Divn of Genetic and Genomic Med., Univ California Irvine Med Ctr, Orange, CA, [2]Univ California Irvine Med Ctr, Orange, CA, [3]Dept Pediatrics, Divn of Genetics and Metabolism, Univ California Irvine Med Ctr, Orange, CA, [4]Univ California Irvine, Irvine, CA

Disclosure Block: **A. Palacios:** None.

This study analyzed if differences in cancer reporting exist between different ethnic groups when collecting family pedigrees in a prenatal genetic counseling setting. Data was collected from 446 prenatal charts at University of California, Irvine from January 1, 2015 - August 31, 2020. A total of 795 pedigrees meeting inclusion criteria (409 maternal pedigrees and 386 paternal pedigrees) were analyzed from four ethnic groups: non-Hispanic White, Hispanic/Latino(a), Asian, and African American/Black. The total number of first- and second-degree relatives and number of these relatives affected with cancer were calculated for each pedigree and analyzed using contingency tables, non-parametric tests, and Poisson regression. Cancer reporting in first- and second-degree relatives was the highest among the non-Hispanic White group. Reporting of a family history of cancer was lower in Hispanics, Asians, and African Americans. Ethnicity was a significant factor in predicting the number of relatives reported to have cancer in a Poisson regression model (controlling for the total number of relatives in the pedigree). The incidence of cancer reported in the pedigrees for Hispanics, African Americans, and Asians was 36.3%, 50.2%, and 65.5% (respectively) of the incidence seen in the non-Hispanic White pedigrees. The cancer reporting differences observed in the Asian pedigrees are similar to differences in population incidence as reported by the CDC, but the reporting in the Hispanic and African American pedigrees is less than would be expected based on population incidence. This suggests that cancer histories in some minority populations may be truncated. Genetic counselors, clinical geneticists, and Maternal Fetal Medicine providers should recognize that certain patient populations may be at risk for limited knowledge of a family cancer history. The study also identified that cancer reporting in the paternal family history was significantly increased when the father was present (p

PrgmNr 3743 - Exploring a role for genetic counselors in changing client health behavior: An Australasian focus group study

View session detail

Author Block: **E. Turbitt**[1], C. Jacobs[1], A. McEwen[1], L. Atkins[2]; [1]Univ. of Technology Sydney, Ultimo, Australia, [2]UCL Ctr. for Behaviour Change, London, United Kingdom
Disclosure Block: **E. Turbitt:** None.
Many cite undergoing genetic testing to gain information that will prompt a change in behavior, leading to better health outcomes. However, provision of genetic information alone has limited influence over health behavior. Genetic counselors possess relevant skills to facilitate health behavior change, though the extent to which they are ready and willing to be more involved in changing client health behavior is unknown.
We conducted a cross-sectional qualitative study to gain an in-depth understanding of genetic counselorsâ current practices and opinions about their involvement in changing client health behavior. Four virtual focus groups were conducted via Zoom video conferencing with genetic counselors (n=20) across Australasia. Evidence-based behavior change models (the Theoretical Domains Framework; TDF, and the Capability, Opportunity, Motivation -Behavior; COM-B) guided development of the focus group schedule, data analysis and interpretation. Themes were identified from verbatim transcripts using thematic analysis.
Our findings revealed three key target behaviors that genetic counselors hope clients would change following genetic counseling: (1) attend recommended screening/health appointments, (2) access information and support, and (3) share accurate information with relevant family members. We further identified genetic counselorsâ behaviors that aim to facilitate clientsâ behavior change such as activating screening/health appointments, providing access to relevant support, and equipping clients with skills for family communication. Influencers and barriers to genetic counselorsâ behaviors included having local knowledge and connections and beliefs about a tension between non-directiveness and behavior change. Influencers and barriers to changing behaviors included clientsâ willingness to act and having resources to carry out behaviors.
Genetic counselors may be interested and willing to have a role in changing client health behaviors. Key influencers and barriers identified in our study will be targeted in an intervention to enhance awareness and understanding of behavior change techniques among genetic counselors. Changing client health behaviors is a key factor to enabling the transformative role of genomics in disease prevention and management.

PrgmNr 3744 - Impact of the COVID-19 pandemic on the training and well-being of Medical Genetics and Genomics trainees

View session detail

Author Block: **J. Chenbhanich**[1], A. Tam[1], A. M. Slavotinek[2]; [1]Univ. of California, San Francisco, San Francisco, CA, [2]Univ California San Francisco, San Francisco, CA
Disclosure Block: **J. Chenbhanich:** None.
Background: The COVID-19 pandemic has an unprecedented impact on healthcare systems and graduate medical education. We sought to understand how the COVID-19 pandemic with telehealth and virtual education has affected the well-being, clinical training, and medical education for clinical trainees in the Medical Genetics and Genomics Residency and Fellowship programs. **Methods**: All clinical trainees in the American Board of Medical Genetics and Genomics (ABMGG)-accredited Clinical Genetics and Genomics, and Clinical Biochemical Genetics training programs in the United States were emailed an anonymous, voluntary, 30-question online survey on March 22, 2021. The survey window closed on April 30, 2021. **Results**: 31 out of a possible 174 trainees (18%) completed the survey. With regard to well-being, trainees reported increased anxiety (18/31), increased depression (10/31), worsening work-life balance (3/31) and worsening physical health (fitness, sleep, and/or nutrition; 13/31). There was an approximate increased utilization of telehealth in outpatient clinical encounters from 3% pre-pandemic to 67% during the pandemic; separately, an approximate increase in telehealth utilization in inpatient clinical encounters from 0% pre-pandemic to 29% during the pandemic. The most commonly reported challenges in telehealth utilization included inadequate physical examination (n=26), technical problems during visits (n=25), and limited access only to patients with internet access (n=20). Eight trainees would like to continue the same amount of telehealth as part of clinical training after the pandemic, whereas 20 trainees believed that the COVID-19 pandemic has negatively impacted overall clinical training. Twenty-five trainees agreed that the pandemic has had a negative impact on education opportunities not provided by their training programs, such as conferences. **Conclusions**: This is the first formal evaluation of the COVID-19 pandemic impact on trainees who are in the Medical Genetics and Genomics clinical training programs to our knowledge. While the sample size is relatively small, we illustrate that the COVID-19 pandemic has negatively impacted many trainees in Medical Genetics and Genomics, with effects on their well-being, clinical training, and education. Telehealth has been increasingly used in both inpatient and outpatient encounters with some challenges. Further studies are needed to optimally integrate what we have learned about virtual training, including telehealth and virtual meetings, into the education of medical genetics in the post-pandemic era.

PrgmNr 3745 - Medical genetics among Internal Medicine residents

View session detail

Author Block: **M. Jose**, A. Pathak; Saint Peter's Univ. Hosp., New Brunswick, NJ
Disclosure Block: **M. Jose:** None.
Introduction - With rapid advances in medicine and patients with genetic conditions surviving to adulthood, medical genetics has expanded to all age groups. A recent study showed that we have two clinical geneticists per one million population. A major step in mitigating the workforce shortage includes filling the void at the training level. Hence, we assessed the awareness of Medical Genetics training among Internal Medicine (IM) residents in a community program. **Objective** - Our study aimed to assess 1) the awareness of medical genetics among IM residents 2) the enthusiasm of IM residents to know more about the field and 3) assess the areas that residents were interested in exploring. **Method** - All internal medicine residents (49 residents except for the two residents who are the authors of the study) at Saint Peters University Hospital in NJ were eligible for the study. The survey was distributed through social media platform using Survey Monkey. The survey consisted of 10 questions. Participation was voluntary. **Results** - 81.6% (40/49) of the residents responded to the survey. 70% of the IM residents identified the primary role of medical geneticist as clinical diagnosis and genetic counseling while 15% identified it as purely genetic counseling and 5% labeled it as research-related. 12.5% of the residents were not aware that training in medical genetics exists. 50% were not aware that a medical geneticist was available at their training site. 10% wanted to refer their patient to a geneticist but did not know how to proceed with it and 12.5% were not aware of the clinical criteria for referral. 17.5% wanted to order a genetic test but did not know how to proceed with it. 30% had interpreted a genetic test result to their patient and 50% of those stated, they wanted to do it better. 80% of the residents wanted to know more about the specialty. 75% of the residents stated that their interest in pursuing medical genetics will depend on knowing more about the specialty and the training. 85% of the IM residents wanted a medical genetics curriculum introduced to their course. **Conclusion** - Our analysis reflects the limited inclusion of medical genetics in the Internal Medicine training curriculum despite the growing demand in the field. More than three-quarters of the residents who participated in the survey wanted a genetics curriculum incorporated into their training. Increasing the awareness among trainees will help with the staffing shortage and also help medical geneticists have a healthy partnership with primary care providers and thus ensure timely referral and early diagnosis.

PrgmNr 3746 - Perspectives of Genetics Professionals on the Reporting of Variants of Uncertain Significance (VUS): Should they always be returned?

View session detail

Author Block: **E. D. Esplin**[1], M. A. Fox[2], S. C. Saitta[3], A. B. Santani[4], S. Aradhya[1], J. Bernstein[5], R. L. Nussbaum[1]; [1]Invitae, San Francisco, CA, [2]Invitae, Encino, CA, [3]David Geffen Sch. of Med. at UCLA, Los Angeles, CA, [4]Veritas Genetics, Philadelphia, PA, [5]Stanford Univ Sch Med, Stanford, CA
Disclosure Block: **E.D. Esplin:** Major Stockholder/Ownership Interest; Invitae. Salary/Employment; Invitae.
Background. Variants of uncertain significance (VUS) are common. With increasing use of multi-gene panels (MGP), the number of VUS grows. Not all VUS have the same degree of uncertainty, presenting challenges to non-genetics healthcare providers (HCPs), patients and families. We report the results of a survey assessing attitudes of genetics professionals on the return of VUS results from MGP, emphasizing cancer genetics professionals in academic settings.
Methods. We designed a survey regarding VUS in MGP and whole exome sequencing (WES); this analysis focused on responses in the context of VUS in MGP. The survey was sent to ASHG and NSGC members to query those having experience with MGP, 2711 confirmed receipt. Initial analysis: 378 respondents (14%), 253 completed the survey (9%); 66% genetic counselors, 21% clinical geneticists, among others; 60% academic, 31% in a private clinical or commercial laboratory setting. 40% work primarily in cancer genetics, 13% in pediatric genetics, 11% adult genetics, skewing the respondents towards those who assess VUS for dominant/incompletely penetrant conditions.
Results. Overall, 47% (total n=167) agree that VUS can be useful for patient care with 30% in disagreement. In the last year, most respondents (75%) received a VUS result they considered clinically significant (prompted family segregation studies, was in trans with P/LP variant in an autosomal recessive condition, etc.), with 67% receiving **Conclusions**. While VUS can be useful in specific circumstances, these data suggest they present challenges in genetic testing for both patients and HCPs, with the potential to induce patient anxiety/stress. These results indicate support for providing the opportunity to opt-out of VUS return for MGP to patients, in the interest of patient autonomy, and to providers to reduce practice burden. The utility of VUS likely correlates with clinical context (e.g. cancer, rare disease, recessively versus dominantly inherited disorders etc). The clinical impact of VUS on patients/families warrants further investigation.

PrgmNr 3747 - Population genetic screening: What are the psychosocial impacts?

View session detail

Author Block: **N. Rao**[1], S. Coe[1], J. Huey[1], S. M. Fullerton[1], A. T. Chen[1], B. H. Shirts[2]; [1]Univ. of Washington, Seattle, WA, [2]Univ of Washington, Seattle, WA
Disclosure Block: **N. Rao:** None.
Population genetic screening has potential to identify individuals who carry a pathogenic variant putting them at risk for preventable hereditary cancers or hypercholesterolemia and who would otherwise be missed under current genetic testing guidelines. However, knowledge about the psychosocial impacts of receiving genetic results in a population screening setting is limited. We sought to understand these impacts among participants of the University of Washington Medical Centerâ□□s (UWMC) population genetic screening study.
This ongoing study invites adults who have received care at the UWMC to participate in targeted screening for hereditary cancers and familial hypercholesterolemia. Participants do not receive traditional genetic counseling prior to screening, but the study FAQ available upon joining details the type of information one might learn from the study as well as potential risks. Participants whose screening identifies no risk variants are notified of this information through an online report, while individuals whose results are positive for a risk variant are contacted by genetic counselors who describe the associated risks and emphasize the need for clinical follow-up. After receiving results, all participants are asked to complete an online survey about the psychosocial impacts of screening using the Feelings About GenomiC Testing Results (FACToR) instrument, which includes 4 subscales: negative emotions, positive emotions, uncertainty, and privacy. Participants can also respond to several open-ended survey questions about their response to results and related plans, and participants who screen positive may be selected for semi-structured interviews.
To date, 55% (N = 18) of participants who received positive screening results and 58% (N = 381) of participants who did not have completed the survey. On average, participants reported feeling some positive emotions and very little negative emotions, uncertainty or privacy concerns after receiving genetic results. Similar responses were seen for participants with positive results and those without. This may be because most individuals with concerns about adverse psychosocial impacts may have chosen not to participate in screening at all. In addition, sample size in the positive results group is limited and some members of this group were already aware of their genetic risk prior to screening. Overall, participants have not expressed any major concerns about receiving genetic results in this population screening setting.

PrgmNr 3748 - Preparing the next generation of healthcare providers for precision medicine in practice: A social justice and equity-oriented clinical genomics training program for pre-clerkship medical school students

View session detail

Author Block: **R. Rajagopalan**[1,2], T. J. Berninger[1,3], C. K. Rubanovich[1,4], C. S. Bloss[1,2]; [1]Ctr. for Empathy and Technology, T. Denny Sanford Inst. for Empathy and Compassion, Univ. of California, San Diego, La Jolla, CA, [2]Herbert Wertheim Sch. of Publ. Hlth.and Human Longevity Sci., Univ. of California, San Diego, La Jolla, CA, [3]Augustana-Sanford Genetic Counseling Graduate Program, Augustana Univ., Sioux Falls, SD, [4]Joint Doctoral Program in Clinical Psychology, San Diego State Univ./Univ. of California, San Diego, San Diego, CA
Disclosure Block: **R. Rajagopalan:** None.
As genomic medicine becomes increasingly widespread across clinical practice specialties, there remains an urgent yet largely unfulfilled need for delivering comprehensive and focused training in precision medicine tools, at all career stages in healthcare professions. At the same time, there have been calls to reform both genetics and medicine, recognizing that structural racism and implicit biases permeate clinical education, research, and practice, reinforcing persistent health disparities among historically disenfranchised, underserved, and marginalized communities. Few medical school training programs, however, currently offer educational content that addresses these needs, much less their intersection.

As part of efforts to bring issues of diversity, health equity, inclusion, and compassion to the fore of medical education in genomics, we describe the design, development, and preliminary evaluation of a novel training program called the Sanford Precision Health Scholars Immersive Learning Experience. This program aims to equip students at the earliest stages of their medical careers with the necessary skills for tackling challenges at the interface of precision medicine and anti-racist healthcare. Patient-driven case-based problem solving empowers students to build a toolkit for the cutting-edge of genomics practice, refracted through the principles of social justice and health equity. Interactive laboratory exercises with real-world genetic test reports anchor a set of learning objectives including: 1) awareness of the histories of racism and health disparities and relevance to contemporary calls for racial justice in genetics and medicine 2) familiarity with clinical genomics testing technologies and platforms 3) appreciation for the complexities of variant interpretation and classification 4) understanding the need for culturally appropriate, respectful, coordinated, and compassionate communication with diverse patients and families to promote psychosocial well-being as part of a clinical genetics care team, 5) knowledge of the benefits and limitations of patient-initiated DTC genomic testing for ancestry and health risks 6) recognition of the ethical dimensions of clinical decision-making around genetic testing, including the processes of informed consent, and the difficulties of interpreting test results especially among diverse communities that are underrepresented in genomic datasets. We discuss the implementation and evaluation of this program, prospects for stimulating student interest in clinical genomics careers, and strategies for scaling this program for replication at other institutions.

PrgmNr 3749 - Reframing translational research in rare diseases in the United States: A mosaic approach

View session detail

Author Block: **M. Halley**[1], H. S. Smith[2], A. Goldenberg[3], H. K. Tabor[4]; [1]Stanford Univ., Palo Alto, CA, [2]Baylor Coll. of Med., Houston, TX, [3]Case Western Reserve Univ, Cleveland, OH, [4]Stanford Univ. Sch. of Med., Stanford, CA

Disclosure Block: **M. Halley:** None.

The cumulative impact of rare diseases is immense, affecting an estimated 25 to 30 million Americans and contributing a tremendous physical, psychological and economic burden for patients, families and the healthcare system. Over 90 percent of rare diseases lack an approved therapy, and the pace of translating scientific discoveries into therapies is frustratingly slow. Recent advances in genome sequencing, molecular biology and machine learning suggest that real progress for the rare disease community could be on the horizon. However, our current approach to translational research in rare diseases in the United States lacks the integrated approach necessary to ensure that all patients and families in the rare disease community can benefit from these advances. In this paper, we lay out a new model for translational research in rare diseases, drawing on the concept of the mosaic, which emphasizes a multi-dimensional approach to identifying similarities within and across rare diseases. We argue that this new approach is essential not only to increase translational efficiency and maximize benefits across rare diseases, but also to move towards more equitable distribution of resources within the large and diverse rare disease community.

PrgmNr 3750 - Researcher Views on Multi-omics Return of Results in the Molecular Transducers of Physical Activity Consortium (MoTrPAC)

View session detail

Author Block: **C. Stanclift**[1], M. T. Wheeler[2], K. E. Ormond[3], J. N. Kohler[4], C. Reuter[5], M. E. Lindholm[6]; [1]Stanford Univ., Stanford, CA, [2]Stanford Univ, Palo Alto, CA, [3]Stanford Univ, Stanford, CA, [4]Palo Alto, CA, [5]San Francisco, CA, [6]Stanford Univ., Palo Alto, CA
Disclosure Block: **C. Stanclift:** None.
Introduction: There is growing consensus in favor of returning individual specific research results that are clinically actionable, valid, and reliable. However, deciding what and how research results should be returned remains a considerable challenge. Researchers are key stakeholders in return of results (ROR) decision-making and implementation. Multi-omics research contains medically relevant findings, therefore could be considered for return. We sought to understand researchers' views regarding the potential for multi-omics ROR.
Methods: We invited multi-omic researchers from the Molecular Transducers of Physical Activity Consortium (MoTrPAC) to participate. A brief recruitment survey was sent out via email to collect limited demographic information. A purposeful sampling of researchers participated in in-depth semi-structured interviews. To assess understanding of potential clinical utility for types of data collected and attitudes towards return of results for MoTrPAC clinical studies, an interview guide focusing on types of results generated in the study which could hypothetically be returned was devised from review of the literature and professional expertise of team members. The interviews were recorded, transcribed verbatim and co-coded, then discussed by the study team to identify thematic trends.
Results: A total of 16 researchers represented 11 sites and 6 consortium roles across MoTrPAC (co-investigator MD or MD, PhD 12.5%, co-investigator PhD 25%, recruitment/consent 18.8%, data production 12.5%, data analysis 25%, and exercise physiologist 12.5%). Many respondents supported hypothetical multi-omics ROR, citing participant rights to their own data and perception of minimal harm. However, ethical and logistical concerns around multi-omics ROR were raised including uncertain clinical validity, a lack of expertise to communicate results, and an unclear obligation regarding whether to return multi-omics results. Further, researchers called for more guidance from funding agencies and increased researcher education regarding ROR.
Conclusion: Overall, researchers expressed positive attitudes toward multi-omic ROR in principle, particularly if considered actionable. However, competing ethical considerations, logistical constraints, and need for more external guidance were raised as key concerns for implementation. Future studies should consider views and experiences of other relevant stakeholders, specifically clinical genomics professionals and study participants, regarding multi-omics ROR.

PrgmNr 3751 - Risk-reducing surgery in unaffected individuals receiving cancer genetic testing for hereditary breast and ovarian cancer in an integrated health care system

View session detail

Author Block: **B. Guo**[1], S. Knerr[2], K. F. Mittendorf[3], H. S. Feigelson[4], M. J. Gilmore[3], G. P. Jarvik[5], T. L. Kauffman[6], E. M. Keast[6], F. L. Lynch[6], K. R. Muessig[3], S. Okuyama[7], D. L. Veenstra[8], J. M. Zepp[3], K. A. B. Goddard[3], B. Devine[8]; [1]Dept. of Epidemiology, Univ. of Washington, Seattle, WA, [2]Dept. of Hlth.Services, Univ. of Washington, Seattle, WA, [3]Dept. of Translational and Applied Genomics, Ctr. for Hlth.Res., Kaiser Permanente Northwest, Portland, OR, [4]Inst. for Hlth.Res., Kaiser Permanente Colorado, Aurora, CO, [5]Dept. of Med., Div. of Med. Genetics, Univ. of Washington Med. Ctr., Seattle, WA, [6]Ctr. for Hlth.Res., Kaiser Permanente Northwest, Portland, OR, [7]Dept. of Med., Denver Hlth.and Hosp. Authority, Denver, CO, [8]Dept. of Pharmacy, Comparative Hlth.Outcomes Police and Economics Inst., Univ. of Washington, Seattle, WA

Disclosure Block: **B. Guo:** None.

Purpose: Germline genetic testing can identify high penetrance variants of hereditary cancers, enabling the early use of risk management options. Risk-reducing surgeries (RRS), such as bilateral mastectomy, bilateral salpingo-oophorectomy (BSO), and total hysterectomy decrease the risk of breast, ovarian, and endometrial cancer. However, prior studies on the uptake of RRS are often limited to those with pathogenic variant in well-studied genes within non-integrated healthcare systems. Therefore, we examined the uptake of RRS in unaffected individuals tested for multiple genes including those influencing breast, ovarian, and endometrial cancer risk between January 1, 2010 and December 31, 2018 in an integrated health care system. **Methods**: We conducted a retrospective cohort study of individuals aged **â¥**18 years without prior cancer history who received genetic testing for at least one hereditary cancer susceptibility genes within Kaiser Permanente Northwest. We described the uptake and timing of RRS by genetic test results (pathogenic/likely pathogenic (P/LP), variants of uncertain significance (VUS), and negative) using electronic health records and claims data. For those with P/LP, we further categorized surgery as recommended, recommended for consideration, or not recommended based on current National Comprehensive Cancer Network guidelines. **Results**: Of 1,020 individuals included, the mean age was 48 years (range: 18-â¥35 years, year of genetic testing, and increasing number of follow-up years. **Conclusion**: The uptake of RRS following hereditary cancer genetic testing was low among unaffected individuals in an integrated health care setting. Limitations of our data included no family history information and the inability to know whether surgery was informed by genetic test results or the reasons for not having/delaying surgery.

PrgmNr 3752 - SeqScreener: a cloud-based software application for analyzing CRISPR experiments with Sanger Sequencing data

View session detail

Author Block: **H. Fu**, Y. Chu; Thermo Fisher Bioscientific, South San Francisco, CA
Disclosure Block: **H. Fu:** Salary/Employment; Thermo Fisher Bioscientific.
Genome editing is poised to revolutionize the life sciences industry due to its precise changes at locus using CRISPR-Cas9 or other nucleases. SeqScreener was released to serve customers with data analysis of gene edit confirmation.Since the CRISPR repair process is not completely accurate, the pool of gene-edited cells needs rounds of screenings to become homogeneous. Pooled screen is to determine the relative fraction of desired edits. After cell expansion, a clonal screen finds clonally pure cells. As a critical step in screening protocols, Sanger sequencing is the most cost-effective measurement method with fast turnaround time to reveal the details around CRISPR cut site and the abundancy of each edited gene.Thermo Fisher Scientific had introduced True Design Genome Editor software for experiment designs. For data analysis, the SeqScreener Gene Edit Confirmation tool deconvolves the sequence trace of the mixture of wild-type and mutated sequences, generating results of gene editing efficiency, frame shift percentage, diversity of edits, and indel spectrum. It completed the Themo Fisher Scientific gene editing end-to-end workflow along with other gene editing products.Seqscreener has both pooled screening and clonal screening workflows. Its processing speed is 6.5 faster than competitors. It has clear visualization tools and the unique gene editing sample ranking system, which helps customers to select clones efficiently. SeqScreener also has capability to suggest related gene editing solutions to customers based on detected sample quality. The future plan is to provide â□□hands-freeâ□□ solutions such that sequencing data will be auto-uploaded directly from CE instruments and get analyzed within minutes without manual steps.SeqScreener simplifies data analysis and empowers the use of Sanger Sequencing as a genome editing confirmation tool.

PrgmNr 3753 - Splice-Switching Oligonucleotide-mediated Correction of a Deep Intronic Splice-variant in TIMMDC1 in Cells of Patients with Severe Early Onset Neurodegenerative Disorder

View session detail

TIMMDC1 encodes the Translocase of Inner Mitochondrial Membrane Domain-Containing protein 1 (TIMMDC1) subunit of complex I of the electron transport chain responsible for ATP production. Variants causing loss of *TIMMDC1* expression have been implicated in a severe, progressive autosomal recessive disorder characterised by failure to thrive in the early postnatal period, poor feeding, hypotonia, peripheral neuropathy and drug resistant epilepsy. We have studied a consanguineous family with two affected children, now deceased, with clinical features overlapping *TIMMDC1* syndrome. Analysis of the genome sequencing data revealed previously reported pathogenic non-coding variant *TIMMDC1* c.597-1340A>G which is also present in gnomAD, (European non-Finnish population, 0.0002). Using RNAseq, on parentsâ and both patientsâ primary skin fibroblasts, we confirmed that this deep intronic *TIMMDC1* c.597-1340A>G variant enhances aberrant splicing, thereby inserting a poison exon that introduces a premature stop codon (p.Gly199_Thr200ins5*) into the *TIMMDC1* transcript that is eventually degraded via nonsense mediated mRNA decay. This leads to undetectable TIMMDC1 protein in patient fibroblasts and resulting in severely compromised mitochondrial complex I function. Carrier parents have reduced TIMMDC1 protein levels, but are unaffected. Subsequently, we have designed and applied two different splice-switching antisense oligonucleotides (SSO) to restore normal *TIMMDC1* mRNA processing and TIMMDC1 protein levels, in patients as well as in their carrier parentsâ fibroblasts. Seahorse real-time cell metabolic analysis of mitochondrial function in patient fibroblasts treated with SSOs also showed 100% restoration of complex I function. This research paves a way to the development of SSO-mediated therapy of this inevitably fatal, progressive neurological disorder, which is due, to likely ancestral, deep intronic variant with ~1/5000 allele frequency.

PrgmNr 3754 - An Embedded ELSI Framework for the Human Pangenome Reference Consortium

View session detail

Author Block: **A. B. Popejoy**[1,2], R. Cook-Deegan[3], N. A. Garrison[4], K. H. Miga[5], B. A. Koenig[6]; [1]Stanford Univ., Stanford, CA, [2]Univ. of California, Davis (UCD), Davis, CA, [3]Arizona State Univ., Accokeek, MD, [4]Univ. of California, Los Angeles (UCLA), Los Angeles, CA, [5]Univ. of California, Santa Cruz (UCSC) Genomics Inst., Santa Cruz, CA, [6]Univ. of California, San Francisco (UCSF), San Francisco, CA

Disclosure Block: **A.B. Popejoy:** None.

A comprehensive collection of diverse and highly accurate human reference genomes is critical to broaden our understanding of genetic variation and realize the promise of genomic medicine. The Human Pangenome Reference Consortium (HPRC) will use cutting-edge sequencing technologies to obtain high-quality phased genomes from a set of 350 diploid genomes, capturing and displaying much more human diversity than current reference sequences. This effort to diversify the human reference genome is arguably one of the most important initiatives in the field, as it has widespread implications for the practice of genomics research and the implementation of genetics in the clinic. While creating an open source, easily available global public data resource, the HPRC will simultaneously address critical ethical, legal, and social issues (ELSI) using an â□□embeddedâ□□ ELSI framework. The main objective of the HPRC-ELSI team is to identify, investigate, and ultimately offer consortium investigators advice about the most pressing issues they face, which must be addressed if the HPRC is to meet its goals. Our presentation will delineate the most immediate and fundamental questions facing the HPRC: 1) how should we define human populations for various purposes (i.e., recruitment, sampling, analysis, reporting) and determine what human â□□diversityâ□□ means in making a reference resource; 2) how can we assure truly informed consent for participation in a global resource; and 3) what constitutes robust data stewardship? By including insights from Indigenous data sovereignty scholars, we will present strategies to address the most pressing issues, concurrently explaining the full historical context of large-scale population genetics projects, such as the Human Genome Diversity Project. A full explication of the social context, including conflicting legal requirements in diverse locales or the political ramifications of misuse of genetic data for surveillance, will be paramount as the embedded ethics team offers guidanceâ□□in real timeâ□□to HPRC investigators. In the embedded model, with ELSI scholars participating in key meetings where decisions are made, investigators can engage these colleagues in discussions that deepen their understanding and appreciation of what is at stake as we seek to improve the human reference genome. As a result, the scientific goals of the HPRC will be substantively enriched through interdisciplinary scholarship that encourages collaboration, deliberation, and ultimately, shared decision-making.

PrgmNr 3755 - Determining Clinical Relevance of Genetic Variants in Newborn Screened Conditions

View session detail

Author Block: **A. M. Brower**; American Coll. of Med. Genetics and Genomics, Dakota Dunes, SD
Disclosure Block: **A.M. Brower:** None.
The goal of newborn screening (NBS) is to improve health outcomes by identifying and treating affected newborns. Each year over 22,000 newborns in the United States are identified with a genetic disease through NBS. NBS began in the 1960s with the discovery that newborns who received a screening test for phenylketonuria, using a blood spot on filter paper taken shortly after birth, benefited from early diagnosis and treatment. This discovery led to PKU screening pilots in several states and the eventual nationwide screening of all newborns using state-based public health laboratories. Over the past sixty years, this process of discovering the technologies to screen, diagnose, and treat has led to an increase in the number of screened conditions from 1 to 81. In addition, screening methodologies have advanced to include genomic sequencing, and treatment regimens have evolved to include gene-targeted therapies. The increasing use of genomics to screen, diagnose and treat conditions in newborns has heightened the need to understand the clinical relevance of genetic variants for newborn screened conditions. To aid in the interpretation of variants for NBS conditions, we created a computational method using longitudinal health information as part of the Newborn Screening Translational Research Network (NBSTRN). NBSTRN is an effort to develop data tools and resources to advance NBS related research and created the Longitudinal Pediatric Data Resource (LPDR). The LPDR enables the collection, storing, analysis, visualization, and sharing of genomic and phenotypic data. It is available for use by the research community and houses longitudinal clinical data on individuals with one of 118 rare genetic diseases. We performed a secondary analysis on data accumulated from a ten-year natural history study of 1904 individuals diagnosed with an inborn error of metabolism. We found 568 variants in 32 diseases and analyzed data on treatment and disease course. 28% (161/568) of the variants were not found in ClinVar and we were able to classify 86% (129/161) of these variants as pathogenic or likely pathogenic using the longitudinal health information. This work demonstrates that secondary analysis of longitudinal data collected as part of newborn screening finds unreported genetic variants. Further, the analysis of these databases provides the opportunity to reduce the number of variants of unknown significance, complicating interpretation and use of genomics to diagnose and treat individuals with genetic diseases.

PrgmNr 3756 - Experience from the 3D health pilot study at UCSF: how to implement and the utility of large scale genomic testing for healthy adult population

View session detail

Author Block: **J. Luevano**[1], S. Biswas[1], A. Rajkovic[2]; [1]Univ. of California, San Francisco, CA, [2]UCSF, San Francisco, CA
Disclosure Block: **J. Luevano:** None.
To better understand the predictive value of whole genome sequencing (WGS) in a healthy adult population, we launched a pilot sequencing study with an enrollment goal of 1,000 participants. We aim to establish institutional best practices to obtain, store, and communicate genomic information. In addition to understanding the utility of performing WGS for healthy adults, it is important to understand what type of genomic results participants want to receive, how to better engage clinicians (like primary care providers) and better engage participants of diverse backgrounds. In the pilot phase, we returned medically actionable variants of the 59 genes identified by the American College of Medical Genetics and an ancestry report. To date 494 adults [277 female (56.1%), 215 male (43.5%), 2 transgender (0.4%); Mean age 52.7 years; Ethnicity: 2 Alaska Native (0.4%), 82 Asian (16.6%), 13 Black or African American (2.6%), 18 Hispanic or Latino (3.6%), 1 Native Hawaiian or Other Pacific Islander (0.2%), 362 White/Caucasian (73.3%), 2 Mixed (0.4%), 7 Declined (1.4%), 11 Not available (2.2%)]. 494 patients have signed the consent form to participate in the study and 403 participantsâ samples have undergone whole genome sequencing, with 37 currently being processed. Of the 403 adults whose genomes were sequenced 11 (2.7%) were identified to have pathogenic (P) or likely pathogenic (LP) variants in the following genes: *BRCA1, KCNQ1, MYH7, APOB , CACNA1S, SCN5A, SDHAF2, RYR1 (2), TP53, BRCA2*. Participants were asked to complete a survey two weeks after receiving their results. Additionally, we have collaborated with the SPHERE (Special Populations and Health Equity in Research and Education) leaders to promote diversity among participants through community engagement. We have engaged with leaders among Black, Asian and Latinx communities, held town hall meetings and focus group studies to understand what the expectations, fears and obstacles are to participating in genomic research studies. The results from this pilot will help inform patient attitudes, develop a roadmap to scaling recruitment efforts and identify potential partners to help us further the effort.

PrgmNr 3757 - Functional annotation of human mitotic gene domains using CRISPR/Cas9 tiling screens

View session detail

Author Block: **P. J. Paddison**, L. Carter, S. Biggins, J. Herman; Fred Hutchinson Cancer Res. Ctr., Seattle, WA
Disclosure Block: **P.J. Paddison:** Major Stockholder/Ownership Interest; Presage Biosciences. Royalty(ies)/Honoraria; RNAi/shRNA Royalties. Consultant/Consulting Fees/Other Remuneration; Cellinta. Receipt of Intellectual Property Rights/Patent Holder; shRNA patents.
A critical knowledge gap for the human genome has arisen from our inability to resolve important functional domains and motifs within protein coding genes at the large scale. Historically, large scale annotation of protein domains and motifs relied on homology based-inference by searching against the current 5494 conserved protein family (Pfam) domains documented in the human genome (e.g., methyltransferase-like domain). This approach is ineffective for the ~45% of the proteome that is devoid of Pfam domains, and still requires validation for the remaining genes. Closing this knowledge gap is critical for both basic and disease-focused biomedical research, where years, if not decades, can be spent dissecting gene functions. Here, we develop a method that leverages CRISPR-Cas9 induced mutations to comprehensively identify key functional regions within protein sequences of the human genome that are required for cellular outgrowth. Our analysis of 48 human kinetochore genes revealed hundreds of regions required for cell proliferation, corresponding to known and uncharacterized protein domains. We biologically validated 15 of these regions, including amino acids 387-402 of Mad1, which when deleted compromise Mad1 kinetochore localization and chromosome segregation fidelity. Altogether, we demonstrate that CRISPR-Cas9-based tiling mutagenesis enables *de novo* identification of key functional domains in protein-coding genes, which elucidates separation of function mutants and allows functional annotation across the human proteome.

PrgmNr 3758 - IEMbase: An online knowledge base and mini-expert tool for the diagnosis of inborn errors of metabolism

View session detail

Author Block: **B. Hewitson**[1], N. Blau[2], W. W. Wasserman[3], C. D. van Karnebeek[4], K. Ã□unap[5], C. R. Ferreira[6]; [1]Univ. of British Columbia, Vancouver, BC, Canada, [2]Univ. Children's Hosp., Zurich, ZH, Switzerland, [3]Univ British Columbia, Vancouver, BC, Canada, [4]Amsterdam UMC, Amsterdam, Netherlands, [5]Univ. of Tartu, Tartu, Estonia, [6]Bolingbrook, IL
Disclosure Block: **B. Hewitson:** None.
Inborn errors of metabolism (IEMs) are inherited disorders that disrupt metabolic pathways as a result of defects in the genes that code for enzymes involved in facilitating the process. The bodyâ□□s inability to successfully synthesize metabolites from substrates can lead to an accumulation of toxic substrates or a deficiency of essential metabolites. Thus, a delay in the diagnosis of IEM disorders can lead to severe consequences for patients such as irreversible organ damage or death. Therapy is available to improve patient outcomes for a number of these rare inherited disorders; however, an accurate and timely diagnosis is required for effective treatment. This is often difficult to achieve due to a large knowledge gap between IEM specialists and the clinicians involved in early diagnoses, as well as nonspecificity of symptoms for IEM disorders. As such, we present the latest version of IEMbase, an online tool aimed at bringing the knowledge of specialized experts to professionals involved in diagnoses. IEMbase consists of an expert-curated knowledge base and mini-expert diagnosis support system, which accepts a list of clinical and/or biochemical phenotypes from the user and returns a list of matching IEM diagnoses. The matched diagnoses are generated using a two-step algorithm to compare the input phenotypic profile with every IEM profile in the IEMbase database. The first step assesses biochemical phenotypes by calculating the cosine similarity of term frequency-inverse document frequency (TFIDF) vectors for the input profile and each IEM profile in the database. The resulting cosine similarity scores are used to rank IEM profiles in the database to determine the disorders that are to be used in the second step of the algorithm. The semantic similarity between the input clinical phenotype and IEM disorder profiles in the database are calculated in the second step of the algorithm, relying on the Human Phenotype Ontology (HPO) as the standard medical vocabulary. The disorders resulting from the mini-expert system can be used to generate differential diagnosis tables, biochemical test panels, and targeted gene panels for users to pursue further investigations for diagnosis. Approximately 400 monthly users access the information in IEMbase, currently consisting of 3430 clinical/biochemical profiles and 8465 disorder/phenotype profiles created from 1540 IEM disorders.

PrgmNr 3759 - Rarediseasegenes.com/phex: A comprehensive locus specific database of *PHEX* gene variants associated with X-linked hypophosphatemia vastly increases the number of known variants

View session detail

Author Block: **S. Daugherty**[1], S. Sarafrazi[1], N. Miller[1], P. Boada[1], T. O. Carpenter[2], L. Chunn[3], M. J. Econs[4], S. Eisenbeis[1], E. A. Imel[4], B. Johnson[5], M. J. Kiel[3], S. Krolczyk[1], P. Ramesan[1], R. M. Truty[5], Y. Sabbagh[6]; [1]Ultragenyx Pharmaceutical, Novato, CA, [2]Yale Univ. Sch. of Med., New Haven, CT, [3]Genomenon, Ann Arbor, MI, [4]Indiana Univ. Sch. of Med., Indianapolis, IN, [5]Invitae Corp., San Francisco, CA, [6]Inozyme Pharma, Boston, MA
Disclosure Block: **S. Daugherty:** Salary/Employment; Ultragenyx Pharmaceutical.
X-linked Hypophosphatemia (XLH), a dominantly inherited disorder caused by loss of function mutations in the *PHEX* gene, is characterized by rickets in childhood followed by progressive skeletal disease. Short stature and deformity often ensue, with lifelong impairment of mobility and quality of life. Early and accurate diagnosis based on clinical, biochemical, and genetic features is complicated by the rarity of the disease, phenotypic variability, and similarities to other forms of congenital and sporadic hypophosphatemia. Advances in sequencing methodologies have led to detection of increasing numbers of *PHEX* variants. A comprehensive summary of *PHEX* disease-associated variants is necessary for accurate and timely interpretation of genetic testing results. We developed a comprehensive locus-specific database (LSDB) for *PHEX* to collect and disseminate information about *PHEX* variants to the scientific community. The database was developed by integrating variants from four different sources: **1.** an archived McGill University *PHEX* LSDB (Sabbagh et al., *Hum Mol Genet.,* 2001.); **2.** a comprehensive, systematic review of all published medical literature; **3.** a sponsored hypophosphatemia gene panel testing program (Rush et al., manuscript in preparation); and **4.** Ultragenyx clinical programs. Variants were annotated with detailed clinical and biochemical phenotypes extracted from literature reports and clinical testing submission forms. As of 28 APR 2021, the *PHEX* LSDB reports 870 unique *PHEX* variants, forming 869 alleles. Single nucleotide variants (n= 321, 36.90%) represent the most common type of unique variant in the database followed by small deletions, duplications, or insertions (n= 282, 32.41%), splicing variants (n= 191, 21.95%), and copy number variants (n= 75, 8.02%). This represents a >200% increase in the number of *PHEX* variants documented in the original archived PHEX LSDB (last updated 2APR2017). Most of the variants have an ACMG call or predicted call of pathogenic or likely pathogenic (n=689, 79.20%) and 167 (19.20%) were categorized as variants of uncertain significance. The comprehensive searchable database of *PHEX* variations is freely available (www.rarediseasegenes.com/phex) and provides an opportunity to add new variants, which will increase the diagnostic yield from genetic testing and be an important tool for XLH research.

PrgmNr 3760 - Re-architecture of ClinGenâ□□s Variant Curation Interface (VCI) to Support Future Enhancements Aimed at Scaling Variant Classification

View session detail

The ClinGen Variant Curation Interface (VCI) is a global open-source variant classification platform for supporting the application of evidence criteria and classification of variants based on the ACMG/AMP sequence variant classification guidelines. The VCI is among a suite of tools developed by the NIH-funded Clinical Genome Resource (ClinGen) Consortium, and supports an FDA-recognized human variant curation process. To facilitate evidence-based improvements in human variant classification, the VCI is publicly available to the genomics community. ClinGen is expanding to involve more curators and an increased scale of activities as we include more genetic variants across a greater number of genes. Here we present interface design decisions made during a recent VCI platform re-architecture that will support future enhancements and enable scalable curation workflows. The new interface system involves moving from a server-based cloud architecture to a serverless architecture. Evidence codes that are amenable to automated application (e.g. allele frequency, predicted loss of function, in silico prediction) will be supported in future versions of the VCI as well as enabling gene-specific specifications and thresholds for applying evidence criteria. These developments support the ClinGen mission of curating the continually-expanding space of the clinical human genome.

PrgmNr 3761 - Significant Sparse Polygenic Risk Scores in 428 traits in UK Biobank

View session detail

Author Block: **Y. Tanigawa**, J. Qian, R. Li, G. R. Venkataraman, J. M. Justesen, R. Tibshirani, T. J. Hastie, M. Rivas; Stanford Univ., Stanford, CA
Disclosure Block: **Y. Tanigawa:** Consultant/Consulting Fees/Other Remuneration; Cipherome, Inc.
Polygenic risk scores (PRSs) have been proposed for disease risk prediction for some traits, but their predictive ability across human traits remains unclear. Most approaches use many variants from GWAS analyses, limiting their biological interpretability. Here, we systematically characterize an atlas of sparse PRSs in more than 1,500 traits (> 450 disease outcomes) in the UK Biobank with penalized multivariate regression using the R snpnet package (batch screening iterative Lasso, BASIL), which simultaneously performs variable selection and effect-size estimation using individual-level data. Using a held-out test set, we systematically compare the predictive ability of the PRSs to baseline models generated with covariates (age, sex, and genotype PCs) and find significant (p -5) improvements in predictive performance in 428 traits. We assess the trans-ethnic predictive performance within the UK Biobank and find limited transferability across ancestry groups for most traits. The results of our systematic evaluation of sparse PRS and the coefficients of each model are publicly available on Global Biobank Engine (https://biobankengine.stanford.edu/prs).

PrgmNr 3762 - Specifications of the ACMG/AMP variant curation guidelines for *MYOC*: Recommendations from the ClinGen Glaucoma Expert Panel

Disclosure Block: **E. Souzeau:** None.

Background: Standardised variant curation criteria are essential for accurate interpretation of genetic results and clinical care of patients. The variant curation guidelines developed by ACMG/AMP in 2015 are widely used by the genetic community but are not gene specific. The Clinical Genome Resource (ClinGen) Variant Curation Expert Panels (VCEP) are tasked with developing gene-specific variant curation guidelines. *Aim & Methods:* The Glaucoma VCEP was created in 2019 and assembled clinicians, researchers and laboratory scientists that aimed to develop and pilot rule specifications of the ACMG/AMP variant curation guidelines for *MYOC* variants, the most common cause of Mendelian glaucoma. *Results:* Among the 28 ACMG/AMP criteria, the Glaucoma VCEP adapted 15 rules to *MYOC* (including 10 strength specifications), while 13 rules were deemed not applicable. Key specifications included calculations of minor allele frequency thresholds, developing an approach to counting multiple independent probands and segregations, and reviewed functional assays that reported on the solubility and secretion of mutant proteins. The specified rules were piloted on 82 variants and led to a change in classification in 14/37 (38%) of those that were classified in ClinVar. Functional evidence led to the reclassification of 19 (44%) of VUS (including 13 from VUS to likely pathogenic and 6 from VUS to likely benign). *Conclusion:* The standardised variant curation guidelines for *MYOC* from the Glaucoma VCEP improved variant classification. *MYOC* variant curation and classifications will be submitted to ClinVar with expert level status.

PrgmNr 3763 - The Atlas of Variant Effects (AVE) Alliance:understanding genetic variation at nucleotide resolution

It has become nearly routine to sequence human exomes and genomes. However, functional impacts are characterized for The Atlas of Variant Effects (AVE) Alliance is a new initiative aimed at comprehensively measuring the biological effect of genetic variation in human and pathogen genomes, to advance clinical diagnosis and disease management, drug development and fundamental mechanistic understanding. We share a long-term vision to generate and apply an Atlas of thousands of variant effect maps for both proteins and non-coding elements.
The AVE Alliance will support and expand the community generating variant effect maps, by coordinating efforts and establishing standards for generating, managing, sharing and using variant effect map data responsibly and with maximum impact. Please see varianteffect.org to learn more and consider joining AVEâ□□s current ranks of 180 members internationally.

