Background Molecular study of BRCA1/2 genes in search for cancer predisposition is currently recommended based on patientsâ age at the diagnosis and/or family history of breast or ovarian cancer. Approximately 10-15% of cases are associated with BRCA germline variants. A few cases are explained by recent predisposition genes, but a majority of cases remain unsolved. This could be related to the impact of unknown genes, but also to a failure in detecting variations by current sequencing techniques. This report illustrates the latest hypothesis by highlighting a genetic predisposition through an unusual technique in a HBOC family. **Case report** We report here the case of a female patient who presented a breast cancer at 46 years-old. Her personal history included in-utero fetal death at 8.5 months, an extra-uterine pregnancy and two spontaneous miscarriages. Her mother also presented with breast cancer at 41 years-old and her maternal grandmother presented with breast cancer at 48 years-old. Amongst her 5 siblings, one of her sisters presented with ovarian cancer at 37 years-old and breast cancer at 43 years-old. The characteristic association of several cases of breast and ovarian cancer in first-degree relatives led to BRCA1/2 genes analysis at the beginning of the 2000s in the two sisters. Both tests were negative. An antenatal karyotype was realized during her sisterâs pregnancy, because of elevated serum markers of Down syndrome. It revealed a translocation t(1;17)(q41;q21.31), also present in our patient. Array-CGH did not show imbalance at break points. As the interested region of chromosome 17 could concern the BRCA1 gene, a FISH analysis was carried out to identify breakpoints: breakpoint was located at BAC RP11-812O05 (intronic) and included the BRCA1 gene. A RT-qPCR was then performed on the circulating RNA of one of the patients and showed a decrease of BRCA1 gene expression. This functional analysis demonstrated the impact of the translocation on BRCA1 expression, allowing predictive tests in the family through karyotype. **Discussion** Alterations in the BRCA1 gene are mainly single nucleotide variants (accounting for 10% to 50% of the germline mutations) and large-scale rearrangements. Balanced translocations are rarely searched for and are not always detectable by gene panel analysis using short reads technic. **Conclusion** We report here an incidental karyotype finding of BRCA1 predisposition to breast/ovarian cancers that reveals the lacks of detection of classical techniques for certain variants and shows the interest of whole genome sequencing in unsolved HBOC families. Further analysis such as genome study and bionano are ongoing in this case.

PrgmNr 2337 - Searching for epigenetic markers with prognostic value in Acute Myeloblastic Leukemia patients of Uruguay

View session detail

Zubillaga[3,4]; [1]Departamento de GenÃ©tica, Facultad de Med., Univ. de la RepÃºblica, Montevideo, Uruguay, [2]Dept. of Genetics, Coll. of Med., Univ. of Leicester, Leicester, United Kingdom, [3]Laboratorio de BiologÃa Molecular, MÃ©dica Uruguaya CorporaciÃ³n de Asistencia MÃ©dica (MUCAM), Montevideo, Uruguay, [4]Laboratorio de BiologÃa Molecular, AsociaciÃ³n EspaÃ±ola Primera en Salud, Montevideo, Uruguay
Disclosure Block: **M. Cappetta:** None.
Acute myeloblastic leukemias (AML) are the most frequent acute leukemias in adults. Genomic and candidate gene studies identified novel recurrent somatic genetic and epigenetic variants in AML patients with biological, clinical and therapeutic significance. In Uruguay, the characterization of AML is dependent on integration of cytomorphology, immunophenotype, cytogenetics and molecular biology (*FLT3*, *NPM1*, *CEBPA*, *cKIT* mutations). This allows stratification in prognostic risk groups and rationalization of therapeutic resources. However, some patients with normal karyotype remain unstratified due to failed detection of available markers.
In order to expand the AML molecular markers analysis in Uruguayan patients, we evaluated methylation levels in promoters of 13 candidate genes in bone marrow or peripheral blood DNA samples from 37 adult AML patients at the onset of the disease and 3 healthy controls. Gene promoters were amplified from sodium bisulfite treated DNA and sequenced using MinION platform (Nanopore). A bioinformatic analysis pipeline was designed by our research group to determine methylation status of each CpG in the promoter regions studied.
In this work we detected hypermethylated regions within the gene promoters of *DNMT3A*, *IDH1*, *FLT3* and *JAK3* in AML patients compared to healthy controls. On the other hand, in the *TP53*, *NRAS*, *WT1*, *ASXL1* and *SH2B3* gene promoters specific differentially methylated CpG sites are described in AML patients (Wilcoxon test, p FLT3, *DNMT3A*, *IDH1*, *TP53*, *JAK3* and *NRAS* show differential methylation in AML patients with an extremely acute manifestation of the disease (with a rapidly unfavorable evolution) compared to the rest of the patients analyzed (Wilcoxon test, p We report for the first time an epigenetic analysis in Uruguayan AML patients. These results will be validated in a larger sample and analyzed in conjunction with the clinical and paraclinical data, in order to study the relevance of these markers. However, this study highlights the relevance of detecting epigenetic variability underlying prognostic risk subgroups to deliver patient tailored clinical decision support.