PrgmNr 3764 - Virtual Registry of 3,500 Leigh Syndrome and Primary Mitochondrial Disease Cases Constructed through Expert Curation and Semi-automated Literature Mining at MSeqDR

View session detail

Mitochondrial Med. Frontier Program, Dept. of Pediatrics, Childrenâ□□s Hosp. of Philadelphia, Philadelphia, PA

Disclosure Block: **L. Shen:** None.

Primary mitochondrial disease (PMD) has a prevalence of at least 1 in 4,300 people. The most common pediatric manifestation of PMD is Leigh Syndrome (LS) with a prevalence of 1 in 34,000 people and more than 100 associated gene causes now recognized. PMD community registry creation has required intensive collaborative effort, with 1,555 participants enrolled in the North American Mitochondrial Disease Consortium (NAMDC) Registry as of 2020 (https://ng.neurology.org/content/6/2/e402).

To enhance knowledge of PMD, we built at MSeqDR a PMD Virtual Registry using both semi-automated literature mining and expert review. Specifically, we developed a semi-automated pseudo-case curation platform, hosted at MSeqDR.org, to aid in the capture, extraction, and standardization of case-level data from publications through semantic matching followed by manual review. In parallel, the NIH funded ClinGen Mitochondrial Diseases Gene Curation Expert Panel (HD-093483, https://www.clinicalgenome.org/affiliation/40027/, https://reporter.nih.gov/project-details/9411950) manually curated ~350 deeply-phenotyped cases associated with 113 nuclear and mtDNA genes from published literature to evaluate the causative gene associations for Leigh Syndrome spectrum (LSS) disorder. Heterogeneous data were mapped to over 100 â□□standardâ□□ clinical, biochemical, and genetic feature terms. Case level data was fully atomized, and divided into over 110,000 atomized feature records. Phenotypes and diseases were mapped to Human Phenotype Ontology (HPO) and OMIM terms.

The Web front-end includes a PMD Virtual Registry Case Browser, which supports querying using single or composite filters constructed from atomized and standardized keywords such as OMIM disease, (causative) genes and variants, phenotypes and HPO terms, inheritance mode, zygosity, consanguinity, sex, age at onset, age at death, ethnicity, PubMed ID and title, and date ranges. Matching cases are hyper-linked to single case report pages, which presents all data elements of a case in both standardized and original terms.

As of June 2021, the MSeqDR PMD Virtual Registry contains ~1,050 LS/LLS cases (>700 from semi-automatic literature mining plus 350 from U24 project expert curation) plus 2,450 other PMD cases. This collection of 3,500 de-identified PMD pseudo-cases exceeds most existing ad-hoc LS/LSS or PMD registries. Full curation of the pseudo cases and in-depth stratification and correlation analysis are ongoing. The PMD Virtual Registry is hosted on the United Mitochondrial Disease Foundation (UMDF) supported MSeqDR platform (https://mseqdr.org/virtualregistry.php).

PrgmNr 3765 - A rare case of Bardet Biedl syndrome presented as acute onset of heart failure and dilated cardiomyopathy

View session detail

Author Block: **H. Wang**[1], A. Stacy[1], A. Munoz[1], J-A. Gold[1,2]; [1]Dept. of Pediatrics, Loma Linda Univ., Sch. Of Med., Loma Linda, CA, [2]Dept. of Pediatrics, Div. of Genetics and Genomics, Univ. of California Irvine, Irvine, CA
Disclosure Block: **H. Wang:** None.
INTRODUCTION: Bardet-Biedl syndrome (BBS) is a rare genetically heterogeneous, autosomal recessive inherited disorder with wide variability in expression. Characteristic features of BBS include retinitis pigmentosa, post axial polydactyly, central obesity, and learning disability. Other manifestations include diabetes mellitus, heart disease, hepatic fibrosis, renal disease and neurological manifestations. BBS presenting as acute onset of heart failure and dilated cardiomyopathy is very rare. **CASE DESCRIPTION:** We present the case of a 11-year-old female, with history of intermittent asthma, obesity, developmental delay (~2nd-3rd grade level), She was admitted for new-onset acute systolic heart failure. She was hypoxic and CXR demonstrated a large right pleural effusion and cardiomegaly. BNP elevated to 3959. Severe LV dysfunction with LV 24%, dilated cardiomyopathy with biventricular dysfunction on her TTE. Right pleural chest tube was placed and found to have chylous effusion. She was intubated and ECMO was initiated. Cardiac biopsy showed hypertrophy and liver biopsy indicated bridging fibrosis consistent with cirrhosis. The previous medical records from another state showed three variants in BBS1 gene: 1). c.1169T>G, (p.Met390Arg), heterozygous, recessive, associated; 2). c.433-2A>C, splice-site mutation, heterozygous, recessive, probably associated. 3). c.7A>G, 3'UTR mutation, heterozygous, not associated. Her brother was tested first he has the same variants. She was diagnosed with BBS. On physical exam, she is tall in 95% percentile with BMI 36, no obvious dysmorphic features were appreciated. The patient subsequently underwent cardiac transplant and is currently in the early postoperative recovery period. **DISCUSSION/CONCLUSION**: Bardet-Biedl syndrome is a rare autosomal recessive multisystem disorder caused by defects in genes encoding for proteins that localize to the primary cilium/basal body complex. A review of the literature did not find reports of BBS with cardiac transplant. More than 20 disease-causing genes have been identified to date. Congenital and acquired heart disease have been reported but cardiac monitoring is not required in surveillance plan. Echocardiographic examination should be included in the clinical evaluation and follow-up of patients with BBS.

PrgmNr 3766 - Further delineating Baraitser Winter syndrome through ACTB and ACTG1 phenotypic characterization

View session detail

Author Block: **L. Forero**[1], A. Lee[2], L. M. Bird[3]; [1]Univ. of California San Diego, San Diego, CA, [2]Univ. of California San Diego, San Diego, CA, [3]Rady Children's Hosp., San Diego, CA
Disclosure Block: **L. Forero:** None.
Baraitser-Winter syndrome (BWS) is characterized by multiple congenital anomalies, including facial dysmorphism, developmental delay, CNS abnormalities, and short stature. BWS is an autosomal dominant disorder caused by mutations in two genes, *ACTB* and *ACTG1*. We performed a comprehensive review of the literature searching for cases of BWS with molecular confirmation and included two patients seen through our institution. This resulted in a cohort of 76 patients, for which we created a database of 31 HPO terms specifying CNS, eye, facial, cardiovascular, hematologic, and growth/limb anomalies. Our goal was to study genotype-phenotype correlation and to assess the severity associated with genotype. Of the 76 patients in our cohort, 24 carried a mutation in *ACTB* and 52 in *ACTG1*. Two by two tables for every HPO term were constructed, and Fisher exact test was used to analyze the data. P ACTG1 group and only 38% (20/25) of patients who carried mutations in *ACTB*. Lissencephaly was reported in 67% (16/24) of patients with mutations in *ACTG1*compared to 31% (16/52) of *ACTB* patients. For *ACTG1* patients, hydrocephalus was present in 21% (5/24), while it was only documented in 4 % (2/52) of patients from the *ACTB* group. These findings are concordant with prior studies reporting a more severe CNS phenotype for patients with mutations in *ACTG1*. Of note, there was no statistically significant difference in intellectual disability/ developmental delay (DD) between the two genes. ID/DD was present in 75% (18/24) of *ACTG1* patients and 60% of patients in the *ACTB* group. We were not able to determine the severity of ID/developmental. To our knowledge, this is one of the largest BWS cohorts looking for genotype/phenotype correlation. It appears that overall, there is significant overlap between the two genotypes except for the mentioned CNS and eye anomalies. We will discuss the reported variant types/functional consequences and their correlation with the severity of phenotype during our presentation.

PrgmNr 3767 - Lessons learned from the first 170 trios from the Genomic Autopsy Study

View session detail

Author Block: **C. Barnett**[1], T. Ha[2], P. Arts[3], A. B. Byrne[4], M. Babic[2], L. Pais[5], A. Schreiber[6], G. Genomic Autopsy Study Research Network[1], K. Kassahn[2], T. Hardy[7], M. Jackson[1], H. S. Scott[7]; [1]Women's and Children's Hosp., North Adelaide, Australia, [2]Genetics and Molecular Pathology Res. Disclosure Block: **C. Barnett:** None.

Background: The cause of pregnancy loss and perinatal death remains unexplained in at least 25% of cases, despite a high perinatal autopsy rate in Australia. The Genomic autopsy study is a national collaborative study aimed at determining the cause. Aim: To apply WES/WGS to identify genetic causes of fetal/newborn abnormalities that result in termination of pregnancy, death in utero or in the newborn period, in view to providing families with answers regarding cause and likelihood of recurrence. Methods: WES/WGS is being performed on parent-fetus trios/quads following standard autopsy and non-informative microarray. High priority cases are consanguineous families, fetuses with multiple malformations, and unexplained fetal/newborn death. Statistical, bioinformatic and experimental laboratory techniques are used to confirm causality of variants. Results: 170 prospective trios (150) or quads (20) have been recruited and sequenced. 89/170 (52%) are either solved or have a strong candidate gene identified. 42/170 (25%) of cases have been clearly solved by identification of a pathogenic mutation in a known gene. An additional 27/170 (16%) have a candidate variant in a known gene that expands phenotype. In 20/170 (12%) of cases, a mutation was identified in a gene not yet linked to human disease. Unexplained stillbirth cases remain the most difficult to solve. Discussion: Our results provide justification for genomic investigation of pregnancy loss and perinatal death, particularly when congenital abnormalities are present. Establishing a clear diagnosis on clinical grounds alone is often challenging. Late stillbirth remains largely unexplained by genomics. Novel techniques for genomic investigation of unexplained stillbirth need further consideration, including genomic investigation of the placenta.

PrgmNr 3768 - Parental Mosaicism in 'De Novo' Tuberous Sclerosis Complex

View session detail

Author Block: **z. ye**[1], S. Lin[2], X. Zhao[2], Y. Yao[2], L. Li[2], L. Chen[2], J. Duan[2], D. Cao[2], Z. Hu[2], S. Berkovic[1], I. Scheffer[1], J. Liao[2], M. Hildebrand[1]; [1]Univ. of Melbourne, Mebourne, Australia, [2]Shenzhen Children's Hosp., Shenzhen, China
Disclosure Block: **Z. ye:** None.
Rationale: Tuberous sclerosis complex (TSC) is a genetic disorder associated with neurological, renal, dermatological and other anomalies. Over 85% of reported patients have germline mutations in *TSC1* or *TSC2*, with a higher yield of pathogenic variants in cohorts with more severe, earlier onset disease. Some patients appear to have â□□de novoâ□□ variants on routine testing of parental blood-derived DNA, yet one parent may have clinical features of TSC or multiple affected children carrying the same germline mutation, indicating the likelihood of low-level parental mosaicism. We aimed to identify parental mosaicism in 7 families with TSC and features suggesting underlying parental mosaicism.
Methods: Seven families had known pathogenic germline mutations previously identified in the probands on clinical genetic testing. All parents were negative for their childâ□□s variant on segregation analysis via clinical Sanger sequencing. Blood, saliva, buccal and urine DNA were obtained from all parents. Droplet digital PCR (ddPCR) or deep targeted amplicon sequencing (5,000x) were used to detect and quantitate the variants in parental tissues.
Results: We found parental mosaicism in blood-derived DNA in five of 7 families at low frequency ranging from 0.1-8.8%, all well below the threshold of detection by Sanger sequencing. In 3 parents with mosaic variants, we determined variant allele frequency (VAF) in different tissues. One parent had mosaicism at a similar level across four different tissues (7.26-9.11% VAF); while in the other two parents, mosaicism was variable (0.9-3.12% VAF across three tissues and 0.39-2.2% VAF across four tissues, respectively). Of the two families without mosaicism detected, one had two affected children carrying the same germline mutation so one parent must have gonadal mosaicism that we could not detect in peripheral tissues. In the second negative family, the mother has unilateral renal hamartoma without any other clinical features of TSC; so, her hamartoma may not be due to TSC.
Conclusions: Our findings confirm that low-level parental mosaicism missed on routine clinical testing can be detected with high levels of coverage. This finding has critical implications for reproductive counseling.

PrgmNr 3769 - *De novo* heterozygous *POLR2A* variant associates with autism spectrum disorder with epilepsy, hypotonia, strabismus and self-injurious behaviours

View session detail

Author Block: **D. Evans**[1], Y. Qiao[2], S. Martel[2], K. Calli[2], S. Jones[2,3], S. Scherer[4], S. M. Lewis[5]; [1]Dept. of Family Practice, Univ. of British Columbia, Vancouver, BC, Canada, [2]Med. Genetics, Univ. of British Columbia, Vancouver, BC, Canada, [3]Canadaâ□□s Michael Smith Genome Sci. Ctr., Vancouver BC, BC, Canada, [4]The Ctr. for Applied Genomics and McLaughlin Ctr., Hosp. for Sick Children and Univ. of Toronto, Toronto, ON, Canada, [5]BC Children's & Women's Hlth.Ctr, The Univ. of British Columbia, Vancouver, BC, Canada

Disclosure Block: **D. Evans:** None.

Autism spectrum disorder (ASD) describes a complex and heterogenous group of neurodevelopmental disorders. Whole genome sequencing studies are beginning to elucidate the multifactorial etiology of ASD. Studies employing pathway analysis for genetic variants in ASD have suggested that dysregulation and dysfunction of transcriptional pathways are linked to neurodevelopmental disorders. *POLR2A* encodes the RBP1 subunit of the RNA Polymerase II Complex (pol II). This fundamentally important enzyme transcribes all ~21,000 protein coding genes. Recent studies demonstrate a putative role for *POLR2A* in neurodevelopmental disorders. In particular, *de novo* *POLR2A* variants were recently implicated in a new neurodevelopmental phenotype called â□□Neurodevelopmental Disorder with Hypotonia and Variable Intellectual and Behavioral Abnormalitiesâ□□ (NEDHIB) (OMIM: 618603). Patients described with NEDHIB are characterized by early-onset hypotonia, delayed walking, poor speech, variable intellectual development impairment, and behavioral abnormalities with a high degree of variability in severity. The disorder segregates in an autosomal dominant manner. In this study, we describe and characterize a novel *de novo* deleterious *POLR2A* variant (c.1367T>C, p. Val456Ala) identified in an 8-year-old girl with ASD. The variant was detected using proband-parent trio whole genome sequencing. In this simplex case, the *POLR2A* p.Val456Ala variant manifests with high functioning ASD, central hypotonia, seizure, macrocephaly, hyperopia, strabismus, and self-injurious behaviour with no obvious dysmorphism aside from subtle right sided facial prominence. She presented with speech delay with flat intonation, and heightened sensitivity to touch, sound, and texture. This study provides further evidence for the role of *POLR2A* in neurodevelopmental disorders, while particularly emphasizing the role for this gene in ASD. Mounting evidence now suggests that disruption of *POLR2A* manifests as a spectrum of multi-system developmental disorders.

PrgmNr 3770 - A CRISPR screen for modifiers of the rare disease DPAGT1-CDG (CDG-Ij)

View session detail

Author Block: **H. M. Dalton**[1], R. Viswanatha[2], R. Brathwaite Jr.[2], S. E. Mohr[2], N. Perrimon[2,3], C. Y. Chow[1]; [1]Univ. of Utah, Salt Lake City, UT, [2]Harvard Med. Sch., Boston, MA, [3]Howard Hughes Med. Inst., Boston, MA

Disclosure Block: **H.M. Dalton:** None.

Partial loss-of-function mutations in glycosylation pathways underlie a set of rare diseases called Congenital Disorders of Glycosylation (CDGs). Glycosylation is a broad category of sugar modifications on proteins and lipids, with functions ranging from complex post-translational modifications through the endomembrane system (e.g. N-glycosylation) to single sugar additions involved in cell signaling (e.g. O-GlcNAc-ylation). CDGs have a range of symptoms, but commonly include severe epilepsy, developmental delay, and disability. CDG Type Ij is caused by loss-of-function mutations in *DPAGT1* - the first step in N-glycosylation. Our goal is to better understand the pathways connected to *DPAGT1* loss, as well as glycosylation disorders as a whole, to develop potential treatment options.

We performed a CRISPR knockout screen using the drug tunicamycin (Tun), a potent inhibitor of DPAGT1 function, on *Drosophila* S2R+ cells. Loss of *DPAGT1* and Tun treatment impair N-glycosylation and cause massive protein misfolding, leading to reduction of cell surface glycoproteins and endoplasmic reticulum (ER) stress. Because many CDGs are caused by mutations in the N-glycosylation pathway, characterizing the genes that affect this pathway will help us better understand these disorders. Using a pooled format, we introduced a whole genome guide RNA library into the S2R+ cells expressing constitutive Cas9. Pooled cell populations were grown for 10 generations under selection with either vehicle or Tun. Final populations were examined for total guide RNA abundance to determine candidate genes causing resistance or sensitivity to *DPAGT1* inhibition.

We validated candidate genes by Concanavalin A (ConA) to assay cell surface glycoproteins in the S2R+ cells, and by RNAi knockdown via an *in vivo* ER stress *Drosophila* model. The ConA assay demonstrated that knockout of some glycosylphosphatidylinositol (GPI) anchor biosynthesis components (e.g. *PIGA* and *PIGH*) restored glycoproteins to the cell surface under Tun stress. This suggests a novel interaction between N-glycosylation and GPI biosynthesis. RNAi in the *Drosophila* ER stress model confirmed that loss of the mannosyltransferase *Dpm1*, involved in mannose addition in several downstream glycosylation pathways, could rescue ER stress phenotypes. Testing these pathways (O- and C-mannosylation [*POMT2* and *DPY19L1*]), N-glycosylation [*ALG3*], GPI biosynthesis [*PIGM*]), we found loss of O-mannosylation and GPI biosynthesis partially recapitulates the *Dpm1* RNAi rescue of ER stress. These findings suggest GPI biosynthesis and/or mannose levels may underlie potential DPAGT1-CDG treatment options.

PrgmNr 3771 - A novel non-canonical splice site variant in *Delta 4-Desaturase, Sphingolipid 1 (DEGS1)* leads to loss of normal *DEGS1* splicing and results in functional deficiency of ceramide desaturase activity in two patients with hypomyelinating leukodystrophy

Saba[6], T. Yip[2], O. M. Vaske[4,5], W. P. Devine[1]; [1]Dept. of Pathology, UCSF, San Francisco, CA, [2]Div. of Genetics, Dept. of Pediatrics, UCSF, San Francisco, CA, [3]Div. of Child Neurology, Dept. of Neurology, UCSF, San Francisco, CA, [4]Molecular, Cell and Dev.al Biology, UCSC, Santa Cruz, CA, [5]Genomics Inst., UCSC, Santa Cruz, CA, [6]Div. of Hematology/Oncology, Dept. of Pediatrics, UCSF, San Francisco, CA, [7]Inst. for Human Genetics, UCSF, San Francisco, CA, [8]Dept. of Epidemiology and Biostatistics, UCSF, San Francisco, CA
Disclosure Block: **C. Badduke:** None.
Delta 4-Desaturase, Sphingolipid 1 (DEGS1), at chromosome 1q42.11, encodes an enzyme that catalyzes the last step of the de novo ceramide biosynthetic pathway in which dihydroceramide (DhCer) is converted to ceramide (Cer). Variants in *DEGS1* have recently been associated with hypomyelinating leukodystrophy (MIM: 618404), a rare autosomal recessive condition that results in a complex neurological regressive disorder. To date, 14 homozygous or compound heterozygous variants have been reported (PMID: 30620337, 30620338, 31186544); 7/14 are truncating (4 nonsense, 3 frameshift), 7/14 are missense, and 2/14 (p.Asn255Ser and p.Trp107*) are recurrent. In this study, we report a novel homozygous intronic *DEGS1* indel at chromosomal position chr1:224378025-224378026 (hg19) detected by whole exome sequencing in 2 unrelated probands whose phenotypes overlap those reported in individuals with hypomyelinating leukodystrophy. Our variant, a non-canonical *DEGS1* splice site variant (c.825+4_825+5delAGinsTT; NM_003676.3), was classified according to ACMG guidelines as a variant of uncertain significance (VUS) as it is absent from population databases (gnomAD and dbSNP), has not previously been associated with disease (ClinVar and literature), and is not unanimously predicted by in silico algorithms to have a deleterious effect on splicing (Alamut). To characterize our VUS, we obtained a peripheral blood sample from one of our probands and performed transcriptome-wide RNA sequencing to study *DEGS1* splicing. *DEGS1* is expressed in whole blood at a similar level to that observed in multiple brain tissues (GTEx). Our results show that the c.825+4_825+5delAGinsTT variant affects the 5â splice donor sequence of exon 2 of *DEGS1* resulting in exon 2 skipping in the majority of transcripts detected in our proband. Other transcripts detected represent the use of various cryptic splice sites both upstream and downstream of the canonical exon 2 splice donor sequence. The resulting isoforms are predicted to be non-functional. Saturated and unsaturated sphingolipids were quantified by mass spectrometry in the plasma of the second proband and five pediatric controls. The ratios of C14, C16, C20, C22, C24, C24.1 and C26 dihydroceramide/ceramide were elevated (from 3-fold to 2,370-fold) in our proband compared to controls confirming functional deficiency of ceramide desaturase activity. In summary, we characterize a novel non-canonical *DEGS1* splice site variant using RNA sequencing and mass spectrometry and provide evidence to support its pathogenicity in hypomyelinating leukodystrophy. To our knowledge this is the first splice effect variant reported in *DEGS1*.

PrgmNr 3772 - An *in vivo* repurposing screen identifies novel therapeutic candidates for NGLY1 deficiency

View session detail

Author Block: **K. Hope**[1], R. Peterson[1], C. Y. Chow[2]; [1]Univ. of Utah Sch. of Med., Salt Lake City, UT, [2]Univ of Utah, Salt Lake City, UT
Disclosure Block: **K. Hope:** None.

Rare diseases impact more than 30 million Americans, however treatment options are limited or non-existent in approximately 90% of cases. NGLY1 deficiency, a rare disease with no effective treatment, is caused by autosomal recessive, loss-of-function mutations in the gene *N-glycanase 1* (*NGLY1*) and is characterized by global developmental delay, hypotonia, alacrima, and seizures. NGLY1 is a deglycosylase that removes GlcNAc sugar chains from glycoproteins that have been retrotranslocated from the endoplasmic reticulum (ER) lumen to the cytoplasm. Recent work demonstrated that the transcription factor NRF1 is translated into the ER membrane, glycosylated, retrotranslocated to the cytoplasm, and immediately degraded. Under proteasome stress, NRF1 is deglycosylated by NGLY1, allowing it to be cleaved and subsequently act as a transcription factor to upregulate proteasome genes. Unfortunately, therapeutic approaches targeting the known interaction between NGLY1 and NRF1 have yielded limited results. Here, we took an unbiased approach and conducted an *in vivo* small molecule screen to identify therapeutic compounds for NGLY1 deficiency. We used a *Drosophila melanogaster* model of NGLY1 deficiency that harbors a null allele of *dNGLY1* (*Drosophila NGLY1* ortholog) and displays lethality at the late pupal stage. In efforts to limit the time and cost associated with bringing a new drug to the NGLY1 deficiency population, we employed the Prestwick Chemical Library, consisting of 1280 off patent small molecules, 99% of which are approved by FDA/EMA regulatory agencies, to screen for compounds that rescue lethality in $dNGLY1^{KO}$ flies. We identified multiple compounds that modulate the serotonergic and dopaminergic signaling pathways, as well as iodine containing molecules, that rescued lethality in $dNGLY1^{KO}$ flies. Although serotonin and dopamine signaling impacts numerous cellular pathways, we hypothesize that serotonin and dopamine modulators rescue lethality in $dNGLY1^{KO}$ flies by inhibiting glycogen synthase kinase 3 (GSK3). Additionally, we utilized the Connectivity Map and identified a GSK3 inhibitor predicted to reverse gene expression changes in *dNGLY1* deficient flies, further supporting this hypothesis. GSK3 negatively regulates NRF1 activity, and disinhibiting NRF1 through GSK3 inhibition may rescue defects in $dNGLY1^{KO}$ flies. Additionally, iodine upregulates the transcription factor NRF2, which may compensate for the dysregulation of NRF1 upon the loss of NGLY1. This study demonstrates the power of *Drosophila* in therapeutic development for rare diseases, and similar small molecule screening strategies can be applied to other disorders.

PrgmNr 3773 - Epilepsy gene variants increase risk of seizure onset in familial Cerebral Cavernous Malformation

View session detail

Author Block: **S. Weinsheimer**[1,2], C. Fox[3], J. Nelson[1], A. Numis[3], M. Mabray[4], J. Zabramski[5], A. L. Akers[6], B. Hart[4], L. Morrison[7], C. E. McCulloch[8], H. Kim[1,2,8], Brain Vascular Malformation Consortium CCM Investigator Group; [1]UCSF Dept. of Anesthesia and Perioperative Care, Ctr. for Cerebrovascular Res., San Francisco, CA, [2]UCSF Inst. for Human Genetics, San Francisco, CA, [3]UCSF Dept. of Neurology, San Francisco, CA, [4]Univ. of New Mexico, Dept. of Radiology, Albuquerque, NM, [5]Barrow Neurological Inst., Dept. of Neurosurgery, Phoenix, AZ, [6]Angioma Alliance, Durham, NC, [7]Univ. of New Mexico, Dept. of Neurology, Albuquerque, NM, [8]UCSF Dept. of Epidemiology and Biostatistics, San Francisco, CA
Disclosure Block: **S. Weinsheimer:** None.
Background: Familial cerebral cavernous malformation (CCM) is an autosomal dominant disorder caused by mutations in *KRIT1*, *CCM2* and *PDCD10* genes. Seizures are a common presenting feature of CCM and clinical heterogeneity of familial CCM suggests a role for genetic modifiers. However, it is unknown whether epilepsy-related genes contribute to risk of seizure onset in familial CCM. We hypothesized that common genetic variants in known epilepsy or epilepsy-related genes are associated with earlier age of seizure onset in familial CCM patients. **Methods:** Familial CCM cases enrolled in the Brain Vascular Malformation Consortium were included (n=335). Time from birth to first seizure censored at last follow-up was assessed by medical records. Individuals were genotyped using the Affymetrix Axiom Genome-Wide LAT1 Human Array. We tested 28,670 single nucleotide polymorphisms (SNPs) mapping within 5kb of 935 genes identified as epilepsy-associated genes or genes related to epilepsy (reviewed in Wang et al, *Seizure* 2017) with minor allele frequency â¥1%. With interval censored survival analysis assuming a Weibull distribution, we tested whether the number of minor alleles was associated with age of first seizure onset, adjusting for age at enrollment and sex. We report hazard ratio (HR) and 95% confidence interval (CI), and significance was based on Bonferroni adjustment for multiple comparisons (P=0.05/28,670 SNPs =1.74E-06).**Results:** Overall, 139 (41.5%) of cases had seizure over a mean analysis time of 33.5Â±22.3 years (11,860 total years). Genetic variants mapping to introns in three genes were significantly associated with seizure onset when adjusting for age and sex. NEDD4 like E3 ubiquitin protein ligase (*NEDD4L*, rs17064791 G>A) stratified seizure risk, with carriers of the minor allele at nearly 5-fold increased risk of earlier seizure onset compared to non-carriers (HR=4.8; CI: 2.6-8.6; P=1.7E-07). In addition, genetic variants in leucine rich repeat kinase 2 (*LRRK2*, rs73106354 A>G, HR=4.4; CI: 2.5-7.7; P=3.3E-07) and erb-b2 receptor tyrosine kinase 4 (*ERBB4*, rs72945032 T>C, HR=2.6; CI: 1.8-3.9; P=9.4E-07) also significantly increased risk of earlier seizure onset.**Conclusion:** Genetic variants in the epilepsy-associated gene *NEDD4L*, and epilepsy-related genes *LRRK2* and *ERBB4* were associated with earlier seizure onset in familial CCM patients, lending further evidence that these genes may be relevant for familial CCM disease severity. Further work is needed to confirm these findings in a replication cohort. The identification of individuals carrying epilepsy genetic variants may aid in CCM patient stratification for more personalized treatment.

PrgmNr 3774 - Genetic modifiers of NGLY1 deficiency identified through a *Drosophila* genetic screen point to the role of NGLY1 in ERAD

View session detail

Author Block: **T. Tu'ifua**[1], D. Talsness[2], K. Owings[2], C. Y. Chow[3]; [1]Dept. of Human Genetics, Univ. of Utah, Salt Lake City, UT, [2]Univ. of Utah, Salt Lake City, UT, [3]Univ of Utah, Salt Lake City, UT
Disclosure Block: **T. Tu'ifua:** None.

N-glycanase 1 (NGLY1) deficiency is a rare disease caused by autosomal recessive loss of function mutations in the *NGLY1* gene and is the only known congenital disorder of deglycosylation. Patients suffer from movement disorder, developmental delay, liver dysfunction, and alacrima. NGLY1 removes N-linked glycans from glycoproteins in the cytoplasm and is thought to help clear misfolded glycoproteins from the endoplasmic reticulum (ER) through the ER associated degradation (ERAD) pathway. Despite this, NGLY1â□□s physiological significance in ERAD is not understood. One way to understand disease pathogenesis is to investigate the effects of genetic variation and modifier genes on disease presentation. Our lab created a *Drosophila* model of NGLY1 deficiency that faithfully recapitulates several disease phenotypes observed in patients, including movement disorder, seizures, and lethality. We crossed this *Drosophila* model of NGLY1 deficiency with the *Drosophila* Genetics Reference Panel (DGRP), a collection of ~200 inbred fly strains with fully sequenced genomes, and scored for proportion of *NGLY1* knockdown flies surviving to adulthood. The genetic variation of the DGRP led to a spectrum of lethality ranging from strains that had 100% lethality to 100% viability. A genome wide association study (GWAS) generated a list of 61 candidate modifier genes of NGLY1 deficiency. Nine of these candidate genes encode ER resident proteins, proteins with known ERAD functions, or are involved with protein homeostasis. *CG31690* and *CG4341* were two independent unlinked hits in the GWAS that are orthologs of a single human gene, *TMTC2*, which encodes an ER adaptor protein involved with calcium homeostasis. *Hrd3* and *CG8405*, orthologs of *SEL1L* and *TMEM259*, were both hits and are known components of ERAD complexes that retrotranslocate misfolded proteins from the ER to the cytoplasm for degradation. We are functionally characterizing several of these candidate modifier genes of NGLY1 deficiency using *Drosophila* and cell culture models. The study of modifier genes can provide new insights into the etiology of the disease and functions of NGLY1, laying the foundation for the development of personalized therapeutics.

PrgmNr 3775 - Human genetics is great: Bone Mineral Density Studies in Patients with IBMPFD using DEXA

View session detail

Author Block: **R. Columbres**[1,2], M. Nguyen[1], V. Kimonis[1]; [1]Univ. of California, Irvine, Irvine, CA, [2]William Carey Univ. Coll. of Osteopathic Med., Hattiesburg, MS
Disclosure Block: **R. Columbres:** None.
Background: Inclusion Body Myopathy (IBM), associated with combinations of Pagetâ□□s Disease of the Bone (PDB), Frontotemporal Dementia (FTD) (IBMPFD), and amyotrophic lateral sclerosis (ALS) is a rare, autosomal dominant, adult-onset, progressive, and multisystem disorder caused by mutations in *VCP* gene. The disorder is characterized by progressive axial and proximal muscle weakness present in 90% starting in their thirties, Paget disease in 42% starting in their thirties, and FTD manifestations such as behavioral, cognitive and language impairment starting in their fifties, which is present in approximately 30% of individuals. Dual-energy X-ray absorptiometry (DEXA) is a gold standard for body composition measurements. It generates values for bone mineral densities (BMD), lean mass, and fat mass. The goal of this cross-sectional study of patients suffering from IBMPFD is to accurately detect differences in bone mineral density (BMD), bone mass %, lean mass %, and fat mass %: 1) at different stages of the myopathic disease 2) in subjects who additionally had Paget disease of bone, 3) to establish correlations between lean mass and bone mass.
Results and Conclusion: Our cohort included 19 subjects with IBMPFD (11 males, 8 females), three carriers, and six controls. Twelve (63.2%) had myopathy without Paget at a mean age of 53.8 Â± 9.4 (mean Â± SD), and mean disease onset of 43.3 Â± 9.1 (mean Â± SD). Seven (36.8%) had myopathy with Paget at a mean age of 49.0 Â± 9.2 (mean Â± SD), and mean disease onset of 39.2 Â± 6.9 (mean Â± SD). Within the myopathy-only group, 4 had osteopenia, and one had osteoporosis. One individual from each carrier, control, and myopathy with Paget groups also had osteopenia. We observed a significant inverse relationship between age and duration of disease with left hip T-score in the myopathy-only group. We found a statistically significant difference in the left hip scan BMD between myopathy-only and control groups. The myopathy-only group exhibited reduced lean mass % and increased total fat % compared to the control group. The myopathy with Paget group had increased T-scores and Z-scores in lumbar (L1-4) vertebrae compared to findings in other groups. Overall, DEXA is a useful method of evaluating BMD, total fat mass, and lean mass estimation in individuals with IBMPFD. Within the myopathy-only group, 33.3% had osteopenia, and 8.3% had osteoporosis. Interestingly, DEXA in individuals with Paget disease of bone showed increased density in the lumbar spine, a common area for Paget. DEXA showed that there was a reduction in lean mass and increasing fat with increasing age. A larger cohort would be needed to show its value in monitoring the progression of the disease.

PrgmNr 3776 - Identification of small and large variants in familial amyotrophic lateral sclerosis

View session detail

Author Block: **S. Chan Moi Fat**[1], E. McCann[1], L. Henden[1], K. Williams[1], D. Rowe[1,2], J. Fifita[1], I. Blair[1]; [1]Macquarie Univ. Ctr. for Motor Neuron Disease Res., Dept. of BioMed. Sci., Faculty of Med. and Hlth.Sci., Sydney, Australia, [2]Dept. of Clinical Med., Faculty of Med. and Hlth.Sci., Macquarie Univ., Sydney, Australia
Disclosure Block: **S. Chan Moi Fat:** None.
Amyotrophic lateral sclerosis (ALS; also known as Lou Gehrigâ□□s disease) is a devastating neurodegenerative disease, caused by the progressive loss of motor neurons in the brain and the spinal cord. To date, gene mutations remain the only proven cause of ALS, with more than 30 ALS genes identified. However, 90% of ALS cases (about 40% of familial and 90% of sporadic ALS) still have an unknown genetic cause. Most research in ALS has focused on small nucleotide level variants only. This project extends ALS gene discovery to also consider large structural variation by using bioinformatic pipelines to analyse whole genome sequencing (WGS) data for the identification of both small and large genetic alterations in a small ALS family that has limited power for traditional gene discovery methods.

WGS was performed on two affected individuals from a family with a history of ALS (MQ52). To identify single nucleotide variants and small insertion/deletions potentially acting as the pathogenic gene mutation causing ALS within this family, shared variant analysis using custom bioinformatics was carried out to filter for novel nonsynonymous and indel variants absent or extremely rare from publicly available control databases. Variants were validated using the Integrative Genomics Viewer and direct sequencing. To identify structural variants (SVs), we have developed a comprehensive pipeline which calls SVs from WGS data using multiple tools such as Manta, Lumpy and MetaSV. The tool Duphold, is then used to filter SVs based on quality scores, followed by SV annotation using Reciprocal Overlap Annotator and AnnotSV to generate a list of shared or overlapping between the two affected individuals in the family.

Initial analysis of family MQ52 identified a total of 14 small candidate variants (13 single nucleotide variants and one indel). Using the SV discovery pipeline, 80 novel/rare SVs (from a total of over 8000 total family SVs) were identified as potential causes of disease in this family, out of which 44 SVs lie in coding regions of the genome. This SV pipeline is still undergoing refinement and following further filtering resultant SVs will be validated in the lab using established PCR techniques.

Our gene discovery pipelines can successfully identify both small and large variants with the potential to cause disease within small ALS families. Identifying novel ALS variants has great potential to identify novel ALS genes and pathways, that could help with the development of future treatments. Given that SVs have been largely understudied in ALS, finding ALS-linked SVs could help to elucidate some of the missing genetic causes of ALS.

PrgmNr 3777 - Identification of X-linked missense variants in *TAF1* in 4 unrelated families with autism spectrum disorder (ASD)

View session detail

Author Block: **J. Lim**[1], Y. Qiao[2], K. Calli[2], S. Martell[2], S. J. M. Jones[3], S. W. Scherer[4,5], S. M. Lewis[2]; [1]Faculty of Med., Univ. of British Columbia, Vancouver, BC, Canada, [2]Med. Genetics, Univ. of British Columbia, Vancouver, BC, Canada, [3]Michael Smith Genome Sci. Disclosure Block: **J. Lim:** None.
TAF1 (TATA-Box Binding Protein Associated Factor 1) is an X-linked gene that encodes the largest component and core scaffold of the TFIID basal transcription factor complex. It plays an important role in neurodegenerative diseases and developmental delay. Recently, an increasing number of cases have been reported with the variants in this gene grouped as a new neurodevelopmental syndrome (TAF1/MRXS33 intellectual disability syndrome). The common clinical features appear early in life with hypotonia, facial dysmorphia, developmental delay, intellectual disability (ID) and/or autism spectrum disorder (ASD). We identified four X-linked variants in this gene (p.Asp1496Ala, p.Pro215Leu, p.Leu619Phe, and p.Gly1391Arg) in four boys from four unrelated Asian families (one of these is a mixed heritage Asian-white family). All of the boys are affected with autism spectrum disorder (ASD). Out of the four probands, one of them showed a more severe phenotype (Complex-5) while the other three had either Simple-1 or Simple-2 according to our phenotype semi-quantitative evaluation criteria. Interestingly, we noticed that the genomic location of the variant in the most severely affected patient was located in the hot region of the gene. This area is enriched with a higher number of reported pathogenic/likely pathogenic variants. A detailed genotype-phenotype correlation analysis will be summarized among our patients and published cases in the future. Finally, other variants in multiple strong ASD candidate genes were found in each of our cases, inherited from both parents. Our data suggest that different types and locations of the variants in *TAF1* genes, as well as the additive or epistatic roles of other variants from different ASD candidate genes might contribute to the diversity of phenotypes in this syndrome.

PrgmNr 3778 - Loss of function variants in DIP2C are associated with neurocognitive delays

The Disconnected (disco)-interacting protein 2 (DIP2) homologues, *DIP2A*, *DIP2B*, and *DIP2C*, are highly conserved and broadly expressed in the central nervous system of vertebrates. We present 5 females and 3 males with heterozygous variants predicting loss of function (LOF) in *DIP2C*. Four patients had *de novo* variants, one child had a nonsense variant inherited from a father with speech delays and two siblings had a nonsense variant inherited from a mother with speech delays. Patients were evaluated at 5-18 years and all manifest developmental delays, with ages of walking ranging from normal to 2.5 years and ages at first word from 13 months to 2 years. Four out of 8 patients had speech limited to single words at 5-10 years of age and attention deficit hyperactivity disorder (ADHD; 3/8), sensory integration disorder (1/8), hypotonia (2/8) and autism (1/8) were noted. Additional anomalies were relatively rare but included a triangular facial shape with a prominent forehead, thin hair with a high anterior hairline, strabismus and hearing loss. Deletion of *DIP2C* has repeatedly been observed with deletion of *ZMYND11* in 10p15.3 microdeletion syndrome that is characterized by global developmental delays, behavioral disturbances, dysmorphic features, brain anomalies, seizures and short stature. Although *ZMYND11* was considered the critical gene for this phenotype, mosaicism for a 67.6 kb deletion impacting *DIP2C* was reported in a patient with cerebral palsy and ADHD who was reported to be a â□□slow learnerâ□□, and a *de novo* frameshift variant in *DIP2C* was identified in a patient with autism. *Dip2c* was expressed in the brain of postnatal mice, and Dip2c$^{Î□2bp}$ mice that were homozygous for a two base pair deletion showed altered expression of genes associated with memory and neuropeptide signaling. We used the BrainSpan Atlas of the developing human brain to examine the expression of *DIP2C* from 8 post-conception weeks (pcw) to 40 years in neocortex and non-neocortex. Expression was highest in neocortex and non-neocortex from 10-24 pcw, although expression was present at all developmental stages. Cell-type specific enrichment analysis of *DIP2C* showed expression in all brain tissue subtypes. We targeted the zebrafish orthologues *dip2ca* and *dip2cb* using CRISPR/Cas9 but did not observe larvae with consistent morphological differences compared to controls although experiments to assess behavior in larvae with stable knockdown are ongoing. The loss of function variants in these patients and brain expression pattern of *DIP2C* support a role for this gene in neurocognitive function, although these families demonstrate that LOF variants may be inherited from parents with milder phenotypes.

PrgmNr 3779 - A mouse model recapitulating Bruck Syndrome provides insight into the role of *Plod2* in bone and cartilage

View session detail

Author Block: **A. Kot**[1], I. Duran[1,2], J. H. Martin[1], D. Wachtell[1], M. Weis[3], D. R. Eyre[3], J. Zieba[1], D. Krakow[1]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]Univ. of Malaga, Malaga, Spain, [3]Univ. of Washington, Seattle, WA

Disclosure Block: **A. Kot:** None.

Bruck Syndrome is an autosomal recessive form of osteogenesis imperfecta characterized by bone fragility, short stature, and joint contractures resultant from biallelic mutations in either the genes encoding *PLOD2* or *FKBP10*. *PLOD2* encodes LH2 which is a component of an endoplasmic reticulum (ER) complex involved in type-I collagen telopeptide hydroxylation. Bruck Syndrome has features distinct from other forms of osteogenesis imperfecta, such as joint contractures, with pathophysiology that is not well understood. Studies on a previously published *Plod2* knockout mouse were limited due to early embryonic lethality. To study the pathophysiology of musculoskeletal development in Bruck Syndrome, we generated a mouse model with a homozygous mutation identified in two independent families with recurrent fractures, scoliosis, and congenital contractures. The mutation, *Plod2* c.1559dupC predicting the amino acid change p.Val523Cysfs*7, was introduced using targeted homologous recombination. *Plod2* is alternatively spliced and translated into short (LH2a) or long (LH2b) isoforms. The c.1559dupC mutation is in exon 13A, specific to LH2b, and is predicted to lead to loss of the long form of the protein. *Plod2*$^{V523fs/V523fs}$ mice did not survive past P0. At E18.5, *Plod2*$^{V523fs/V523fs}$ mice were smaller, had bilateral forelimb and hindlimb contractures, and absent cervical spine curvature. LH2b mRNA was near absent in *Plod2*$^{V523fs/V523fs}$ mouse calvaria. LH2 protein levels in *Plod2*$^{V523fs/V523fs}$ osteoblasts were also decreased compared to wild type. Type I collagen C-telopeptide lysine residue hydroxylation was significantly reduced in *Plod2*$^{V523fs/V523fs}$ bone suggesting that crosslinking is negatively impacted, contributing to impaired bone properties. Compared to wild type, *Plod2*$^{V523fs/V523fs}$ growth plates showed increased length of the hypertrophic zone, increased hypertrophic chondrocyte volume, and diminished collagen production as detected by picrosirius staining suggesting a role for *Plod2* in chondrocyte development. This mouse model will aid in determining the function of *Plod2* in the musculoskeletal system and help uncover the molecular mechanisms underlying Bruck Syndrome.

PrgmNr 3780 - Expanding clinical and molecular evidence of *CYP26B1* involvement in retinoic acid catabolism defects

View session detail

Author Block: **K. C. Silveira**[1], I. Chacon Fonseca[2], O. ArtigalÃis[3], A. Iacovone[4], E. Campos[5,6], D. P. Cavalcanti[4], P. Kannu[1]; [1]Dept. of Med. Genetics, Univ. of Alberta, Edmonton, AB, Canada, [2]Clinical Genetics, Dept. of Oncology, Lakeridge Hosp., Oshawa, ON, Canada, [3]Clinical Genetics Unit, Children's Hosp., Grupo Hosp.ar ConceiÃ§Ã£o, Porto Alegre, Brazil, [4]Skeletal Dysplasia Group, Univ. of Campinas, Campinas, Brazil, [5]Genetics & Genome Biology program, Hosp. for Sick Children, Toronto, ON, Canada, [6]Dept. of Molecular Genetics, Univ. of Toronto, Toronto, ON, Canada

Disclosure Block: **K.C. Silveira:** None.

Homozygous missense variants in *CYP26B1* have been described in very few individuals with skeletal abnormalities. The P450 cytochrome CYP26B1 metabolizes retinoic acid (RA) in the developing embryo to tightly control RA levels and locally regulates signaling. The *CYP26B1* mutation phenotype ranges from a severe lethal presentation with skull defects, craniosynostosis, encephalocele, radiohumeral fusion, oligodactyly and a narrow thorax to a milder presentation described in an adult affected by craniosynostosis, radiohumeral joint limitation, hearing loss and intellectual disability. Here, we describe three novel *CYP26B1* variants in two unrelated families. Family 1 with two siblings affected by arachnodactyly, reduced radio-ulnar joint movement, conductive hearing loss and a mild to moderate learning disability. Craniosynostosis was not present in either sibling. In a second unrelated and consanguineous family, a lethal presentation in a female stillbirth with large hydrocephalus associated with generalized spina bifida occulta and poor mineralization of the whole skeleton and limb defects including oligodactyly was found. Whole exome sequencing of family 1 revealed two novel CYP26B1 variants in trans: c.353C>T (p.Pro118Leu) and c.701G>A (p. Arg234Gln). We hypothesize that these variants generate a protein with reduced enzyme activity and the degree of retained enzymatic activity drives phenotypic severity. However, further studies are still necessary to prove their pathogenicity. These siblings represent a milder *CYP26B1* phenotype when compared to previously described cases. In family 2, a novel homozygous point variant (c.1083C>A) was identified through Sanger sequencing of *CYP26B1*. In silico analysis suggested that the variant activates a cryptic splice site altering splicing. A minigene assay showed the variant leads to a deletion of part of exon 5 generating mRNA with a deletion of 21 amino acids (p.Val361_Asp382del). This deletion includes the ExxR motif and SRS-5 region, which are related to the stabilization of the meander loop and the maintenance of the CYP tertiary structure and the orientation of the substrate near the heme center, respectively. This deletion leads to the most severe clinical presentation so far. Taken together, we propose the phenotype associated with *CYP26B1* varies depending on the type of variant, although all are inherited in a recessive matter. Furthermore, we describe here the first patient associated with a splicing variant resulting in a severe and lethal phenotype. With their description, we add to the genotypic and phenotypic spectrum seen with defects of the catabolism of RA.

PrgmNr 3781 - FDXR Mitochondriopathy: The challenges of reclassifying variants of unknown significance in a newly described syndrome

View session detail

Author Block: **A. Lee**[1], L. Forero[2], J. Lenberg[3], M. Wright[4], L. Guidugli[4], R. R. Mardach[5]; [1]Univ. of California, San Diego, San Diego, CA, [23]Rady Children's Hosp., San Diego, CA, [4]Rady Children's Inst. for Genomic Med., San Diego, CA, [5]Rady Children's Hosp. of San Diego, San Diego, CA
Disclosure Block: **A. Lee:** None.
Recently emerging genetic technologies such as whole genome sequencing (WGS) have begun to uncover new and uncharted genetic changes, many of which have associations with previously described phenotypes. We present two affected family members found to have biallelic compound heterozygous missense Variants of Uncertain Significance (VUS) in FDXR identified by genome-wide sequencing. FDXR is associated with autosomal recessive Auditory neuropathy and optic atrophy (MIM: # 617717), but emerging evidence suggests an association with a yet unnamed mitochondriopathy syndrome encompassing a wide range of severity, which we have designated FDXR Related Neurodegenerative Infantile Optic Atrophy. Evidence for gene-disease association includes a cohort of over 20 individuals harboring missense variants, murine studies, in-vitro studies, and supports genotype-phenotype correlations. Notably, previously reported missense variants are located in regions of the gene where our probands' missense variants are also located, suggesting a potential important functional region. Variant reclassification is important for the genetic and medical community at large but also to patients who may not be able to access necessary surveillance, therapy, insurance coverage for further testing, supportive services, or parental prenatal or preimplantation testing without a definitive diagnosis. The ACMG has set forth evidence-based criteria for variant classification, but generating the evidence needed for reclassification in a timely manner is a difficult feat. Here, we provide additional evidence and an official designation for a newly described and rare syndrome involving variants in the FDXR gene. In addition, we detail steps taken towards providing a diagnosis for this family and expand upon the overall process of reclassification as an essential and impactful scenario which will continue to be increasingly common as access to genetic sequencing increases.

PrgmNr 3782 - Long-Chain Fatty Acid Oxidation Disorder Gene Variants Identified Through a Gene Panel Sponsored Program from Clinically Confirmed and Suspected LC-FAOD

View session detail

Author Block: **V. Rangel Miller**[1,2], T. Chettiath[2], B. A. Johnson[3], D. L. Marsden[2], J. L. Merritt[2], S. Sarafrazi[2], A. Willcock[3], N. Miller[4]; [1]Ultragenyx, Kirkland, WA, [2]Ultragenyx Pharmaceutical Inc., Novato, CA, [3]Invitae Corp., San Francisco, CA, [4]Ultragenyx, Brisbane, CA
Disclosure Block: **V. Rangel Miller:** Salary/Employment; Ultragenyx Pharmaceutical Inc.
Long-chain fatty acid oxidation disorders (LC-FAOD) are rare autosomal recessive conditions caused by defects in genes encoding mitochondrial enzymes that convert long-chain fatty acids into energy. Patients with LC-FAOD may have characteristic elevations in plasma acylcarnitine profiles, identified through newborn screening follow-up and through testing patients with ongoing clinical signs and symptoms. **Methods**: Patients in the US, Canada, and Mexico of all ages who have either a clinical diagnosis or suspicion of LC-FAOD with a confirmatory acylcarnitine test either ordered or performed are eligible for this no-charge genetic testing program. The next generation sequencing gene panel with copy number variant (CNV) detection includes the 6 genes associated with LC-FAOD (*ACADVL, CPT1A, CPT2, HADHA, HADHB, SLC25A20*) plus 18 additional genes associated with disorders that cause a similar acylcarnitine profile. **Results**: 283 patients have been tested as of May 12, 2021. Newborn screening results provided for 198 patients were as follows: 144 (73%) positive, 32 (16%) unknown, 22 (11%) negative; and confirmatory results provided for 165 patients were as follows: 39 (24%) positive, 98 (59%) inconclusive, 28 (17%) negative. Clinical signs reported for 82 patients demonstrated rhabdomyolysis and myopathy as most common among adolescents and adults (n= 46), while hypoketotic hypoglycemia and elevated creatine kinase were most common among younger patients (n= 36). Test results identified one or more LC-FAOD gene variant in 110 patients, including 54 variants of uncertain significance (VUS), 7 likely pathogenic (LP), and 41 pathogenic (P) variants. Results provided a positive diagnosis (P/P, LP/P, LP/LP) for 14 patients, and potential positive diagnosis (LP/VUS, P/VUS) for 16 patients. Variants were found in 14 additional non-LC-FAOD genes on the panel (*ACADM, ACADS, ACADSB, ETFA, ETFB, ETFDH, HADH, HMGCL, HMGCS2, MLYCD, NADK2, SLC22A5, SLC52A1, SLC52A3*), including 36 VUS, 6 LP, and 30 P. 4 patients had heterozygous variants in two or more LC-FAOD genes and 17 patients had heterozygous variants in a LC-FAOD gene and one or more non-LC-FAOD genes. 61 patients had only 1 LC-FAOD gene variant identified and 119 patients had no variants identified in any gene on the panel. **Conclusion**: Program results demonstrate the diverse composition of gene variants in this patient cohort and suggest the need for further approaches to resolve VUS variants and identify previously undetected variants in patients with suspected LC-FAOD.

PrgmNr 3783 - Novel heterozygous *OPA3* mutation in a family with congenital cataracts, sensorineural hearing loss and neuropathy, without optic atrophy

View session detail

Author Block: **M. Penon Portmann**[1], A. J. Kruse[2], J. So[1]; [1]Univ. of California, San Francisco, San Francisco, CA, [2]Univ. of Washington, Seattle, WA
Disclosure Block: **M. Penon Portmann:** None.
Autosomal dominant optic atrophy is caused by heterozygous pathogenic variants in *OPA3* (OMIM #165300), and is characterized by optic atrophy with cataracts, peripheral neuropathy and hearing loss (PMID: 1119193, 28050599). *OPA3* encodes a mitochondrial protein likely involved in the regulation of mitochondrial fission. To date, only ten pathogenic variants in *OPA3* have been reported. Here, we characterize the phenotype in a family with a novel variant in *OPA3* and notably without optic atrophy.Two probands with multiple affected relatives were assessed. Proband 1 is a 71-year-old male with bilateral congenital cataracts and bilateral sensorineural hearing loss, as well as tremor and distal sensorimotor polyneuropathy on electromyography (EMG) and nerve conduction studies (NCS). Proband 2 is the 27-year-old daughter of proband 1 with a history of bilateral sensorineural hearing loss, congenital bilateral cataracts, paresthesias in both distal lower extremities and tremor. Family history is remarkable for an autosomal dominant pattern of inheritance with multiple similarly affected family members.Clinical exome showed variants of uncertain significance (VUS) in *OPA3*, *DMPK*, *MYH14*, *TECTA* and *TTN*. Only the variants in *OPA3* (NM_025136:c.30G>C, p.Lys10Asn) and *DMPK* (NM_001081563:c.91G>C, p.Gly31Arg) segregated with 5 affected family members and were absent from 2 unaffected family members. The missense variant in *OPA3* is absent from gnomAD, with damaging *in silico* predictions, and occurring in a highly conserved residue, yet is not a previously reported pathogenic variant.The familyâ□□s clinical presentation has significant phenotypic overlap with previously reported cases of *OPA3*-related disorder, except for a notable lack of optic atrophy. Given the *DMPK* variant also tracks with affected individuals in the family, we cannot dismiss its significance, though no family members are reported to have myotonia or weakness, EMG/NCS in proband 1 was inconsistent with a myopathy and *DMPK* missense variants are not known to be associated with myotonic dystrophy. Our case broadens the clinical and genetic spectrum associated with *OPA3* mutations and highlights that optic atrophy is not an obligate feature of OPA3-related disorders.

PrgmNr 3785 - Recessive genetic risk factor for hemochromatosis is associated with damaging iron deposition in motor circuits of the human brain

View session detail

Author Block: **R. Loughnan**, J. Ahern, C. Tompkins, C. E. Palmer, W. Thompson, T. Jernigan, A. Dale, M. Boyle, C. Chieh Fan; Univ. of California, San Diego, La Jolla, CA
Disclosure Block: **R. Loughnan:** None.
Hereditary hemochromatosis (HH) is an autosomal recessive genetic disorder that leads to iron overload in the body causing oxidative damage to affected organs. HH type 1 appears to be predominantly associated with homozygosity for the mutation p.C282Y - with an odds ratio of 411 in men. Previous case studies have reported tentative links between HH and movement disorders, e.g. Parkinson's disease, and some have found abnormalities on brain magnetic resonance imaging (MRI) scans in regions related to movement (basal ganglia). Here we sought to investigate the impact of p.C282Y homozygosity by i) associating T2 intensity differences across all imaging voxels of the human brain (lower intensities indicate higher iron deposition) and ii) their associations with movement disorders within UK Biobank. For those with neuroimaging data (154 p.C282Y homozygotes, 595 matched controls), we found p.C282Y homozygosity was associated with signal profile changes that are consistent with substantial iron deposition in motor circuits of the human brain (basal ganglia, red nucleus and cerebellum; Cohen's d > 1 for differences in T2 intensities). Across the whole UK Biobank sample with qualified data (5,568 p.C282Y homozygotes, 496,968 controls), we found a significant enrichment for movement disorders in male homozygotes (OR (95% CI) = 1.82 (1.27-2.61), p=0.001), but not females (OR (95% CI) = 1.10 (0.69-1.78), p=0.71). This result is consistent with previous findings of higher disease burden for p.C282Y homozygote males vs females. Among the 31 p.C282Y homozygote males with a movement disorder only 7 had a concurrent HH diagnosis. This is of importance given the differences in treatments for HH vs movement disorders like Parkinsonâ□□s disorder. These findings suggest considering p.C282Y homozygosity as a risk factor for movement disorders in males.

PrgmNr 3786 - RNA-sequencing of tissue from family members identifies causal mutation in children

View session detail

Author Block: **R. Wang**[1], J. Woods[2], F. Barthelemy[3], E. D. DOUINE[4], C. Miceli[1], S. F. Nelson[5]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]Universit of California Los Angeles, Los Angeles, CA, [3]615 charles e young, los angeles, CA, [4]UCLA, Los Angeles, CA, [5]UCLA Med Ctr, Los Angeles, CA
Disclosure Block: **R. Wang:** None.
Duchenne muscular dystrophy (DMD, OMIM #310200) is a rare X-linked pediatric disorder characterized by progressive muscle weakness. The incidence is about 1:3,500 male births, making DMD one of the most common serious genetic diseases of childhood. DMD follows a well-defined progression beginning with delayed walking and muscle weakness in early childhood followed by loss of ambulation and full time wheelchair use around age 10. Death occurs by the second or third decade usually resulting from cardiorespiratory failure. The genetic cause of DMD is a defect in the massive 2.2Mb *DMD* gene which encodes the structural protein dystrophin. The most common mutations are exonic deletions (72%), duplications (10%), indels (5%), splice site mutations (3%) and point mutations (9%). Still, 2-5% of cases lack a molecular diagnosis. We present two cases of DMD - one with a known cause and the other unsolved despite standard genetic testing using multiplex ligation-dependent probe amplification and Sanger sequencing of *DMD* exons - where we identified the causal mutations by performing RNA-seq on needle biopsy samples taken from their mothers. In the case of the previously known mutation, we clearly observed a 1bp deletion in *DMD* exon 30 in roughly half the reads of the mother indicating biallelic expression across the muscle RNA-seq as expected. Since this is an X-linked gene subjected to X-inactivation, we are effectively observing the mixture of mutant and non-mutant DMD transcripts within the maternal muscle biopsy. This result matched the gene test results from a clinical lab on the affected son. The second case had strong suspicion of muscular dystrophy based on clinical course and high serum creative kinase. However, clinical testing was inconclusive, and by the time of evaluation, the patient had such severe muscle wasting in his 20s that no muscle biopsy could be reasonably obtained. RNA-seq analysis of the muscle biopsy from the mother identified a tandem duplication of the region between intron 44 and intron 63 of the *DMD* gene, which was confirmed as the causal DNA mutation (duplication of exons 45-63) in her son. Both carrier moms showed heterozygous expression of the mutation at the RNA level. In this context, using physiologically relevant tissue from family members enables a search by RNA-seq to identify mutations that affect mRNA and may be otherwise cryptic from DNA studies.

PrgmNr 3787 - Transcriptomic profiling of paired skeletal muscles from healthy donors using bulk RNAseq and snRNAseq to identify DMD susceptibility factors

View session detail

Author Block: **S. Nieves-Rodriguez**[1], F. Barthelemy[2], J. Woods[3], E. D. DOUINE[4], R. T. Wang[5], D. Scripture-Adams[1], K. Chesmore[1], M. Miceli[1], S. F. Nelson[6]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]615 charles e young, los angeles, CA, [3]Valley Children's Hosp., Madera, CA, [4]UCLA, Los Angeles, CA, [5]Univ California los Angeles, Los Angeles, CA, [6]UCLA Med Ctr, Los Angeles, CA
Disclosure Block: **S. Nieves-Rodriguez:** None.
In Duchenne Muscular Dystrophy (DMD), the absence of dystrophin results in a progressive and irreversible loss of skeletal muscle causing loss of ambulation (LOA). The age at LOA can be variable between patients independent of the causal variant, suggesting the existence of environmental and/or genetic disease modifiers. Furthermore, the disease process is characterized by differential progression of muscle groups indicating specific, but not yet elucidated, mechanisms of myofiber susceptibility of different muscles. Various muscular dystrophies have differential muscle group susceptibility. In DMD, vastus lateralis (VL) is affected earlier in the disease process relative to the tibialis anterior (TA), which is substantially relatively protected for years. Thus, querying for genes with differences at the whole tissue and/or single cell level between these differentially susceptible muscles should provide insights into epigenetic mechanisms in muscle development, and provide insights into disease susceptibility mechanisms more broadly. To observe differences between muscle groups, we performed paired core needle biopsies of TA and VL in healthy young adults (n=11). Using bulk RNA sequencing (RNAseq), we found that 2299 (of 18,254) genes are differentially expressed between paired healthy VL and TA. Strikingly supportive of a functionally relevant role in protection/susceptibility to damage from loss of dystrophin, 10 of 14 (71%) genes that are described DMD modifiers were identified among these genes. We found relatively higher expression of extracellular matrix (ECM) genes and lower expression of ribosomal processes genes in TA. Using single nuclei RNAseq from frozen tissue, we found different cell type proportions between TA and VL (n=3). Genes higher in TA in bulk RNAseq are localized to expression from fibroblasts, pericytes, endothelial cells and smooth muscle, and those higher in VL are more expressed from myofibers nuclei. Our findings suggest that the cell types that predominate in the production of ECM, such as fibroblasts (more abundant in TA), may be an important component of intrinsic muscle protection to dystrophy. Understanding molecular signatures underlying phenotypical heterogeneity across muscles is of importance to: i) better understand the inter- and intra-individual heterogeneity observed in muscular dystrophies, ii) develop treatments to mimic the intrinsic protection against disease observed in typically less affected muscles, with the goal of using them as complements to treatments to further preserve muscle integrity and function.

PrgmNr 3788 - Translating precision medicine into the world of speech-language pathology: First follow-up results of the proactive Babble Boot CampÂ© intervention in infants with classic galactosemia

View session detail

Author Block: **B. Peter**[1], J. Davis[2], L. Finestack[3], C. Stoel-Gammon[4], M. VanDam[5], D. Williams[5], N. Scherer[1], N. Potter[5]; [1]Arizona State Univ, Tempe, AZ, [2]Arizona State Univ., Tempe, AZ, [3]Univ. of Minnesota, Tempe, MN, [4]Univ. of Washington, Seattle, WA, [5]Washington State Univ., Spokane, WA
Disclosure Block: **B. Peter:** None.
Precision medicine is an active area of research and practice in medical fields such as cardiology and oncology, where known genotype-phenotype associations drive proactive and personalized management. Because genetic influences on disorders of spoken language are less well understood, principles of precision medicine are less commonly practiced in speech-language pathology. Here, we present preliminary results from the first clinical trial of a proactive treatment focusing on communication abilities in infants with classic galactosemia (CG). Diagnosed via newborn screening, this metabolic disease is caused by a recessively inherited disruption of the GALT gene. Among the most common traits are severe delays in speech sound production and expressive language, seen in ~60% of children with CG. Typically, speech and language skills cannot be measured until child age 2 to 3 years, precluding early identification and treatment. Because newborns with CG are at known predictable risk for these disorders, they are the ideal participants in a clinical trial of a proactive intervention.
Babble Boot CampÂ© (BBC) is the first comprehensive proactive intervention focusing on communication skills, beginning at age Of 12 children with CG who underwent the BBC, all had expressive language skills in the typical range at follow-up, and all but one had typical speech production skills. These findings are above expectation under random conditions (Fisherâ□□s exact p = .014 for speech and .002 for language). Of three untreated controls with CG, one had speech and language scores â□¤ 1st percentile, while two had typical scores in both areas. These findings are consistent with a beneficial effect of proactive behavioral management of symptoms of a genetic disease. A better understanding of the genetic influences on speech and language disorders may motivate more widespread use of proactive and personalized interventions in these disorders.

PrgmNr 3789 - A Clinicopathologic Study of Malignancy in VCP Associated Multisystem Proteinopathy

View session detail

Author Block: **A. Shmara**; UCI, Irvine, CA
Disclosure Block: **A. Shmara:** None.
Valosin containing protein (VCP) is an important protein with many vital functions mostly related to the ubiquitin-proteasome system that provides protein quality control. VCP-associated inclusion body myopathy with Paget disease of bone and frontotemporal dementia (IBMPFD) is an autosomal dominant disorder caused by mutations in the *VCP* gene on human chromosome 9. *VCP* mutations are also associated with amyotrophic lateral sclerosis (ALS), Parkinson's disease and Charcot-Marie-Tooth disease type 2. VCP has also been strongly involved in cancer, with over-activity of VCP found in several cancers such as prostate and pancreatic cancers, endometrial and esophageal carcinomas, and osteosarcoma. The overexpression of VCP has been associated with poor prognosis and increased metastasis, proving it valuable as a marker for the advancement of these cancers. The inhibition of VCP has been suggested as a treatment of metastasis in certain cancers. Since IBMPFD is caused by gain of function mutations in *VCP*, our hypothesis was that we would find an increased tendency of developing malignancies amongst our patients. We present cases of unusual tumors in patients with classic features of *VCP* associated disease including malignant peripheral nerve sheath tumor, anaplastic pleomorphic xanthoastrocytoma with multiple recurrences, thymoma as well as common cancers. These findings expand the phenotype of IBMPFD to potentially include unusual cancers and highlight the importance of *VCP* mutations in cancer development.

Purpose: To report the relative frequencies of childhood and early-onset glaucoma subtypes and their genetic findings, in a large single cohort.**Design:** Retrospective clinical and molecular study.**Participants:** All individuals with childhood glaucoma (diagnosed 0 to Methods: We retrospectively reviewed the referrals of all individuals with glaucoma diagnosed at Main Outcome Measures**:** The phenotype and genotype distribution of glaucoma diagnosed at Results**:** 290 individuals (533 eyes) with childhood glaucoma and 370 individuals (686 eyes) with early-onset glaucoma were referred to the ANZRAG. Primary glaucoma was the most prevalent condition in both cohorts. In the childhood cohort, 57.6% of individuals (167/290, 303 eyes) had primary congenital glaucoma (PCG) and 19.3% (56/290, 109 eyes) had juvenile open-angle glaucoma (JOAG). JOAG constituted 73.2% of the early-onset glaucoma cohort (271/370, 513 eyes). Genetic testing in probands resulted in a diagnostic yield of 24.7% (125/506) and a reclassification of glaucoma subtype in 10.4% of probands (13/125). The highest molecular diagnostic rate was achieved in probands with glaucoma associated with nonacquired ocular anomalies (56.5%). Biallelic variants in *CYP1B1* (n=29, 23.2%) and heterozygous variants in *MYOC* (n=24,19.2%) and *FOXC1* (n=21, 16.8%) were most commonly reported among probands with a molecular diagnosis. Biallelic *CYP1B1* variants were reported in twice as many female individuals as male individuals with PCG (66.7% vs 33.3%, P = 0.02). **Conclusion:** We report on the largest cohort of individuals with childhood and early-onset glaucoma from Australasia using the CGRN classification. Primary glaucoma was most prevalent. Genetic diagnoses ascertained in 24.7% of probands supported clinical diagnoses and genetic counselling. International collaborative efforts are required to identify further genes as the majority of cases still lack a clear molecular diagnosis.

PrgmNr 3791 - Deciphering the role of PTPN14 in BMP9 signaling and vascular malformations in Hereditary Hemorrhagic Telangiectasia

View session detail

Author Block: **D. T. Beleford**, O. Mamai, S. Basu, R. J. Akhurst; Univ California San Francisco, San Francisco, CA
Disclosure Block: **D.T. Beleford:** None.
Hereditary Hemorrhagic Telangiectasia (HHT) is a rare genetic condition characterized by multiple arteriovenous malformations (AVMs). AVMs may form in different organs including lung (PAVM), brain, liver, and skin. Catastrophic hemorrhage from visceral or cerebral AVMs may occur and are sometimes fatal. Most cases of HHT are caused by heterozygous loss of function variants in *ENG* (HHT1) or *ACVRL1* (aka *ALK1*) (HHT2), which encode endothelial receptors for TGF-Î²s and BMPs. Our group previously showed that single nucleotide polymorphisms (SNPs) in the genetic modifier *PTPN14* (protein tyrosine phosphatase, nonreceptor-type, 14, OMIM 603155) associate with PAVMs in both HHT1 and HHT2. The current study investigates the molecular genetics of interactions between *Eng* and *Ptpn14* during PAVM formation in HHT, in part by characterizing a novel conditional endothelial cell-specific knockout for *Ptpn14*. Our overarching hypothesis is that PTPN14 interacts with BMP9-Smad/Hippo-TAZ signaling pathways to stabilize blood vessels such that reduced expression or loss of *PTPN14* will potentiate the formation of AVMs under conditions of genetic loss of an *ENG* allele. To test this hypothesis, we will investigate the natural development of the retinal vascular network during the first seven days of life in a novel, conditional *Cdh5-Cre*^{ERT2}*.Ptpn14*$^{flox/flox}$ mouse line that, upon treatment with tamoxifen, activates cre recombinase to delete the *Ptpn14* gene specifically in endothelial cells. The novel mouse *Ptpn14*^{flox} allele co-expresses mCherry from the endogenous *Ptpn14* gene reporter before tamoxifen induced Cre-recombinase deletion, and eGFP from the gene promoter after deletion of *Ptpn14.* The characterization of this mouse line will be presented. Primary endothelial and microvascular mouse cell lines will also be developed for *in vitro* assessment of Ptpn14 binding partners, including Smads and Hippo pathway components. Ultimately, this study will impact on our understanding of the pathogenesis of vascular malformations and hemorrhage control in both HHT and other vascular conditions, and may provide novel insights into therapies for HHT.

PrgmNr 3792 - Genotype-phenotype correlations within type IV collagen glomerulopathy

View session detail

Author Block: **M. Elliott**[1], N. Vena[2], M. Marasa[1], A. G. Gharavi[3]; [1]Columbia Univ. Irving Med. Ctr., New York, NY, [2]Hammer Hlth.Sci. Building, New York, NY, [3]Columbia Univ, New York, NY
Disclosure Block: **M. Elliott:** Royalty(ies)/Honoraria; Otsuka Canada.
Type IV collagen glomerulopathy is the second most common cause of genetic kidney disease and is associated with a range of phenotypes. We assessed the phenotypic spectrum associated with type IV collagen variants in a cohort of 2465 kidney disease patients who underwent exome sequencing as part of a biobanking study. Multiethnic patients were recruited at Columbia University. Variants in *COL4A3, COL4A4* and *COL4A5* were interpreted per ACMG guidelines and modified per ClinGen Sequence Variant Interpretation Working Group and Savige *et al*. Patients were categorized as having a pathogenic/likely pathogenic (P/LP) variant or suspicious variant of uncertain significance (VUS). 128 patients with a variant in *COL4A3, COL4A4* or *COL4A5* were identified (5% of cohort) including 3 digenic and 8 compound heterozygote cases. 39% carried a diagnosis of Alport syndrome (AS), 16% focal segmental glomerulosclerosis (FSGS), 25% CKD of unknown cause, 9% thin basement membrane and the remaining 10% carry distinct clinical diagnoses. 75 cases had a kidney biopsy with 34 showing FSGS. Within the 21 cases presenting with a diagnosis of FSGS, 32 with CKD of unknown cause, and 34 with biopsy-proven FSGS, extra-renal symptoms of AS are present in 1, 4, and 6 and a suggestive family history was present in 4, 13, and 9 cases respectively. We identified 137 variants including 21, 34 and 52 P/LP variants and 10, 8 and 12 VUS in *COL4A3*, *COL4A4*, and *COL4A5*, respectively. Of the 108 P/LP variants: 75 missense, 3 nonsense, 16 frameshift, 14 splice-site. VUS covered all variant types except frameshift and truncating. Clinical features did not differ between cases with variants classified as P/LP or VUS. Cases with variants in *COL4A5* reached kidney failure at an earlier age than *COL4A3* or *COL4A4* (42 vs 65 vs 58 years, p=0.0003), but no differences were noted in hematuria, proteinuria, kidney transplantation and failure rates, hearing loss, ocular abnormalities, or a family history of the above. Digenic and compound heterozygote cases had similar rates of kidney failure as single variant cases (64% vs 47%, p=0.55). Frameshift variants associate with hearing loss, receiving a kidney transplant and developing kidney failure at a younger age compared to the other variant types, but other clinical features including kidney failure rate were similar. Clinical phenotype was similar across *COL4A3,4,5* genes. Frameshift variants associate with hearing loss and age of kidney failure. Many patients with an identified variant in *COL4A3, COL4A4* or *COL4A5* present with FSGS or CKD of unknown cause and lack extra-renal symptoms of AS or a concerning family history, showing the importance of genetic testing in these populations.

PrgmNr 3793 - Lower penetrance estimates for neurosusceptibility loci using an improved formula

View session detail

Author Block: **S. Goh**[1], R. Bowden[2], M. Pinese[3], E. Kirk[1]; [1]Sydney Children's Hosp., Sydney, Australia, [2]Monash Univ., Melbourne, Australia, [3]Unviersity of New South Wales, Sydney, Australia
Disclosure Block: **S. Goh:** None.
Introduction: Accurate penetrance estimates are important for diagnosing genetic conditions and providing prenatal advice. Penetrance has been defined as the proportion of individuals with a given genetic change who display a phenotypic change. However, we show that this definition is ambiguous and has led to a misunderstanding when applied to a mathematical formulation of Bayesâ theorem. As a result, penetrance estimates of many neurosusceptibility loci have been overestimated.
Methods: We provide a mathematical rationale for a more clinically-meaningful formula for estimating penetrance. We also identify that the background rate of intellectual disability is an important variable for the formula. Therefore, we use clinically-appropriate cohorts of individuals who have intellectual disability, rather than any disability, in our calculations.
Results: We show that penetrance estimates for most neurosusceptibility loci are markedly lower than previously published. Small 15q13.3 (*CHRNA7*) duplications are shown to have a penetrance of 0%. Others like 16p11.2 (*SH2B1*) distal duplications, 16p13.11 (*MYH11*) duplications, large 15q13.3 (*CHRNA7*) duplications and 17p13.3 (*YWHAE*) duplications, have a recalculated penetrance for intellectual disability of 1-5%, with a 95% confidence interval that may include 0%. Some higher penetrance estimates of 40% show a recalculated penetrance of approximately 10-15%.
Conclusion: Most neurosusceptibility loci have a lower penetrance than previously estimated. Many higher published penetrance estimates in previous works were based on a mathematical misunderstanding in the formulation of Bayesâ Theorem. This finding corrects a long-standing iatrogenic miscalculation of penetrance estimates for copy number variants and has significant diagnostic and counselling implications in both the prenatal and postnatal settings.

PrgmNr 3795 - Analytical performance of germline genome sequencing for clinical exome diagnostic testing

View session detail

Author Block: **N. Hammond**[1], P. Tong[1], D. Fisk[1], S. White[1], E. Spiteri[1,2], E. Ashley[3], S. A. Scott[1,2], Y. Yang[1,2]; [1]Clinical Genomics Lab., Stanford Hlth.Care, Palo Alto, CA, [2]Dept. of Pathology, Stanford Univ., Palo Alto, CA, [3]Stanford Ctr. for Inherited Cardiovascular Disease, Palo Alto, CA
Disclosure Block: **N. Hammond:** None.
Diagnostic panel and exome testing commonly employ target enrichment-based sequencing; however, germline genome sequencing has potential technical advantages, including relatively unbiased coverage, copy number and structural variant detection, and flexible interrogation of clinical regions of interest (ROI). In addition to diagnostic testing, genome sequencing will likely have potential utility for carrier screening, pharmacogenomic and polygenic risk score screening, and molecular karyotyping, among other applications. Given the potential utility of genome sequencing for clinical exome testing, we evaluated its analytical performance compared to enrichment-based exome sequencing. A commercial exome ROI was intersected with our novel clinical exome ROI, and the shared genomic region was utilized for performance evaluation across Genome in a Bottle (GIAB) reference material samples (n=5) that were subjected to both enrichment-based and genome sequencing with small variant (98% exome ROI coverage, which required a depth of >140X using enrichment-based sequencing. Compared to high-confidence GIAB truth sets, overall single nucleotide variant (SNV) recall and precision within the exome ROI were >99.8% for enrichment-based and genome sequencing. However, the accuracy for insertion/deletion (indel; 1-50 bp) detection was markedly enhanced by genome sequencing, as indel recall and precision within the exome ROI were 96.8% and 95.5% for enrichment-based sequencing, compared to 99.7% and 99.7% for genome sequencing, respectively. Moreover, genome stratification determined that SNV/indel accuracy was notably improved across GIAB-defined difficult regions that intersected the exome ROI, with recall and precision of 94.9% and 93.1% for enrichment-based sequencing, compared to 99.6% and 99.6% for genome sequencing. Genome sequencing across the exome ROI was also very robust, as the average SNV/indel inter- and intra-run, inter-instrument, and inter-flowcell non-reference genotype concordance was 98.5%. These results indicate that clinical diagnostic exome testing using genome sequencing has superior small variant calling compared to enrichment-based sequencing and strongly support the implementation of this technology when cost-effectiveness can be justified by clinical laboratories.

PrgmNr 3796 - Clinical validation of germline genome sequencing copy number variant confirmation using qPCR

View session detail

Author Block: **C. Reavey**[1], C. Ho[1], M. E. Grove[1], L. Villaneuva[1], L. Chen[1], K. Dumas[1], K. S. Weymouth[1], P. Tong[1], L. Gojenola[1], E. Spiteri[1,2], Y. Yang[1,2], S. A. Scott[1,2], W. Qiao[1,2]; [1]Clinical Genomics Lab., Stanford Hlth.Care, Palo Alto, CA, [2]Dept. of Pathology, Stanford Univ., Stanford, CA
Disclosure Block: **C. Reavey:** None.
Copy number variants (CNVs) are increasingly implicated in Mendelian genetic disorders and as risk alleles for complex diseases with incomplete penetrance, prompting their recent incorporation into diagnostic panel testing. In addition to microarrays and other hybridization-based technologies, germline CNVs can be inferred from short-read multi-gene panels, exome and genome sequencing by several publicly available bioinformatic algorithms. However, the accuracy and precision of sequencing-based CNV detection necessitates orthogonal confirmation for most clinical testing applications. To facilitate the implementation of genome sequencing-based diagnostic panel testing and CNV calling using Illumina DRAGEN pipeline (Manta and CNV Caller), we developed and validated a rapid and flexible quantitative polymerase chain reaction (qPCR) assay to confirm clinically significant germline CNVs identified by clinical genome sequencing. A total of 63 CNV control specimens and publicly available reference material samples characterized by orthogonal methods were included in this qPCR validation. The evaluated performance characteristics included accuracy, precision (repeatability and reproducibility), efficiency and linear range, reference interval (copy number range), analytical sensitivity, and analytical specificity. The qPCR assay employed the KAPA SYBR FAST qPCR kit with amplification performed on the LightCycler 480 instrument II, and data analysis using the 2-ddCt method. PCR efficiency and standard curves were evaluated (average R^2 >99.7), which enabled the definition of ratio ranges for germline copy numbers ranging from zero to four. Importantly, assessment of all CNV control specimens (deletions, duplications, triplications) by qPCR resulted in an analytical sensitivity, specificity, and accuracy of >99.9% across all interrogated autosomal and sex chromosome copy number values (0-4). In addition, the germline qPCR assay was very robust, as repeatability and reproducibility of copy number calling were completely concordant across triplicate testing (relative ratio standard deviation

PrgmNr 3797 - Detecting absence of homozygosity using high-resolution optical genome mapping

View session detail

Author Block: **A. R. Rao**, E. T. Lam, J. A. Velazquez-Muriel, D. Zhang, N. Miller, A. W. C. Pang, A. R. Hastie, A. Chaubey, M. Oldakowski; Bionano Genomics, San Diego, CA

Copy-neutral loss of heterozygosity (CN-LOH), which could be a result of uniparental disomy, is associated with meiotic errors resulting in developmental diseases. CN-LOH may also occur as a somatic event in several cancers. Events have traditionally been identified using microarray and microsatellite analysis. Optical genome mapping (OGM) has the potential to replace most of these traditional analyses. Using information about structural variant (SV) call zygosity, it is also possible to infer the absence or loss of heterozygosity (AOH/LOH). Here we describe a method for AOH analysis based on OGM results from the Bionano Genomics Saphyr platform. Regions of homozygosity are identified by a consistent decrease in heterozygous SV calls across a genomic region in the case sample compared to the level observed genome-wide in controls. DNA was processed on the Bionano Genomics Saphyr instrument and analyzed using the Bionano Solve pipeline. After filtering SV calls for high-quality, informative sites, AOH events were simulated by splicing together SV calling datasets from 153 controls and 4 haploid samples, where regions derived from haploid genomes represented AOH events. A Hidden Markov Model (HMM) was used to model the spatial dependence between neighboring SVs of a given zygosity, and the model parameters were estimated by fitting the model to the simulated dataset. Performance was evaluated on newly simulated samples and additional samples with known AOH/LOH events that were previously identified using microarray technology. In simulated data, our method achieved high sensitivity and precision in detecting large AOH regions typical of the sizes that underpin uniparental disomy, with 92% sensitivity and 97% precision, where true positives were defined as an overlap of 80% between simulated and predicted regions. Using a small cohort of samples with known AOH/LOH events, we have validated the utility of this method, and were able to detect high variant allele frequency events larger than 10 Mbp. Our results show that it is possible to detect AOH/LOH regions using OGM alone. Future developments incorporating additional data will greatly improve the resolution to reliably detect events of smaller size, and those with low variant allele frequency, which would expand the utility of the method to analyzing tumor samples. The software is available as part of the Bionano Access v1.7.

PrgmNr 3798 - Detection of *RHD*/*RHCE* hybrid genes using the Axiomâ¢ Universal Blood Donor Typing research array

View session detail

Author Block: **R. Varma**[1], M. Aguad[2], A. Roter[1], J. Schmidt[1], W. J. Lane[2], J. Gollub[1], on behalf of the Blood transfusion Genomics Consortium; [1]Thermo Fisher Scientific, Santa Clara, CA, [2]Brigham and Womenâ€™s Hosp. / Harvard Med. Sch., Boston, MA
Disclosure Block: **R. Varma:** Salary/Employment; Thermo Fisher Scientific.
Blood transfusion requires matching blood types between donor and recipient to avoid hemolytic reactions. The most important blood group systems are ABO and Rh. The Rh system includes five main antigens (D, C, c, E and e) which are encoded by the RHD and RHCE genes. These genes are highly homologous and inversely adjacent on chromosome 1p36.11. Hybrid RH alleles have evolved by replacements of RHD fragments with corresponding regions from the RHCE gene or vice versa. Detection of such hybrid genes is critical for accurate Rh antigen typing. The Applied Biosystemsâ¢ Axiomâ¢ Universal Blood Donor Typing (UBDT_PC1) research array has been designed to detect variants underlying erythrocyte, leukocyte, platelet, and neutrophil antigens. Detection of structural variants within RHD and RHCE is enabled using about 500 probesets interrogating mostly intronic sequences over the entire length of both genes. Measured probeset signal intensities are used to estimate copy number in defined regions. Copy number changes within each gene provide evidence of rearrangements and thereby enable hybrid gene detection. Cell line genomic DNA samples (N=270) from four HapMap populations were assayed on the UBDT_PC1 array. Several rearrangement events were detected with high reproducibility on the RHD and RHCE genes and were compared to high coverage Whole Genome Sequencing (WGS) data of 1000 Genomes Project (1000G) samples. Seven YRI (Yoruba in Ibadan, Nigeria) samples, including members of two families, showed copy number decreases over RHD exons 4 to 7 with normal diploid copy number states on flanking exons. In these same samples, copy number increases were detected in RHCE exons 4 to 7, indicating potential rearrangement events. These samples were confirmed as heterozygous or homozygous DIIIa-CEVS(4-7)-D by WGS, which is a D- allele (RHD*03N.01) found in African populations. One CHB (Han Chinese in Beijing, China) sample showed a copy number decrease over RHD exons 3 to 9 with a corresponding increase in RHCE. High coverage WGS data identified this individual as a D-CE(3-9)-D heterozygote type, which is a D- allele (RHD*01N.04) found in Asian populations. One sample with European ancestry showed a copy number decrease over RHCE exons 2 to 5 with a corresponding increase in RHD. This individual was identified as a novel CE-D(2-5)-D heterozygote by WGS. Other events indicative of the common C+ antigen RHCE*Ce or *CE allele have also been detected on the UBDT_PC1 array and confirmed by WGS. These results show that the Axiom array platform accurately detects complex structural variants of the RH genes and offers a promising approach for analyzing blood types in transfusion research applications.

PrgmNr 3799 - Identification of structural variants in constitutional disorders by optical genome mapping

View session detail

Author Block: **A. Pang**[1], H. Barseghyan[1,2], A. Hastie[3], A. Chaubey[1]; [1]Bionano Genomics, San Diego, CA, [2]Children's Natl. Res. Inst., Washington, DC, DC, [3]BioNano Genomics, San Diego, CA
Disclosure Block: **A. Pang:** Salary/Employment; Bionano Genomics.
Chromosomal structural variation contributes towards most constitutional genetic disorders. Karyotyping, fluorescence in situ hybridization (FISH) and chromosomal microarrays (CMA) are currently used in clinical cytogenetics and molecular diagnostics. CMA is the first line test recommended by the American College of Medical Genetics (ACMG), American Academy of Pediatrics (AAP), and America Academy of Neurology (AAN); however, the limitations of CMA include the inability to detect balanced translocations and inversions, and it cannot differentiate segmental duplication and repetitive regions of the genome.
Recent advances in chromosomal analysis with optical genome mapping (OGM) have the potential to address these shortcomings. Bionano Genomicsâ Saphyr platform images linearized, megabase-size, DNA molecules, labeled at specific sequence motifs in nanochannel arrays. Imaged molecules (>150kbp) are de novo assembled or aligned directly to the human genome reference for structural variant (SV) calling. OGM can detect germline SVs >500 bp in size, including repeat expansions (FMR1) and contractions (DUX4), balanced events, such as inversions, reciprocal translocations, and more recently, copy-neutral regions with absence of heterozygosity (AOH). SV population frequencies are estimated by comparison against a control database consisting of OGM samples from >26 populations with no reported disease phenotype.
OGM was applied to study the genomes of individuals with multiple constitutional disorders. Segmental duplication mediated deletions such as a 1.9 Mbp deletion in 7q11.23 (Williams-Beuren Syndrome), and a 3.7 Mbp deletion in 17p11.2 in (Smith-Magenis Syndrome). OGM also captured autosomal trisomies (+13 and +21), monosomy X, t(2;10) and t(9;21) translocations were all detected. In addition to SV detection, the chromosome structures of SVs, such as the location and orientation of duplications, can be elucidated by OGM, and these structures have been validated by FISH analysis.
In conclusion, OGM has the potential to identify a large range of SVs and to improve the characterization detected by conventional methodologies.

PrgmNr 3800 - Predicting Genes from Phenotypes using Human Phenotype Ontology (HPO) terms

View session detail

Author Block: **A. M. Slavotinek**[1], H. Prasad[1], T. Yip[1], S. Rego[1], P-M. Martin[1], J. van Ziffle[1], W. Devine[1], U. Hodoglugil[2], H. Hoban[1], M. Kvale[3]; [1]Univ California San Francisco, San Francisco, CA, [2]Genomic Med. Lab., UCSF, San Francisco, CA, [3]Inst. for Human Genetics, San Francisco, CA
Disclosure Block: **A.M. Slavotinek:** None.
The interpretation of genomic variants following exome sequencing (ES) can be aided by using HPO terms to standardize clinical features and predict gene relevance. The Pediatric arm of the P3EGS study at UCSF has performed ES on 474 probands and parents, largely from underserved populations. We studied patients who received pathogenic (P) or likely pathogenic (LP) variant results and ascertained 114 P or LP variants and corresponding genes. We used PhenoDB to manually extract HPO terms from a single clinical note and used Phen2Gene and the HPO terms to predict and rank the gene corresponding to each causative variant. Phen2Gene gene rankings were assigned to 6 rank classes, with class 1 covering ranks 1-10 and class 2 covering ranks 11-50. We found that the rank class was inversely correlated to the Phen2Gene gene score (p -16). Phen2Gene was able to rank the causative gene into rank classes 1 or 2 in just over 25% of cases. Most of the genes in rank class 1 were associated with well-characterized phenotypes, such as Noonan syndrome. We then examined the effects of patient and gene variables to affect the Phen2Gene scores and rank classes. A linear regression analysis showed a significant association between the number of years since the gene was first published with higher Phen2Gene scores (p -16; Bonferroni threshold p 0.5 was reported 9 or more years ago. There was a significant correlation between a higher number of OMIM terms associated with the gene and a higher score (p = 0.0011) and this relationship demonstrated a threshold effect, as only one gene with 0.5). The number of terms with an HPO hierarchal depth greater or equal to 11 was also statistically significant (p = $2.5x10^{-4}$), implying that terms deep in the HPO hierarchy had the best chance of producing a high scoring gene. Autosomal dominant inheritance of the gene and a diagnostic category of â□□ID with MCAâ□□ also trended towards a relationship with score but were not significant. Many causative genes were not highly ranked, possibly because of non-specific presentations, rarity of the gene, and inclusion of HPO terms distracting to the phenotype. We conclude that gene prediction using HPO terms and software tools may play a role in association with well delineated and distinctive clinical presentations, especially for established genes. The significant associations with Phen2Gene score for a higher number of OMIM terms and number of terms with HPO depth greater or equal to 11 suggests that pleiotropy, comprehensive phenotyping, and specificity of clinical terms may be important factors in successful gene prediction.

PrgmNr 3801 - Resolving complex pathogenic alleles using HiFi sequencing for long-range amplicon data with a new clustering algorithm

View session detail

Author Block: **J. Harting**[1], C. Heiner[2,1], I. McLaughlin[3], Z. Kronenberg[1]; [1]Pacific BioSci.s, Menlo Park, CA, [2]LA HONDA, CA, [3]Pacific BioSci.s of California, Inc., Menlo Park, CA
Disclosure Block: **J. Harting:** Salary/Employment; Pacific Biosciences.
Many genetic diseases are mapped to structurally complex loci. These regions contain highly similar paralogous alleles (>99% identity) that span kilobases within the human genome. Comprehensive screening for pathogenic variants amongst paralogous sequences is incomplete and labor intensive using short reads or optical mapping. In contrast, long-range targeted amplification and PacBio HiFi sequencing fully and directly resolve and phase a wide range of pathogenic variants without assembly or inference. To capitalize on the accuracy of HiFi data, we designed a new amplicon analysis tool, pbaa, which uses a newly developed sequence clustering algorithm to rapidly deconvolve (separate) a mixture of haplotypes, enabling precise diplotyping, and disease allele classification.
In this experiment, we analyzed two sets of gene-pseudogene systems, GBA and CYP, that are the second and eighth most common carrier disease alleles, respectively. Samples tested were selected from the Coriell catalog known to have pathogenic variants troublesome to test for with standard short-read assays. Co-amplified long-range PCR amplicons were generated for GBA (12 kb)/GBAP1 (15 kb) responsible for Gaucher disease, as well as CYP21A2 (10 kb)/CYP21A1P (8 kb) responsible for congenital adrenal hyperplasia. We obtained 7 samples to test the CYP21A2 region and 13 separate samples for GBA. HiFi reads were then generated from the amplicon libraries on both Sequel and Sequel II Systems, with replicated samples, to achieve a 24-sample multiplex for each target. Consensus amplicons were produced using pbAA and variants were determined using minimap2 alignments along with a custom SQL database for characterizing and reporting results. From these data we were able to accurately call all pathogenic variants in the test samples for all replicates, including whole-gene deletions, gene duplication, gene fusions, recombinant exons, and phased complex heterozygotes. In one trio affected by adrenal hyperplasia, three large structural variants were correctly and independently attributed to the parents and proband, including a duplication of CP21A1P and a CYP21A1P-CYP21A2 gene fusion in the mother and a CYP21A2 deletion in the father. This experiment demonstrates how PacBio HiFi data, analyzed with pbaa, simplifies targeted disease allele identification.

PrgmNr 3803 - Biallelic loss of function ATM due to pathogenic synonymous and novel deep intronic variant c.1803-270T>G identified by genome sequencing in child with ataxia-telangiectasia

View session detail

Author Block: **T. Maroilley**[1,2,3], N. A. M. Wright[3,4], C. Diao[1,2,3], L. MacLaren[2,3], G. Pfeffer[2,5], J. R. Sarna[5], P. Y. B. Au[2,3,6], M. Tarailo-Graovac[1,2,3,6]; [1]Dept. of Biochemistry and Molecular Biology, Cumming Sch. of Med., Univ. of Calgary, Calgary, AB, Canada, [2]Dept. of Med. Genetics, Cumming Sch. of Med., Univ. of Calgary, Calgary, AB, Canada, [3]Alberta Children's Hosp. Res. Inst., Univ. of Calgary, Calgary, AB, Canada, [4]Section of Pediatric Hematology-Immunology, Dept. of Pediatrics, Alberta Children's Hosp., Univ. of Calgary, Calgary, AB, Canada, [5]Dept. of Clinical NeuroSci.s and Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada, [6]contributed equally, Calgary, AB, Canada
Disclosure Block: **T. Maroilley:** None.
The majority of rare disease (RD) patients remain undiagnosed or partially diagnosed. Genome sequencing has the potential to explore non-coding regions and help increase the diagnosis. However, interpreting the pathogenicity of variants in non-coding regions is challenging. Ataxia-telangiectasia (AT) is a complex neurodegenerative RD characterized by progressive ataxia and movement disorder (chorea and dystonia), telangiectasias, immune defects and increased risk of malignancy. AT is caused by biallelic loss of function variants in *ATM,* which encodes a phosphatidylinositol 3-kinase that responds to DNA damage by regulating DNA repair and cell cycle control pathways. Here we report a child with progressive ataxia and chorea. A GeneDx clinical ataxia gene panel identified maternally inherited synonymous variant (NM_000051.3: c.2250G>A: p.Lys750=) but no second variant. The c.2250G>A variant was previously described to result in exon 14 skipping. Although AFP in this child was normal, chromosome analysis identified the presence of frequent t(7;14) and t(7;22) translocations, which was highly suggestive of AT. To identify the second variant in *ATM*, we performed genome sequencing. We discovered a deep intronic variant (NM_000051.3: c.1803-270T>G) inherited from father. Transcript analyses revealed that c.1803-270T>G variant results in aberrant splicing and the inclusion of 56 base-pairs of intron 11. *In silico* tests predict that this causes a premature stop codon, suggesting likely non-functional ATM. Exon 14 skipping due to the maternal synonymous variant was also confirmed. Functional analyses by DNA damage repair assessment in lymphocytes in blood by flow cytometry (DDRFL; Nationwide Children's) revealed substantial decrease in pATM, pSMC1 and gamma H2AX in T, B and NK cells at 1h post-irradiation with 2Gy. Furthermore, persistence of gamma H2AX 24hr post-radiation was indicative of impaired DNA double-strand break repair, consistent with abnormal pATM function. Together, these analyses confirmed biallelic functional loss of ATM. The unanticipated finding of compound heterozygosity for a synonymous and a deep intronic variant further highlights the power of genome sequencing in reducing missing heritability by enabling consideration of more complex genetic mechanisms when diagnosing RD patients. Importantly, even though a clinical diagnosis of AT was highly suspected here, identification of the second variant not only confirmed the diagnosis for the child but also has significant clinical implications for the detection of carriers, who are at risk for cancer predisposition and require preventative surveillance and management.

PrgmNr 3804 - End ALS Kaggle challenge: Insights from aberrant transcriptome analysis

View session detail

Author Block: **M. Celik**[1], F. Brechtmann[2], J. Gagneur[3], F. HÃ¶lzlwimmer[4], M. MÃ¼eller[4], X. Xie[1], V. YÃ©pez[4], M. Zech[5], N. Wagner[4]; [1]UC Irvine, Irvine, CA, [2]Technical Univ. Munich, Munich, Germany, [3]Technical Univ. of Munich, Garching, Germany, [4]Technical Univ. of Munich, Munich, Germany, [5]Munich, Germany

Disclosure Block: **M. Celik:** None.

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative neuromuscular disease with poor survival prognosis and no cure. To progress in our understanding of ALS, Answer ALS, EverythingALS and Roche Canada's Artificial Intelligence Centre of Excellence initiated an AI modeling challenge via the platform Kaggle providing participants with genetic, transcriptome and phenotypic data of 138 ALS patients and 32 controls. We present here the winning analysis to the challenge task 1 (One mechanism of action or multiple independent mechanisms of action?).

Given the heterogeneity of genetic causes of ALS, we assumed that no single gene or pathway would collectively explain all cases. Therefore, we developed an approach focusing on discovering aberrations that could be specific for a single or a few cases. To this end, we first identified expression outliers using OUTRIDER, a denoising autoencoder that we previously adapted to work with RNA-seq data. To ensure that the outliers are driven by genetics, we filtered them down to genes that carried rare genetic variants likely disrupting gene expression (VEP high and moderate impact, MMSplice and SpliceAI). This analysis yielded 109 genetically-supported outlier genes.

Among these, three genes (NEK1, OPTN, SPG11) corresponded to catalogued ALS mutations or known ALS genes, supporting the validity of the approach and possibly yielding a more detailed genetic diagnosis of those patients. We then searched for new ALS genes using a two-fold strategy. First, we considered genes functionally linked to established ALS genes by applying network diffusion on the STRING gene network. This revealed 16 genetically-supported outliers which are functionally linked to ALS genes or are well established disease genes. Second, we asked whether new potential pathways would emerge as clusters of functionally related genetically-supported outliers. This second analysis revealed gene groups that are members of nucleopores, kinetochores, DNA repair and machinery, as well as ribosomal RNA biogenesis.

In conclusion, our main results include:

- variants associated with aberrant expression for known ALS genes, potentially characterising those affected patients
- new high impact variants in further cases in a gene potentially related to ALS, which would improve our catalogue of pathogenic variants
- new candidate genes in known pathways
- new candidate pathways
- methodological showcase of combining expression outlier and network diffusion analysis to genetic predisposition analysis

Our submission and notebook is accessible at tinyurl.com/xh9jr8kt.

PrgmNr 3805 - Establishing a platform for the functional study of oligogenic novel ALS genes

View session detail

Author Block: **S. Wu**[1], J. A. Fifita[2], S. Yang[1], I. P. Blair[3]; [1]Macquarie Univ. Ctr. for Motor Neuron Disease Res., Sydney, Australia, [2]Macquarie Univ., Sydney, Australia, [3]Macquarie Univ, Sydney, Australia

Disclosure Block: **S. Wu:** None.

Amyotrophic lateral sclerosis is a deadly neurodegenerative disease with a genetic basisâ□□the disease is monogenic in 60% of ALS families. The remaining unsolved ALS families do not exhibit classical Mendelian inheritance patterns and are thus challenging to solve via traditional genetic analyses alone. We have developed an *in vitro* functional pipeline using cells transiently expressing each candidate gene variant to prioritize individual candidates based on their capacity to induce known ALS cellular pathology. This pipeline was applied to five candidate gene variants in an ALS family negative for known ALS-causative gene mutations. Of the five, two candidates exhibited strong potential for ALS pathogenicity. Interestingly, the genomic proximity of these two candidate genes suggest that they are likely co-inherited, and potentially produce oligogenic disease effects. This refers to when two or more gene mutations are required for pathogenicity. Although oligogenicity has been implicated in ALS, rapid reliable functional screens are sorely lacking. To investigate the compound effect of both candidates, we attempted to apply our *in vitro* pipeline to cells transiently co-expressing both candidate variants. Unfortunately, low co-transfection and -nucleofection efficiencies necessitated a strategy change. Thus, we sought to express both candidates from a single vector. To accommodate the large size of one candidate gene, we designed a multicistronic vector using two 2A peptide sequences derived from the *porcine teschovirus-1* and *thosea asigna* viruses, which allows candidate gene expression at an equal ratio. Preliminary results showed that co-transfection efficiency dramatically increased and that the spatial-temporal expression pattern of each candidate gene remained consistent with previous findings. We have successfully prioritized two novel candidate ALS genes, and developed a promising molecular platform for the functional study of oligogenicity in ALS that allows the continued application of our *in vitro* functional pipeline in our novel gene discovery strategy. These genes will be further investigated first in zebrafish to provide *in vivo* support for their roles in ALS before progressing to mice models. Disease gene discoveries not only drive our understanding of the mechanisms underlying ALS but also offer fresh diagnostic and therapeutic targets.

PrgmNr 3806 - High-throughput classification of pathogenic *SLC6A1* variants

View session detail

Author Block: **M. Trinidad**, S. Froelich, G. Berguig, W. Wallace, J. H. LeBowitz, K. Estrada, A. Wuster; BioMarin Pharmaceutical, San Rafael, CA
Disclosure Block: **M. Trinidad:** Salary/Employment; BioMarin Pharmaceutical.
Protein-coding variants in *SLC6A1* are associated with early onset epilepsy, autism and schizophrenia. *SLC6A1* encodes the GABA transporter GAT1 and is expressed at the synapses of GABAergic neurons. The primary function of neuronal GAT1 is to re-uptake the inhibitory neurotransmitter GABA from the synaptic cleft in order to sustain its synaptic concentrations. Recently, variants in *SLC6A1* have been associated with a spectrum of epilepsy syndromes and neurodevelopmental disorders.
Pediatric patients present with seizures, neurodevelopmental delay, autism-like behaviors and other neurological and developmental symptoms. The average age of onset of seizures is 3.7 years. *De novo* mutations in *SLC6A1* have also been associated with schizophrenia. Schizophrenia patients with *SLC6A1* mutations are typically diagnosed in early adulthood and do not present with the symptoms seen in pediatric patients.
Although advances in genomic sequencing have enabled aggregation of patient variants and observed clinical manifestations, the functional impact of many of the disease associated variants remains unknown. Experimental characterization remains a valuable method for validating the impact of variants. Here, we present a high-throughput cellular assay to determine the functional impact of more than 180 *SLC6A1* missense-variants on GABA transport. Of those, 88 are seen in epilepsy or neurodevelopmental delay patients and 13 in schizophrenia patients. The remaining mutations are rare variants of unknown significance (VUS).
To expand the understanding of the genotypic and phenotypic spectrum of the disorder, we quantified GABA uptake activity using plasmid expression constructs for each missense variant with HEK293T GAT1-knockout cells. Cells were incubated with deuterated GABA, then analyzed by mass spectrometry to assess GAT1 transporter activity. While the screen is ongoing, our preliminary results find this method to be highly concordant with variant activities previously reported in the literature. These results will allow us to classify variants based on activity to generate a more accurate estimate of the prevalence of *SLC6A1*-associated disorders, and to better understand the molecular biology of *SLC6A1*-associated conditions. The acquired knowledge will help guide therapeutic decisions and enable the development of targeted therapies that enhance transporter function and improve symptoms.

PrgmNr 3807 - Immune cell specific epigenetic and regulatory mapping of variants associated with multiple sclerosis in hispanic populations

View session detail

Author Block: **S. Cruz-Gonzalez**[1], H. Bai[2], A. H. Beecham[3], K. Miskimen[2], C. Manrique[3], W. F. Hulme[4], A. J. Griswold[3], J. McCauley[3], W. S. Bush[5]; [1]Univ. of California, San Francisco, San Francisco, CA, [2]Case Western Reserve Univ., Cleveland, OH, [3]Univ. of Miami, Miami, FL, [4]Univ. of Miami Miller Sch. of Med., Miami, FL, [5]Case Western Reserve Univ, Cleveland, OH
Disclosure Block: **S. Cruz-Gonzalez:** None.
Multiple Sclerosis (MS) is a chronic, autoimmune disease that affects the central nervous system (CNS). MS affects individuals of all ages and often involves periodic â□□attacksâ□□ that severely damage the CNS causing permanent damage. The disease affects approximately 2-3 million individuals worldwide, with prevalence varying by a countryâ□□s economic status. Notably, the prevalence of MS among Latin American individuals has been reported to be increasing in the last decade. Thus, it is essential to generate actionable molecular insights about this disease that can benefit these individuals. Presently, mechanistic understanding for MS is lacking, but previous studies have found MS has a genetic component that includes the major histocompatibility complex (MHC) and 200 single nucleotide polymorphisms (SNPs) outside the MHC. These associated MS variants were discovered almost exclusively in individuals of European ancestry. Functionally, these SNPs have been found to induce regulatory changes to immune cells (e.g.: T cells and Myeloid cells) which have also been associated with the development of MS. While these genetic aspects of MS are well-studied in patients of European descent, their influence on Latin American individuals has not been examined. As a demonstration of approaches that can be used to fill this research gap, we have recruited 9 Puerto Rican MS patients for functional genomics assays. Both whole blood samples and sorted CD4+ T-cells, CD8+ T-cells, and CD33+ monocytes were processed to produce three types of data: genotypes, whole-blood, and sorted-cell RNA-seq, and sorted-cell ATAC-seq. We found that 57 of the 200 MS risk SNPs were present in the Puerto Rican samples (MAF > 1%), with a mean Odds Ratio (OR) of 1.14. We next investigated if any of these SNPs overlapped chromatin accessibility peaks that were significantly associated with an increase in local gene expression (p TNFRSF9 (peak = 6330140-6343170, p = 0.00303), *PPP4C* (peak = chr16: 30085590- 30098400, p = 0.04236), and *CDC14A* (peak = chr1: 100943510- 100955300, p = 0.04198). In conclusion, our functional genomics approach has provided a pioneering overview of the molecular landscape of MS in Puerto Rican individuals, which is a proof of concept for future multi-omics studies of diseases with genetic components in admixed individuals.

PrgmNr 3808 - Paternal allele of origin, radiosensitivity and the effect of genetic modifiers on the 3q29 Microdeletion Syndrome phenotype

View session detail

Author Block: **N. Kopp**[1], J. C. Hodge[2], A. D. Besterman[3], A. Eskin[1], K. M. Squire[1], M. J. Dasouki[4], N. Di Donato[5], R. A. Gatti[6], S. F. Nelson[7], J. A. Martinez-Agosto[8], F. Quintero-Rivera[9]; [1]UCLA, Los Angeles, CA, [2]Indiana Univ., Indianapolis, IN, [3]Rady Children's Hosp. / Univ. of California San Diego (UCSD), San Diego, CA, [4]AdventHlth.Med. Group Genomics and Personalized Hlth., Orlando, FL, [5]Faculty of Med., TU Dresden, Dresden, Saxony, Germany, [6]UCLA Sch. of Med., Los Angeles, CA, [7]UCLA Med Ctr, Los Angeles, CA, [8]Univ California Los Angeles, Los Angeles, CA, [9]Sch. of Med., Univ. of California Irvine (UCI), Orange, CA

Disclosure Block: **N. Kopp:** None.

The 3q29 microdeletion syndrome is a heterogeneous disorder. The cause, a recurrent heterozygous genomic loss spanning approximately 1.6 Mb, likely arises through non-allelic homologous recombination mediated by multiple sets of flanking low-copy repeats. Even within patients of the same deletion size, the phenotype is quite variable, with features that are not specific or clinically diagnostic. The association of psychiatric phenotypes with the 3q29 microdeletion syndrome was first reported in 2010 by Quintero-Rivera and Martinez-Agosto (PMID: 20830797), based on 26 published cases. Since then, more patients have been described with complex psychiatric phenotypes, including autism, bipolar disorder, schizophrenia, attention deficit hyperactivity disorder and depression. Previous studies have reported variants in the *DGL1, SLC51A, and TCTEX1D2* as potential modifiers. Furthermore, recessive loss-of-function mutations in *RNF168*, another gene located in the deleted region, are associated with RIDDLE, a radiosensitivity, syndrome. We performed trio exome sequencing of six patients (3M/3F/Caucasian/Latino/Asian) with 3q29 microdeletion in an effort to identify alterations in their genome, specifically on the remaining allele suggesting a recessive mechanism potentially associated with psychiatric phenotypes. The parent of origin of the deleted allele was determined. Radiosensitivity testing (Colony Survival Assay and Western blot) was also performed on the probandâ□□s lymphoblastoid cell lines to determine the impact of hemizygosity for the *RNF168* gene. We demonstrated that hemizygous disruption of *RNF168* does not affect radiosensitivity. Exome sequencing revealed a range of 35-160 variants in the remaining undeleted 3q29 locus . No additional rare pathogenic variant in a known disease gene was identified. We summarize the 113 variants detected in the deleted region that overlap all cases in this study. Of the variants previously reported, two were identified in our cohort: rs1134986, a missense variant in *DLG1* (NM_001204387: c.485G>A:p.R162Q,(n=1/6)), and rs939885, a variant in *SLC51A* (NM_152672: c.604G>A:p.V202I (n=2/6)), with an allele frequency of 15% and 48%, respectively, suggesting that these are most likely benign polymorphisms. In addition, the SNP data on the remaining allele revealed that the parental allele of origin of the deletion in five of six cases is the fatherâ□□s allele.

PrgmNr 3809 - Rapid Identification of Genetic Factors Contributing to Autism Spectrum Development with Disproportionate Megalencephaly in a Model System

View session detail

Author Block: **S. Nishizaki**[1], C. W. Nordahl[1], D. G. Amaral[1], M. Y. Dennis[2]; [1]Univ. of California Davis, Davis, CA, [2]Univ. of California, Davis, Davis, CA
Disclosure Block: **S. Nishizaki:** None.
Among autism spectrum development (ASD) individuals some of the worst prognoses come from comorbidity with accelerated brain growth, known as disproportionate megalencephaly (DM). However, little is known about the genetic factors contributing to ASD-DM. In this study we identified de novo variants potentially contributing to ASD-DM using trio and quad whole genome sequencing data from the MIND Instituteâ□□s Autism Phenome Project (APP) and Simonâ□□s Simplex Collection (SSC) cohorts. Through this analysis we have identified multiple genes previously associated with ASD, including *PAX5*, *SCP2*, and *ADCY5*. We are now examining the consequence of these proband loss-of-function variants on head-size phenotypes by generating knockout zebrafish using CRISPR gene-editing technology of the genes we identified as putatively associated with ASD-DM. Here, we demonstrate the utility of the VAST BioImaging System to rapidly image knockout zebrafish of a known macrocephaly-associated gene, *wdfy3*. We hope to quickly identify novel ASD-DM associated genes to further advance the identification of relevant disease pathways, potential genetic therapy targets, and early detection markers in ASD-DM.

PrgmNr 3810 - Regulating translation of the *GJB1* 5' UTR

View session detail

Author Block: **B. Grosz**[1], J. Svaren[2], G. Perez-Siles[1], G. A. Nicholson[3], M. L. Kennerson[1]; [1]ANZAC Res. Inst., Concord, Australia, [2]Univ. of Wisconsin-Madison, Madison, WI, [3]Molecular Med. Lab., Concord, Australia

Disclosure Block: **B. Grosz:** None.

Mutations of *GJB1* coding and non-coding regions cause the second most common form of Charcot-Marie-Tooth neuropathy, CMTX1. The non-coding *GJB1* c.-103C>T mutation [chrX:71,223,249 (hg38)] is in exon 1b of the *GJB1* P2 5â□□ untranslated region (5â□□ UTR) and has been reported to cause CMTX1 in multiple unrelated families. *GJB1* c.-103C>T is in an evolutionarily conserved region that is flanked by two non-pathogenic SNPs, c.-109C>T (rs746618959) and c.-102G>A (rs753207004). To investigate whether the c.-108_-103 region is a regulatory element that may be disrupted by *GJB1* c.-103C>T, a suite of luciferase constructs was generated. The *GJB1* neural-specific P2 promoter and 5â□□ UTR was inserted upstream of the firefly luciferase (FLuc) gene in the pGL4 vector, and the *GJB1* 3â□□ UTR was inserted downstream of the FLuc gene. *GJB1* c.-103C>T and *GJB1* c.-108_-103del were then introduced separately into the *GJB1*-pGL4 vector. These vectors were separately transfected into the RT4 rat Schwann cell line, using the pRLuc-TK vector as a transfection control. Relative expression was assessed by determining the ratio of FLuc:RLuc for *GJB1*-pGL4 vectors containing *GJB1* c.-103C>T and *GJB1* c.-108_-103del and comparing this to FLuc:RLuc ratios from the wild type *GJB1* vector and an empty pGL4 vector. The *GJB1* c.-108_-103del construct resulted in a 46% decrease (M=0.54, SD=0.19) in FLuc expression when compared to the wild type *GJB1* construct (p=.014). The *GJB1* c.-103C>T mutation resulted in an 88% decrease (M=0.12, SD=0.02) in FLuc expression when compared to the wild type *GJB1* construct (p<.00001 although>GJB1 c.-108_-103del resulted in a significant decrease in expression, it remained significantly different to the c.-103C>T mutation (p=.019). While this region may represent an important *GJB1* regulatory element, the loss of expression due to the *GJB1* c.-103C>T mutation should be investigated further so that a suitable therapeutic approach can be developed.

PrgmNr 3811 - Transcriptome analysis provides insights into the possible function(s) of *SPATA5L1*

View session detail

Author Block: **S. Shetty**; Univ. of Arizona, Phoenix, AZ
Disclosure Block: **S. Shetty:** None.

SPATA5L1 is a paralog of SPATA5 (spermatogenesis associated 5). Autosomal recessive mutations in SPATA5 has been associated with intellectual disability, sensorineural hearing loss (SNHL), movement disorders and epilepsy. GWAS studies have associated multiple SNPs on SPATA5L1 with chronic kidney disease but none with neurological symptoms. This study was conducted with the help of GeneMatcher and reports 28 unique SPATA5L1 variants in 47 affected individuals with neurological findings in 25 patients (18 families). Exome sequencing, neuroimaging and RNA-Seq was performed on this multi-center cohort. 25 of these variants were present in a compound heterozygous form, three were homozygous variants and all variants were rare or absent in gnomAD. Most of these patients demonstrated either spasticity (17/25, 68%) or dystonia (15/25, 60%) or a combination of both (13/25, 52%). There was significant to profound cognitive impairment in these patients. Microcephaly (13/25, 52%) and facial dysmorphism (9/25, 36%) was also observed. Neuroimaging showed reduced cortical volume, periventricular leukomalacia, widened Sylvian fissures and hypoplastic corpus callosum. 22/47 individuals with biallelic SPATA5L1 variants showed isolated sensorineural hearing loss (SNHL) and all these individuals were of Ashkenazi Jewish descent. Principal component analysis of transcriptomic data generated from fibroblast cell lines was able to discriminate SPATA5L1 affected individual from unaffected controls, with the first two principal components explaining 54% of the variance. Over-representation analysis (ORA) of significantly down-regulated genes showed clustering for Gene Ontology (GO) terms in mitosis (mitotic spindle organization, sister chromatid segregation), DNA replication (DNA conformation change, single stranded DNA binding, DNA helicase activity) and adhesion receptors, which connect cell-substrate junctions and include fibronectin-binding, integrins, cadherins, and immunoglobulin superfamily members. We thus present the first reported pathogenic variants in SPATA5L1 associated with a mixed/complex neurological phenotype, spastic-dystonic cerebral palsy, and/or SNHL from unrelated families. This study provides insights into the role of SPATA5L1 in auditory perception and brain development.

PrgmNr 3813 - Comprehensive survey of the functional impact of SNP accessible variants in *PSAT1* using a high throughput yeast assay

View session detail

Author Block: **M. Xie**[1,2], G. A. Cromie[1], R. Lo[1], K. Owens[1,2], N. J. Kutz[2], R. N. McLaughlin[1], A. M. Dudley[1]; [1]Pacific Northwest Res. Inst., Seattle, WA, [2]Univ. of Washington, Seattle, WA
Disclosure Block: **M. Xie:** None.
Loss of function mutations in genes of the serine biosynthesis pathway (*PHGDH*, *PSAT1*, and *PSPH*) cause a set of rare, autosomal recessive diseases known as Neu-Laxova syndrome (NLS) or serine deficiency disorders. The phenotypic spectrum of these inborn errors of metabolism includes severe neurological symptoms, failure to thrive, and lethality. However, timely detection of pathogenic variants can have an enormous, positive impact on patient health. Prenatal and postnatal supplementation with serine and glycine can ameliorate, and in some cases, completely prevent the onset of symptoms. To aid variant annotation for this rare and devastating disease, we developed a yeast â□□surrogate geneticsâ□□ assay in which the highly conserved human protein coding sequence for the second enzyme in the pathway, phosphoserine aminotransferase (PSAT1), functionally replaces the deletion of its yeast ortholog (*SER1*). In this assay, yeast growth in the absence of serine provides a quantitative readout of the human enzymeâ□□s function. Previous work from our group demonstrated that results from this assay agree well with clinical annotations and the disease literature. Here, we extend that analysis to present quantitative results for the functional impact of >80% (n=1986) of all single nucleotide polymorphism (SNP) accessible *PSAT1* missense variants. Our approach leverages the availability of low-cost, large-scale gene synthesis and the development of high-throughput in vivo assays of protein function (Multiplexed Assays of Variant Effect, MAVEs) in the model organism, *Saccharomyces cerevisiae*. We will discuss the extent to which these results agree with a set of recently published pathogenic variants and the spectrum of Variants of Uncertain Significance (VUS) that have been detected in the human population. We will also present our results in the context of the published PSAT1 crystal structure. Taken together, our work provides an example of the ways in which large-scale functional assays in model systems can be powerfully applied to the study of rare diseases.

PrgmNr 3814 - Development of multiplex synthetic positive controls for an expanded *CFTR* mutation testing

View session detail

Author Block: **T. E. Angeloni**[1], S. Rosenthal[1], R. E. Nakles[1], A. Gerasimova[2], D. Root[1], Y. Liu[1], H. K. Chong[1], K. Kazmierkiewicz[1], D. Xu[1], A. Bhattacharya[3], R. Owen[1], F. L. Lacbawan[4]; [1]Quest Diagnostics, San Juan Capistrano, CA, [2]San Diego, CA, [3]Quest Diagnostics, Ladera Ranch, CA, [4]Quest Diagnostics Nichols Inst, San Juan Capistrano, CA
Disclosure Block: **T.E. Angeloni:** Salary/Employment; Quest Diagnostics.
Introduction: Cystic fibrosis (CF) is one of the most common autosomal recessive conditions in Caucasians, with a prevalence of approximately 1 in 2,500 to 3,300 live births. Pathogenic variants in the *CFTR* gene cause CF. With the improvement of molecular diagnostic technologies and genetic knowledge, a *CFTR* variant panel that expands beyond the American College of Medical Genetics-recommended population-screening panel of 25 variants may be appropriate for certain diagnostic testing purposes. However, the lack of readily available positive controls beyond the core panel challenges the development, validation, and quality control of an expanded *CFTR* variant panel. In this study, we report a simple approach to generate multiplex synthetic *CFTR* indel controls, particularly valuable for development of next-generation sequencing (NGS) pipelines. **Methods**: A total of 95 *CFTR* hotspot indel mutations were curated using gnomAD, OMIM, ClinVar, HGMD, and CFTR2 database. Artificial DNA sequences containing multiplex hotspot indel mutations were created and 8 fragments of 1.3 to 2.7 kb, each with 6 to 21 indels in 2 to 8 exons with flanking intronic sequences, were synthesized. The flanking sequences were retained to serve primer binding sites and to include intronic mutations. Two control fragment pools, each with 68 and 27 indels, were prepared by diluting 3 or 5 synthetic fragments within genomic DNA background and were sequenced by validated PCR-based or capture-based NGS methods along with patient samples. **Results**: Multiplex control fragment pools generated 100% coverage for all the target regions in every trial by both PCR-based and capture-based NGS methods, equivalent performances compared to genomic DNA samples. No sign of control fragment cross contamination was observed from 8 independent set-ups for over 2,500 patient samples. All expected indel mutations were detected by both NGS methods with informatics pipelines developed in-house except c.1820_1903del84, which was only detected by capture-based NGS method. Approximately 25% (24/95) of indel mutations with complex or repetitive neighboring sequences were called at a shifted genomic coordinate, up to 5 bp upstream from the reported position by mutation databases. **Conclusions**: We described here a simple approach to generate multiplex synthetic *CFTR* indel controls that can facilitate development, validation, and quality control of an expanded *CFTR*-variant panel. The synthetic multiplex indel controls demonstrated equivalent performances compared to patient genomic DNA samples yet minimized the number of positive controls to be tested owing to the simultaneous detection of multiple mutations.

PrgmNr 3815 - Down syndrome in patients with otitis media is associated with changes in the nasopharyngeal microbiota

View session detail

Author Block: **C. Elling**[1,2], S. Haville[3], K. Tholen[3], D. Curtis[1], T. M. Wine[1,3], N. R. Friedman[1,3], K. H. Chan[1,3], D. N. Frank[4], B. Herrmann[1,3], R. P. Santos-Cortez[1,5]; [1]Dept. of Otolaryngology- Head & Neck Surgery, Sch. of Med., Univ. of Colorado Anschutz Med. Campus, Aurora, CO, [2]Human Med. Genetics and Genomics Program, Univ. of Colorado Anschutz Med. Campus, Aurora, CO, [3]Dept. of Pediatric Otolaryngology, Children's Hosp. Colorado, Aurora, CO, [4]Div. of Infectious Diseases, Dept. of Med., Sch. of Med., Univ. of Colorado Anschutz Med. Campus, Aurora, CO, [5]Ctr. for Childrenâ□□s Surgery, Childrenâ□□s Hosp. Colorado, Aurora, CO

Disclosure Block: **C. Elling:** None.

Otitis media (OM) is inflammation of the middle ear (ME) that is usually due to infection. Globally, OM is the most frequently diagnosed disease in young children and infants and is a leading cause of hearing loss. Children with Down syndrome (DS) demonstrate even higher incidence rates of OM and experience more severe OM with worse outcomes, often requiring multiple surgeries. Although individuals with DS have increased susceptibility to infections, no studies to date have investigated whether bacterial commensal or pathobiont profiles of DS children with OM differ from non-DS children with OM. Greater knowledge of the microbiota changes associated with DS will aid in pinpointing which mucosal and epithelial processes that regulate the microbiotas are disrupted in DS. Using 16S rRNA gene sequencing, we examined the microbiotas of the nasopharynx (NP) and ME of 14 children with DS and10 non-DS children; all individuals had OM. Data were analyzed in terms of microbial diversity indices and relative abundance of individual taxa. In the ME, neither alpha- or beta-diversity indices were significant. DS is associated with *Finegoldia* (nominal-p=0.05), though sample sizes for both groups were very low due to the difficulties and limitations of obtaining ME samples. In the NP, DS samples had increased alpha-diversity (S_{obs} p=0.03, Shannonâ□□s Index p=0.03) with more taxa observed compared to non-DS children. Additionally, 13 taxa were associated (nominal-pActinomyces, Atopobium, Corynebacterium, Propionibacterium, Rothia, Abiotrophia, Anaerococcus, Bacillus, Lactobacillales, Streptococcus, Veillonella, Gammaproteobacteria and *Halomonas*. Of these, *Corynebacterium*, *Halomonas* and *Lactobacillales* were previously identified as commensals in the NP, whereas *Actinomyces, Propionibacterium, Anaerococcus, Bacillus, Streptococcus* and *Gammaproteobacteria* are taxa known to include OM pathogens. Additionally, in previous studies, *Rothia, Propionibacterium* and *Streptococcus* were increased in the oral and/or subgingival microbiotas of DS individuals, potentially contributing to increased incidence of gingivitis and periodontitis related to DS. Overall, in children with OM, DS is associated with increased biodiversity and higher relative abundance of specific taxa in the NP, suggesting that dysbiosis in the NP contributes to OM susceptibility in children with DS. These findings increase our knowledge of how Down syndrome influences regulation of the mucosal microbiota and contributes to OM pathology.

PrgmNr 3816 - Dynamic cell-type-specific eQTL from single-cell RNA-seq of inflamed and non-inflamed colon elucidate biological mechanisms of ulcerative colitis

View session detail

Author Block: **K. Jagadeesh**[1], K. K. Dey[2], D. T. Montoro[1], H. Shi[3], A. Nathan[4], H. Huang[5], A. Gusev[6], C. Smillie[1], S. Raychaudhuri[7], A. Regev[8], R. J. Xavier[1], A. L. Price[9]; [1]Broad Inst. of MIT and Harvard, Cambridge, CA, [2]Harvard Sch. of Publ. Hlth., BOSTON, MA, [3]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [4]Harvard Univ., Boston, MA, [5]Boston, MA, [6]Dana-Farber Cancer Inst., Boston, MA, [7]Brookline, MA, [8]Broad Inst. of MIT and Harvard, Cambridge, MA, [9]Harvard Sch Pub Hlth, Boston, MA
Disclosure Block: **K. Jagadeesh:** None.
GWAS have successfully identified thousands of disease-associated variants, but an understanding of the underlying molecular mechanisms and the cell types through which they act remains elusive. Bulk RNA-seq expression quantitative trait loci (eQTL) have provided valuable insights into gene regulation, but do not reach the fine resolution of cell types and states. Identifying cell type eQTL and dynamic cell type eQTL using scRNA-seq data has substantial potential to bridge this gap.
We analyzed scRNA-seq data from 306K cells in both inflamed and non-inflamed colon tissue from 25 genotyped individuals with or without ulcerative colitis (UC), aiming to identify cell type eQTL and dynamic cell type eQTL (specific to inflamed tissue) impacting UC risk. We observed high concordance in eQTL associations between cell type pseudobulk linear models and Poisson mixed effect models (r=0.91), and report results from pseudobulk models below. Across 9 immune, epithelial and stromal cell types, we identified 4,264 genes with significant cell type eQTL (FDRWe leveraged the cell type eQTL results to pinpoint disease genes and cell types of action at UC GWAS loci. Examples include *ANKRD55* in T lymphocytes and *PPIF* in macrophages, both of which are biologically plausible and with the eQTL SNP in strong LD with the GWAS SNP but have not previously been strongly implicated in UC disease risk. We also performed a dynamic transcriptome-wide association study (TWAS) by constructing separate gene expression prediction models for inflamed and non-inflamed tissue and contrasting their associations to UC. Genes associated with IBD specifically by the inflamed TWAS model (and further validated by MAGMA z-score > 5) include *QRICH1* (in B lymphocytes), which plays a central role in ER stress and inflammatory colon disease; *CARD9* (in B lymphocytes), which functions in gut microbe sensing; and *IL12RB2* (in fibroblasts), which contributes to the inflammatory response and host defense. eQTL fine-mapping of *IL12RB2* in inflamed fibroblasts implicated 4 strongly linked SNPs (average r^2=0.99) located 700kb upstream of *IL12RB2* (and closer to 8 other genes). Our findings highlight the potential of cell type eQTL and dynamic cell type eQTL to elucidate cell-type-specific and cell-state-specific disease biology.

PrgmNr 3817 - Functional Validation of *SOX2* Variants Contributing to Isolated GnRH Deficiency

View session detail

Author Block: **J. Cassin**[1], M. Stamou[2], K. W. Keefe[3], K. Sung[1], A. Chin[1], R. Balasubramanian[2], S. B. Seminara[2], P. L. Mellon[1]; [1]UCSD, San Diego, CA, [2]Massachusetts Gen. Hosp., Boston, MA, [3]Brigham and Women's Hosp., Boston, MA

Disclosure Block: **J. Cassin:** None.

Isolated GnRH deficiency (IGD) is a disorder characterized by low circulating sex steroids and delayed or absent puberty. Mutations in the *SOX2* gene have been previously linked to a syndromic form of IGD with additional ocular and neurodevelopmental phenotypes. The role of *SOX2* variants in non-syndromic forms of IGD remains unclear. To close this gap, we reviewed whole exome sequencing data in a large cohort of IGD (n=1453) patients ascertained by a reproductive phenotype. We identified a total of 9 heterozygous *SOX2* rare variants (3 *de novo*) contributing to both syndromic and non-syndromic forms of IGD. To determine the pathogenicity of the discovered variants, we utilized several *in* vitro methods. First, we confirmed that *SOX*2 is expressed in kisspeptin neurons *in vivo* in the mouse brain. SOX2 colocalizes with kisspeptin in the arcuate nucleus of both male and female mice and in the anteroventral periventricular nucleus in female mice. We next investigated the effect of SOX2 on kisspeptin expression *in vitro.* We showed that SOX2 binds to the human kisspeptin promoter, and represses kisspeptin luciferase expression in two immortalized hypothalamic cell lines, KTaR and KTaV. Of the nine *SOX2* variants identified, four diminished or reversed this repression. Finally, we investigated the molecular mechanism behind the phenotype of each of the four functionally deleterious mutations. Two missense mutations prevent proper localization to the nucleus. Two truncating mutations retain their ability to bind DNA and appear to act as dominant negative mutations when titrated in luciferase assays. This study demonstrates that the *SOX2*-related human disease spectrum may include IGD without severe ocular or neurodevelopmental phenotypes. We also show novel mutational mechanisms including dominant-negative effects contributing to *SOX2*-related human disease. This study greatly expands the understanding the mutational spectrum and the underlying mechanisms of the mutations leading to IGD and informs a more complete picture of the complexity of the genetic landscape governing the hypothalamic-pituitary-gonadal axis.

PrgmNr 3818 - Harnessing natural genetic variation in *Drosophila* to characterize the underlying mechanisms of ER stress preconditioning reveals role of histone methylation

View session detail

Author Block: **K. Owings**[1], C. Y. Chow[2]; [1]Univ. of Utah, Salt Lake City, UT, [2]Univ of Utah, Salt Lake City, UT
Disclosure Block: **K. Owings:** None.
Organisms face many stressors, and an ongoing challenge is understanding how an individual can respond to numerous insults over a lifetime. The accumulation of misfolded proteins results in cellular stresses, including endoplasmic reticulum (ER) stress. Many studies examine the ER stress response in isolation. In reality, cellular stresses rarely occur in isolation but often in the context of other stresses. Little is known about ER stress preconditioning, whereby conditioning with low levels of stress alters the ability to withstand subsequent ER stress. This project aims to use natural genetic variation to characterize ER stress preconditioning and its underlying mechanisms.
I began with an ER stress preconditioning screen that utilized the 200 strains of the *Drosophila* Genetic Reference Panel (DGRP). Flies were subjected to heat shock (or no heat shock control), allowed to recover, placed on tunicamycin to induce ER stress until death, and survival was measured. Different genetic backgrounds led to a striking range in phenotypic responses to ER stress preconditioning, ranging from dying half as fast to 4.5 times faster with preconditioning than with no preconditioning. A genome-wide association study revealed that histone H3-K4 methylation is a strong potential mechanism of ER stress preconditioning. Several candidate modifiers have known roles in histone methylation. H3-K4 methylation marks promoters at transcribed genes and may play a role in transcriptional regulation. These hits solidify a potential role of transcriptional regulation underlying ER stress preconditioning. RNAseq was performed in the phenotypically extreme DGRP strains at different points in the preconditioning protocol to identify potential predictive gene expression signatures. Differentially expressed genes indicate a potential role of immune genes in ER stress preconditioning.
An effective ER stress response is critical for healthy development and aging. Disruptions in this response have been implicated in multiple human diseases, from diabetes to neurodegeneration. Understanding how previous stress events influence the ER stress response will provide insight into this pathway's fundamental biology and have important implications for approaching therapeutic development.

PrgmNr 3819 - High throughput, yeast-based functional assays of genetic variants in human genes associated with inherited anemias

View session detail

Author Block: **M. Tang**, R. Lo, G. Cromie, M. Timour, J. Ashmead, A. Sirr, A. M. Dudley; Pacific Northwest Res. Inst., Seattle, WA
Disclosure Block: **M. Tang:** None.

Inherited anemias are highly actionable genetic disorders. Early diagnosis can help physicians flag drug contraindications and prescribe dietary restriction or supplementation. However, most polymorphisms detected by clinical genome or exome sequencing are Variants of Uncertain Significance (VUS), which cannot inform diagnosis. High throughput assays or Multiplexed Assays for Variant Effect (MAVEs) performed in model systems are one means of generating functional information needed for variant interpretation at scale. Functional studies in *Saccharomyces cerevisiae* can be developed and performed in less time and at lower costs than in human cell lines due to the speed and ease with which yeast can be genetically modified, robotically manipulated, and quantitatively assayed. Here, we describe the development of yeast-based functional assays for three human metabolic genes (*G6PD, PGK1 and TPI1*) that are associated with inherited anemias. The prevalence of the associated Mendelian diseases ranges from common to extremely rare. G6PD deficiency is the most common human enzymopathy, affecting an estimated 400 million people worldwide. In contrast, PGK1 deficiency has been documented in only ~40 individuals. Because these genes are highly conserved and the enzymes they encode perform the same biochemical functions, the human protein coding sequences can functionally replace (genetically complement) deletions of their corresponding yeast orthologs. As such, yeast growth in media conditions that require their activity provide quantitative readouts of the human enzymeâ□□s function. Our functional assays are robust, quantitative, and easily expandable to a scale that permits a single researcher to construct and assay all SNP-accessible amino acid substitutions across the length of the protein. Importantly, our results with a small set of well characterized disease alleles in each gene show good agreement with disease severity in the literature. Thus, our assays provide the foundation for comprehensive testing of the functional impact of amino acid substitutions in the human protein sequence of these genes. Our goal is to make data generated using these assays available and accessible to clinical geneticists performing variant interpretation.

PrgmNr 3822 - 90% of cryptic-donors activated in genetic disorders are present in variant-free RNA-Seq samples

View session detail

Author Block: **R. E. Dawes**, H. Joshi, S. J. Bryen, A. Bournazos, S. Cooper; Kids NeuroSci. Ctr., Sydney, Australia
Disclosure Block: **R.E. Dawes:** None.
Predicting which cryptic-donors may be activated by a genetic variant has proven intractable. We show rare mis-splicing events in variant-free RNA-seq samples are a highly accurate predictor of cryptic-donor selection in rare disease, through analysis of cryptic-donors activated by 4,811 variants, versus decoy-donors (any GT or GC not used). Conversely, the *a priori* utility of most splicing algorithms is limited. While *In silico* analysis accurately predicts variantsâ deleterious effect on authentic-donors (85 - 99 % weakened) or beneficial effect on cryptic-donors (67-98% strengthened), 29 - 62% of cryptic-donors do not out-compete the (variant) authentic-donor, and 34 - 67% are not the strongest decoy-donor within 250 nt. The influence of auxiliary splicing elements is likely to blame for current algorithmic insufficiency - we show G-repeats in the first 50nt of the intron can mask the presence of otherwise strong decoy-donors. Evidence of a donor's *splice-competence* from variant-free RNA-Seq samples is a potent predictor of cryptic-donor activation, with 90% of activated cryptic-donors present and 95% of unused decoy-donors absent.

PrgmNr 3823 - Automated annotation of human centromeres

View session detail

Author Block: **A. Bzikadze**[1], O. Kunyavskaya[2], T. Dvorkina[2], I. Alexandrov[2], P. Pevzner[1]; [1]Univ. of California, San Diego, La Jolla, CA, [2]Ctr. for Algorithmic Biotechnology, Inst. of Translational Biomedicine, Saint Petersburg State Univ., Saint Petersburg, Russian Federation
Disclosure Block: **A. Bzikadze:** None.

Recent advances in long-read sequencing technologies led to rapid progress in centromere assembly. Last year, we presented *centroFlye* â the first automated tool for centromere assembly from long error prone reads (Bzikadze and Pevzner, *Nature Biotechnology*, 2020). The same year, we joined efforts with the Telomere-to-Telomere Consortium that, in May 2021, announced a landmark achievement â the first *complete* assembly of the whole human genome (Miga et al., *Nature*, 2020; Logsdon et al., *Nature*, 2021; Nurk et al., *bioRxiv* 2021). This progress opened a possibility to address the long-standing questions about the architecture of human centromeres.

Centromeres are tandem repeats that are formed by units repeated thousands of times with limited nucleotide-level variations but extensive variations in copy numbers in the human population. Each unit represents a tandem repeat formed by smaller repetitive building blocks thus forming a nested tandem repeat. Partitioning all blocks into *n* clusters of similar blocks defines *n* monomers. A canonical order of monomers (referred to as a higher-order repeat or HOR) is specific for each centromere and is defined as the ancestral order of monomers that has evolved into the complex organization of extant centromeres. The current view of the centromere evolution is summarized by the *Centromere Evolution (CE) Postulate*: each centromere has evolved from a single ancestral HOR formed by different monomers. Although the CE postulate is universally accepted, we are not aware of a rigorous proof of this postulate or an algorithm that, given an extant centromere, derives its HOR. We developed *CentromereArchitect* that addresses both the monomer inference and HOR inference as two separate problems (Dvorkina et al., *Bioinformatics*, 2021). However, more recent analysis revealed that, to generate a biologically adequate centromere annotation, the monomer and HOR inference should be viewed as two interconnected problems.

We present the *HORmon* algorithm that incorporates the monomer and HOR generation into a single pipeline and generates the first automated centromere annotation that is largely consistent with the CE Postulate and previous manual centromere annotations (Uralsky et al., 2019). Recognizing that HORs represent an important evolutionary concept, we show how HORmon can be used to automatically derive the currently known HORs. At the same time, we argue that the ancestral HORs do not necessarily represent the best way to annotate the extant centromeres and introduce an alternative concept of a monorun graph. We project that it will complement the concept of a HOR in future centromere studies.

PrgmNr 3824 - Cell type deconvolution of whole blood bulk RNA-Seq to reveal biological insights

View session detail

Author Block: **T. A. Boltz**[1], T. Schwarz[1], M. Bot[1], C. Duan[1], B. Pasaniuc[2], R. A. Ophoff[3]; [1]UCLA, Los Angeles, CA, [2]Geffen Sch. of Med. at UCLA, Los Angeles, CA, [3]Univ California Los Angeles, Los Angeles, CA

Disclosure Block: **T.A. Boltz:** None.

GWAS have successfully discovered loci associated with various phenotypes, including quantitative biological measurements or risk for diseases. Given that the majority of these loci are in non-coding regions of the genome, a common approach in pursuit of discovering causal biological mechanisms is eQTL analysis. However, eQTL analysis of bulk tissue can often dilute cell-type specific signals and mask trait-relevant mechanisms, while single-cell sequencing can be prohibitively expensive in large cohorts. Here, we use bMIND to compute the cell-type specific (CTS) gene expression estimates of a bulk RNA-seq dataset from whole blood samples of 1,996 individuals, including patients with bipolar disorder and schizophrenia, as well as controls. Using the LM22 signature matrix from CIBERSORT as a reference and non-negative least squares deconvolution results in eight different immune cell types with proportions >= 0.1 within our dataset, including: neutrophils, naÃ¯ve B cells, memory B cells, CD8 T Cells, naÃ¯ve CD4 T cells, memory CD4 T cells, NK resting cells, and monocytes. These proportions were used to derive the CTS expression estimates for >19,000 genes per individual, across the eight cell types. We ran separate eQTL analyses per cell type, finding >2,500 significant (FDR 50%). We characterized these sets of eGenes per cell type using MAGMA to reveal enrichment with various traits. We find that the eGene sets from all cell types except naÃ¯ve CD4 T cells have significant (FDR

PrgmNr 3825 - Comprehensive variant calling in the *GBA* gene using whole-genome sequencing data

View session detail

Author Block: **M. A. Eberle**[1], X. Chen[1], M. Toffoli[2], F. J. Sedlazeck[3], S. Scholz[4], A. H. V. Schapira[2], C. Proukakis[2]; [1]Illumina Inc., San Diego, CA, [2]Univ. Coll. London Queen Square Inst. of Neurology, London, United Kingdom, [3]Baylor Coll. Med., Houston, TX, [4]NIH, Bethesda, MD

Mutations in the *GBA* gene cause Gaucher disease when inherited in an autosomal recessive manner. Carriers of these mutations are at an increased risk of two closely related neurodegenerative conditions, Parkinsonâ□□s disease (PD) and Lewy body dementia (LBD). The presence of a highly homologous nearby pseudogene (*GBAP1*) predisposes *GBA* to gene conversion and reciprocal recombination resulting in copy number gains or losses, as well as small pathogenic variants. Genetic testing and analysis of *GBA* are complicated due to the homology with *GBAP1* and a variety of recombinant variants that are *GBAP1*-derived, where the *GBA* sequence is replaced by the corresponding sequence of *GBAP1*.

Here, we present a novel bioinformatics method, Gauchian, that detects *GBAP1*-derived recombinant variants in the homology region as well as other *GBA* mutations based on short-read whole genome sequencing (WGS) data. Gauchian shows high performance with validation of key *GBAP1*-derived variants by Oxford Nanopore Technologies (ONT) targeted sequencing and copy number variants by digital PCR, outperforming the GATK Best Practices pipeline, as standard aligners have difficulty in accurately aligning reads derived from *GBAP1-GBA* hybrids.

Applying Gauchian to 10,623 samples from the 1000 Genomes Project and Accelerating Medicines Partnership - Parkinsonâ□□s Disease (AMP-PD) data sets reveals that copy number gains involving *GBA* and *GBAP1* are much more common and more variable in Africans, but do not appear to be associated with a risk of PD or LBD. Gauchian further confirms the elevated *GBA* mutation rate in LBD (11.8%) compared to PD (7.8%) cases. Compared with the GATK Best Practices pipeline, Gauchian doubles the number of *GBAP1*-derived variant calls in the homology region, including p.A495P, p.L483P, p.D448H and c.1263del, RecNciI and c.1263del+RecTL.

These findings highlight the importance of accurate *GBA* mutation detection across patient populations, particularly as targeted treatments are already at the clinical trials stage. Gauchian is the first short-read WGS-based tool for identifying carriers of *GBA* variants, particularly the *GBAP1*-derived variants, enabling *GBA* testing to be offered as part of a comprehensive test in carrier screening or other clinical settings where WGS is performed.

PrgmNr 3826 - Computational framework for consensus variant calling and variant call aggregation

View session detail

Author Block: **M. Samadi**[1], J. Ng[2], P. Vats[1], S. Onken[1], S. Sarkar[2], A. Sethia[1], T. Harkins[1], T. Turner[2]; [1]NVIDIA, Santa Clara, CA, [2]Washington Univ. Sch. of Med., St. Louis, MO
Disclosure Block: **M. Samadi:** None.
The development of different bioinformatics pipelines has continuously improved the variant calling accuracy for gene panels, exomes, and whole-genome sequencing; however, different variant callers can yield widely differing lists of variants from the same data set. The main reason is that each variant caller uses a different statistical method providing unique strengths and weaknesses of each approach. In order to overcome these discrepancies, recent studies show that consensus calling approaches are generally more robust and accurate than depending on an individual caller; however, running multiple variant callers and aggregating the results in a substantial increase in the required computational resources, turnaround time, along with the need to employ a complex workflow.
To overcome this challenge, we developed a computationally accelerated framework for consensus variant calling and variant call aggregation (VCA). This framework enables bioinformaticians to run multiple variant callers on the same data and gather the results in an easy and efficient way. To provide orders of magnitude faster turnaround, we optimized the whole framework to use Graphics Processing Units (GPUs) as accelerators. We have accelerated multiple variant callers on GPU such as GATK Haplotype Caller and Mutect2, Google DeepVariant, SomaticSniper, BCFtools, LoFreq, VarScan, and MuSE by orders of magnitude while maintaining output equivalence. As these tools are all optimized, users can run them all on a single GPU server in a few hours for a whole human genome. Moreover, users can add their own variant callers to the analysis, running them in conjunction with the accelerated variant callers. We also provide multiple simple VCA tools to use such as union, intersection, vote based vcf merger. Similar to variant callers, users can add their own VCAs to the framework.
As an example of this framework, we implemented a consensus caller for the Detection of de novo variants (DNVs). In this work, we used accelerated Google DeepVariant and Haplotype Caller and our customized VCA. The whole DNV workflow runs in ~1 hour providing a clear advantage over CPU-based approaches. We analyzed 602 publicly available trios from the 1000 Genomes Project as a control. We detected 445,711 DNVs, having a bimodal distribution, with peaks at 200 and 2000 DNVs. The excess DNVs are cell line artifacts that are increasing with cell passage. Reduction in DNVs at CpG sites and in percent of DNVs with a paternal parent-of-origin with an increasing number of DNVs supports this finding. These findings at this scale would not be possible without running multiple variant callers in an efficient and accelerated way.

PrgmNr 3827 - Evaluation of genome similarity for a twin family using 23andMe genotyping technology

View session detail

Author Block: **R. Huang**; Eastside Catholic Sch., Sammamish, WA
Disclosure Block: **R. Huang:** None.
Monozygotic twins, usually referred to as Identical twins, are two siblings who theoretically inherit exactly the same genetic information produced by the division of a single fertilized egg. Yet, in reality, somatic mutations may occur during cell division throughout the lifetime. Today, scientists still have a limited understanding of how much genetic variation exists between twins. This study aims at exploring this question using a case study based on the genomes of a family that includes a mother, a son, and a pair of twin daughters. The genotype information was obtained from direct-to-consumer genotyping services, namely 23andme. The results of this study provide insights into where and how mutations arise between twins. In total, 1,974 SNP genotypes, excluding â□□no calls,â□□ are compared, and only 12 genotypic differences from eight chromosomes are found. Among these chromosomes, chromosomes 11 contain the highest number of differences. In addition, SNPs found in chromosome 11 of two sets of public 23andme data downloaded from the Harvard Personal Genome Project were analyzed to compare and contrast twin and non-twin genomic differences. The result shows that non-twin data each has 83.82% and 83.64% of differences, while the twin data has only 0.36% of differences. This study not only confirms that identical twins have much higher genetic similarity than non-twins but also gives an accurate number of differences between typical twin genomes as an example for later studies. Also, by comparing motherâ□□s and children's data, we found the genotyping technology accuracy varied for each trial but the overall proportion remains within a reasonable range.

PrgmNr 3828 - Findings from the Critical Assessment of Genome Interpretation, a community experiment to evaluate phenotype prediction

View session detail

Author Block: **C. Bakolitsa**[1], S. Jain[2], G. Andreoletti[3], R. A. Hoskins[4], S. Repo[5], S. M. Fullerton[6], P. Radivojac[2], J. Moult[7,8], S. E. Brenner[1], CAGI Participants; [1]Univ. of California, Berkeley, Berkeley, CA, [2]Northeastern Univ., Boston, MA, [3]Univ. of California San Francisco, San Francisco, CA, [4]Univ. of California Berkeley, Berkeley, CA, [5]Elixir, Wellcome Genome Campus, Cambridge, United Kingdom, [6]Univ. of Washington, Seattle, WA, [7]Inst. for BioSci. and Biotechnology Res., Univ. of Maryland, Rockville, MD, [8]Dept. of Cell Biology and Molecular Genetics, Univ. of Maryland, College Park, MD
Disclosure Block: **C. Bakolitsa:** None.
Interpretation of genomic variation plays an essential role in the analysis of cancer and monogenic disease risk, and increasingly also in the context of complex disease susceptibility, with applications ranging from basic research to clinical decisions. Yet the field lacks a clear consensus on the appropriate level of confidence to place in variant â□□impactâ□□ and interpretation methods. The Critical Assessment of Genome Interpretation (CAGI, 'kÄ□-jÄ□) is a community experiment to objectively assess computational methods for predicting the phenotypic impacts of genomic variation. CAGI participants are provided genetic variants and make blind predictions of resulting phenotype. Independent assessors evaluate the predictions by comparing with experimental and clinical data. CAGI has completed five editions with the goals of establishing the state of art in genome interpretation, and of encouraging new methodological developments. Challenges have been predominantly based on human data, mirroring problems in clinical practice and much basic research. The focus has been on interpreting nonsynonymous variants, splicing variants, structural variation, whole-exomes and whole-genomes, with phenotypes ranging from molecular and cellular measurements to organismal phenotypes in inherited disease and cancer. Results from previous CAGI experiments have been described in two special issues of *Human Mutation* (https://onlinelibrary.wiley.com/toc/10981004/2017/38/9, https://onlinelibrary.wiley.com/toc/10981004/2019/40/9). Each edition of CAGI has revealed new aspects of methods, and a number of themes have emerged. Independent assessment has highlighted a strong signal in predicting the functional effects of missense variation. We have also found methods provide compelling evidence for use in clinical classification of variants. Structure-based missense methods excel in a few cases, while evolution-based methods have more consistent performance. CAGI has contributed to the interpretation of cancer variants. Interpretation of non-coding variants shows promise but is not at the level of missense. In examples using clinical data, predictors identified causal variants overlooked in the initial clinical analysis. CAGI challenges have also revealed complications in interpreting whole genomes, limitations of *in vitro* data, and a need for more sophisticated assessment strategies and experimental design. Future rounds of CAGI challenges will seek to incorporate larger datasets, explore polygenic models, and continue to assess the state of the art. Detailed information about CAGI may be found at https://genomeinterpretation.org.

PrgmNr 3829 - Full lifecycle continuous workflow-enabled variant benchmarking

View session detail

Author Block: **J. Leipzig**, J. Schnebly, J. Rudolph, C. Brown, K. Sebby; Truwl, Whitefish, MT
Disclosure Block: **J. Leipzig:** None.
Performance testing and benchmarking are critical prerequisites to the development of sequencing-based tests. The substantial demand for these capabilities is underserved and many groups struggle to re-implement these functionalities in-house. Particularly of high interest is pipelines for variant calling. These tools have received renewed interest with the advent of machine learning and deep learning approaches that promise to push the limits of sensitivity and accuracy in genomic analysis. Truwl enables performance testing with easy-to-use dashboards of metrics and benchmarks that allow any user to evaluate and iterate on their analysis pipelines. Truwl hosts various bioinformatics pipelines whose inputs can be defined through the platformâ□□s web-based input editor and then executed directly on the cloud. Multiple tool and parameter choices are available for sequence alignment and variant calling. For each executed job the system tracks job run statistics, parameter settings, and all inputs and outputs. Results from variant calling pipelines can be fed directly into a previously existing small-variant benchmarking pipeline that we refactored into the Workflow Description Language. This pipeline uses hap.py and bcftools to generate metrics from comparisons of VCF files to known truth-sets over user-specified regions. We have compiled reports and visualizations generated by the pipeline into notebooks that display directly in the web browser. Unique to this system is an interactive dashboard specifically designed to compare runs across truth sets, tool choices, and parameter distributions. The interface and internal implementation borrow concepts of model and hyperparameter exploration tools from the machine learning community, namely MLFlow. A high-level dashboard quickly allows users to display subset columns among the dozens of manipulated parameters and relevant metrics and between facets of the benchmarking analysis such as whole-exome vs coding region. This dashboard enables a data-driven approach to pipeline selection, optimization, and validation and can also be used in production environments to validate that pipelines and assays continue to perform properly.

PrgmNr 3830 - Length Variability in Short Tandem Repeats and Its Applications

View session detail

Author Block: **P. Vijay**[1], S. Batalov[2], Y. Ding[1], S. F. Kingsmore[3], S. Chowdhury[4], C. A. Hobbs[5,6], M. N. Bainbridge[7]; [1]Rady Children's Inst. for Genomic Med., San Diego, CA, [2]Rady Childrens Inst., Genomic Med., San Diego, CA, [3]Rady Children's Inst. for Genomic Med., Coronado, CA, [4]Rady Children's Inst., Genomic Med., San Diego, CA, [5]Univ. of Arkansas for Med. Sci., Little Rock, AR, [6]Rady Children's Inst., Genomic Med., San Diego, CA, United States, San Diego, CA, [7]Rady Children's Hosp., San Diego, CA
Disclosure Block: **P. Vijay:** None.
Short Tandem Repeats have been found to play a role in a myriad of complex traits and genetic diseases. Using GangSTR, an algorithm for genome-wide genotyping of short tandem repeats, we examined the variability in the lengths of over 800,000 STR loci under four different scenarios. First, we analyzed the variability in the length of STRs across six separate genetically determined ethnic groups: Africans, Europeans, East Asians, Mixed Americans, homogenized Americans, and Pacific Islanders. Europeans were compared with the other five ethnicities and STRs with significantly (Absolute Z-Score > 5) different lengths were identified. Mixed Americans and Pacific Islanders presented with the fewest number of STRs with significantly altered lengths, with 623 and 1560 positions respectively, while East Asians, at 3606 positions, and Africans, at 4933 positions, showed the highest number of STR loci with differing lengths. Secondly, we focused on repeat expansions at known pathogenic loci. *TCF4, AR*, and *DMPK* were the STR loci with the highest number of patients with expansions. Forty-nine and 6 pathogenic expansions were detected in TCF*4* and *DMPK*, respectively. Although 162 individuals presented with expansions in the *AR* gene, none of these patients contained expansions greater than the pathogenic length for this locus. Next, we focused on individuals with divergent STR lengths in STRs that appear highly stable across all ethnic groups. We observed long, divergent STR expansions in both known disease and non-disease genes and in coding and non-coding regions of these genes. STR expansions were observed in the protein coding regions of two genes, *ZBTB4* and *SLC9A7*, the latter of which is the cause of Intellectual developmental disorder, X-linked 108. Finally, we identified *de novo* expansions occurring in our proband cohort. One hundred eighty-four parent-child trios were identified and allele lengths were compared between proband and both parents. Alleles where the probandâ□□s length was greater than two times that of either parent were flagged as a *de novo* expansion, while probands with allele lengths shorter than the shortest allele length of either parent were flagged as a *de novo* contraction. In total, we observed 3179 potentials *de novo* expansions and just 9 *de novo* contractions with 297 expansions associated with disease causing genes and 0 contractions associated disease causing genes.

PrgmNr 3831 - Maverick: Variant prioritization for Mendelian diseases using deep learning

View session detail

Author Block: **M. C. Danzi**[1], S. Zuchner[2], M. Dohrn[1], S. Fazal[1], A. P. Rebelo[2], B. Aaron[1], V. Cintra[1]; [1]Univ. of Miami, Miami, FL, [2]Univ Miami, Miami, FL
Disclosure Block: **M.C. Danzi:** None.
Thousands of genes have been discovered to cause Mendelian-inherited diseases, according to current data from OMIM. Yet, a sizable proportion of patients with many Mendelian disorders do not currently receive a genetic diagnosis. Identifying the causal variants in these unsolved cases is an important and challenging task. We developed MAVERICK, a transformer-based neural network, to differentiate among Mendelian disease-causing dominant variants, recessive variants and all others. MAVERICK is able to classify non-synonymous SNVs and protein altering indels simply by comparing the referent and altered amino acid sequences. Patient exomes typically contain hundreds of rare, protein altering SNVs and Indels. We developed MAVERICK to filter those results down to a more manageable number of probable causal variants. Using only genotype information to rank all the variants in a patient, this approach gave the causal variant top prioritization over 77% of the time for known disease genes and over 50% of the time for novel disease genes. Furthermore, the causal variant fell within the top five ranked variants over 90% of the time for both known and novel disease genes. In these test cases, the method considered both dominant and recessive inheritance patterns and scored all possible monogenic compound heterozygous pairs in addition to single heterozygous or homozygous variant solutions. MAVERICK additionally supports the incorporation of phenotype information as HPO terms and inheritance information, which can often improve performance considerably. Here, we introduce MAVERICK: a Mendelian approach to variant effect prediction. We believe this approach will greatly reduce the time and effort required to solve cases with novel variations and even help elucidate new disease genes. MAVERICK is currently in open beta testing on the GENESIS platform, which hosts genomic data from over 11,000 Mendelian disease patients.

PrgmNr 3832 - Predictive Interpretation and Scoring Model (PrISM) increases efficiency of variant classification by reducing manual review time

View session detail

Author Block: **T. Smart**, N. Sanapareddy, E. Choo, B. Gall, I. Rakova, D. Keen-Kim; Natera, Inc., San Carlos, CA
Disclosure Block: **T. Smart:** Major Stockholder/Ownership Interest; Natera, Inc..
Salary/Employment; Natera, Inc..
Variant classification is a stepwise, resource-intensive process that incorporates the ACMG guidelines to accurately curate and classify genetic variants. Doing so requires variant curator expertise to provide a thorough review of literature, clinical and experimental evidence, databases, and other evidence sources, which is a manual and time-consuming process. In addition, periodic reassessment of pathogenic, likely pathogenic, and variants of uncertain significance (VUSs) requires time, further increasing manual review time. To improve the efficiency of our current variant classification workflow, we propose the Predictive Interpretation and Scoring Model (PrISM) for variant classification. Whereas other proposed models focus on an automated modelling process, which can skip expert review altogether, PrISM improves variant classification by gathering evidence obtained through an automated workflow to assign a confidence score to variants that have previously undergone manual review. Variants with higher confidence scores are assigned a final classification, whereas variants with a lower confidence score require manual review before a final classification is assigned.At the core of our PrISM model is a naive decision tree, incorporating several evidence categories from the manual review workflow, which was developed to identify high confidence, autosomal recessive variants. If positive (likely pathogenic/pathogenic), variants can qualify for single review, and if negative (VUSs), variants can be exempted from manual review. Evidence categories used to determine confidence scores include previous classification, concordance with a consensus ClinVar assessment, and new literary or clinical evidence. To determine the potential reduction in manual reviews achievable by PrISM, we performed a retrospective analysis calculating the number of variants that would qualify for reduced manual review. Of the total 159,553 unique variants that we previously assessed in our HorizonTM carrier screening database, 2,768 pathogenic, 547 likely pathogenic, and 9,003 VUSs qualified for either single review or exemption from manual review. The analysis included all pathogenic, like pathogenic, and VUSs existing in the database before May 2021.In this dataset, implementing our model would potentially reduce manual review for 12,318 variants, which is 7.7% of all unique variants, allowing for a faster laboratory turnaround time. Therefore, implementation of PrISM provides a low-risk method of increasing variant classification efficiency of previously reviewed variants without compromising the stringency of the manual review process.

PrgmNr 3833 - Small indel detection within VNTRs using short-read sequencing data

View session detail

Author Block: **J. Park**, M. Bakhtiari, V. Bafna; Univ. of California San Diego, La Jolla, CA
Disclosure Block: **J. Park:** None.

Motivation: Tandem repeats (TRs) are highly polymorphic regions in DNA where approximated motifs are replicated in tandem. In the human genome, there are more than one million TRs accounting for significant genetic variation. The most common variation at TRs is repeat copy number variation, and over 50 diseases are known to be caused by repeat expansion. Another type of variant is small indels within repeat units, and a couple of diseases are caused by indels in variable number tandem repeats (VNTRs) such as mendelian disorder medullary cystic kidney disease type 1 (MCKD1) and monogenic type 1 diabetes. However, small indels are relatively unexplored mainly due to the long and complex structure of VNTRs with multiple repeat units.
Methods: We extended a genotyping tool for VNTRs, adVNTR, to handle the long and complex VNTRs with short-reads. Unlike the previous version, adVNTR allows multiple repeat units to be individually modeled in VNTR allowing for more accurate capture of repeat variations. A speed-up technique was used to improve the genotyping process.
Results: In a simulated dataset, adVNTR outperformed GATK with 100% median accuracy for 20 simulation sets. We also genotyped 2237 VNTRs in coding regions using 1000 Genomes dataset and found 265 common VNTRs (occurring in > 1% of the population with non-reference allele length). Out of 265 common VNTRs, 232 (87.5%) have repeat unit length with multiple of three implicating in-frame variants. Finally, we tested our tool on 3 MCKD1-positive samples caused by a frame-shift insertion in MUC1 VNTR and successfully identified the known pathogenic variants demonstrating the ability of adVNTR to detect small indels in long and complex VNTRs.

PrgmNr 3834 - Systematic evaluation and Improvements for trans-eQTL Detection Methods Allows Identification of Novel trans-eQTLs in the GTEx data

View session detail

Author Block: **C. Wu**, T. Xu, A. Goren, M. Gymrek; Univ. of California, San Diego, San Diego, CA
Disclosure Block: **C. Wu:** None.
Studies of expression quantitative trait loci (eQTLs) have aimed to discover genetic variants that explain variation in gene expression levels due to associations with complex traits and human diseases. While thousands of cis-eQTLs have been reliably identified, consistently replicating trans-eQTL effects proved to be challenging due to insufficient statistical power, lack of comparable tissues and cohorts, and putative false positive associations. In particular, technical covariates lead to a substantial variation in expression datasets and result in multiple false positive eQTL calls. As a result, biological mechanisms and characteristics of trans-eQTLs remain largely unknown.
Here we present x-qtl â a novel trans-eQTL detection method. For a given trans-eQTL, we assume the distribution of association statistics to be a mixture of two distributions â for the target and non-target genes. x-qtl addresses two critical limitations of existing methods. First, the method allows downstream characterization of trans-eQTLs by predicting the number of target genes. Second, x-qtl applies principal component analysis to the expression matrix to account for gene correlations. Specifically, we represent the variables (genes) as the uncorrelated principal components which reduces noise from correlated genes that can obfuscate true trans-eQTL signals.
Next, we develop a simulation framework to evaluate trans-eQTL detection tools. Our framework enables for varied effect size distribution and number of target genes for each trans-eQTL, includes pairwise correlation between expression of different genes, and simulates effects of technical covariates. We use our framework to evaluate the power of x-qtl and two existing eQTL frameworks, MatrixeQTL and CPMA, to detect trans-eQTLs with a variety of characteristics. Our results indicate that only trans-eQTL with extremely large effect sizes, or affecting hundreds to thousands of target genes, can be reliably detected. Remarkably, x-qtl is more sensitive in detecting trans-eQTLs with a small number of targets than existing methods.
We benchmark x-qtl against existing tools using yeast expression data containing documented eQTLs. Then, we apply all methods to the recently released Genotype-Tissue Expression (GTEx) project v8 dataset with 838 human donors and 15,201 samples from 52 tissues. We observe a putative trans-eQTL in Nerve-Tibial involved in signal transduction pathways and another in Thyroid that is located in a thyroid-specific transcription factor. Additionally, we detect novel trans-eQTLs that are replicated among different tissues but were missed by traditional trans-eQTL analysis methods.

PrgmNr 3835 - Towards evidence-based recommendations and protocols for the use of computational tools in missense variant pathogenicity classification

View session detail

Current ACMG/AMP guidelines for interpreting sequence variants permit the use of computational (in silico) predictors as supporting evidence in assessing pathogenicity. However, these guidelines lack quantitative support and leave clinicians and scientists without standardized rules in applying them (e.g., PP3 and BP4 guidelines ask for consensus of two uncalibrated predictors, an approach not justified by evidence). We believe the recommendations for PP3 and BP4 should be replaced by an evidence-based, quantitative strategy. We investigated quantitative revisions of these rules.
We evaluated fourteen tools (BayesDel, CADD, EA, hEAt, FATHMM, GERP++, MPC, MutPred2, PhyloP, PolyPhen-2, PrimateAI, REVEL, SIFT, VEST4), selected based on mention in the 2015 ACMG guidelines, availability of training data, performance in the Critical Assessment of Genome Interpretation, community adoption, and balance between primary models and meta-models. We assembled a data set that excluded variants in any of these toolsâ training sets, comprised of 5,762 pathogenic or likely pathogenic (P, LP) variants and 6,208 benign (B) or likely benign (LB) variants from ClinVar. Performance criteria and score thresholds for each tool were derived through a novel approach that first calculates local posterior probabilities (Post_P) for each score and then defines score intervals based on Odds of Pathogenicity (OddsPath) criteria. We validated thresholds for each tool using an independent data set from ClinVar (3,078 P/LP and 13,531 B/LB variants).
Modeling of ACMG rules provides specific thresholds of OddsPath for Supporting, Moderate, and Strong evidence. A consensus approach using developer-defined thresholds for SIFT and PolyPhen-2 reached Moderate level of evidence for PP3 and Supporting level for BP4 for an average variant with a consensus prediction of P/LP. Because several issues raised questions about clinical application, we then selected new thresholds to account for confidence intervals around point estimates of the Post_P of pathogenicity. These thresholds apply to all (not just average) variants achieving a given level of support for pathogenicity or benignity and are more stringent than developer-defined ones. We found that all tools achieved Supporting level evidence for both pathogenic and benign classification using these data-driven thresholds. Importantly, at appropriate score thresholds, in silico methods can also provide Moderate and Strong evidence levels. We conclude that our approach and these quantitative criteria can improve confidence for in silico prediction tools as evidence for pathogenicity in variant interpretation.

PrgmNr 3836 - Variant Calling of 50,000 UK Biobank Exomes in a Weekend

View session detail

Author Block: **A. Sethia**[1], O. Krasheninina[2], T. Polanco[2], T. Zhu[1], S. Onken[1], M. Samadi[1], W. Salerno[2], T. Harkins[1]; [1]Nvidia, Santa Clara, CA, [2]Regeneron Genetics Ctr., Tarrytown, NY

The promise of human genetics and precision medicine has exploded the number of DNA samples that are analyzed every year. It is common to find studies with cohort sizes of tens to hundreds of thousands of samples. At these scales, even minor inaccuracies can occur in large enough numbers to impact downstream analyses. To maximize insight from such datasets, deep learning methods such as Googleâ□□s DeepVariant are being applied to these large datasets leading to higher accuracy of variant calling. Analysis of such a large number of samples, combined with the computational complexity of deep learning based variant callers create significant computational burden.
To overcome this challenge, we accelerate DeepVariant to run on GPUs. GPUs are renowned for their complete computing stack from hardware to software, to accelerate computation time, while increasing throughput for deep learning applications. We integrate these hardware and software technologies in the GPU accelerated version of DeepVariant to accelerate deep learning inference using a custom model. Furthermore, we accelerate the data processing workflow in DeepVariant that does not use deep learning to run in an accelerated fashion using GPUs.
We evaluated the accelerated DeepVariant using 100 samples from the UK Biobank by running the out-of-the box DeepVariant compared to the GPU accelerated DeepVariant. While the standard DeepVariant takes 58 minutes to process an exome, the GPU accelerated DeepVariant can process the same dataset in less than 5 minutes. This ~12 fold acceleration results in over 2.5 times lower cost of analysis. Across the 100 samples, 7.5 million sample level variants were called with 100% concordance between the two instances of DeepVariant. We found 1 zygosity mismatch and MEAN GQ difference of 0.43 on Phred scale between the two methods across all 100 samples.
The custom DeepVariant model shows 25% and 20% reduction in mendelian SNP and INDEL error rate respectively for 281 trios in the UK Biobank data compared to the native DeepVariant WES model.
Using the GPU accelerated variant caller using the custom model, we could analyze 50,000 UK Biobank exomes in 42 hours by using 100 spot GPU instances on Amazon Web Services (AWS). By using spot instances, we could process all the 50,000 samples for $4,800. Due to the small time it needs to run the variant calling, only 1.5% of spot instances failed and were restarted.

PrgmNr 3837 - VizCNV: A tool for orthogonal CNV validation using whole genome sequence data

Copy number variation (CNV) is a significant contributor to human disease traits and genomic disorders. To date, most CNV data have been obtained using comparative genomic hybridization arrays (aCGH) or SNP arrays and as a result, most tools are designed to be compatible with those data. With the emergence of whole genome sequencing (WGS) in clinical diagnosis, identifying and characterizing pathogenic or risk-alleles for thousands of CNV calls from WGS is a significant challenge. Here, we present a visualization tool that facilitates identifying CNV events from WGS data. This tool, VizCNV, inputs WGS data and outputs paired plots of variant frequency from the genome vcf (gvcf) file and copy number variation in aCGH format based on read depth from the BAM file. Reads with low mapping quality are masked to reduce false positive calls. To test the utility of VizCNV, we analyzed data from 19 WGS trios (average coverage > 30x), 16 from an aCGH positive for *MECP2* duplication syndrome cohort and three families with probands carrying marker chromosomes. These consisted of nine *de novo* and 10 inherited CNVs, one of which contained a triplication and another with a mosaic CNV. B-allele (alternate allele) frequencies from gvcf files were extracted and the inheritance pattern inferred which established the chromosome of origin in *de novo* CNVs. Read depth was extracted from the corresponding BAM files and $\log_2$ ratios were calculated to create matching aCGH plots. The resulting read depth plots accurately displayed the CNVs identified in aCGH plots for all 19 probands. In contrast, combining output from three structural variant/CNV callers, Manta, Delly, and Lumpy, just 9/19 of aCGH observed events were called. In addition, all inheritance patterns were evident in the read depth plots, the triplication event was detected by expected $\log_2$ ratio, and the mosaic proband registered at 27% in VizCNV read depth plots which corroborates the mosaic findings in the array and FISH results. Serendipitously, because the WGS gvcf gathered information at a nucleotide level, zoomed in plots were useful to map the breakpoint junctions. The corresponding B-allele plots provided confirmation of the inheritance mode for a CNV event, if it had occurred *de novo*, or if it was mosaic in 100% of the trios. The current method of CNV calling from WGS data is still relatively inaccurate with low sensitivity and specificity. This tool is a complementary way to analyze WGS data and has close to 100% correlation with actual aCGH plots for the same sample. We propose to use VizCNV for WGS data analysis as an orthogonal validation of CNV calls and potentially a replacement for arrays for diagnostic purposes.

PrgmNr 3838 - Benefits of Hybrid Capture for Viral Surveillance of *SARS-CoV-2*

View session detail

Author Block: **D. Antaki**, T. Liu, K. Butcher, B. HÃ¶glund, J. Challacombe, E. Toro; Twist BioSci., San Francisco, CA
Disclosure Block: **D. Antaki:** Salary/Employment; Twist Bioscience.
Since its immediate outbreak in late 2019, the SARS-CoV-2 (SCV-2) virus has led to an abrupt interruption to the way of life for communities all over the world. As the virus circulated from one continent to another, novel mutations created more virulent and deadlier strains. To combat these novel strains with therapies and vaccines, researchers have begun relying on viral genome sequencing. A widely used method for targeted viral genome sequencing is amplicon sequencing, which relies on PCR amplification of short fragments. Although cost-effective, amplicon sequencing is not robust to mutations when they occur in primer sequences. However, hybrid capture, another method used for targeting the viral genome, can tolerate mismatches better resulting in fewer dropouts as viruses accumulate mutations. In this work, we provide an in silico model to predict dropouts based on mutations found in the ARTIC amplicon sequencing primer sets and the probes found in the SARS-CoV-2 NGS Assay.

Throughout this process, we aligned 383,656 high-quality genome sequences belonging to variant of concern (VOC) or variant of interest (VOI) strains in GISAID. We then profiled mismatches in ARTIC V3 primers and SARS-CoV-2 NGS Assay probes and identified isolates that would lead to diminished sequencing coverage. We detected 101,432 viruses (27%) with >=1 mismatch in the last 6 base pairs of the 3â end of ARTIC primers; of these, 413 had >=2 mismatches in one primer. In contrast, only 38 viruses (0.01%) had enough mutations (>=10) in a hybrid capture probe to have a similar effect on coverage.

Using these results, we synthesized 11 viral sequences with mutations in ARTIC primers and Twist probes. We observed that mutations in ARTIC primers led to complete dropout of the amplicon for 4 isolates and diminished coverage in an additional 4. Twist probes showed uniform coverage with little to no dropouts. Using control material (Wuhan-1 isolate Twist Bioscience) the SARS-CoV-2 NGS Assay covered 99% of the SCV-2 genome at high titers and 93% at low titers in contrast to 92% and 38% for high and low titers respectively for ARTIC amplicon sequencing.

We have shown that amplicon sequencing is limited by mutations, posing a serious concern for viral surveillance. Therefore, hybrid capture poses a better solution for variant calling and monitoring of viral strains and is more resilient to mutations as they arise. Our results establish the research only use workflow of the SARS-CoV-2 NGS Assay as a comprehensive method for viral surveillance and demonstrates the benefits of using hybrid capture vs. amplicon sequencing in order to continue to monitor for mutations found in the SCV-2 viral genome, outbreaks, and novel VOC.

PrgmNr 3839 - First Report of Spatial Whole Transcriptome Profiling of Histological Structures of Multiple Organs

For thousands of years, our understanding of an organâ□□s architecture and function was based on careful visual characterization of the various tissues and substructures. Over the past decades, advances in molecular profiling techniques have increased our understanding of the underlying genetic, biochemical, and cellular factors that govern tissue organization and function. However, those molecular techniques largely relied upon dissociating or digesting the tissue, which irreparably disrupts the connection of the molecular target of interest and its physical location within the tissue. Furthermore, when the target-location information was preserved, it could only be done simultaneously for a handful of targets. In the last few years, the advent of spatial biology has finally broken that barrier, and new tools and methods are available for high plex profiling of targets in situ. For the first time, it is now possible to generate a complete understanding of the organized transcriptional patterns that define cells and tissues comprising the organs and confer their function. To realize the potential of spatial profiling to define normal organs at the cellular and molecular level, we have started an ambitious project to map the architecture of normal tissues using spatially resolved whole transcriptome profiling. In this pilot phase of the project, 5 organs (kidney, pancreas, brain, colon, and lymph node) were characterized with the GeoMxÂ® Digital Spatial Profiler using region of interests (ROI) in the key multicellular structures that confer organ function (e.g. pancreatic islets). ROI consists of geometric areas centered on the functional unit or cell type-enriched ROIs to characterize particular cell populations within the functional units. Spatial transcriptomic data are then benchmarked to orthogonal platforms as independent validation of the results. Multiple ROI per tissue and multiple donors per organ have been profiled to permit evaluation of the diversity within and between individuals. All data will be made publicly available as a resource for the community. Future expansion of this program will encompass additional organs and larger cohorts for each organ to increase the utility of this resource.

PrgmNr 3840 - Optical Genome Mapping for High Throughput Analysis of Repeat Expansion Disorders

View session detail

Author Block: **D. Zhang**[1], E. Lam[1], J. Wang[1], T. Wang[1], J. Lee[2], B. Ramandi[1], N. Miller[1], A. Pang[1], H. Sadowski[1], A. Hastie[2], M. Oldakowski[1]; [1]Bionano Genomics, San Diego, CA, [2]BioNano Genomics, San Diego, CA

Disclosure Block: **D. Zhang:** Salary/Employment; Bionano Genomics.

Expansions and contractions of simple sequence repeats are associated with more than 40 diseases including Huntingtonâ□□s disease, myotonic dystrophy, facioscapulohumeral muscular dystrophy (FSHD), Friedreichâ□□s ataxia and Fragile X Syndrome, the most common heritable cause of intellectual disability. Expanded trinucleotide repeats are the most frequent however more recently tetra-, penta-, hexa- and dodeca-nucleotide expansion have been identified as being causal in human disease. Expanded repeats are unstable and may expand during intergenerational transfer and associated disorders tend to increase in severity with each successive generation. Most repeat disorders have no direct treatments. Phenotype severity is often correlated with the amount of pathogenic expansion or contraction. Thus, accurate sizing of the repeats is crucial. Southern blotting is the gold standard for analyzing pathogenic repeats. The repetitive and polymorphic nature of these regions presents difficulties for both polymerase chain reaction (PCR), where the polymerase is unable to traverse through long repeats, and sequencing based methods which face limitations in read lengths Optical genome mapping (OGM) with the Bionano Genomics Saphyr platform has the potential to address these shortcomings. The Saphyr platform images DNA molecules up to a megabase in size labeled at specific sequence motifs in nanochannel arrays. Molecules > 150kbp are analyzed through de novo assembly or aligned to a reference genome for structural variant detection. OGM can detect germline SVs >500 bp in size including repeat expansions/contractions, inversions, reciprocal translocations, and regions with absence of heterozygosity (AOH) (>10 Mbp). Bionano Genomics has developed targeted analysis workflows for FSHD and Fragile X Syndrome. To evaluate the capability of detecting disease causing repeat expansions, we analyzed the *FMR1* repeats relevant to Fragile X syndrome using Coriell cell lines with known repeat sizes and control samples. We observed the expected expansion alleles in the Coriell cell lines, with sizes consistent with annotation and with the largest expansion being almost 1000 copies. The control samples had repeats below the pathogenic cutoff. The single-molecule data also allowed us to analyze the repeat allele spectrum, which can be indicative of the stability of the alleles. We also analyzed the DZ4Z repeat on chromosome 4 for FSHD. In addition to the canonical repeat contractions, OGM detected structural variants and other rearrangements in the vicinity of the D4Z4 locus.

PrgmNr 3841 - Simultaneous isolation of high-quality RNA and DNA from post-mortem human central nervous system tissues for omics studies

View session detail

Author Block: **N. Grima**, L. Henden, O. Watson, I. P. Blair, K. L. Williams; Ctr. for Motor Neuron Disease Res., Faculty of Med., Hlth.& Human Sci., Macquarie Univ., Sydney, Australia
Disclosure Block: **N. Grima:** None.
Post-mortem human central nervous system (CNS) tissue has garnered growing attention from multi-omics approaches, particularly for the investigation of the pathological processes underlying neurodegeneration. While most genes linked to neurodegenerative disease are ubiquitously expressed, pathology tends to occur in discrete CNS regions, making region-specific analyses of interest. Paramount to the accurate and reliable analysis of transcriptomic and epigenomic data sets in parallel, is the co-isolation of high-quality DNA and RNA. This is particularly pertinent in the case of post-mortem CNS tissues where sample availability is limited and where regional heterogeneity may mask correlations between different omics datasets. High lipid content is recognised to complicate RNA isolation from CNS tissues and consequently, existing literature has exclusively used organic solvent-based reagents and kits due to their ability to separate nucleotides and lipids into distinct fractions. In contrast, commercially available DNA/RNA co-purification kits employ guanidinium thiocyanate-based lysis in combination with column purification, forgoing use of hazardous organic solvents. It is yet to be reported whether co-purification kits can isolate high-quality nucleotides from post-mortem CNS tissues. We have developed a detailed strategy for the simultaneous isolation of high-quality DNA and RNA from post-mortem human CNS tissue. Tissue from motor cortex, frontal cortex, hippocampus, occipital cortex, anterior cingulate cortex, cerebellum and spinal cord were obtained from 22 individuals diagnosed with motor neuron disease and 13 neurologically normal controls (n = 245 tissues). We demonstrated that a DNA/RNA co-purification kit consistently isolated DNA and RNA of high yield and quality from all six brain regions. Importantly, we determined that an organic solvent-based methodology was essential to isolate RNA from spinal cord tissue. Quality assessment and RNA sequencing confirmed that the isolated RNA was suitable for downstream omics analysis. Furthermore, cerebellum RIN and tissue pH were demonstrated to be predictors of RNA integrity across all CNS regions, making them useful quality markers for future cohort selection.

PrgmNr 3842 - Single cell RNA sequencing and binary hierarchical clustering identify distinct normoxia and hypoxia associated interstitial macrophage cell types in mice exposed to hypoxia

Stenmark[1]; [1]Univ. of Colorado, Anschutz Med. Campus, Aurora, CO, [2]Stanford Univ., Stanford, CA, [3]Univ. of California, San Francisco, San Francisco, CA
Disclosure Block: **N. Campbell:** None.
Lung interstitial macrophages (IMs) are acknowledged to contribute to pulmonary hypertension (PH), yet few studies have examined their molecular phenotypes at the single-cell level. Therefore, we aimed to determine IM diversity and its association with PH, rationalizing that single-cell RNA sequencing (scRNAseq) and binary hierarchical clustering (BHC) within and across IMs would provide the highest single-cell resolution. Moreover, we hypothesized that these methods could identify IM heterogeneity and its association with PH. $Cx3cr1^{GFP+}$ reporter mice were exposed to normoxia (~21% FiO_2), one day (D1), or seven days (D7) of hypoxia (~10% FiO_2). $Cx3cr1^{+}$ IMs were isolated by flow cytometry. We used the 10X Genomics platform for scRNAseq, and the Cell Ranger software (v1.2.0) for alignment to the mouse genome, quality control, and filtering, resulting in n = 5144 IMs. Seurat3, ClusterMap, and Monocle2 were used for the downstream analyses. Ingenuity Pathway Analysis and Fisherâ□□s exact test (q-value

PrgmNr 3843 - Spatial Whole Transcriptome Analysis of human kidney histological Structures

Author Block: **Y. Liang**[1], A. Vanshoiack[1], W. Yang[1], L. Zhang[1], P. Danaher[1], J. Reeves[1], E. Piazza[1], M. Grout[1], C. Glaser[1], D. Kroeppler[1], E. Brown[1], K. Ton[1], M. Hoang[1], G. Demirkan[1], K. Fuhrman[1], S. Ranade[1], M. D. Rhodes[2], S. Warren[1], J. M. Beechem[1]; [1]NanoString Technologies, Seattle, WA, [2]Nanostring Technologies, Seattle, WA
Disclosure Block: **Y. Liang:** Salary/Employment; NanoString Technologies.
A thorough understanding of normal tissue biology is crucial to advances in disease treatment. However, until the advent of spatial biology, it was challenging to generate detailed molecular profiles of the individual structures that comprise organ architecture and function. In this study, we report a deep understanding of kidney function by analyzing whole transcriptomes of histological structures, encompassing both what decades of detailed molecular studies have unveiled along with novel insights into organ physiology.
Using the GeoMx DigitalÂ® Spatial Profiler (DSP) and accompanying Whole Transcriptome Assay, we analyzed four non-diseased kidneys as a proof of principle for spatial Organ profiling studies. We profiled fundamental functional structures within kidney nephrons: glomeruli, glomerular filtration membrane, proximal and distal convoluted tubules, loops of Henle, and collecting ducts. GeoMxÂ® DSP allowed the selection of each of the histological structures for specific profiling of the whole transcriptome with high precision.
We detected 9,779 genes across the various structures, with the average detection in distinct compartments ranging from 3800-7000 genes. Data were benchmarked against the protein expression data from Human Protein Atlas as independent validation of key markers of distinct structures, with approximately 90% concordance between RNA expression and known protein localization. Additionally, deconvolution based on single-cell RNASeq enabled us to calculate the proportion of distinct cell types within each structure, confirming the previously known cell composition of these features. We also observed that each of the kidney sub-structures had enrichment in specific genes and pathways as per expectation, e.g., ion and metabolite transporters expressed explicitly in proximal and distal tubules, recapitulating 50 years of kidney physiology in a single experiment. Moreover, the retention of spatial information facilitated the resolution of differentially expressed genes between the cortical and juxtamedullary glomeruli Finally, the characterization of expression differences between the four kidney samples enables preliminary examination of the variation between individuals.
In conclusion, we have collected whole transcriptome data for establishing normal spatial gene expression profiles for key structural components of the kidney. These data will be publicly available and can be used as standards to inform future profiling studies in normal and diseased kidney tissue.

PrgmNr 3844 - Spatial whole transcriptome profiling uncovers unique functional insights into the histological structures of the human pancreas

Author Block: **E. Piazza**[1], Y. Liang[1], A. Vanshoiak[1], W. Yang[1], L. Zhang[1], P. Danaher[1], J. Reeves[1], M. Grout[1], C. Glaser[1], D. Kroeppler[1], E. Brown[1], K. Ton[1], M. Hoang[1], G. Demirkin[1], K. Fuhrman[1], S. Ranade[1], M. D. Rhodes[2], S. Warren[1], J. M. Beechem[1]; [1]NanoString Technologies, Seattle, WA, [2]Nanostring Technologies, Seattle, WA

Disclosure Block: **E. Piazza:** Salary/Employment; NanoString Technologies.

Until the advent of spatial biology, it was not easy to generate detailed molecular profiles of the individual structures that comprise organ architecture and function. In this study, we report a deep characterization of pancreas function by analyzing whole transcriptomes of histological structures, encompassing both what decades of detailed molecular studies have unveiled along with novel insights into organ physiology.

Using the unique ability of GeoMxÂ® Digital Spatial Profiler (DSP) to select histological structures of organs specifically and measure their gene expression with the Whole Transcriptome Assay, we analyzed four non-diseased pancreas samples. Our data demonstrate capability of GeoMxÂ® to profile critical functional structures within the pancreas with high precision. We focused the study on the islet of Langerhans, acini, and ducts within the pancreas, quantitating expression of the whole transcriptome across these different structures with the average detection in distinct compartments ranging from 6,000-8,000 genes.

Data were benchmarked against Human Protein Atlas protein expression data as independent validation of key markers of distinct structures, with approximately 90% concordance between RNA expression and known protein localization. Deconvolution based on single-cell RNASeq enabled us to calculate the proportion of distinct cell types within each structure, confirming known cell compositions. For example, while ductal components consist of small islands of cells punctuating the acini, by direct illumination of these cells we identified over 3000 genes that were highly specific to either structure (FDR In conclusion, we have collected whole transcriptome data for establishing normal spatial gene expression profiles for key structural components of the pancreas. These data will be publicly available and can be used as standards to inform future profiling studies in normal and diseased tissue.

PrgmNr 3845 - Targeting clinically significant dark regions of the human genome with high-accuracy, long-read sequencing

View session detail

Author Block: **I. McLaughlin**, J. Harting, Z. Kronenberg, L. Aro, C. Heiner; Pacific BioSci.s, Menlo Park, CA
Disclosure Block: **I. McLaughlin:** Major Stockholder/Ownership Interest; Pacific Biosciences. Salary/Employment; Pacific Biosciences.
Introduction: There are many clinically important genes in â□□darkâ□□ regions of the human genome. These regions are characterized as dark due to a paucity of NGS coverage as a result of short-read sequencing or mapping difficulties. Low NGS sequencing yield can arise in these regions due to the presence of various repeat elements or biased base composition while inaccurate mapping is attributable to segmental duplications. Long-read sequencing coupled with an optimized, robust enrichment method has the potential to illuminate these dark regions. **Materials and Methods:** Using PacBio highly accurate long-read (HiFi) sequencing, coupled with a long-PCR targeted enrichment method, we investigated two important dark region genes that are challenging to accurately type with short-read sequencing due to associated pseudogenes: *CYP21A2*, responsible for congenital adrenal hyperplasia, and *GBA*, responsible for Gaucher disease. For each gene, our aim was to cover regions of pathogenic mutations in a single contiguous sequence or set of sequences that can be assayed in a single reaction. *CYP21A2* and an associated pseudogene *CYP21A1P* were co-amplified in a single long-range PCR reaction generating a 10.2 kb and 8.9 kb amplicon, respectively. Similarly, *GBA* and an associated pseudogene *GBAP1* were co-amplified in a single long-range PCR reaction generating a 12.6 kb and 16.0 kb amplicon, respectively. Seven Coriell samples for the *CYP21A2* target region and 13 Coriell samples for the *GBA* target region containing known pathogenic mutations were studied in replicate. SMRTbell libraries were generated from pooled amplicons for each target gene and sequenced on a PacBio Sequel II System. Accounting for replicates, each library contained a multiplex of 24 samples. A new PacBio sequence clustering algorithm, pbaa, designed for rapid analysis of HiFi reads from amplicons was used in variant typing. **Results:** All pathogenic *CYP21A2* and *GBA* variants were accurately called in the test samples. These variants included whole-gene deletions, gene duplication, gene fusions, recombinant exons, and phased compound heterozygotes. **Conclusion:** We demonstrate that HiFi sequencing provides new opportunities for sequencing clinically relevant but previously dark regions of the human genome that are underrepresented in short-read sequencing. Accurate long reads provide important phasing information, identify structural variations, and avoid potential confusion with pseudogenes. HiFi sequencing of these regions enables a better understanding of the relationship between genetic factors and personal health and has the potential to ultimately help guide health-related decisions.

Disclosure Block: **K. Cunningham:** None.
Whole genome sequencing (WGS) is increasingly used to detect variants in coding and non-coding regions of the human genome in clinical and research settings. The sample processing steps upstream of sequencing (including extraction of DNA and WGS library preparation) can be time-consuming, labor intensive, and subject to variations in benchtop technique. Automation solutions for processing whole blood are often standalone and disjointed from liquid handling instruments used for library preparation steps. Here, we introduce a novel digital microfluidic (DMF)-based system, composed of: the Miro Canvas instrument, single-use electronics-free cartridges, and an intuitive drag-and-drop protocol building application. Miro Canvas offers the convenience and consistency of automation, with the flexibility to run individual samples and easily implement new workflows. Miro Canvas has automated all the steps required for the Illumina Lysis Reagent Kit to extract DNA from whole blood, followed by the Illumina DNA PCR-Free Prep workflow. The steps include blood lysis, DNA binding to beads, washes and elution (cartridge 1), followed by tagmentation of purified DNA, bead cleanup, ligation, library cleanup and final elution (cartridge 2). Using 20 Î¼l of whole blood, we compared DNA extraction and library preparation automated on Miro Canvas to manual preparations. Final libraries were sequenced on the MiSeq platform (PE150). Automated libraries had comparable final library yields (9.67Â±1.56 nM vs. 10.73Â±1.58 nM), percent coverage (percent of genome with 1X coverage at 350,000-500,000 passed filter reads), and decreased percent excluded bases (an average of 0.9% less) when compared to manual libraries. In conclusion, the Miro Canvas system readily extracts gDNA from whole blood samples and creates consistent, high-quality NGS libraries for WGS with the hands-off automation of high throughput liquid handlers, and the flexibility to easily run individual samples on demand for a wide variety of protocols. This end-to-end workflow has the potential for personalizing and widely distributing WGS-based testing in clinical and research settings.

PrgmNr 3847 - Comparison of fully automated to Semi-Automated Variant Curation in Genetic Carrier Screening

View session detail

Author Block: **B. Gall**[1], T. Smart[2], S. Kolluri[1], H. Tadepally[1], K. Phaik Har Lim[1], N. Sanapareddy[1], D. Keen-Kim[1]; [1]Natera, Inc., San Carlos, CA, [2]Natera, Inc, San Carlos, CA
Disclosure Block: **B. Gall:** Major Stockholder/Ownership Interest; Natera, Inc.. Salary/Employment; Natera, Inc..
The rapid integration of artificial intelligence (AI) in genomic testing has resulted in the increased use of AI in genomic variant curation. While AI is highly efficient, it is hypothesized that manual curation can more accurately capture nuances such as â□□borderlineâ□□ or complex data in the literature. We therefore investigated internal data as a case study by comparing the sensitivity and specificity of one commercially-available fully automated variant curation software against an AI-assisted semi-automated curation using the same software. Though each process applies the ACMG guidelines to reach a final pathogenicity classification, insight into the AI adaptation of ACMG criteria was limited due to proprietary constraints of the automated variant classification software used for this comparison. We also compared the sensitivity and specificity of fully automated curations to curations where semi-automated curations and high-confidence ClinVar classifications were concordant. We performed our analysis using historical data from the HorizonTM carrier screening panel (Natera, Inc.), collected between November 2019 and November 2020. Our analysis of fully-automated variant curation compared to semi-automated variant curation in calling a variant positive (likely pathogenic or pathogenic) or negative (variant of uncertain significance (VUS), likely benign and benign) had a sensitivity and specificity of 90.60% and 97.39%, respectively (n=116,721). Comparison of a fully-automated variant curation and a semi-automated curation which was concordant with high-confidence ClinVar classifications resulted in a sensitivity and specificity of 77.29% and 98.28%, respectively (n=5,531). The likelihood of a false positive report from a fully-automated classification was calculated to be between 9.40-22.71%. This disparity is likely a result of inadequate AI collation and interpretation of literature-derived data necessary for applying ACMG criteria. Analysis of a subset of these discrepancies (n=78) occurring over a period of six months confirmed that AI-computed curations omitted or overinterpreted literature with clinical cases (24.36%) and/or failed to interpret mixed pathogenic and benign evidence (15.38%). Despite the rising popularity of AI, our data comparing one AI curation program to semi-automated classification demonstrates that AI-computed curation is less accurate than semi-automated classification. Our analysis supports the use of manual curation in combination with AI-supported curation, to increase productivity and streamline processes, while preserving the accuracy associated with manual curation.

PrgmNr 3848 - Designing Probesets for Interfering Variant Awareness on Genotyping Microarrays

The number of known polymorphic variants in the human genome has increased significantly throughout the past decade, ranging from about 80 million variants in the 1000 genomes Phase 3 study (2015) up to over 700 million variants in the gnomADv3.1 study (2020). A significant fraction of these polymorphisms overlap in genomic locus, resulting in potentially multiallelic loci. However, public databases of human polymorphisms such as dbSNP and gnomAD do not consistently account for these possible overlaps. To accurately genotype a target locus on the hybridization-based genotyping microarrays, it is crucial to account for interfering polymorphisms. Failure to do so may result in unintended hybridization to spurious targets. Using the gnomADv3.1 data set, we performed a comprehensive check for overlapping variants against several different catalogs of known mutations, while also accounting for varying allele frequencies across different superpopulations. The ClinVar database of ~625,000 variants (Dec 2020) are particularly enriched in overlapping variants. By screening the ClinVar variants against the 707.9 million known polymorphic sites in gnomADv3.1 across 5 superpopulations (AFR, AMR, EAS, NFE, SAS), we found that 31.7% of the Clinvar variants overlapped with at least one other polymorphic site. Within the ACMG 59 genes, 30% of ClinVar variants overlapped another polymorphic site. We also demonstrate the ability to correctly genotype overlapping variants by using probes specifically designed to factor in the overlapping variants on the Applied Biosystemsâ□¢ CarrierScanâ□¢ and AxiomTM Precision Medicine Diversity (PMD) Research arrays. We show several examples of pathogenic variants associated with severe traits and conditions where multiallelic probe designs were able to correctly resolve the more common interfering variant from the relatively rare target variant. Example of overlapping variants includes the short deletion rs1805177 overlapping with the SNP rs10229820 with MAFs of 6.2% and 13.1% respectively, and the rare delATC variant rs121908745 overlapping with the relatively common delCTT variant rs113993960 with MAFs of 0.014% and 0.26% respectively (AFR superpopulation, gnomADv3.1). Both complex loci were resolved using multiallelic genotyping on the CarrierScanâ□¢ array.This study demonstrates the importance of screening and designing for overlapping variants. With the steadily increasing number of rare genomic variants being published in literature, common interfering variants become increasingly relevant.

PrgmNr 3849 - DNAscopeTM: A novel chromogenic in-situ hybridization technology for high-resolution detection of DNA copy number and structural variations

View session detail

Author Block: **V. Murlidhar**, L-C. Wang, F. Tondnevis, C. Todorov, J. Gaspar, A. Sahajan, B. Zhang, X-J. Ma; Bio-Techne, Newark, CA

Genomic DNA anomalies such as copy number variations (gene duplication, amplification, deletion) and gene rearrangements are important biomarkers and drug targets in many cancer types. DNA in-situ hybridization (ISH) is the gold standard method to directly visualize these molecular alterations in formalin-fixed paraffin-embedded (FFPE) tumor tissues at single-cell resolution within a histological section. However, currently available fluorescent ISH (FISH) assays provide limited morphological detail due to the use of fluorescent nuclear staining compared to chromogenic staining. Furthermore, FISH techniques rely on expensive fluorescence microscopes, risk loss of fluorescent signal over time and involve tedious imaging at high magnifications (100X). There is thus an unmet need for a sensitive and robust chromogenic DNA-ISH assay that can enable high-resolution detection of genomic DNA targets with the ease of bright-field microscopy. We present here DNAscope - a novel chromogenic DNA-ISH assay - for detecting and visualizing genomic DNA targets under a standard light microscope. DNAscope is based on the widely used RNAscopeÂ® double-Z probe design and signal amplification technology and provides unparalleled sensitivity and specificity with large signal dots readily visualized at 40X magnification and with full morphological context. Furthermore, DNAscope ensures specific DNA detection without interference from RNA due to the use of a novel RNA removal method. Using a duplex chromogenic detection assay in red and blue, we demonstrate highly specific and efficient detection of gene rearrangements (ALK), gene amplification (ERBB2, EGFR, MET) and deletion (TP53 and CDKN2A). The DNAscope assay has been carefully optimized for probe signal size and color contrast to enable easy interpretation of signals under conventional light microscopy or digital pathology. Compared to conventional FISH assays, DNAscope probes are standard oligos that are designed in silico to be free of any repetitive sequences and can be rapidly synthesized for any DNA target. In conclusion, the DNAscope assay provides a powerful and convenient alternative to commonly used FISH assays in many research applications.

PrgmNr 3850 - Immunophenotyping of TCR and BCR clonotypes

Disclosure Block: **A. Chenchik:** None.
TCR and BCR repertoire profiling holds great potential for understanding the disease mechanisms and development of new therapeutics in infectious disease, auto-immunity and immuno-oncology. However, this potential could be greatly improved by combining information about receptor clonotypes with immuno-phenotypes of T and B cells. To facilitate these studies, we developed a novel technology for combined profiling of all human TCR and BCR variable regions and phenotypic characterization of immune cells in bulk and at the single-cell level in PBMC and immune cell fraction samples. The developed TCR/BCR Immunophenotyping method involves multiplex RT-PCR amplification and sequencing of CDR regions of TCR and BCR genes and of a set of the most informative T- and B-cell phenotyping genes. Bioinformatics analysis of NGS data allows us to profile TCR/BCR clonotypes, as well as identify major immune cell subtypes and their activation status. Data will be presented showing how combined TCR/BCR clonotype analysis combined with targeted expression profiling of immune cells can be applied for large-scale discovery of novel cell typing and activation biomarkers in several immune-response model systems. Preliminary studies demonstrate the assay has unparalleled throughput, sensitivity, and improved cost-effectiveness for high-throughput immunity biomarker discovery applications.

PrgmNr 3851 - Implications of biological networks: Search for the basal gene network using plasma proteomic signatures of COVID-19 patients

View session detail

Author Block: **A. Podder**[1], N. J. Schork[1,2]; [1]Translational Genomics Res. Inst. (TGen), phoenix, AZ, [2]The City of Hope Natl. Med. Ctr., Duarte, CA
Disclosure Block: **A. Podder:** None.

The prime components of human biological machinery, e.g., genes, proteins, and metabolites, do not function in isolation. Instead, a range of specific interactions occur between various micro- and macro-molecules inside a cell. These molecular interactions define nearly all biological processes, and their knowledge is essential to manage the perturbations contribute to the onset of disease pathogenesis. Such interactions can be outlined by the graph theory, which uses assorted models from mathematics and physics. In the past decade, significant progress has been made in researching common diseases, and numerous high-throughput datasets have emerged across multiple layers of cellular physiology including genomic, transcriptomic, proteomic, and metabolomic. These datasets can be utilized to construct a graph-based representation of biological interactions to delineate critical gene regulatory processes, protein-protein interactions, signal transduction pathways, metabolites, and reaction maps that can be interrogated to understand disease processes.

We have investigated such elemental molecular interactions for various diseases and traits, including COVID-19, the current pandemic that has spread rapidly across the globe. Even after rigorous year-long research, COVID-19 poses a significant risk to human health, we therefore have actively sought to understand how the SARS-CoV-2 virus of the Corona-virus family infects the human body and what molecular disturbances take place during infection. We employed a network approach based on physical protein-protein interactions to find cellular processes dysregulated as a whole in response to a COVID-19 infection. For this, we have used available data reflecting the differential expression of 1,420 plasma proteins for 306 COVID-19 patients and 78 control individuals featured across four different time points in a three weeks infection. We show that, based upon this approach, we can uncover novel insights and promising drug targets for COVID-19 that go beyond those focusing on limited list of individually altered genes.

PrgmNr 3852 - Large-scale functional assays to comprehensively assess SNP-accessible variants in the Urea Cycle Disorder genes, *OTC*, *ASS1*, and *ASL*

View session detail

Author Block: **G. Cromie**[1], R. Lo[1], K. Owens[2], A. Sirr[1], J. N. Kutz[2], R. McLaughlin[1], A. M. Dudley[1]; [1]Pacific Northwest Res. Inst., Seattle, WA, [2]Dept. of Applied Mathematics, Univ. of Washington, Seattle, WA

Disclosure Block: **G. Cromie:** None.

Here, we report our progress in developing high-throughput functional assays of variant effect for the three human urea cycle disorder (UCD) genes encoding ornithine transcarbamylase (OTC), argininosuccinic acid synthetase (ASS1), and argininosuccinic acid lyase (ASL).

Urea cycle disorders are highly actionable diseases for which understanding the functional implications of genetic variation in the causative genes can positively impact patient health. Neonatal onset is associated with severe enzyme deficiency. These infants appear normal at birth, but can rapidly accumulate high levels of ammonia, potentially resulting in cerebral edema, lethargy, seizures, coma, and death. As such, in the United States, biochemical assays of ASL and ASS1 protein function are included in the newborn screening panels of all 50 states, and OTC activity is screened in eight. In contrast, individuals harboring moderate to mild loss of function alleles may remain undiagnosed into childhood or even adulthood. Late onset UCDs generally involve environmental triggers (e.g. surgery, pregnancy, or chemical exposure) in individuals with reduced enzyme function. The late-onset form often presents with episodic psychosis, bipolar disorder and major depression, and without treatment, prognosis is poor. Thus, knowledge of the functional implications of genetic variation in these genes could reduce the morbidity and mortality associated with delayed treatment or underdiagnosis.

Our approach leverages the advent of low-cost, large-scale gene synthesis and the development of high-throughput *in vivo* assays of protein function (Multiplexed Assays of Variant Effect, MAVEs) in the model organism, *Saccharomyces cerevisiae*. Because OTC, ASS1 and ASL are enzymes in the highly conserved arginine biosynthesis pathway, the human protein coding sequences can functionally replace (genetically complement) deletions of their corresponding yeast orthologs. Therefore, yeast growth in the absence of arginine provides a quantitative readout of human enzyme function with disease alleles showing significant reduction relative to wild-type. We will present quantitative results for the functional impact of 1755 (93%) of all SNP-accessible amino acid substitutions in the OTC protein. We also discuss these results in the context of the published OTC crystal structure and the extent to which they agree or conflict with published annotations of pathogenicity, and when available, disease severity.

PrgmNr 3853 - Optimizing performance of copy number variant calling based on improved baseline selection

Disclosure Block: **A. Bhattacharya:** None.
Detecting copy number variation (CNV) using read count from next-generation sequencing (NGS) data is often challenged by separating true CNV events from background noise. Commonly used read count-normalization techniques address this challenge by removing various sources of background noise (eg, batch effects, GC bias, or low coverage in low complexity or pseudogene regions) or by removing higher order principal components. Even after normalization, CNV callers often fail to separate real events when coverage is below 200X or when event sizes are small or partially covered by capture probes. To address the challenges, we developed a computational approach that uses a systematic selection of baseline (normal) samples. This new baseline-selection method initially includes all the samples in a sequencing batch as initial baseline and then excludes all the low coverage and volatile samples to form final baseline.
Detection rates were compared for our CNV calling pipeline (detecting outliers from normalized coverage data) with the new versus old (baseline includes all samples in a sequencing batch) baseline-selection methods. Coverage data from 43 low-coverage (average coverage less than 200x) samples with 118 confirmed CNV events (using a validated orthogonal method i.e., array, MLPA) were used; 40% of CNVs were small 1- to 2-exon deletions or duplications. Without the baseline-selection, 39 (33%) CNVs were detected. With baseline-selection, 112 (95%) CNVs were detected. These results show the baseline-selection method presented here can improve detection of CNVs in samples with low coverage.

PrgmNr 3854 - Plasma protein profiling of Alzheimerâ□□s and mild cognitive impairment subjects with a novel approach for identification of known and unknown candidate biomarkers

View session detail

Author Block: **R. Benz**, M. Goldberg, J. C. Cuevas, W. Manning, X. Zhao, T. L. Platt, M. Ko, H. J. Ha, H. Liou, E. M. Elgierari, M. Figa, H. Xia, D. Harris, P. Ma, O. C. Farokhzad, J. E. Blume, A. Siddiqui; Seer, Redwood City, CA

Blood plasma, which contains valuable information from most tissues, is a rich source of protein biomarkers for early detection of diseases, but its large dynamic range of protein concentrations necessitates complex workflows and trade-offs between throughput, scalability, coverage, and precision. Here we use a deep and quantitative proteome profiling platform, Proteograph™ Product Suite, which leverages multiple nanoparticles, engineered with distinct physicochemical properties to provide broad coverage of the plasma proteome at scale. In this study we aim to identify protein biomarkers for Alzheimerâ□□s disease (AD) from blood with this untargeted plasma protein profiling approach, for AD and Mild Cognitive Impairment (MCI) conditions.
Methods. Plasma samples from 200 subjects comprising 50 AD, 50 MCI, and 100 controls were profiled using the Proteograph plasma protein profiling platform[1]. Using a 5-nanoparticle panel and 85 ÂµL of plasma per nanoparticle, proteins were quantified by data-independent acquisition (DIA) liquid-chromatography mass-spectrometry (LC-MS) in about 6 weeks. Normalized peptide intensities were used in ten rounds of 10-fold cross-validation to develop random forest models for class discrimination.
Results. Across the samples, 2,391 plasma proteins were detected, with 2,085 in at least 25% of samples. 36 proteins with the highest AD OpenTargets[2] scores were detected, including Amyloid Beta (A4) Precursor Protein. 25,593 protein-comprising peptides were detected, with 15,661 in at least 25% of the samples. Univariate analysis identified 441 and 526 proteins that were significantly different in AD or MCI versus control, respectively. Random-forest classification for AD and MCI produced ROC AUCs that were at least 0.90. Top features by importance included known and unknown candidate biomarkers.
Conclusions. These analyses have identified novel combinations of candidate plasma protein markers, many without prior known relevance to AD. More broadly, the Proteograph platform confirmed its ability to generate profiling data in a deep, broad, and rapid fashion, enabling large-scale studies to detect novel insights with clinically useful potential.

Disclosure Block: **M. Donovan:** None.
Introduction: Next-generation sequencing studies at scale have revealed novel biological insights into the molecular link between genotype and human biology through the measurement of the multiple biological steps occurring between genome, epigenome, and transcriptome. Similarly scaled and comprehensive studies examining the human proteome have been challenging to achieve due to the complexity of distinguishing between multiple protein variants arising from a single gene due to allelic variation, alternative splicing, post translational modifications, and degradation. Scalable, deep and unbiased proteomics studies have been historically impractical due to cumbersome and lengthy workflows required for complex but easily accessible samples, like blood plasma. Here, we demonstrate the power of Proteograph, a next generation nanoparticle-based automated plasma proteome profiler, in a proof-of-concept proteogenomic analysis of 80 healthy controls and 61 early stage non-small-cell lung cancer (NSCLC) samples to dissect differences between protein isoforms arising from alternative gene splicing and to identify peptide variants arising from allelic variation.
Methods and Results: Processing the 141 plasma samples with Proteograph yielded 21,959 peptides corresponding to 2,499 protein groups. Using peptides with significant abundance differences (p **Conclusions**: Proteograph can generate unbiased and deep plasma proteome profiles that enable identification of protein isoforms and variants present in human plasma with potential to scale to sufficient sample sizes enabling population-scale proteogenomic studies.

PrgmNr 3856 - Proteograph™ Analysis Suite: A cloud-scalable software suite for proteogenomics data analysis and visualization

View session detail

Author Block: **A. Vadapalli**, Y. Berk, H. Auluck, A. Gajadhar, Y. Lou, A. Siddiqui; Seer, Inc, Redwood City, CA
Disclosure Block: **A. Vadapalli:** Salary/Employment; Seer, Inc.
Researchers are increasingly adopting multi-omics approaches to understand the complex biological processes that underlie human diseases. Next generation sequencing (NGS) is widely used for identifying genetic variants and gene function while mass-spectrometry is used to quantify protein abundances, modifications, and interactions from complex samples like plasma. A new plasma profiling platform called the Proteograph Product Suite was developed that leverages multiple nanoparticles with distinct physiochemical properties to provide deep plasma proteomic analysis at scale. The analysis of proteomics and genomics data typically requires a wide collection of different tools, which is further complicated by the prevalence of command-line interfaces and operating system-specific requirements that can act as a barrier for researchers to adapt new data analysis tools due to their steep learning curve and implementation costs. In this abstract, we present a cloud-based analysis software platform called Proteograph Analysis Suite (PAS) that analyzes proteomics data derived from the Proteograph workflow along with genomic variant results imported from NGS experiments. The main features of the software suite include an experiment data management system, analysis protocols, an analysis setup wizard, and tools for reviewing and visualizing results. PAS can support both Data Independent Analysis (DIA) and Data Dependent Analysis (DDA) proteomics workflows and is compatible with widely accepted format of variant call files from NGS workflows. For each analysis run, users are able to view various quality control metrics like peptide/protein group intensity, protein sequence coverage, relative protein abundance distribution, peptide and protein groups stratified by nanoparticle. Various visualizations such as principal component analysis, hierarchical clustering, and heatmaps allow intuitive identification of dataset trends. Quantitative differential expression tools such as volcano plots, protein interaction maps and protein-set enrichment simplify data interpretation enabling functional insights.In conclusion, we present a comprehensive proteogenomic analysis software suite to enable user-friendly and reproducible multi-omics analyses of proteomic and genomic data.

PrgmNr 3857 - Quantification of gene expression changes in mouse disease models using a high-throughput spatial omics platform

View session detail

Author Block: **T. Awad**, O. Marcos, R. Yin, N. Kotova, I. Oh; Rebus BioSci.s, Santa Clara, CA
Disclosure Block: **T. Awad:** None.
Batch effects due to technical variability are a major problem in single cell transcriptomics. Spatial methods are no exception - their low throughput requires high numbers of technical replicates, reducing the statistical power needed to quantify differential gene expression across experimental conditions. To overcome this problem, we took advantage of the large imaging area of the Rebus Esper spatial omics platform. We processed brain sections from three mouse genotypes in parallel - one wild type and two disease models. In addition, the Esper High Fidelity assay, based on single-molecular fluorescent in situ hybridization (smFISH), requires no amplification, yielding quantitative results with minimal batch effect. The combination of low technical variation and balanced experimental design allowed us to integrate more than 500,000 cells from multiple datasets for analysis without the need for batch correction. We were able to identify more than 12 neuronal and glial cell type clusters using 20 cell type-specific genes, and further dissect these cell types by anatomical structure utilizing the spatial information. We then performed differential gene expression of 10 disease-related genes on each cell-type subset. These results demonstrate the ability of the Rebus Esper spatial omics platform to yield high-throughput spatial omics data with single cell resolution, low technical variation, and the sensitivity and specificity required for differential gene expression quantification.

PrgmNr 3858 - Reducing variability of breast cancer subtype predictors by grounding deep learning models in prior knowledge

View session detail

Author Block: **J. Davidson**, W. A. Johnson, R. Gadgil, E. Schwab, P. Anderson; Cal Poly, San Luis Obispo, San Luis Obispo, CA
Disclosure Block: **J. Davidson:** None.
INTRODUCTION:The benefit of biomedical informatics research is the synthesis of computational power and biomedical insight. Deep learning networks in biology exemplify such a synthesis, having successfully streamlined various bioinformatics problems like cancer subtype classification, drug sensitivity prediction, and imaging analysis. However, many networks suffer from underspecification, with multiple groups of near-optimal predictors. This is quite problematic in biomedicine, where datasets increasingly include far more input predictors than data samples. Deep neural networks allow for analysis of such high-dimensional data without pre-processing or feature extraction. We aim to provide a framework in which curated knowledge can be added to a neural network to address underspecification and improve network interpretability. METHODS: We developed a three-stage pipeline for incorporating prior knowledge into predictive modeling. Our approach encourages researchers to share and reuse curated knowledge and methodology in an iterative manner. For this study a 3-gene model incorporates master regulator genes ESR1, ERBB2, and AUKRA as appropriate predictors are for subtypes basal-like, HER2-enriched, luminal A, and luminal B. We combine curated knowledge with an experimental dataset to produce derived knowledge, with the goal of quantifying the derived knowledge for downstream modeling and analysis. For this study, our experimental data are gene expression values from a set of 2,133 participants of the METABRIC cohort with known subtype classifications. The patient data and the curated knowledge are combined to produce a graph of patient-patient relationships that encodes which patients exhibit similar profiles under the three-gene model. The final stage, derived knowledge from stage 2 are embedded into machine learning systems. In this work, we apply the derived knowledge from stage 2 to the deep learning neural network designed for breast cancer subtyping. RESULTS:Our approach introduces a new parameter, knowledge loss weight, to study the effect of increasing the importance of knowledge in the overall loss function. We studied the performance of the model after the incorporation of knowledge into the loss function both on the training and the validation dataset. We studied the stability of the results by examining the variability of the importance of each gene over multiple repetitions of the training algorithm. CONCLUSIONS: Combining the versatility and predictive power of deep neural networks with the insight of biological knowledge provides a solution to the problems of data scarcity and model interpretability in bioinformatics.

PrgmNr 3859 - 'Drugging' PTPRD (AD, RLS and Addiction-associated gene) PTPRD

Author Block: **G. R. Uhl**[1], W. Wang[2], T. Prisinzano[3], D. Johnson[4], I. Henderson[1]; [1]UNM/NMVAHCS, Albuquerque, NM, [2]Univ. of Arizona, Tucson, AZ, [3]Univ. of Kentucky, Lexington, KY, [4]Univ. of Kansas, Lawrence, KS

Disclosure Block: **G.R. Uhl:** None.

Variants in the human PTPRD gene provide polygenic associations with vulnerability to addictions and ability to quit. They provide oligogenic associations with densities of neurofibrillary pathology (NFTs) in Alzheimer's disease (AD) brains, vulnerability to restless leg syndrome (RLS) and levels of PTPRD mRNA expression in postmortem human brains. Mouse models support the findings in addiction and RLS. In vitro data supports association with AD NFTs since PTPRD dephosphorylates the regulatory phosphorylation of GSK3s, principal serine/ threonine kinases on the path to forming NFTs. In aggregate, these data support strategies to reduce PTPRD phosphatase activity to reduce reward from addictive substances and to enhance this activity in order to reduce vulnerability to AD NFTs and possibly reduce symptoms in RLS.We have synthesized and tested over 40 novel analogs of our lead compound PTPRD phosphatase inhibitor, 7-BIA, and have identified an analog with greater potency, selectivity vs other phosphatases, selectivity in relation to targets of other known drugs, oral bioavailability, therapeutic index between 100 and 1000x proposed therapeutic dose and ability to reduce a measure of stimulant reward, cocaine conditioned place preference, by half in wildtype mice but not in mice with reduced PTPRD expression. We have also identified flavonol positive allosteric modulation of PTPRD's phosphatase. Quercetin can enhance PTPRD's ability to dephosphorylate GSK3 by more than 1.5-fold. Our results support the ability of a target identified by oligo- and polygenic association signals to provide a site for development of potentially useful novel therapeutics. Quercetin is generally recognized as safe by the FDA, facilitating human trials of its tolerability and utility in slowing progression to AD in aging.

Disclosure Block: **D. Portik:** Salary/Employment; Pacific Biosciences.
Pharmacogenomic testing in personalized medicine has the potential to improve patient treatment outcomes and reduce healthcare costs associated with medication efficacy and adverse drug reactions. Several technologies are commonly used for germline pharmacogenomic testing, including targeted genotyping, short-read sequencing, hybridization arrays, qPCR, and MLPA. Unfortunately, many clinically-significant pharmacogenomic loci remain challenging to accurately interrogate by these methods due to low sequence complexity and/or the presence of highly homologous pseudogenes. Long-read amplicon sequencing using Pacific Biosciences (PacBio) technology has previously been reported to accurately and precisely interrogate problematic pharmacogenomic loci, including *HLA*, *CYP2D6*, and *SLC6A4*; however, multi-gene pharmacogenomic HiFi sequencing panels have not been described. We developed a novel method to comprehensively interrogate a panel of 43 pharmacogenomic genes using an enrichment-based capture strategy (IDT) coupled with HiFi sequencing. Gene selection was centered on incorporating content with Clinical Pharmacogenetics Implementation Consortium (CPIC) guidelines and/or FDA recommendations, including selected variants with evidence for clinical actionability, translating to 935 kb of enrichment content. Performance of the novel panel and sequencing strategy was evaluated by subjecting reference material specimens with previously characterized variant calls and star (*) allele diplotypes to enrichment and HiFi sequencing on the Sequel IIe System. Consensus HiFi read clustering and alignment to GRCh38 used pbaa and pbmm2, respectively. Small variants (CYP2D6 variants, and enrichment-based HiFi sequencing correctly called the *CYP2D6*5* deletion allele in HG00276. These data indicate enrichment-based capture and HiFi sequencing is an effective approach for multi-gene panels, including historically challenging pharmacogenomic genes, for accurate variant discovery and full-gene haplotype phasing.

PrgmNr 3861 - Genomic analysis of angiotensin converting enzyme (ACE) inhibitor - induced angioedema

View session detail

Author Block: **M. A. Kennedy**[1], Y. Liau[1], S. D. S. Maggo[1], K. Lehnert[2], M. P. Doogue[1], A. Scull[1], A. L. Miller[1], J. F. Pearson[3]; [1]Univ. of Otago, Christchurch, New Zealand, [2]Univ. of Auckland, Auckland, New Zealand, [3]Univ. of Otago Christchurch, Christchurch, New Zealand
Disclosure Block: **M.A. Kennedy:** None.
Angioedema is a rare but serious adverse drug reaction associated with angiotensin converting enzyme inhibitors (ACEi). Prior research has indicated that specific ethnic populations are at a higher risk of ACEi - induced angioedema (ACEi-A), and several hereditary forms of angioedema exist, suggesting a genetic link. Several candidate gene and genome wide association studies have been conducted for ACEi-A, but no candidate genes or genetic variants of major effect have been identified. Using a model of monogenic predisposition to this adverse reaction, we set out to find variants that were rare in the population but highly enriched in ACEi-A. To achieve this, we conducted whole exome sequencing or whole genome sequencing on 20 ACEi-A cases. We identified one synonymous exonic variant in the *ACE* gene (rs4365) that was present in 40% of our ACEi-A cases compared to 4% of our controls (p-value=1.7e-05) and 3% of the gnomAD total dataset (p-value ACE and other genes. Using the WGS data, we also sought variants in candidate genes previously implicated in drug induced or hereditary angioedema, but found no evidence for consistent involvement of such variants in our cohort. In a separate analysis on the same dataset, we applied SKAT-O to evaluate rare variants within a larger set of genes linked to angioedema, and the main finding here was that aggregated variants in *ACE2* were nominally associated with reduced risk of angioedema. Finally, we examined copy number variants (CNV) called from the WGS data, and identified several rare duplication/deletion events in ACEi-A cases. A duplication encompassing *ADGRE1* was present in three angioedema cases, although this CNV is rare in the wider population. In conclusion, this analysis identified several interesting potential genetic contributors to ACEi-A, however, the small cohort size limits statistical power and these findings need to be evaluated in larger cohorts.

PrgmNr 3862 - Identification of pharmacogenetic predictors of methotrexate-induced mucositis in children with cancer

View session detail

Author Block: **C. Loucks**[1,2], A. Man[1,2], K. Li[1,2], S. R. Rassekh[1,3], C. J. Ross[4,1,5], B. C. Carleton[1,2,5,6]; [1]BC Children's Hosp. Res. Inst., Vancouver, BC, Canada, [2]Div. of Translational Therapeutics, Dept. of Pediatrics, Faculty of Med., Univ. of British Columbia, Vancouver, BC, Canada, [3]Div. of Oncology, Hematology and Bone Marrow Transplant, British Columbia Children's Hosp. and Univ. of British Columbia, Vancouver, BC, Canada, [4]Univ British Columbia, Vancouver, BC, Canada, [5]Dept. of Med. Genetics, Faculty of Med., Univ. of British Columbia, Vancouver, BC, Canada, [6]Pharmaceutical Outcomes Programme (POPi), British Columbia Children's Hosp., Vancouver, BC, Canada
Disclosure Block: **C. Loucks:** None.

Methotrexate is effectively used to treat acute lymphoblastic leukemia (ALL), yet some patients develop mucositis, a painful inflammation/ulceration of mucosal linings found at various locations throughout the body (e.g., the eyes, ears, mouth, digestive tract and vagina). In severe cases, mucositis is life-threatening due to increased susceptibility to infection or the inability to proceed with anti-cancer drug treatment. Studies exploring the potential impact of individual genetic susceptibility to methotrexate-induced mucositis have identified 28 genetic variants; however, their predictive value remains uncertain due to limited replication attempts or inconsistency between studies. Here, we aimed to discover and replicate genetic variants predictive of methotrexate-induced mucositis. We recruited children with ALL from six Canadian pediatric oncology centres and collected genomic DNA, captured detailed clinical/demographic information and conducted rigorous characterization of mucositis events to determine the probability they were methotrexate-induced. Overall, 584 methotrexate-treated children were enrolled in this study, and an observational case-control study design using logistic regression is being used to identify genetic predictors of mucositis. Cases (n=130; 22.2%) suffered serious mucositis defined as CTCAE/WHO grade â¥ 2 toxicity, controls (n=366; grade 0) did not experience mucositis, and children with mild mucositis (n=88; grade 1) were excluded to improve case/control separation. In preliminary genetic analyses, we first focused on children treated with high-dose methotrexate (â¥ 1000 mg/m^2; 86 cases; 192 controls), in which the majority of previous pharmacogenetic studies have been conducted. While these analyses revealed no significant associations with previously-identified variants (P â¥ 0.05), we uncovered an association with a novel genetic variant in close proximity to two genes (*AMDHD1* and *HAL*) involved in histidine catabolism (recently linked to methotrexate sensitivity) that puts patients at 5 times increased risk of developing serious mucositis (95% CI: 2.4-10.2; P=2.4x10^{-5}). Analyses are underway to determine the consistency/robustness of genetic findings by assessing the impact of case definition (e.g., considering more serious cases), treatment regimen (i.e., by incorporating children treated with lower methotrexate doses), and clinical factors (e.g., by adjusting analyses for radiation treatment that also impacts mucositis). Ultimately, identified genetic variants will form the basis of a mucositis-predictive test to help select the safest and most effective treatment strategy.

PrgmNr 3863 - Latino and Indigenous American populations may have five times as many pharmacogenetic variants as Europeans yet remain underrepresented in pharmacogenetic studies

View session detail

Author Block: **S. Hernandez**[1], L. A. Hindorff[2], J. Morales[1], E. M. Ramos[2], T. A. Manolio[3]; [1]Natl. Human Genome Res. Inst., Bethesda, MD, [2]NIH, Bethesda, MD, [3]NHGRI, Bethesda, MD
Disclosure Block: **S. Hernandez:** None.
Background: Pharmacogenetic (PGx) variants play a key role in the safety and efficacy of commonly prescribed drugs and are known to differ across ancestral groups, but frequency and impact of PGx variants among persons of Latino and Indigenous American ancestry are less well-characterized than in persons of European ancestry. If unrecognized, these differences may worsen health disparities experienced by Latino and Indigenous American populations. **Methods:** Allele frequencies for altered function variants in 11 PGx genes in â□□European,â□□ â□□Latino,â□□ and â□□Americanâ□□ populations were extracted from published Clinical Pharmacogenetics Implementation Consortium (CPIC) guidelines. CPIC reviews and curates published allele frequencies to calculate population allele frequencies for each gene, using PharmGKB definitions for European (primarily European descent, including European Americans), Latino (Mestizo descent, from Latin America, and self-identified Latino persons in the US), and American (from the Americas with ancestors predating European colonization) ancestries. After removing obvious duplicate persons reported in large databases such as gnomAD, total numbers of persons genotyped in CPIC guideline data for each of 11 genes with variants classified as normal or altered function (*CACNA1S, CYP2B6, CYP2C9, CYP2C19, CYP2D6, CYP3A5, DPYD, NUDT15, SLCO1B1, TPMT, UGT1A1*) were summed to calculate percentages of representation of these three groups and compare allele frequencies. **Results:** Allele frequencies for these 11 genes were reported for 632,000 persons of European, Latino, or American ancestry, of whom 520,000 (82%) were of European, 99,000 (16%) of Latino, and 13,000 (2%) of American ancestry. In contrast, population sampling consistent with 2019 US Census estimates would have yielded proportions of 75%, 23%, and 1.3%. Of 78 alleles with altered function, 28 were detected only in Latino or American populations or at $\geq$ 2-fold higher frequency than in European populations, while 27 alleles were detected only or at $\geq$ 2-fold higher frequency in European than Latino and American populations. Yield of altered function alleles were thus 0.52/100,000 European persons genotyped compared to 2.5/100,000 Latino or American persons genotyped. **Conclusions:** Allelic data used in CPIC guidelines for 11 PGx genes underrepresent Latino populations, while Latino and Indigenous American populations combined have a roughly 5-fold higher frequency of altered function variants. This could have important clinical implications and widen health disparities experienced by these two groups as PGx recommendations are brought into clinical practice.

PrgmNr 3864 - Research clinical pilot project for in silico pharmacogenomics concurrent with whole-genome sequencing in the pediatric ICU

View session detail

Author Block: **S. Batalov**, A. Hemperly, K. Rodriguez, A. Besterman, E. Sanford Kobayashi, N. Coufal, D. Dimmock, M. N. Bainbridge; Rady Children's Hosp., San Diego, CA
Disclosure Block: **S. Batalov:** None.
Pharmacogenomics is an important field for precision medicine, however its utility in the Pediatric and Neonatal intensive care units is not known. Rady Childrenâ□□s Clinical Genome Center (RCIGM-CGC) provides CAP/CLiA licensed clinical WGS testing and has a computational biobank of >2500 clinical genomes (and >4000 unaffected parental genomes for baseline). Genotyping CYP2D6 and other Pharmacogenomics genes is important for precision drug therapy because the enzyme it encodes metabolizes approximately 25% of drugs, and its activity varies considerably among individuals. Thus, patients on either end of the activity spectrum are at risk of subtherapeutic or supratherapeutic medication levels. Therefore, we aimed to assess the utility of the concurrent calling standard Pharmacogenomics genotyping (PGx) using WGS data for predicting opiate and other drug dosing for children in the Pediatric ICU. **Methods**: Subject genomes were interrogated by Illumina SBS chemistry (HiSeq, NovaSeq) to an average genome-wide coverage of >40x. Following the clinical bioinformatics WGS workflow (DRAGEN-based alignments to reference genome and variant calling, both small, indel, structural and copy number variants), read data was extracted for 34 PharmGKB level 1 gene loci (including but not limited to *CYP*-family, G6PD, RYR1, TPMT*) and *HLA* regions and processed with a combination of computational tools: Stargazer, PHLAT, OptiType (as per published protocols). The phenotype data for patients with computational prediction of poor/rapid metabolizer or unfavorable response was then collected and clinically correlated by targeted review of EPIC records for medical history and treatment and treatment responses. **Results**: An extensive dataset for precision and sensitivity evaluation was drawn from 1100 clinical genomes sequenced in 2020 at RCIGM-CGC. Computational analysis time was CYP3A4, and a wide variable spectrum for *CYP2D6* and the rest of pharmacogenes. Over 100 haplotypes (star alleles) have been detected for *CYP2D6*, some involving a gene conversion with nonfunctional paralog *CYP2D7*. Clinical correlation with neonatal ICU patients was minimal due to little overlap with age of onset, while higher in pediatric cohort (10+ yo). **Conclusion:** Accurate genotyping of pharmacogenes with WGS and subsequent allele calling with Stargazer, PHLAT, OptiType is feasible in clinical setting and will aid the implementation of precision drug therapy. In retrospective study, a small fraction of pediatric patients is identified, and clinical interaction is being followed up.

PrgmNr 3865 - Space-optimized HLA typing using Axiomâ¢ PGx research solutions

View session detail

Author Block: **C. Bruckner**; Thermo Fisher Scientific, Santa Clara, CA
Disclosure Block: **C. Bruckner:** Salary/Employment; Thermo Fisher Scientific.
The human leukocyte antigen (HLA) complex is the human version of the major histocompatibility complex (MHC). This complex includes genes responsible for immune function. Variations in these genes can affect adverse reactions to drugs, disease susceptibility, and immune response including transplant rejection. The highly polymorphic nature of this region and the prevalence of pseudogenes create challenges for traditional genotyping methods. Combining the use of direct genotyping with advanced imputation methods over the extended MHC region allows accurate HLA typing from SNP genotype data.
Applied Biosystemsâ¢ Axiomâ¢ microarrays are designed to measure approximately one thousand to nine hundred thousand markers as needed. Content prioritization is particularly important for space-constrained arrays. The Axiom Precision Medicine Diversity (PMD) Research Array genotypes over 850,000 markers, including around 8,000 for HLA typing. The Axiomâ¢ PharmacoFocusâ¢ array, designed for population-scale preemptive pharmacogenomics research, genotypes around 8,000 markers. HLA typing capability on Axiom PharmacoFocus Array was enabled by optimizing HLA module to around 1,500 markers. HLA marker selection was guided to enable efficiency while maintaining high HLA typing concordance by imputation, offering HLA typing across 11 MHC loci inclusive of: HLA-A*31:01, HLA-B*15:02, HLA-B*57:01, HLA-B*58:01.
A study used three Axiom microarrays with different density of HLA markers to genotype 1000 Genomes Project samples with diverse ancestries. The evaluated arrays are the PMD Array, PharmacoScanâ¢, and Axiom PharmacoFocus. HLA types for all 11 classical loci were imputed using the HLA*IMP:02 algorithm by Dilthey et al. (2013), as implemented in Axiom HLA Analysis software. High HLA typing concordance was maintained as the number of available markers was reduced by around 80% for the Axiom PharmacoFocus array. HLA types imputed by tested arrays also compared favorably to *in silico* HLA typing by Abi-Rached et al. (2018) of 1000 Genomes Project sequencing data.
References: [1] Dilthey AT et al. Multi-Population Classical HLA Type Imputation. PLoS Comput Biol. 2013; 9(2):e1002877. [2] Abi-Rached L et al. Immune diversity sheds light on missing variation in worldwide genetic diversity panels. PLoS One, 2018; 13(10):e0206512.

PrgmNr 3866 - The Study of *HLA-B*48:01* and *HLA-B*55:01* Frequency in Healthy Thai Population

View session detail

Author Block: **S. Chanuntranont**[1], A. Srisodsai[2], P. Satapornpong[3]; [1]Univ. of California, Riverside, Riverside, CA, [2]MedCoach Inst., Bangkok, Thailand, [3]The division of general pharmacy practice, Dept. of pharmaceutical care, Coll. of Pharmacy, Rangsit Univ., Pathum-Thani, Thailand
Disclosure Block: **S. Chanuntranont:** None.
Introduction: Penicillin, an antibiotic included in the beta-lactam (BL) class, is commonly used to treat bacterial infections in adults and children. It has been reported that approximately 10-20% of children who have received antibiotics in the beta-lactam class have developed a hypersensitivity reaction. In previous studies, it has been proven that *HLA-B*48:01* has an association with BL hypersensitivity in Thai children (OR = 37.4, 95%CI: 1.69-824.59; p = 0.016), and *HLA-B*55:01* has an association with penicillin hypersensitivity (OR = 1.41, 95%CI: 1.33-1.49; p = 2.04 $x10^{-31}$) in European ancestry. **Objective:** The aim of this study is to explore whether there is a distribution of *HLA-B*48:01* and *HLA-B*55:01* in healthy Thai individuals. **Methods:** 200 unrelated healthy Thai individuals were recruited in this study. *HLA-B* alleles using the Lifecodes HLA SSO typing kits (Immucor, West Avenue, Stamford, USA). **Results:** We found that the *HLA-B* alleles that show the most frequency in healthy Thai individuals were *HLA-B*46:01* (14.25%), *HLA-B*40:01* (7%), *HLA-B*58:01* (7%), *HLA-B*15:02* (6.75%), *HLA-B*13:01* (6.25%), *HLA-B*44:03* (4.75%), *HLA-B*51:01* (4.25%), *HLA-B*52:01* (4.00%), *HLA-B*35:05* (3.00%), and *HLA-B*40:06* (2.75%). Furthermore, there was not much distribution between *HLA-B*48:01* (0.25%) and *HLA-B*55:01*(0.25%) in Thais. Interestingly, the distribution of *HLA-B*48:01* was more prominent in Asian individuals: 2.88% of Japan, 3.56% of South Korea, 1.16% of Hong Kong, 1.00% of China, and 8% of Philippines. Whereas, *HLA-B*55:01* has 3.60% in Europeans and less than 1% in Asians. **Conclusion:** Thus, the distribution of pharmacogenetics markers could be used for screening among different ethnicities before initiation of penicillin treatment to avoid hypersensitivity reactions.

PrgmNr 3867 - A first exploration of the genetic architecture of linea nigra and its relationship with pigmentation

View session detail

Author Block: **S. Bivol**, J. Painter, P. Lind, C. Olsen, D. Whiteman, M. Law, S. Medland; QIMR Berghofer Med. Res. Inst., Brisbane, Australia
Disclosure Block: **S. Bivol:** None.
Introduction: Genome-wide association studies (GWAS) and follow-up meta-analyses have identified numerous genetic polymorphisms associated with melanocytic nevi (mole) count, and various pigmentation traits including hair, skin, and eye color. However, the genetic architecture of a common pregnancy hyperpigmentation - linea nigra - has not been explored before. Our aim was to conduct the first genetic analyses of this pregnancy complication and examine the genetic relationships with other pigmentation phenotypes. **Methods**: Phenotype data was collected via an online survey and DNA was extracted from saliva samples. The samples were genotyped on the Illumina Global Screening Array and imputed to the HRC reference panel. GWAS was conducted to explore genetic variations associated with linea nigra in a sample of 275 cases and 701 control Australian women of European descent. We computed a polygenic risk score (PRS) using data from a GWAS of mole count (N ~ 20,000, QSkin Sun & Health Study, QIMR Berghofer) to examine the relationship with linea nigra. **Results**: As expected given the low power, no genome-wide significant loci were found. However, several lead variants were nominally associated with linea nigra, including rs4734915 in *OXR*1 ($p = 4x10^{-6}$) and rs7634124 in *CLTN2* ($p = 7x10^{-6}$). Notably, *OXR1* and *CLTN2* genes have been associated with gestational age at birth and eye color, respectively, in previous GWAS analyses. The mole count PRS using a threshold of $1x10^{-6}$ significantly predicted linea nigra and accounted for 1.2% of the variance (P= 0.00057). **Conclusion:** A mole count PRS predicted linea nigra which suggests that linea nigra has shared genetic risk factors with melanocytic nevi. Although, no significantly associated loci were found, GWAS and PRS analyses will contribute to our understanding of the genetic architecture of linea nigra. Further work in larger samples is needed to identify causal loci for linea nigra and clarify its relationship with nevus count, pigmentation, and gestational age at birth.

PrgmNr 3868 - Clinical experience of an alpha thalassemia carrier screening assay with an increased detection rate due to novel variant calling

View session detail

Author Block: **G. Gould**, L. Collins, S. Pierson, R. Ben-Shachar, J. Wang, K. E. Erickson, K. Winters, K. Johansen Taber; Myriad Genetics, Inc., South San Francisco, CA
Disclosure Block: **G. Gould:** Salary/Employment; Myriad Genetics, Inc..
Background:
Carrier screening for alpha thalassemia, a prevalent genetic disease up to 200x more common than cystic fibrosis in certain ethnic populations, is recommended for all women who are pregnant or planning a pregnancy (1). Disease severity varies from mild anemia to in utero fetal demise. Most alpha thalassemia carrier screening assays detect only common copy number variants (CNVs) and the Constant Spring (CS) variant (2). To increase our detection rate, particularly across ethnicities to meet the needs of a diverse population, we expanded our assay to include novel variant calling of single nucleotide variants and insertions/deletions. Here we present the clinical experience of our improved assay.
Methods:
We collected data from 72,394 patients that received the Foresight Carrier Screen over a five-month period. We compared the percentage of patients that would have been identified as alpha thalassemia carriers before and after the addition of novel variant calling. Variants were classified according to case, functional and structural data, consistent with ACMG/AMP variant interpretation guidelines (3).
Results:
Detection rate improvement due to novel variants was highest in ethnicities that are frequently alpha thalassemia carriers. For example, ~8.5% of Middle Eastern patients were carriers of a CNV or CS while ~2% were carriers of a novel variant. Thus, novel variant calling increased carrier detection in the Middle Eastern population by >20%. Other ethnicities with the highest increases in detection rate include South Asian (4%), Southeast Asian (3%), East Asian (3%), Southern European (2%) and African/African American (1%).
In our cohort, we detected one novel variant - HBA2:c.95+2_95+6del5 - more often than CS, a well-characterized pathogenic variant. The c.95+2_95+6del5 variant is common in Mediterranean populations and leads to reduced Î±-globin expression. This variant produces a more severe phenotype than the corresponding deletion of the same gene. Clinically relevant phenotypes are seen in subjects with only two inactivated Î±-globin copies while deletional Hb H disease is only seen in subjects with 3 inactivated Î±-globin copies.
Conclusions:
Our results demonstrate novel variant calling for alpha thalassemia increases carrier detection rate. Despite the clinical importance of identifying novel variants, the inclusion of novel variant calling is not a routine part of all carrier screening and should be considered by healthcare providers.

PrgmNr 3869 - Developmental and temporal characteristics of clonal sperm mosaicism

View session detail

Author Block: **M. W. Breuss**[1,2,3], X. Yang[2,3], J. G. Gleeson[2,3]; [1]Univ. of Colorado, Sch. of Med., Aurora, CO, [2]Univ. of California, San Diego, La Jolla, CA, [3]Rady Children's Inst. for Genomic Med., San Diego, CA

Disclosure Block: **M.W. Breuss:** None.

Throughout development and aging, human cells accumulate mutations that result in genomic mosaicism and genetic diversity at the cellular level. Within the individual, in which mosaic variants arise, they have been connected to a range of diseases-including cancer or dementia. Those present in the gonads, however, can affect not only the individual, but also the offspring and subsequent generations. Indeed, we and others have demonstrated that pathogenic *de novo* mutations may be present as mosaic mutations in the germ cells of the father. Here we explore the patterns and temporal stability of clonal mosaic mutations in male gonads by sequencing ejaculated sperm and contrasting it with blood cells. We performed 300Ã whole-genome sequencing of both tissues from 17 healthy men, and we include assessment across multiple samples and age groups. We find that each male carries, on average, more than 30 clonal mosaic variants in their sperm, which are detected in serial sampling, and with the majority absent from sampled somal tissues. Across age groups, mosaicism detected in sperm remains stable, whereas blood mosaicism undergoes dynamic changes which are indicative of processes of clonal hematopoiesis. Moreover, two out of five individuals with advanced age harbored almost an order of magnitude more detectable mosaic variants in their blood than individuals of young age. The temporal stability and mutational signature of sperm mosaic variants suggest an origin during embryonic development, and a largely immutable stem cell niche during aging. Thus, clonal mosaicism in sperm is not correlated with the observed increase in mutational load in offspring of men with advanced paternal age. Nevertheless, this mosaicism contributes a transmissible, predicted pathogenic exonic variant for 1 in 15 men, representing a life-long threat of transmission for these individuals, and a significant burden on human population health. This knowledge allows for the development and implementation of prevention strategies for a subset of those disorders caused by *de novo* mutations; and it results in a framework that can counsel families with existing monogenetic disorders or prospective parents prior to conception.

PrgmNr 3870 - Exploring the use of whole genome sequencing for carrier screening

View session detail

Author Block: **X. Chen**[1], D. L. Perry[1], A. J. Coffey[2], N. J. Burns[1], R. J. Taft[1], M. A. Eberle[1]; [1]Illumina Inc., San Diego, CA, [2]Illumina United Kingdom, Cambridge, United Kingdom
Disclosure Block: **X. Chen:** Salary/Employment; Illumina Inc..
Advances in bioinformatic approaches provide an opportunity to conduct carrier screening via whole genome sequencing (WGS) by capturing clinically relevant conditions in a single assay and providing the ability to expand investigation across the genome. Here, we present an exploratory analysis using the 1000 Genomes Project dataset and retrospective analysis of clinical WGS cases with a diagnostic finding associated with an autosomal recessive (AR) or X-linked (XL) condition.
We developed a bioinformatics pipeline that filters variant calls genome-wide for ClinVar pathogenic (P) and likely pathogenic (LP) variants, as well as variants with severe consequences in ~2800 genes associated with known AR or XL diseases. Our pipeline also includes targeted variant calling for difficult genes, such as *FMR1* (fragile X syndrome), *SMN1* (spinal muscular atrophy), *HBA1*/*HBA2* (alpha thalassemia) and *CYP21A2* (21-Hydroxylase-Deficient Congenital Adrenal Hyperplasia). We applied the pipeline to 2504 individuals from the 1000 Genomes Project and found that ~80-90% of the individuals in each population carry at least one variant. Random pairing of male and female individuals revealed that 2.6% of the couples from the same ethnicity are at risk for an AR disorder, and 1.8% of the couples are at risk assuming pairing across all ethnicities.
Separately, we reviewed clinical WGS cases of patients with genetic diseases analyzed through the Illumina Clinical Services Laboratory and the iHope Program. Of 826 cases, 96 (11.6%) had a diagnostic variant (P or LP) in a gene associated with an AR or XL disorder. Of these, 44 were due to compound heterozygous variants and 38 were due to a homozygous variant associated with an AR disorder, 10 were due to a hemizygous variant associated with an XL disorder, and 4 were due to a heterozygous variant associated with an XL disorder (females). Review of these variants in the context of our carrier screening pipeline described above indicates that 75.3% of individual parents would have been identified as carriers and 97.9% of couples could be identified with more lenient filtering criteria. Preliminary retrospective analysis of 51 of these variants indicates that 48 (94%) would reach an LP or P classification in the parents alone and 3 variants (homozygous and classified as LP in the proband) would be classified as uncertain significance (VUS) due to inability to apply ACMG criteria relating to phenotype and segregation.
WGS-based carrier screening with the integration of targeted callers has the potential to provide a comprehensive carrier screening analysis in a single assay. Future work includes refinement of an interpretation and reporting workflow.

PrgmNr 3871 - Genematching candidates from the Genomic Autopsy Study to elevate variant classification for prenatal clinical use

View session detail

Schreiber[2,5], A. O'Donnell-Luria[3], C. P. Barnett[6,7], H. S. Scott[1,2,4,7]; [1]Dept. of Genetics and Molecular Pathology, Ctr. for Cancer Biology, an alliance between SA Pathology and the Univ. of South Australia, Adelaide, Australia, [2]ACRF Genomics Facility, Ctr. for Cancer Biology, An alliance between SA Pathology and the Univ. of South Australia, Adelaide, Australia, [3]Ctr. for Mendelian Genomics, Broad Inst. of MIT and Harvard, Cambridge, MA, [4]Australian Genomics, Melbourne, Australia, [5]Sch. of Biological Sci., Univ. of Adelaide, Adelaide, Australia, [6]Paediatric and Reproductive Genetics Unit, South Australian Clinical Genetics Service, Womenâ□□s and Childrenâ□□s Hosp., North Adelaide, Australia, [7]Sch. of Med., Univ. of Adelaide, Adelaide, Australia

Disclosure Block: **T. Ha:** None.

Background: Trio analysis from the Genomic Autopsy Study revealed that a molecular diagnosis can be ascertained in half of clinically unresolved cases of early miscarriage or perinatal death (n=89/170). However, only half (n=41/89) of these putative disease genes can be used prenatally for assessing recurrence risk, despite compelling evidence from available animal models, gene constraints and expression data. The ACMG guidelines are heavily weighted towards existing genotype to phenotype delineations in the post-natal setting, which can confound the interpretation of prenatal cases, with little to no hindsight on severe or lethal in utero presentations[1].

Aim: Assess the proportion of cases with variants and/or genes of uncertain significance, which can be reclassified based on identifying additional kindreds from genematching.

Methods: Between 2018 to 2021, we submitted 35 genes to the genotype matching platform, MatchMaker Exchange, to seek additional, unrelated kindreds with similar clinical phenotype and/or initiate collaborations with expert curators of genes or disease subgroups for each case[2].

Results: We received matches for 33/34 genes submitted, with an average 7 participants responding per gene and contact initiated between 1-25 months after submission. The genematching identified additional kindreds with clinical overlap (10/33) and/or initiated functional validation (5/33) and diagnosis for publications (3/33).

Conclusion: Phenotype matching is critical for clinical interpretation, which can be accelerated through the use of genotype sharing platforms like MatchMaker exchange. Additional kindreds can be identified in a fifth of cases with variants or genes of uncertain significance.

PrgmNr 3872 - Leveraging variant classification evidence from diagnostic genetic testing to improve the rate of positive results in reproductive carrier screening

View session detail

Author Block: **J. Wilkinson**, S. Garcia, A. Mitchell, S. Poll, S. Aradhya; Invitae, San Francisco, CA
Disclosure Block: **J. Wilkinson:** Salary/Employment; Invitae.
Background: With the increasing use of expanded carrier screening (ECS) for hundreds of genes, accurate and definitive classification of some variants becomes a major challenge as available evidence to interpret clinical significance may not be sufficient. In such cases, additional evidence may be obtained through diagnostic genetic testing of individuals who are clinically affected and have those same variants. Advances in variant classification that incorporate evidence from a functional modeling platform (FMP) for missense variants, and from applying clinical pathognomonic criteria for characteristic diseases, have enhanced diagnostic testing. This study aimed to quantify this increase in positive carrier screening results as a result of leveraging diagnostic testing data and improved variant classification.
Methods: Reproductive carrier screening was performed for 134,841 individuals for up to 301 genes. We collected positive carrier variants which used internal case reports that met pathognomonic criteria or evidence from FMP. Data was then matched to ClinVar to identify instances in which this internal data constituted additional evidence for variant classification. Only substitutions and indels were considered for this analysis to ensure accurate matching.
Results: A total of 59,494 individuals were carriers for one or more pathogenic or likely pathogenic substitutions or indels. There were 3,071 unique variants, in 18,259 (28%) individuals, for which the clinical classification depended in part on evidence from pathognomonic criteria or FMP. While ~25% of these were truncating variants and therefore easier to classify as pathogenic, 924 unique variants in 2,519 individuals (~4% of cases) were uniquely classified using novel information derived from diagnostic testing.
Discussion: As larger numbers of individuals pursue expanded carrier screening, many more novel variants will require accurate clinical classification. By leveraging data from diagnostic testing performed for the same genes in affected individuals, and by appropriately applying pathognomonic criteria and FMP evidence to variant interpretation, informative results for reproductive risk assessment can be provided to a significantly higher number of individuals undergoing ECS.

PrgmNr 3873 - Male microchimerism in females: A quantitative study of twin pedigrees to investigate mechanisms

View session detail

Author Block: **B. Johnson**[1], H. E. Peters[2], C. B. Lambalk[2], C. V. Dolan[3], G. Willemsen[3], L. Ligthart[3], V. Mijatovic[2], J-J. Hottenga[3], E. A. Ehli[1], D. I. Boomsma[3]; [1]Avera Inst. for Human Genetics, Sioux Falls, SD, [2]Amsterdam UMC, Amsterdam, Netherlands, [3]Vrije Univ. Amsterdam, Amsterdam, Netherlands
Disclosure Block: **B. Johnson:** None.
Background: The occurrence of natural chimerism has been most commonly identified as microchimerism (Hypothesis: We hypothesized that characteristics of an individualâ□□s pedigree, such as having a male co-twin, older brothers, or sons, would increase an individualâ□□s risk of presenting with male microchimerism.
Study design, materials, methods: To explore this complex phenomenon we have employed a twin pedigree study to investigate the prevalence and patterns of male microchimerism within families. This study includes 446 adult female participants recruited by the Netherlands Twin Register (NTR), including female twins, mothers and sisters of monozygotic, same-sex dizygotic, and opposite-sex dizygotic twin pairs. Biobanked DNA isolated from peripheral blood samples was tested via a high sensitivity quantitative PCR assay to measure male specific Y chromosome gene *DYS14* relative to total measure of a beta-globin gene *HBB*.
Results: This assay produced detectable measure of male microchimerism in 26.9% of participants with similar median concentrations of male genome among types of twins, their sisters and their mothers (P = 0.28). Pedigree analysis found the prevalence of male microchimerism is not explained by having male offspring (OR = 0.90: SE 0.19, P = 0.63), an older brother (OR = 1.46: SE 0.32, P = 0.09) or a male co-twin (OR = 1.23: SE 0.40, P = 0.61). Correlation among monozygotic twin pairs (0.27; SE 0.37) and first-degree relatives (0.091; SE 0.092) is statistically similar (P = 0.66). There is a significant positive relationship between the age at time of biobanking and detection of male microchimerism (P = 0.02; Nagelkerke R2 = 0.017), however quantitative outliers (>80 male genome equivalents) among positive participants present with a lower age at time of biobanking (P = 0.034).
Implications: While this study does not reveal a specific pedigree characteristic that promotes male microchimerism prevalence, this may support time, molecular traits, and environmental exposures as contributors to the general prevalence of persistent microchimerism. This study further necessitates study of molecular underpinnings of natural microchimerism to understand implications on immunology, autoimmune diseases, and overall womenâ□□s health.

PrgmNr 3874 - Whole-exome sequencing confirms GDF15 is the greatest genetic risk factor for Hyperemesis Gravidarum and identifies rare and novel variants in appetite genes GDF15 and GFRAL

View session detail

Author Block: **M. Fejzo**[1], K. MacGibbon[2], P. Mullin[1]; [1]Univ. of Southern California, Los Angeles, CA, [2]Hyperemesis Ed. and Res. Fndn., Clackamas, OR
Disclosure Block: **M. Fejzo:** Consultant/Consulting Fees/Other Remuneration; Materna Biosciences, Inc.
Many people experience nausea and vomiting of pregnancy and 18% require medication. The most severe form, Hyperemesis Gravidarum (HG), occurs in approximately 2% of pregnancies and is associated with weight-loss and undernutrition. HG can cause serious maternal morbidity and lead to suicidal ideation and PTSD. It is associated with adverse outcomes including preterm birth, neurodevelopmental delay, and autism spectrum disorder. It is highly heritable. Previously, our GWAS showed the placenta, appetite, and cachexia gene *GDF15* is the greatest genetic risk factor for HG. *GFRAL*, encoding the receptor for GDF15, is also associated. Herein we report results from whole-exome sequencing (WES) of 888 cases with HG, 661 unaffected controls, and 31 families. WES confirmed the paradigm-changing association between *GDF15* and HG- the *H6D* variant, previously associated with body weight and abdominal fat in a cachexia mouse model, was the only variant to reach genome-wide significance ($p=9.98x10^{-11}$). To identify rare variants in *GDF15* and *GFRAL*, variants were filtered and annotated to include rare (global frequency 0.05), non-synonymous variants unique to cases. Ancestry/relationships were predicted. Non-segregating variants were removed. Rare variants in *GDF15* and *GFRAL* were identified in 23 and 17 cases, respectively. Notably, in *GDF15*, 11 cases of European ancestry had variant C211G including a mother/daughter. In addition, 2 novel missense variants predicted to be damaging in patients of European ancestry (R193C, mature peptide cleavage site; C203S, mature peptide) and 1 novel stopgain variant (S174*) in a patient of African ancestry were identified. Six cases of 5 ancestries had upstream variant rs77109188. In *GFRAL*, 3 damaging missense variants were identified. M370T (transmembrane domain) was found in a case of European/American and a case of African ancestry, and variants in the GDF15 binding domain (E203A, Q184R) were found in cases of European ancestry.
This study confirms *GDF15* is the greatest genetic risk factor for HG and identifies rare variants in *GDF15* and *GFRAL*, providing further evidence the hormone pathway plays a role in disease etiology. Drugs targeting this pathway are currently under intense investigation to potentially treat obesity and conversely, cancer cachexia. Further work to explore the function of these variants will help elucidate molecular mechanisms of HG and provide clues to developing treatments for disorders of appetite, nausea, and vomiting.

PrgmNr 3875 - A variational Bayesian approach to characterize latent genetic components using GWAS summary statistics

View session detail

Author Block: **Z. Zhang**[1], J. Jung[1], N. Suboc[1], S. Gazal[1], N. Mancuso[2,3,4,1]; [1]Ctr. for Genetic Epidemiology, Dept. of Preventive Med., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA, [2]Univ. of Southern California, Los Angeles, CA, [3]Dept. of Quantitative and Computational Biology, Univ. of Southern California, Los Angeles, CA, [4]Norris Comprehensive Cancer Ctr., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA
Disclosure Block: **Z. Zhang:** None.
Genome-wide association studies (GWAS) have identified thousands of genetic variants associated with multiple phenotypes, providing opportunities to gain insight into their biological function. Recent work aiming to characterize these shared latent genetic factors using truncated singular-value decomposition (tSVD) of GWAS summary data has been applied to numerous traits, however its model-free approach leaves unclear 1) what genetic parameters are modelled and 2) how uncertainty in observed summary data influences estimates.
To address these limitations, we derive from first principles a factor analysis model to identify latent genetic factors shared across phenotypes using GWAS summary data. Our approach accounts for uncertainty in effect-size estimates and uses an automatic relevance determination (ARD) prior to prune uninformative factors. In simulations, we found our approach identifies the true number of latent factors and outperforms tSVD in reconstruction error of unobserved allelic effect sizes. We observed that by directly modelling standard errors, unlike tSVD, our approach remains unbiased when there is differential power across GWAS studies.
We applied our approach to GWAS summary data from 158 metabolites in the Finnish Metabolic Syndrome in Men cohort (N=6263). To explore the functional roles of inferred latent genetic factors, we performed a phenotype enrichment analysis using Phenome-wide Association Studies (PheWAS) catalogues weighted by factor loadings. Focusing on the top 10 factors, we found that loadings from our method identified significantly more PheWAS phenotypes (182) in contrast to tSVD (99; P=9.97E-8). For example, the fourth factor from our method is enriched for SNPs associated with cervical human papillomavirus (HPV), uveitis, disturbance in tooth eruption, and respiratory diseases (FDR Padj=0.03), which is consistent with shared genetic components related to inflammation.
We found the number of identified phenotypes decreased per latent factor when ordered by inferred ARD parameters (P=7.35E-4), with little evidence when using tSVD orderings (P=0.07). This suggests that latent genetic factors identified by our approach better reflect biological informativeness compared with tSVD factors.
Taken together, our results suggest that our approach prioritizes biologically meaningful genetic factors underlying observed GWAS signals.

PrgmNr 3876 - Biobank-scale estimation of the proportion of trait variance explained by gene-environment interactions

View session detail

Author Block: **A. Pazokitoroudi**[1], A. Dahl[2], N. A. Zaitlen[3], S. Rosset[4], S. Sankararaman[3]; [1]Computer Sci., UCLA, Los Angeles, CA, [2]Univ. of Chicago, Chicago, IL, [3]UCLA, Los Angeles, CA, [4]Tel Aviv, Israel

Studies of gene-environment interactions (GxE) aim to demonstrate how environmental factors and genetic markers jointly explain complex traits. Understanding the role of GxE has the potential to provide insights into mechanisms and pathways underlying disease risk, explain sources of heritability, and improve the accuracy of genetic risk prediction. The availability of large biobanks that measure both genetics and diverse phenotypes offers the promise of obtaining novel insights into GxE. However, current methods for polygenic GxE inference, typically based on maximizing the likelihood in a linear mixed model (LMM), do not scale to the biobank setting, where hundreds of thousands of individuals are measured across hundreds of traits with accompanying genotypes over millions of SNPs.

In this work, we propose a scalable algorithm, GENIE, to jointly estimate the proportion of trait variance that can be explained by genetics, environment, and gene-by-environment interactions, which can improve GxE estimates and eliminate false positives when the assumptions of existing methods are not satisfied. Our algorithm is a randomized method-of-moments estimator that has a runtime linear in each of the number of environmental variables and the number of SNPs while scaling linear in the number of individuals. We evaluate the accuracy and scalability of GENIE for estimating the variance components under different settings. In small-scale simulations, where GENIE can be compared to other computationally intensive estimators, we show that GENIE obtains estimates of GxE that are of accuracy comparable to maximum-likelihood estimates. More importantly, GENIE is highly scalable and can estimate GxE on 300K individuals, 500K SNPs and 10 environments in a few hours, a setting where established tools fail.

We applied GENIE to estimate the proportion of phenotypic variance explained by gene-by-statin interaction for 50 quantitative phenotypes (5 anthropometric, 45 blood biomarkers) with genotypes from 300,000 unrelated white British individuals. Across the fifty traits, we observed statistically significant evidence for gene-by-statin interaction (p

PrgmNr 3877 - Capturing fine-scale structure of single-cell expression and chromatin accessibility using a topic model

Grade of membership models have been widely used to model admixture in population genetics and to identify topics in document clustering applications. Recent papers have highlighted the potential for grade of membership models to identify structure from single-cell RNA-seq and ATAC-seq data, and in particular structure that is not well captured by clustering. However, important methodological and practical barriers remain, including the high computational cost of model fitting, and the question of how to interpret the structure identified by these models. To address these challenges, we developed a new approach for efficiently fitting grade of membership models to large data sets, and we developed extensions of differential expression and enrichment analysis that allow for partial membership of cells to topics. Applying this approach to published single-cell RNA-seq and ATAC-seq data sets, we identified both discrete cell types and continuously varying or transitional states that would not be easily captured by conventional methods. For example, in a population of mouse epithelial cells we identified rare transitional *Krt13*+ (â□□hillockâ□□) cells. These hillock cells were originally discovered via an ad hoc two-stage analysis using diffusion maps, whereas here they emerged as a single topic in the grade of membership model. Our analysis of single-cell chromatin accessibility profiles of kidney cells suggests that some specialized kidney cells exist as discrete cell types, whereas others vary along a spectrum, most strikingly among distal tubule and collecting duct cells. In a population of hematopoietic cells, we identified continuous differentiation processes among and within hematopoietic progenitor cell types that would be missed by clustering. In summary, we have developed a unified topic-model-based analysis pipeline for single-cell RNA-seq and ATAC-seq data that is simple, scalable, and can flexibly capture different types of structure in cell populations. Our methods are implemented in the R package fastTopics.

PrgmNr 3878 - Combining SNP-to-gene linking strategies to pinpoint disease genes and assess disease omnigenicity

Although genome-wide association studies (GWAS) have identified thousands of disease-associated common SNPs, these SNPs generally do not implicate the underlying mechanisms and target genes, as most disease SNPs are regulatory with unknown function. Many SNP-to-gene (S2G) linking strategies have been proposed to infer the function of regulatory SNPs and link them to the genes that they regulate, but it is unclear which of these strategies should be prioritized in the context of human disease.

We developed a framework for evaluating and combining different S2G strategies to optimize their informativeness for human disease, using polygenic analyses of disease heritability. We define an S2G strategyâ□□s *precision* and *recall* for identifying disease genes by evaluating the heritability enrichment of SNPs linked to a critical gene set (e.g. genes with highly constrained exons and promoters), relying on the hypothesis that a precise S2G strategy should maximize the heritability linked to the critical gene set compared to the heritability linked to all genes; recall is computed using the heritability linked to all genes. We applied our framework to GWAS summary statistics from 63 diseases and complex traits (average N=314K), evaluating 50 S2G strategies, and validated our precision and recall metrics using gold standard sets of causal SNP-gene pairs. Our optimal combined S2G strategy included 7 S2G strategies (Exon, Promoter, 2 fine-mapped cis-eQTL strategies, EpiMap enhancer-gene linking, Activity-By-Contact (ABC), and Cicero), and achieved a precision of 0.75 and a recall of 0.33, more than doubling the precision and/or recall of any individual strategy.

We describe two applications of our combined S2G strategy. First, we applied our optimal combined S2G strategy to fine-mapping results for 49 UK Biobank traits to predict 7,111 causal SNP-gene-disease triplets (with S2G-derived functional interpretation) with high confidence. Second, we applied our optimal combined S2G strategy to genome-wide fine-mapping results for these traits (not restricted to GWAS loci) to rank genes by the heritability linked to each gene, providing an empirical assessment of disease *omnigenicity* (Boyle et al. 2017 *Cell*); averaging across traits, we determined that the top 200 (1%) of ranked genes explained roughly half of the heritability linked to all genes.

Our results highlight the benefits of combining different S2G strategies to pinpoint disease genes. We anticipate that precision and recall will increase further under our framework as improved functional assays lead to improved S2G strategies.

PrgmNr 3879 - Development of a Polygenic Risk Score to Predict Severe Outcome of a COVID19 Infection

View session detail

Author Block: **D. E. Condon**, P. Cherukuri, S. Gu, L. Carmichael, C. Hajek; Sanford Hlth., Sioux Falls, SD
Disclosure Block: **D.E. Condon:** None.
COVID19 is a contagious respiratory viral infection. Patient outcome varies from an asymptomatic viral infection to a severe pulmonary infection, possibly requiring respiratory support and even to death. Our study leverages machine learning using machine learning to predict which patients that test positive for COVID-19 are likely to require enhanced care, which we define as hospitalization and/or use of respiratory support. Sanford Healthâ□□s Enterprise Data Analytics created an index score within [0,1] that directly correlates with a patientâ□□s likelihood to require hospitalization. The index score is based on known risk factors for an adverse event during COVID-19 infection, such as age, excessive BMI, male sex, known comorbidities, etc. We aim to improve on the index score by including genetic data as measured by Illuminaâ□□s Global Screening Array (GSA) version 1 to construct a polygenic risk score (PRS). Clinical data was extracted from the medical record and de-identified for approximately 11,000 patients that have tested positive for COVID-19 within the Sanford Health system. We use a combination of known alleles that can be directly measured by the GSA and proxy assays for alleles that are not present on the GSA to create different PRSs: 1) a conventional PRS which uses a sum of risk allele counts, 2) a conventional weighted PRS, and 3) a non-standard PRS that attempts to account for Mendelian inheritance, i.e. where 0 and 1 risk alleles, or 1 and 2, could have the same effect, 4) XGBoostClassifier machine learning based prediction of outcome likelihood. The results are compared, and proposed as a tool to supplement physician decision-making.

PrgmNr 3880 - Estimating heritability explained by local ancestry and evaluating stratification bias in admixture mapping from summary statistics

View session detail

Author Block: **T. Chan**[1], C. W. Chiang[1,2], N. Mancuso[1,2,3]; [1]Ctr. for Genetic Epidemiology, Dept. of Preventive Med., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA, [2]Dept. of Quantitative and Computational Biology, Univ. of Southern California, Los Angeles, CA, [3]Norris Comprehensive Cancer Ctr., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA
Disclosure Block: **T. Chan:** None.
Admixture mapping aims to identify genomic regions associated with a phenotype through the ancestry components of an admixed population. It leverages the fact that local ancestry can tag underlying causal genetic variants, both common and rare, that differ in allele frequencies in the ancestral populations. The proportion of heritability explained by local ancestry, or h_A^2, can provide insights into the latent genetic architecture by proxy for narrow-sense heritability when underlying causal variants are poorly genotyped or imputed in GWAS. Indeed, recent work has demonstrated that narrow-sense heritability can be inferred directly as a function of h_A^2, this approach produces an estimate from unrelated individuals while capturing the heritability due to uncommon variants that is missing from genotyped SNP heritability. However, we identify two primary limitations with this approach. First, estimating h_A^2 from individual-level data is computationally limiting due to likelihood evaluation in linear mixed models and relatedness estimation. Second, estimates of h_A^2 may be susceptible to biases due to stratification in ancestral populations. To address these limitations, here we propose a computationally efficient approach to infer h_A^2 from admixture mapping summary statistics that is robust to ancestral population stratification. Our method models the genome-wide covariance across local ancestry markers using a computationally efficient truncated SVD approach while maintaining unbiased estimation of model parameters. Using extensive population genetic simulations, we demonstrate that ancestral stratification inflates estimated effect sizes at local ancestries and biases estimates of h_A^2 in individual-level data. We show that our approach provides approximately unbiased estimates of h_A^2 (slope=1.00, 95%CI: 0.90, 1.10) across a variety of trait architectures and ancestral demographies. As an illustration of downstream applications, we leverage our model to perform a genetic-architecture-aware sampling procedure to infer the genome-wide significance threshold for admixture mapping. We demonstrate that our improved sampling procedure adequately controls the FWER under a variety of genetic architectures and demographies, unlike previous approaches. For example, when 16% of phenotypic variance is explained by stratification, our approach controls FWER at 5% compared with 13% when using previous sampling procedures. Overall, our approach utilizes in-sample summary statistics and admixture history to estimate h_A^2 that is robust to stratification bias.

PrgmNr 3881 - Explainable and extendable machine learning models for identifying prognostic radiogenomic biomarkers from breast cancer multimodal imaging and genomic data

View session detail

Author Block: **Q. Liu**, P. Hu; Univ. of Manitoba, Winnipeg, MB, Canada
Disclosure Block: **Q. Liu:** None.
Background: Radiogenomics is a field where medical images and genomic profiles are jointly analyzed to answer critical clinical questions. We proposed a novel framework to identify prognostic radiogenomic biomarkers from multi-modal breast cancer (BC) magnetic resonance imaging (MRI) and multi-omics data, which may serve as a substitute for genetic testing.
Methods: Bayesian tensor factorization (BTF) was used to extract the integrated multi-omics features from gene expression, DNA methylation, and copy number variation data of 762 BC patients. The potential biological functions of these BTF multi-omics features were explored using Gene set enrichment analysis (GSEA). A deep learning (DL)-based imaging segmentation model was built to extract multi-modal MRI radiomic features for 61 of the BC patients with MRI data. Two explainable tools (Gradient and Gradient*Input) were embedded into the DL model structure to explore biological implications of the radiomic features. Predictive least absolute shrinkage and selection operator (LASSO) models were trained to translate the radiomic features from the BTF multi-omics features for the BC patients without MRI data. Survival analyses were then performed to estimate the prognostic significance of each radiomic feature. Statistical mediation analyses were performed to further explore the underlying biological mechanisms of the identified biomarkers. Traditional semi-auto radiomic features and previously established single-omics features (e.g., BC risk gene expressions, pathway activity scores, and gene signature scores calculated from the gene expression profile) were used as baselines for comparison.
Results: Saliency maps of the multi-modal MRI radiomic features showed the excellent explainability of the built DL models. Three DL-based multi-modal MRI radiogenomic biomarkers were successfully identified. which were confirmed to have significant differences in overall survival (log-rank test, Bonferroni corrected *P* valueAPITD1, *HNF4*) and several metabolism related pathways (Purine metabolism pathway and Tryptophan metabolism pathway), which has a significant mediation effect on the relationship between one specific BTF multi-omics feature, representing the function of natural killer cells based on the GSEA analysis, and the BC survival time (adjusted *P* value**Conclusion:** The results may promote MRI as a non-invasive examination for BC prognosis and multi-level molecular status, and ultimately increase precision in BC prognosis and improve patient care.

Disclosure Block: **R. Shemirani:** None.

Detection of segments of the genome shared among individuals identical-by-descent (IBD) is an essential step in many genomic analysis pipelines. New IBD estimation techniques are able to process hundreds of thousands of samples in large biobanks using phased genotype data and hashing heuristics. However, the resolution of IBD estimation in these approaches is limited by factors such as the density of the genotype array and phasing errors which may increase the rate of false-positive and false-negative results. Clustering algorithms have been previously shown to be able to address these challenges. Applying clustering algorithms to local IBD segments works as follows: first, each chromosome is divided into short windows. Secondly, for each window, a local IBD graph is created where nodes represent sample haplotypes and edges represent IBD sharing among individuals in that window. Ideally, in the absence of false-positive and false-negative edges, these graphs should solely be composed of cliques, that is, groups of individuals who share the same IBD-haplotype homologously from a recent common ancestor. Clustering algorithms help recover the cliques at each window. The resulting set of edges provides a fine-grained refinement of the IBD estimation results, where false-negative edges are interpolated and false-positive edges are removed. Previous clustering algorithms used to analyze local IBD graphs are not scalable and depend on *a priori* knowledge about IBD segments. Here, we introduce a scalable pipeline for local IBD clustering, iCURL (Identity-by-descent Clustering of Related Loci). Utilizing high-performance computing clusters, iCURL analyzes the entirety of UK Biobank IBD data in an hour (N=487,330 individuals, n=14,402,404,038 pairwise IBD-haplotypes). Our algorithm could also estimate the number of false-positive and false-negative IBD segments in each window. Applying our method to the UK Biobank, we found a total of 975,646,819 local IBD clusters. We evaluated the results of iCURL using whole-exome sequence data. Local IBD clusters generated with iCURL recovered 23% of rare variants with minor allele counts of 2 or 3 in the whole-exome sequence data. This recovery rate decreased as the minor allele frequency increased, replicating the results of other high-resolution IBD estimation approaches. These clustered IBD segments can be utilized for a variety of downstream analyses, including IBD mapping applications, to search for causal rare variants not captured in array data. We conducted IBD mapping analysis on a number of phenotypes successfully to further evaluate the results of iCURL and report on novel associations with height and lipids.

PrgmNr 3885 - Improving Polygenic Risk Score Transferability by Leveraging GWAS Signals from Diverse Populations

Author Block: **J. Shi**[1], W. Wang[2], S. S. Shringarpure[3], 23andMe, Inc. Research Team, A. Auton[4]; [1]23andMe Inc., Sunnyvale, CA, [2]Santa Clara, CA, [3]23andMe, Sunnyvale, CA, [4]23andMe, Mountain View, CA

Disclosure Block: **J. Shi:** Salary/Employment; 23andMe Inc..

Polygenic risk scores (PRS) from large scale genome-wide association studies (GWAS) can provide useful information for personalized risk stratification and disease risk assessment. However, to date, GWAS are predominantly based on European populations, trailed by Asian populations, while all other ancestry groups comprise less than 5%. PRS based on European training data suffer reduced accuracy in non-European target populations, exacerbating health disparities and limited generalizability across other ancestral populations. Here, we propose MultiPRS, a method that improves trans-ethnic polygenic prediction by borrowing strength from GWAS signals in multiple populations. To construct MultiPRS for a phenotype in a given (non-European) population, we first applied the Pruning and Thresholding (P+T) method (with various P-value and LD-clumping thresholds using population-specific LD panels) to perform variant selection on GWAS summary statistics in each of the European, Latino, African American, East Asian and South Asian ancestries. We then constructed ancestry-specific P+T PRS as the weighted sum of the target populationâ□□s imputed dosages, where the weights were GWAS effect size estimates from the P+T selected variants in each of the five populations. Lastly, we applied logistic regression with elastic-net regularization on the ensemble of P+T PRS across populations and parameter settings to obtain the final MultiPRS. We assessed the MultiPRS prediction performance in the African American population on asthma, chronic kidney disease, gout, T2D and uterine fibroids. Compared with PRS that were purely based on the African American GWAS summary statistics, our approach led to approximately a 6.87% AUC relative increase on average, ranging from 3.15% to 11.55%. For example, the AUC of T2D PRS increased from 0.603 (95% CI: 0.591 - 0.615) to 0.652 (95% CI: 0.640 - 0.664) by transferring GWAS signals from the other populations. MultiPRS also yielded similar AUC compared to PRS constructed from the trans-ethnic meta-analysis summary statistics (e.g., for T2D, MultiPRS AUC = 0.652 v.s meta-analysis PRS AUC = 0.650), but to further boost prediction power, one can easily add additional PRS (from genetically correlated phenotypes with stronger GWAS signals) in the elastic-net ensemble step of MultiPRS, which is not feasible if using the trans-ethnic meta-analysis summary statistics.

PrgmNr 3887 - Repeat Expansions and Somatic Instability Observation using Optical Mapping

Disclosure Block: **A. Hastie:** Salary/Employment; Bionano Genomics.
Tandem repeats are expansions of a sequence forming a repetitive pattern in the genome. These regions are often unstable and can be associated with genetic disorders, with the size of expansions correlating with the severity and age of onset. Therefore, being able to accurately detect the total length of expansion and any somatic expansions is important. Here we show that using intact high molecular weight optical genome mapping (OGM) molecules, the length of stable and mosaic repeat expansions across the genome can be revealed efficiently. PCR based techniques are sufficient for sizing of low range expansions, but expansions over a few hundred base pairs are challenging due to polymerase slippage and stuttering. Southern blot is currently the gold standard for longer repeat length detection, but it is locus-specific, laborious and expensive. Using OGM, we can select within the reference genome the two labels flanking the repeats of interest, measure the interval lengths in the aligned molecules, and estimate the mean and variance of the repeat sizes. For example, a mosaic repeat expansion with a wide distribution of repeat lengths from 7 kbp to 17 kbp is observed in an amyotrophic lateral sclerosis (ALS) sample. Using the label distances in the optical mapping molecules, a histogram of repeat sizes and a Gaussian mixture model can be used to identify the zygosity of the repeat expansion region. Moreover, with the standard deviations of the clusters, a mosaic expansion of various repeat sizes is observed. This method has also been applied to other repeat expansion disorders such as myotonic dystrophy (DM), Spinocerebellar ataxias (SCAs) and Fragile X syndrome (FXS). In conclusion, for long tandem repeats, above ~500 bp, optical genome mapping provides an efficient method to identity repeat lengths across multiple loci simultaneously. With long intact molecules spanning repeats even kilobases in size, mosaic expansions or somatic instability can be detected with high confidence.

PrgmNr 3888 - Residual Proteome-wide Association Study Identifies Genes for Blood-Related Traits

View session detail

Author Block: **Z. Lu**[1], J. Jung[2], S. Gazal[3], N. Mancuso[1]; [1]Univ. of Southern California, Los Angeles, CA, [23]USC, Los Angeles, CA
Disclosure Block: **Z. Lu:** None.
Transcriptome-wide Association Studies (TWAS), are a recent approach to identify genes whose expression levels are associated with complex traits in large-scale GWAS data. TWAS operates by predicting mRNA levels from expression quantitative trait loci (eQTL) panels using cis-regulatory variation into large-scale GWAS cohorts. Recent studies have shown that 60% of protein QTLs (pQTL) do not colocalize with eQTLs, suggesting independent post-transcriptional/translational regulatory mechanisms which may have separate results for complex traits.
To identify genes whose total and eQTL-independent protein levels are associated with complex traits, here we describe an approach that integrates pQTL and eQTL panels with large scale GWAS summary statistics to perform a residual Proteome-wide Association Study (rPWAS), defined as a Proteome-wide Association study (PWAS) adjusted for eQTL-specific effects. We show using extensive simulations and theory that approaches to identify rPWAS genes computed directly from TWAS and PWAS summary statistics exhibit biases when eQTL partially mediates pQTL effects. To attenuate this bias, we propose an adjustment during rPWAS testing.
Having validated our approach in simulations, we integrated plasma proteomics from the INTERVAL study (N=3301), whole blood transcriptomics from GTEx (N=574), together with 27 blood-traits from the UK Biobank (mean N=350470) and performed cis-SNP heritability analyses (cis-h2g), TWAS, PWAS, and rPWAS. Of the 1139 genes matched in GTEx, we estimated an average cis-h2g of 0.042 in eQTL-residualized protein levels compared with 0.052 in total levels showing independent pQTLs explain a large portion of protein variation. Integrating total and residualized protein levels with 27 blood-traits, we identified 11122, 1448, and 472 gene-trait associations for TWAS, PWAS, and rPWAS, respectively. We found rPWAS associations were enriched for GWAS signals independent of PWAS and TWAS (P Next, we computed an enrichment score that quantifies the extent that GWAS risk is explained by predicted mRNA, protein, and residual-protein levels compared with grand association signals. We found TWAS signals to be most enriched for association signal (z = 105.47), followed by PWAS (34.54), and rPWAS (17.88), suggesting eQTL-dependent regulation is a primary mediator underlying GWAS signals.
Overall, our work sheds light onto gene regulatory mechanisms underlying blood phenotype architecture.

PrgmNr 3889 - Searching for consistent associations with a multi-environment knockoff filter

This work develops a multivariate statistical method for the analysis of GWAS data that allows one to precisely discover which genetic loci are consistently associated to a certain polygenic phenotype across human populations with different ancestries. One reason why this problem is interesting is that consistency across different populations mitigates the risk of reporting spurious associations due the presence of unmeasured variants, thereby facilitating the discovery of causal associations that may be used to build more robust predictive models of genetic risk. The proposed method expands upon the existing model-X methodology of *KnockoffGWAS*, inheriting the ability of the latter to control the false discovery rate while rigorously accounting for linkage disequilibrium, population structure, and cryptic relatedness. These results are achieved without any parametric assumptions about the distribution of the phenotype, which may be either a continuous trait or a discrete disease status, for example. Numerical experiments with realistic genotype data and simulated phenotypes confirm empirically the validity of this approach. Applications to the analysis of several phenotypes in the UK Biobank data set lead to the discoveries of several consistent associations that are largely validated by other studies.

PrgmNr 3890 - Shared Genomic Segment Analysis in a Large High-Risk Chronic Lymphocytic Leukemia Pedigree Implicates *CXCR4* in Inherited Risk

View session detail

Author Block: **J. E. Feusier**, M. J. Madsen, B. J. Avery, J. A. Williams, D. M. Stephens, B. Hu, A. E. G. Osman, M. J. Glenn, N. J. Camp; Univ. of Utah, Salt Lake City, UT
Disclosure Block: **J.E. Feusier:** None.
Aim: Chronic lymphocytic leukemia (CLL) has been shown to cluster in families. First-degree relatives of individuals with CLL have an ~8 fold increased risk of developing the malignancy. Strong heritability suggests pedigree studies will have good power to localize pathogenic genes. However, CLL is relatively rare and heterogeneous, complicating ascertainment and analyses. Our goal was to identify CLL risk loci using unique resources available in Utah and methods to address intra-familial heterogeneity.**Methods**: We identified a six-generation high-risk CLL pedigree using the Utah Population Database. This pedigree contains 24 CLL cases connected by a common ancestor. We ascertained and genotyped eight CLL cases using a high-density SNP array, and then performed shared genomic segment (SGS) analysis - a method designed for extended high-risk pedigrees that accounts for heterogeneity.**Results**: We identified a genome-wide significant region (P = 1.9 Ã 10-7, LOD-equivalent 5.6) at 2q22.1. The 0.9 Mb region was inherited through 26 meioses and shared by seven of the eight genotyped cases. It sits within a ~6.25 Mb locus identified in a previous linkage study of 206 small CLL families. Our narrow region intersects two genes, including *CXCR4* which is highly expressed in CLL cells and implicated in maintenance and progression.**Conclusion**: SGS analysis of an extended high-risk CLL pedigree identified the most significant evidence to-date for a 0.9 Mb CLL disease locus at 2q22.1, harboring *CXCR4*. This discovery contributes to a growing literature implicating *CXCR4* in inherited risk to CLL. Investigation of the segregating haplotype in the pedigree will be valuable for elucidating risk variant(s).

PrgmNr 3891 - The Dynamic and Heritable Epigenetic Landscape

View session detail

Author Block: **S. Mohazzab-Hosseinian**[1], C. Breton[1], D. C. Thomas[2], D. Weisenberger[1]; [1]Univ. of Southern California, Los Angeles, CA, [2]Univ of Southern California, Los Angeles, CA

Title: The Dynamic and Heritable Epigenetic Landscape Introduction DNA methylation is the most extensively studied epigenetic mark and is associated with many environmental exposures. A source of variability that is not well understood is multi-generational DNA methylation heritability: the stability of DNA methylation across generations that is independent of the underlying DNA sequence. Moreover, there are limited numbers of studies investigating the effect of intra-individual variation in DNA methylation. This study aims to explore heritable and dynamic epigenetic changes in a sample of 666 individuals and 732 buccal samples from 203 families in the Southern California Childrenâ□□s Health study (CHS). Among the 203 families, 66 have DNA methylation across three generations. The remaining have data on child-parent trios. Unrelated individuals with samples across two timepoints (N=66), in childhood and adulthood, were used to explore intra-individual variation and to generate methylation quantitative trait loci (mQTLs). **Methods** After quality control and normalization of the HumanMethylation EPIC array (EPIC) data, linear mixed effects models with a random effect for family or individual were used to extract intraclass correlation coefficients (ICC) for each locus. The ICC is interpreted as the variability in DNA methylation due to family or intra-individual structure. The ICC falls between zero and one, with increasing values indicating greater stability. Stability of each locus was explored across mQTLs and sequence-independent loci. Exploration of conserved versus non-conserved mQTLs across the life course was also explored. **Results** Less than 1% of features, measured by the HumanMethylation EPIC array (EPIC), were potentially heritable (ICC > 0.5). Approximately 3% of intra-individual variation was stable (ICC > 0.5). mQTL analysis indicated more significant sites in adult (N=15,709) versus child (n=8,524) samples. However, the distribution of conserved versus non-conserved mQTL loci across the life course did not vary in terms of variant consequence, genomic region, genomic feature type, epigenetic region, and epigenetic feature type. **Conclusions**Heritability from sequence independent DNA methylation loci in buccal cell samples is low. Intra-individual stability is also low. Effects of aging and the environment may contribute more variation to the epigenetic landscape than these factors.

PrgmNr 3892 - Transethnic genetic-correlation estimation and partitioning

View session detail

Author Block: **Y. Wu**, S. Sankararaman; UCLA, Los Angeles, CA
Disclosure Block: **Y. Wu:** None.
The increasing number of genetic association studies in different populations has implied the discrepancies in the genetic architecture of complex traits in different populations. Furthermore, the previous studies of non-transferability of polygenic risk scores across populations also suggest there is population-specific genetic architecture. Transethnic genetic correlation, i.e, the correlation of the effect sizes of a trait across a pair of populations, is defined in order to quantify these differences in genetic architecture. Similarly, transethnic genetic-impact correlation is another parameter defined that corrects for population-specific allele-normalization of SNP effect sizes. Additionally, it is of interest to further pin down the genetic architecture differences into smaller regions of the genome. While several methods for estimating the genome-wide transethnic genetic correlation have been proposed, there is no existing method that can estimate genome-wide transethnic genetic correlation as well as partition transethnic genetic correlation.
We propose a scalable randomized Method-of-Moments (MoM) estimator, which estimates genome-wide and partitioned transethnic genetic and genetic-impact correlation efficiently and simultaneously. This method leverages the structure of genotype data to obtain runtimes that scale sub-linearly with the number of individuals in the input dataset (assuming the number of SNPs is held constant). First, we perform extensive simulations to validate the accuracy of the estimated genome-wide transethnic genetic correlation. This method is scalable and can perform the analysis on the UK biobank dataset consisting of 430,000 individuals and 460,000 SNPs in 3 hours on a stand-alone compute machine, and partition the transethnic genetic correlation with no additional cost. We applied our method within the UK biobank on White British, Irish, and South Asian, and found novel significant transethnic genetic correlations. For example, we found the transethnic genetic correlation of HDL is 0.74(0.11) and LDL being 0.37(0.08) between White British and South Asian.

PrgmNr 3893 - Using adopted singletons to partition maternal genetic effects into pre- and post-natal effects on offspring phenotype

View session detail

Disclosure Block: **L. Hwang:** None.

Maternal genetic effects can be defined as the effect of a motherâ□□s genotype on the phenotype of her offspring, independent of the offspringâ□□s genotype. Maternal genetic effects can act via the intrauterine environment during pregnancy and/or via the post-natal environment. Here we develop a new model using structural equation modelling (SEM) to partition maternal genetic effects into pre- and post-natal effects. We assume that in biological families, offspring phenotypes are influenced prenatally by their motherâ□□s genotype and postnatally by their parentsâ□□ genotypes, whereas adopted individualsâ□□ phenotypes are influenced prenatally by their biological motherâ□□s genotype and postnatally by their adoptive parentsâ□□ genotypes. Critically, SEM allows us to model unobserved genotypes of the biological and adoptive parents of the adopted individuals as latent variables, permitting us to leverage the thousands of adopted singletons in the UK Biobank. We examine the utility and power of our model using simulations and asymptotic power calculations. We apply our model to educational attainment and birth weight, in up to 5178 adopted individuals, 983 trios, 3650 mother-offspring pairs, 1665 father-offspring pairs and 350330 singletons from the UK Biobank. Our results show expected patterns of maternal effects on offspring birth weight, but unexpected large prenatal effects on offspring educational attainment. Sensitivity analyses suggest this result may be due to adopted individuals in the UK Biobank being fostered by their relatives. We conclude our model can be used to estimate pre-natal and post-natal maternal genetic effects, which has exciting implications for developing pleiotropy-robust Mendelian randomization approaches for investigating the effects of maternal exposures on offspring outcomes.

PrgmNr 3894 - A benchmarking study of SARS-CoV-2 whole-genome sequencing protocols using COVID-19 patient samples

View session detail

Author Block: **Z. Chen**[1], T. Liu[1], W. Chen[1], X. Chen[1], M. Hosseini[1], Z. Yang[2], J. Li[3], D. Ho[1], D. Turay[4], C. P. Gheorghe[5], W. Jones[6], C. Disclosure Block: **Z. Chen:** None.

The COVID-19 pandemic is a once-in-a-lifetime event, exceeding mortality rates of the flu pandemics from the 1950â□□s and 1960â□□s. Whole-genome sequencing (WGS) of SARS-CoV-2 plays a critical role in understanding the disease, particularly on the identification of newly emerging variants. Performance variation exists across SARS-CoV-2 viral WGS technologies, but there is currently no benchmarking study comparing different WGS sequencing protocols. We compared seven different SARS-CoV-2 WGS library protocols using RNA from patient nasopharyngeal swab samples under two storage conditions. We constructed multiple WGS libraries encompassing three different viral inputs: 1,000,000, 250,000 and 1,000 copies. Libraries were sequenced using two distinct platforms with varying sequencing depths and read lengths. We found large differences in mappability and genome coverage, and variations in sensitivity, reproducibility and precision of single-nucleotide variant calling across different protocols. We ranked the performance of protocols based on six different metrics. Our results indicated that the most appropriate protocol depended on viral input amount and sequencing depth. Our findings offer guidance in choosing appropriate WGS protocols to characterize SARS-CoV-2 and its evolution.

PrgmNr 3895 - An Epigenome-wide association study of body mass index (BMI) in the Multiethnic Cohort Study

View session detail

Author Block: **J. Zhu**[1], Y. M. Patel[2], S. Murphy[3], M. Tiirikainen[4], D. O. Stram[5], L. Le Marchand[6], S. L. Park[1]; [1]Univ. of Hawaii, Cancer Ctr., Honolulu, HI, [2]Univ. of Southern California, Los Angeles, CA, [3]Univ. of Minnesota, Minneapolis, MN, [4]UH Cancer Ctr., Honolulu, HI, [5]Univ of Southern California, Los Angeles, CA, [6]Univ Hawaii, Honolulu, HI
Disclosure Block: **J. Zhu:** None.
Background Epigenome-wide association studies (EWAS) of blood leukocytes have identified numerous CpG sites associated with body mass index (BMI). However, many of these studies were conducted in populations of European ancestry. The observation that BMI varies across populations and differentially influences obesity-related disease risk warrants the study of DNA methylation and BMI across racially diverse populations. We conducted an EWAS to investigate the association of DNA methylation of blood leukocytes with BMI in five racial/ethnic groups involving a total of 1,996 smokers from the Multiethnic Cohort Study (MEC). **Methods** DNA methylation of blood leukocytes were quantified from 364 African Americans, 398 Whites, 311 Native Hawaiians, 523 Japanese Americans and 400 Latinos. BMI (kg/m^2) was self-reported at time of blood draw and treated as a continuous variable. Methylation levels were assessed as a beta-value, the ratio of methylated to combined intensity at that CpG site. Linear multivariable regression analyses was conducted for all 1,996 participants for trans-ethnic estimates and for each racial/ethnic separately, with adjustment for age, sex, genetic ancestry, and cell-type distribution. Likelihood ratio test was used to test the heterogeneity of effects by race/ethnicity. To account for potential confounding by smoking dose, given that all participants were current smokers at time of blood draw, models were additionally adjusted for the urinary biomarker total nicotine equivalents (TNE). **Results** Of the 794,783 CpG sites evaluated, 670 trans-ethnic signals were found associated with BMI after Bonferroni-correction. The strongest signal was found in *ABCG1* (cg06500161, P=7.01Ã□10^{-27}), followed by *RARA* (cg17739917, P=2.28Ã□10^{-19}) and *SRRBF1* (cg11024682, P=6.21Ã□10^{-16}). These sites were all found to have an increase in methylation for increasing BMI. Our findings remained even after further adjustment for TNE, suggesting that they are independent of smoking dose. Among the 670 significantly associated CpG sites, 90 sites were found globally heterogeneous (P-interaction Conclusion This EWAS in a multiethnic population of smokers identified a great number of BMI-associated loci, many of which were also reported in previously published EWAS. Our findings suggest that while many BMI-related differentially methylated CpG sites have trans-ethnic effects, heterogeneity of the associations between DNA methylation and BMI across race/ethnicity are present and may provide mechanistic insight into observed differences in obesity-related disease risk. Replication of study findings are in progress.

PrgmNr 3896 - Evidence of causality between type 2 diabetes and dementia in the Million Veteran Program

Disclosure Block: **E. Litkowski:** None.

Background: Diabetes and dementia are diseases of high healthcare burden worldwide, and individuals with diabetes have 1.4 to 2.2 higher risk of dementia. Given previous work in the Million Veteran Program (MVP) demonstrating that a genetic risk score (GRS) for type 2 diabetes (T2D) is associated with dementia (an association that disappears when adjusting for T2D case status), our goal was to evaluate causality in the diabetes-dementia association. **Methods:** We used a two stage least squares Mendelian Randomization (MR) approach in MVP to estimate the causal associations between T2D and four types of dementia. In stage 1, we regressed a standardized, weighted genetic risk score of 331 published variants and effect sizes (GRS331) from Genome-Wide Association Studies (GWAS) against the log odds of T2D in the MVP biobank. In stage 2, we evaluated the association of the standardized genetically predicted probability of T2D from stage 1 with four nested definitions of dementia: strict Alzheimerâ□□s Disease (AD), AD plus non-specific dementias (AD-Plus), AD-related dementia (ADRD), and all-cause dementia. We used logistic regression to assess associations stratified by European (EUR, 61,986/210,469 cases/controls), African (AFR, 14,354/28440 cases/controls), and Hispanic (HIS, 6,200/11,850 cases/controls) ancestries, using a significance threshold of 0.0033 to account for multiple testing. **Result**: GRS331 predicted T2D in all three ancestries (p= 5.73e-300 to 1.54e-117). In EUR, the genetically predicted probability of T2D was associated with all dementia subtypes except strict AD (p = 4.60e-10 to 4.50e-12, OR = 1.05 to 1.06). In EUR, compared to the lowest decile of the genetically predicted probability of T2D, those in the top decile had higher odds for all dementia subtypes except strict AD (p = 0.001 to p = 5.02e-12, OR = 1.18 to 1.31). There were no associations between the genetically predicted probability of T2D and dementia in AFR and HIS. **Conclusion:** We found evidence of causality between diabetes and dementia in EUR. A limitation of this study is the lack of statistical power in AFR and HIS. Further analysis is required to systematically evaluate pleiotropy in all ancestries.

PrgmNr 3897 - Examining genetic associations with liver steatosis in Mexican-origin adults

View session detail

Author Block: **M. Trejo**, K. E. Morrill, Y. C. Klimentidis, D. O. Garcia; Univ. of Arizona, Tucson, AZ
Disclosure Block: **M. Trejo:** None.
Background: Various studies have identified single-nucleotide polymorphisms (SNPs) related to non-alcoholic fatty liver disease (NAFLD), specifically ones located in or near the *LYPLAL1*, *GCKR*, *PPP1R3B*, *TM6SF2*, *MBOAT7*, and *PNPLA3* genes. However, these SNPs were identified primarily in populations of European ancestry. This study examined the associations of these previously identified SNPs with liver steatosis in a sample of Mexican-origin adults living in Southern Arizona. **Methods:** A total of 307 Mexican-origin adults between the ages of 18 and 64 with a body mass index (BMI) of 25 kg/m^2 or higher were genotyped at the following SNPs: rs12137855 (*LYPLAL1*), rs1260326 (*GCKR*), rs4240624 (*PPP1R3B*), rs58542926 (*TM6SF2*) rs641738 (*MBOAT7)* and rs738409 (*PNPLA3*). All had liver steatosis assessed through transient elastography (FibroScanÂ®). Additive, dominant, and recessive regression models examined the association between the six SNPs and liver steatosis. Age and BMI were examined as potential modifiers of genetic associations. **Results:** Participants were, on average, 45 years old and mostly female (63%) with an overall mean liver steatosis of 288.1 dB/m, indicative of steatosis >5%. Models showed no association between *LYPLAL1*, *GCKR*, *PPP1R3B*, *TM6SF2*, or *MBOAT7* and liver steatosis. Only *PNPLA3* was statistically significantly associated with liver steatosis in both additive and recessive models (pConclusion: SNPs associated with NAFLD in populations of European descent did not strongly contribute to liver steatosis in individuals of Mexican-origin, except for rs738409 (*PNPLA3*). Further efforts are necessary to explore additional SNPs that may be associated with NAFLD in this high-risk population.

PrgmNr 3898 - Genetic determinants of prostate-specific antigen levels improve cancer screening utility

View session detail

Author Block: **L. Kachuri**[1], R. E. Graff[1], J. P. Shelley[2], K. Schaffer[2], J. D. Mosley[2], P. J. Goodman[3], C. Till[3], I. Thompson[4], R. Klein[5], S. K. Van Den Eeden[6], T. J. Sinai, New York, NY, [6]Kaiser Permanente Northern California, Oakland, CA, [7]Univ California San Francisco, San Francisco, CA

Disclosure Block: **L. Kachuri:** None.

Prostate-specific antigen (PSA) testing is controversial due to issues related to sensitivity and specificity, resulting in overdiagnosis and overtreatment of prostate cancer (PCa). Genetic determinants of PSA in cancer-free men could be used to correct observed PSA values by accounting for PSA variation that does not reflect PCa.

We conducted the largest ever genome-wide association study (GWAS) of PSA in men without PCa (N=65,962; 63,338 European ancestry) using longitudinal measures from the UK Biobank (UKB; n=26,491), BioVU (n=8078), and Genetic Epidemiology Research on Adult Health and Aging (GERA; N=30,088) cohorts. Our GWAS discovered 87 variants associated with PSA levels (P-8), including 37 loci independent of previously reported associations (r^2PSA) constructed from these variants was validated in the Prostate Cancer Prevention Trial (PCPT; P=8.7Ã□10^{-54}). In the PCPT, which enrolled PCa-free men with PSAâ□¤3 ng/mL, PRS explained a larger proportion of PSA variation than age (4.0% vs. 1.3%).

Consistent with the hypothesis that genetic predisposition to elevated PSA increases the detection of low-grade PCa, PRS_{PSA} was inversely associated with Gleason score (â□¤6 vs. â□¥8: OR=0.83, P=8.4Ã□10^{-5}; 6485 GERA cases) and PCa mortality (HR=0.82, P=7.4Ã□10^{-9}; 8834 UKB cases). We then evaluated how genetically corrected PSA values affect reclassification at cut-offs used for biopsy recommendations in GERA. Among non-cases with a negative biopsy, 18.4% were reclassified below the referral threshold, while 2.7% moved upward. In cases, downward reclassification (3.9%) was higher than upward (1.9%) when considering PSA values â□¥2 years before diagnosis. This trend was more pronounced in cases with low-risk disease (Gleason Lastly, we explored the role of PSA-related selection bias on associations with PCa risk and mortality. There is substantial sharing of genetic loci between PSA and PCa, illustrated by the high correlation between their genetic scores (r=0.287, P-500) in UKB (n=164,669 not included in the PSA GWAS). Although this may partly reflect pleiotropy, there was evidence of bias due to screening (P=2.1Ã□10^{-130}). Re-fitting PRS_{PCa} using bias-corrected risk allele weights attenuated its correlation with PRS_{PSA} (r=0.049, P=5.5Ã□10^{-93}) and revealed a previously absent association with PCa mortality (HR=1.18, P=0.035).

Our work provides preliminary evidence that genetic correction of PSA levels may improve PCa screening. Larger and more diverse study populations are required to fully characterize the genetic basis of PSA variation and optimize its clinical utility.

PrgmNr 3899 - Genetic factors explain varying glaucoma prevalence and pressure subtype across ancestries

View session detail

Author Block: **P. Gharahkhani**[1], X. Han[2], J. ONG[3], S. Macgregor[1]; [1]QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [2]300 Herston Road, BRISBANE, Australia, [3]QIMR Berghofer Med. Res. Inst., HERSTON, Australia
Disclosure Block: **P. Gharahkhani:** None.
Glaucoma is the leading cause of irreversible blindness. Increases in intraocular pressure (IOP) and in optic nerve vertical cup-to-disc ratio (VCDR) are associated with greater glaucoma risk. Glaucoma has the highest prevalence in individuals of African ancestry, followed by Latinos, then Europeans and East Asians. East Asians are much more frequently diagnosed with a low pressure glaucoma subtype, but the reasons for this are hotly debated. We aimed to investigate whether variation in glaucoma presentation can be explained by differences in the distributions of polygenic risk across ancestries.We applied an artificial intelligence approach to allow accurate and uniform optic nerve phenotyping in two large independent biobanks, UK Biobank and Canadian Longitudinal Study on Aging. We then derived polygenic risk scores (PRS) for glaucoma, IOP and VCDR and applied them to a large independent multi-ethnic cohort (Kaiser Permanente). Within Kaiser, Africans had greatly elevated (~1 standard deviation higher) glaucoma PRSs, followed by Latinos, Europeans and East Asians, mirroring reported prevalences. The ordering of the ancestries was similar for the IOP PRS, mirroring observations that Africans have high glaucoma rates (particularly high pressure glaucoma), whilst Asians are affected at lower rates (with the low pressure subtype common). The VCDR PRS was higher in East Asians/Africans than in other ancestries. After adjusting for the IOP and VCDR PRSs, glaucoma PRS means were indistinguishable across ancestries, suggesting the observed ancestry differences are primarily due to genetic effects on IOP and VCDR. The results were essentially unchanged in our sensitivity analyses investigating population structure biases.Together, our findings indicate that, relative to Europeans, African ancestry individuals have both genetically elevated VCDR and IOP, explaining the elevated prevalence of glaucoma. By contrast, a combination of genetically lower IOP but elevated VCDR may explain the similar glaucoma prevalence in Europeans and East Asians, and suggesting a genetic explanation for the â□□low tensionâ□□ form of glaucoma common in East Asia. These findings are consistent with our findings at the phenotypic level (Han et al., AJHG 2021), suggesting there are genetic drivers behind the different prevalence and types of glaucoma which manifest in different ancestries.

PrgmNr 3900 - Heritability of audiometric phenotypes using multigenerational pedigrees

View session detail

Author Block: **J. Duran**[1], S. Mansour[1], H. Coon[2], L. B. Jorde[3]; [1]Dept Human Gen, Univ of Utah, Salt Lake City, UT, [2]Univ. of Utah Sch. of Med., Salt Lake City, UT, [3]Univ of Utah, Salt Lake City, UT
Disclosure Block: **J. Duran:** None.
Little is known about the heritability of audiometric phenotypes. Current heritability estimates are based on twin studies, which often yield upwardly biased estimates due to violations of assumptions about shared environment and gene-environment interactions. We have employed the Sequential Oligogenic Linkage Analysis Routines (SOLAR) algorithm to estimate the heritability of hearing phenotypes in the Utah CEPH pedigrees. SOLAR uses pedigree data intersected with phenotype and genotype data to build identity by decent matrices to estimate heritability. Additionally, SOLAR uses maximum likelihood methods to decide whether a trait has a significant genetic component and whether the mode of inheritance is Mendelian or polygenic. Previous twin studies of hearing acuity provide a wide range of heritability estimates: 45 to 75 percent for standard audiometric measures and an even larger range of variation for hearing loss. We hypothesize that twin studies overestimate the heritability of hearing acuity and that using three-generational pedigree data will produce a more accurate estimate of the heritability of hearing acuity. We quantified hearing acuity as the two-ear average of hearing thresholds at high frequency and pure-tone frequency (frequencies at which human voices are heard). Our analysis controlled for age and sex as covariates, which were not previously accounted for in twin studies. Our findings indicate that high-frequency hearing acuity has a polygenic mode of inheritance with an estimated heritability of 23 percent. Similarly, pure-tone hearing acuity has a polygenic mode of inheritance and a heritability is 27 percent. Thus, for both phenotypes, heritability estimates are decreased compared to previously reported twin studies.

PrgmNr 3901 - Methylation patterns associated with inflammation traits in racially and ethnically diverse populations

Background. Inflammation is a complex immune response including chronic low-grade inflammation that contributes to the pathophysiology of chronic diseases such as cardiovascular disease, cancer and diabetes. Genome-wide association studies have identified candidate loci of genetic variants associated with biomarkers of inflammation clustered by immune pathways and liver metabolic pathways. However, the proportion of variance explained by genetic loci remains small and has largely been evaluated in only European Ancestry populations. In this study we extend this evaluation to the epigenome to evaluate DNA methylation associated with biomarkers of inflammation across multiple races and ethnicities. **Methods.** We meta-analyzed epigenome-wide association studies (EWAS) of inflammation biomarkers (C-reactive protein, CRP; IL-6; fibrinogen) measured in peripheral blood samples with DNA methylation levels (from whole blood assays) in the Womenâ□□s Health Initiative (WHI) cohort (discovery) along with diverse replication cohorts. We analyzed CpG sites common to the Infinium HM450K and EPIC arrays using mixed effects linear regression with the inflammation marker level as the outcome variable, and DNA methylation as the predictor, adjusted for age, sex, body-mass index (BMI), smoking (ever, former, current), population structure (via PC1-10), cell type composition (proportion of WBC species), and batch effects (as random effect). Significance was defined as pResults. The discovery stage (n=4,378 from the WHI cohort) identified 100 significant CpG sites associated with CRP values, 24 associated with fibrinogen, and 5 with IL-6 in the multi-racial/ethnic analyses. The nearby genes for 14 of the top 20 most significant DNA methylation sites associated with CRP level (pConclusion. Large-scale EWAS of inflammation biomarkers identified significant CpGs associated with CRP, fibrinogen, and IL-6. Next steps include exploring biological pathways, inflammation related disease (e.g., cardiovascular disease, diabetes), and associated medication use as potential confounders and effect modifiers, and extending these analyses to replication cohorts including ancestrally diverse populations. It is currently unknown whether the identified CpG-lipid associations could be generalized to other racial/ethnic groups or replicated for African Ancestry. Further analyses include performing race/ethnic-specific EWAS models to explore the generalizability and heterogeneity of inflammation marker-associated CpG sites.

PrgmNr 3902 - ML-based COPD phenotype denoising using volumetric flow data improves genomic discovery and disease risk prediction

Complex disorders such as chronic obstructive pulmonary disease (COPD) have multiple etiologies with similar manifestations, making the process of phenotyping a large cohort arduous. Even after curating a COPD phenotype using over 600 self-reported, general practitioner, and hospital records from the UK Biobank (UKB), a GWAS for 364,256 individuals identified only 5 genome-wide significant (GWS) loci, failing to replicate most known COPD-associated loci. COPDâ□□s low prevalence (~4%) and the large fraction of undiagnosed (81%) and false positive (62%) cases imply that, although sourced from medical records, these manually-defined labels are inherently noisy. Here we show that deep neural networks (DNNs) can denoise such labels, allowing us to improve genomic discovery by amplifying sparse signals found in manually-generated phenotypes.
Using our noisy labels, we trained an ensemble of 10 DNNs to predict COPD status from raw volumetric flow data, consisting of 1,000 flow-volume measurements collected at 10ms intervals. Our model achieved an AUPRC=0.27 (95% CI: 0.25-0.30; n=31,965; prevalence=3.95%), outperforming spirometry-based predictions defined using the global initiative for chronic obstructive lung disease (GOLD) criteria (AUPRC=0.19 [0.17-0.21]). We split unrelated UKB individuals of European ancestry into two folds, trained a model on each fold, and applied each model to the other fold.We then ran a GWAS using COPD risks predicted by our model on 269,405 individuals (ML-based GWAS), controlling for age, sex, height, BMI, genetic PCs, smoking status, and the data fold. The ML-based GWAS identified 215 GWS loci, replicating 39 out of 41 previously reported COPD loci (Sakornsakolpat et al., Nat. Genet. 2019). The top locus is *4q24*, encompassing *NPNT* (rs34712979, P=9.9e-106), a known COPD susceptibility locus. Functional enrichments of the GWS loci highlight development and morphogenesis of respiratory (3) and cardiac (11) terms, consistent with known cardiac comorbidities of COPD. A GWAS using the GOLD criteria phenotype identified only 17 GWS loci, 16 of which were also identified by the ML-based GWAS, and no functional enrichments.
To validate these GWASs on an independent cohort, we computed polygenic risk scores (PRSs) for the COPDGene dataset, a clinically curated cohort of ~10k individuals. The ML-based and GOLD PRSs resulted in AUPRCs of 0.61 (0.60-0.63; prevalence=52.7%) and 0.57 (0.55-0.59) on 5,269 individuals of European ancestry, respectively. This work illustrates the potential for using ML to improve genomic discovery by amplifying signals from otherwise noisy phenotypes into quantitative risk scores.

PrgmNr 3903 - Multitrait and AI-enhanced GWAS of glaucoma and its risk factors enables PRS based prediction of risk which is portable across ancestries

View session detail

Author Block: **S. Macgregor**[1], Y. Wu[1], X. Han[1], P. Gharahkhani[1], A. W. Hewitt[2], J. E. Craig[3], D. A. Mackey[4], J. L. Wiggs[5], A. P. Khawaja[6], M. Trzaskowski[7]; [1]QIMR Berghofer Med. Res. Disclosure Block: **S. Macgregor:** Major Stockholder/Ownership Interest; I hold stock in StratifEYE Pty Ltd. Receipt of Intellectual Property Rights/Patent Holder; I am an author of a filed glaucoma genetic risk score patent.
Glaucoma, one of the most heritable human diseases, is the leading cause of irreversible blindness. Glaucoma is usually treatable but only if diagnosed in time. Previous studies in European ancestry populations have shown that polygenic risk scores (PRS) offer excellent potential for stratifying people into glaucoma risk categories. Glaucoma incidence is highest in those of African ancestry, followed by Asians, then Europeans. Alas, genetic studies to date have focused on the latter two, particularly Europeans.
Some early studies suggested that the genes underlying glaucoma risk differ across ancestries. However, the latest cross-ancestry GWAS showed there is substantial concordance in the effect sizes at implicated risk loci, suggesting that PRS from one population will have utility in the others.We performed a cross ancestry multitrait GWAS harnessing data from both glaucoma cohorts (International Glaucoma Genetics Consortium) and glaucoma endophenotypes, with AI based phenotyping used to maximize precision. We built a PRS and tested its predictive performance in independent cohorts of European, South Asian, East Asian and African ancestry.
The multitrait GWAS greatly increased the effective sample size, resulting in increased prediction accuracy relative to our 2020 PRS in all ancestries (e.g. AUC increases over non-genetic baseline 0.05 and 0.07 for 2020 and 2021 PRS, respectively in Europeans; analogous figures in Africans 0.03 and 0.06). As expected given the Euro-centric training set, PRS performance in non-Europeans was typically reduced relative to Europeans but AUC increases were significant relative to baseline. In Africans those in the top PRS decile had >7 fold increased risk relative to the bottom decile. In South Asians, those in the top PRS decile reached 3% glaucoma prevalence 18 years earlier than those in the bottom decile.
Future GWAS should better represent all ancestry groups to ensure good PRS performance worldwide. In the meantime, our current cross-ancestry GWAS enables construction of a PRS which performs acceptably in all major ancestries, including African ancestry populations where glaucoma rates are very high. Our new glaucoma PRS has excellent potential to help prevent glaucoma blindness worldwide.

PrgmNr 3904 - Multi-trait Genome-wide association study identifies variants associated with corneal parameters that contributing to keratoconus risk

View session detail

Author Block: **W. HE**[1], X. Han[2], J. ONG[3], P. Gharahkhani[1], S. Macgregor[1]; [1]QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [2]300 Herston Road, BRISBANE, Australia, [3]QIMR Berghofer Med. Res. Inst., HERSTON, Australia

Disclosure Block: **W. He:** None.

Keratoconus (KC) is a condition in which the cornea thins, bulges, and flattens into a conical shape. Sequelae of KC include myopia and astigmatism. KC is the main cause of corneal transplantation, with a prevalence of 1.38 per 1000 worldwide. Obtaining large KC datasets for GWAS is problematic because of the relative rarity of KC. However, recent large studies have measured quantitative corneal parameters and investigating them may provide insight into the pathogenesis of KC. Central corneal thickness (CCT) is a corneal parameter directly related to the corneal thinning character of KC. Another parameter that has been found to be significantly lower in keratoconus patients is the corneal resistance factor (CRF). Many large-scale cohorts with genetic data have collected CCT or CRF data, but not both. Here, we performed a multi-trait GWAS with European ancestry CRF data from the UK Biobank and the Canadian Longitudinal Study on Aging (CLSA) (N_{UKB}=105427, N_{CLSA}=18190), and European ancestry CCT data from International Glaucoma Genetics Consortium (IGGC) (N=17803). We identified 383 CRF and 238 CCT loci, including 171 CRF and 176 CCT loci that had not previously been reported. We replicated our result in UK Biobank and IGGC Asian ancestry groups. The power to replicate individual loci was low but overall they displayed a strong concordance in effect size across ancestries, indicating the possible cross-ancestry effects within CRF and CCT loci. We looked up the novel CRF/CCT-associated loci (160 CRF and 161 CCT) in a recent KC GWAS (4669 cases, 116547 controls). As expected many of the CCT/CRF loci were strongly associated with KC (P CCDC80, FBXO31, HERC2, CD34 and MAMDC2. We found negative correlations in effect size between two corneal parameters and KC. A two-sample Mendelian randomisation analysis revealed that CRF and CCT are likely to increase the risk of KC causally. These findings demonstrate the power of multi-trait GWAS using corneal parameters to identify new KC risk loci.

PrgmNr 3905 - Perceived aging in the UK Biobank - A proxy measure for skin aging?

View session detail

Author Block: **N. Ingold**[1,2], X. Han[1], C. M. Olsen[3,4], D. C. Whiteman[3,4], J. Ong[1], S. Macgregor[5], M. H. Law[1,2]; [1]Statistical Genetics, QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [2]Sch. of BioMed. Sci., Faculty of Hlth., Queensland Univ. of Technology, Brisbane, Australia, [3]Dept. of Population Hlth., QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [4]Faculty of Med., The Univ. of Queensland, Herston, Queensland, Australia, [5]QIMR Berghofer Med. Res. Inst., Brisbane, Australia
Disclosure Block: **N. Ingold:** None.
Age is perceived through the presentation of a range of features on the skin such as wrinkles. These features can arise from sources both intrinsic (e.g. physiological changes over time) or extrinsic (e.g. sun exposure). Some components of skin aging are also associated with risk of skin cancer. To date, the largest genome-wide-association study (GWAS) of perceived (relative) age using the UK Biobank (N=~400,000) identified 74 genetic loci. We proposed two aims; 1) to leverage power from genetically correlated phenotypes to identify additional loci associated with perceived aging, and 2) to evaluate the overlap between the genetics of perceived age and facets of skin aging relevant to skin cancer. Genetic correlations (rg) between perceived younger age and multiple traits were assessed using LD score regression (LDSC), both generally and by sex. LDSC indicated that perceived age in men and women may have differing genetic architecture (female vs. male rg = 0.75, 95% CI = 0.69 to 0.80). Higher BMI (rg = -0.2, 95% CI = -0.24 to -0.17) and greater cigarettes per day (rg=-0.15, 95% CI=-0.21 to -0.10) were genetically associated with older perceived age in both sexes, while baldness was correlated with greater perceived age in males(rg = -0.36, 95% CI = -0.41 to -0.30) and pigmentation traits were correlated with looking younger in females (rg = 0.21, 95% CI = 0.10 to 0.33). Phenotypes that directly measure components of skin aging were not correlated with perceived age (rg = 0.02, 95% CI = -0.19 to 0.22), nor was melanoma (rg = -0.01, 95% CI = -0.12 to 0.08). We will report on using multi-trait analysis of GWAS summary statistics (MTAG) to identify additional genes associated with perceived age, and to further explore aim 2 we will apply GWAS subtraction to attempt to identify components of perceived age (e.g. extrinsic skin aging). We hypothesised that additional loci can be identified for perceived age in the UK-Biobank using multi-trait analysis, and that perceived age could also provide a measure of components of skin aging relevant to skin cancer risk. While the results do not reflect perceived age as being strongly driven by skin aging, our analysis is a rare example of a complex trait with differences in genetic architecture by sex.

PrgmNr 3906 - Quantifying uncertainty and variability of recessive disease prevalence using Monte Carlo estimates

View session detail

Author Block: **S-G. Ji**, P. Komar, K. Shah, M. Soliai, C. Barnhill; BridgeBio Pharma, Palo Alto, CA
Disclosure Block: **S. Ji:** Salary/Employment; BridgeBio Pharma.

Disease prevalence is a key metric of biomedical research and therapeutic development prioritization. The more accurately the number of individuals who may benefit from a potential therapy can be predicted, the better informed decisions can be made. Unknowns such as rate of underdiagnosis, and regional or ethnic variability induce significant uncertainty, sometimes on the order of 100x. Quantifying this uncertainty is necessary for informed public health decision making regarding the disease burden.

We present a statistical approach to robustly estimate the ethnicity- and region-specific incidence rate of recessive diseases based on allele count data from large population cohorts. In turn, prevalence is computed from the estimated incidence and life-expectancy. Multiple population-level data (gnomAD, UK Biobank, TOPMed), with different inclusion criteria, are used to increase the precision of the estimates. First, we limit the variants to those with pathogenic and likely pathogenic mutations based on ACMG guidelines for lower bound estimates. Second, we draw Monte Carlo Markov chain (MCMC) samples of ethnicity-specific allele frequencies from a non-linear random-effect model with binomial outcome and logit-normal prior shared between ethnic groups. Finally, allele frequency samples are combined across variants to produce ethnicity-specific frequencies of carriers, assumed to be unaffected, and aggregated to yield region-specific incidences assuming Hardy-Weinberg. For an upper limit, we repeat the approach with a relaxed variant filtering. We filter based on functional annotation from sources ranging from pLoF to multiple computational predictions. Computing with MCMC samples allows one to characterize the uncertainty and enables propagating it to downstream analyses accurately. A Python implementation completes one such analysis in a few minutes.

We validated our method by comparing its results on 24 autosomal recessive diseases for which genetic newborn screen data is available. Our method was capable of accurately predicting the incidence of both ultra-rare (1 in a million births) and rare (1 in 10,000 births) diseases. The results were concordant within a margin of factor of 3 for 21 of the 24 diseases. After validation, we successfully employed the method on Recessive Dystrophic Epidermolysis Bullosa to predict 75% higher incidence (5.4, 95%CI:[2.8, 9.6] in 1 million births) than epidemiology literature (3 in 1 million births) that was corroborated by expert review and extrapolation from claims data. This method is reliable for inherited, recessive diseases with clear genetic causes.

PrgmNr 3907 - Tissue-specific functional annotations highlight association of liver polygenic risk score with Alzheimerâ□□s disease and related biomarkers

Alzheimerâ□□s disease is a neurodegenerative disease whose causal mechanisms are not yet fully known. The use of functional annotation in genetic analyses has been shown to be able to enhance polygenic risk score (PRS) models, improving their power and identifying new insights into disease mechanisms. Here, we leveraged genomic functional annotations from GenoSkyline-PLUS that provide a tissue-specific measure of which genomic regions are expected to be functional. Using these annotations, individual-level genetic data from participants of European ancestry from the Wisconsin Registry for Alzheimerâ□□s Prevention (WRAP, n = 1,198) and Wisconsin Alzheimerâ□□s Disease Research Center (WADRC, n = 212) cohorts, and genome-wide association study summary statistics from the International Genomics of Alzheimerâ□□s Project (IGAP 2019), we built tissue-specific PRS models for 13 tissues and applied the scores to two longitudinal cohort studies of AD that include both cognitive diagnoses and a rich set of cerebrospinal fluid biomarkers for AD, neurodegeneration, and inflammation measured with the Roche NeuroToolKit immunoassays. The model most strongly associated with AD diagnosis (and the only model statistically significantly associated after the strongly associated APOE locus was removed) was the liver PRS: n = 1,116; OR = 2.19 (1.70-2.82); P = 1.46×10^{-9}. This liver PRS was also statistically significantly associated with two major AD biomarkers in the cerebrospinal fluid: amyloid (P = 3.53×10^{-6}) and phosphorylated tau (P = 1.45×10^{-5}). These findings highlight the potential of functional annotation in PRS studies and provide new evidence highlighting the role of the liver-functional genome in AD.

Colorectal cancer (CRC) is a leading cause of cancer-related mortality, yet many CRC are preventable by screening individuals at increased disease risk. Polygenic risk score (PRS) offer the prospect of precision prevention by defining individualâ□□s risk of CRC and tailoring screening. Genome-wide CRC-PRS built upon European (EUR) data (PMID: 32758450) have limited performance in non-EUR populations because of small number of non-EUR populations included in the training data set. To address this deficiency, we expanded our PRS development to include non-EUR populations.

We derived PRS by leveraging GWAS summary statistics and LD structure from EUR and East Asian (EAS) ancestry. Our training data contains 78,473 cases & 107,142 controls of EUR ancestry and 21,737 cases & 47,444 controls of EAS ancestry. We examined 3 approaches for PRS development, using 1) 180 CRC known loci, 2) genome-wide EAS and EUR summary statistics and LD matrices, 3) combined genome-wide EUR and EAS summary statistics and weighted LD matrices with weights defined as the proportion of subjects from each ancestry. For Approaches 2 and 3, we used LDpred2 to derive PRS including ~1M SNPs. For Approaches 1 and 3 we derived a single PRS across EAS and EUR populations, whereas for Approach 2 we first derived ancestry-specific PRSs (PRSEUR and PRSEAS) and then final PRS for each ancestry by leveraging PRS from other ancestry using a weighted sum of PRSEUR and PRSEAS where the weights were obtained from a multivariate regression model, using 2,627 cases & 3,797 controls for EAS and 29,864 cases & 31,629 controls for EUR ancestry. To evaluate the performance, we analyzed independent data from Genetic Epidemiology Research on Adult Health and Aging cohort of 101,987 individuals, which included 1,699 CRC cases.

The AUC of the best performing approach, which combined genome-wide EUR and EAS summary statistics and LD matrices (Approach 3), were 0.67, 0.65, 0.63 and 0.57 for European, East Asian, Latinx, and African American ancestry groups, respectively, with hazard ratios of top 30% vs. remaining for corresponding groups of 2.52, 1.61, 2.15 and 1.37. Compared to EUR-based PRS (PMID: 32758450), the AUCs for Approach 3 are improved by 3%, 6%, 5% and 2% for European, East Asian,

Latinx and African American ancestry groups, respectively.
A trans-ethnic PRS has the potential to reduce disparities in PRS performance between non-EUR and EUR which is critical if PRS is going to be implemented in clinical practice or populations screening programs. As the performance remains lower in non-EUR populations, larger and more racially and ethnically diverse study populations may further improve equitable risk prediction.

PrgmNr 3909 - mTOR inhibition improves lymphatic dysplasia caused by*PIK3CA*p.H1047L in preclinical models

Lymphatic malformations (LM) are debilitating congenital lesions that arise from abnormal development of the lymphatic system. The child was born at 26 weeks due to premature rupture of membranes and required invasive ventilation for three months. After extubation, a vascular area on the tongue was noted with concern for vascular malformation. Around 9 months of age he had CO_2 laser excision of a large laryngeal cyst obstructing the airway. Histology demonstrated irregular D-240 and CD31 positive lymphatic channels, consistent with the diagnosis of lymphatic malformation. Although he has had multiple sclerotherapies, he has a persistent LM of his cheek. A gene panel to evaluate for pathogenic variants associated with overgrowth and vascular malformations was performed from LM tissue and identified somatic activating *PIK3CA* variant (c.3140A>T; p.H1047L). This variant has been reported before in lymphatic malformations and generalized lymphatic anomaly (RodriguezâLaguna et al 2019, Zenner et al 2019). Previous work in a mouse model demonstrated that expression of the *PIK3CA* p.H1047R variant in LECs causes lymphatic hyperplasia and dysfunction which is prevented by rapamycin, an mTOR inhibitor. To understand the etiology of our patient's variant and identify a targeted therapy, we performed functional analysis *in* vivo and *in vitro*. Expression of the variant in a 3D lymphatic organoid model using human dermal lymphatic endothelial cells resulted in more capillary-like structures emanating from spheroids *in vitro.* Expression of *pik3ca* p.H1047L in the lymphatic endothelium using a *mrc1a* promoter led to dilation of the thoracic duct and posterior cardinal veins in zebrafish. mTOR inhibition with rapamycin or OSI-027 was effective in rescuing the hyperproliferative sprouting phenotype observed *in vitro.* In conclusion, preclinical modeling of lymphangiogenesis recapitulated his disease and identified mTOR as a potential therapeutic target for the treatment of his condition. Future work is needed to identify an effective therapy *in vivo* and evaluate the efficacy of PI3K inhibitors or combined inhibitors of the PI3K-AKT-mTOR pathway.