PrgmNr 2338 - Translocation t(8;14)(q11;q32) in Leukemia, a literature review

The translocation t(8;14)(q11;q32) is an abnormality that affects *CEBPD* (8q11) and *IGH* (14q32) genes; and is defined as a distinct cytogenetic entity of precursor B ALL. This study compiles all the cases with t(8;14)(q11;q32) found in the Mitelman database (https://mitelmandatabase.isb-cgc.org/). It was found a total of 76 cases: 44 male and 32 female patients with ages ranged from 3 to 64 years-old (average age: 16.9). The leukocyte count (WBC) ranged from 0.7 to 172.1x10^9/L (average WBC: 25.49x10^9/L). The most frequent diagnosis was ALL; however, a case of AML and another of CML were also found. 21 patients presented the t(8;14)(q11;q32) as the only detectable abnormality; 12 cases presented the der(14)t(8;14)(q11;q32); 25 cases with constitutional trisomy 21 (Down Syndrome) and 6 with acquired trisomy 21. Most abnormalities associated with the t(8;14)(q11;q32) were the constitutional trisomy 21 (33%), followed by gain of X chromosome (18%), t(9;22)(q34;q11)(12%) and acquired trisomy 21 (8%). Other abnormalities found in this study include i(17)(q10)(n=4), +5(n=4), +4(n=3). In conclusion as it is described in the literature review, the t(8;14)(q11;q32) is a non-common abnormality and is associated with B-cell phenotype and often present high-risk features.

PrgmNr 2339 - *BRCA1* and *BRCA2* variants of unclear significance in hereditary breast and ovarian cancer patients. Looking for novel pathogenic variants

View session detail

Disclosure Block: **A. Fiorino:** None.

About 10-20% of hereditary breast and/or ovarian (HBOC) cancer patients undergoing germline *BRCA1/2* genetic testing harbour Variants of Uncertain Significance (VUSs). Poor is the knowledge about the prevalence of germline *BRCA1/2* VUSs in HBOC patients of Southern Italy. Our study is aimed at describing the spectrum of these variants detected in HBOC patients in order to improve the patientâ□□s stratification with the identification of potentially high-risk *BRCA1/2* variants helpful for patient clinical management. 874 breast (BC) or ovarian (OC) cancer patients, enrolled from October 2016 to April 2021 at the â□□Sicilian Regional Center for the Prevention, Diagnosis and Treatment of Rare and Heredo-Familial Tumorsâ□□ of University Hospital Policlinico â□□P. Giacconeâ□□ of Palermo, were genetically tested for germline *BRCA1/2* variants through Next-Generation Sequencing analysis. The screening results showed that 639 (73.1%) out of 874 patients were *BRCA*-wild-type, whereas 67 (7.7%) were carriers of germline *BRCA1/2* VUSs and 168 (19.2%) harboured germline *BRCA1/2* Pathogenic/Likely Pathogenic Variants. Overall, the mutational analysis revealed the presence of 59 different VUSs detected in 67 patients, 46 of which affected by BC and 21 by OC. Twenty-one (35.6%) out of 59 variants were located on *BRCA1* gene, whereas 38 (64.4%) on *BRCA2*. We have identified six alterations in *BRCA1* and two in *BRCA2* with unclear interpretation of clinical significance. Familial anamnesis of a patient harbouring *BRCA1*-c.3367G>T suggests for this variant a potential of pathogenicity as well as the *BRCA1*-c.4963T>G variant identified in three unrelated OC patients. Understanding clinical significance of germline *BRCA1/2* VUSs could improve the identification of potentially high-risk variants useful for clinical management of BC/OC patients and family members. Reclassifying these variants could make them useful for predictive, prognostic and preventive purposes in clinical practice. Advances in molecular biology, such as the use of multi-gene panels, exome sequencing and/or RNA-seq, are increasing the amount of data in the field of research about VUSs. Further linkage analyses will be able in the future to provide additional information useful for understanding inherited variants of unclear clinical significance associated with HBOC.

PrgmNr 2340 - Breast and prostate cancer risks for male *BRCA1* and *BRCA2* pathogenic variant carriers using recently-developed polygenic risk scores

Recent population-based female breast cancer and prostate cancer polygenic risk scores (PRS) have been developed. We assessed the associations and implications on cancer risk prediction of these PRS with breast cancer and prostate cancer risks for male *BRCA1* and *BRCA2* pathogenic variant carriers. We analyzed data from 483 *BRCA1* and 1,318 *BRCA2* male carriers of European ancestry available through the Consortium of Investigators of Modifiers of *BRCA1* and *BRCA2* (CIMBA). A 147-single nucleotide polymorphism (SNP) prostate cancer PRS (PRS_{PC}) and a 313-SNP breast cancer PRS were evaluated. There were three versions of the breast cancer PRS, optimized to predict overall (PRS_{BC}), estrogen-receptor (ER) negative (PRS_{ER-}) or ER-positive (PRS_{ER+}) breast cancer risk. The PRS_{ER+} yielded the strongest association with breast cancer risk. The odds ratio (OR) per PRS_{ER+} standard deviation estimates were OR=1.40 (95%CI: 1.07-1.83) for *BRCA1* and OR=1.33 (95%CI: 1.16-1.52) for *BRCA2* carriers. The PRS_{PC} was associated with prostate cancer risk for both *BRCA1* (OR=1.73, 95%CI: 1.28-2.33) and *BRCA2* (OR=1.60, 95%CI: 1.34-1.91) carriers. The estimated breast cancer ORs were larger after adjusting for female relative breast cancer family history, whereas the breast and prostate cancer ORs, adjusted for family history of male breast and prostate cancer, respectively, were similar to unadjusted estimates. By age 85 years, for *BRCA2* carriers, the breast cancer risk varied from 8% to 18% and prostate cancer risk from 34% to 88% between the 5^{th} and 95^{th} percentiles of the PRS distributions. Population-based prostate and female breast cancer PRS are associated with a wide range of absolute breast and prostate cancer risks for male *BRCA1* and *BRCA2* carriers. These findings warrant further investigation aimed at providing personalized cancer risks for male carriers and to inform clinical management.

Protein truncating variants (PTVs) in *ATM*, *BRCA1*, *BRCA2*, *CHEK2* and *PALB2* are associated with an increased risk of breast cancer, but the risks associated with missense variants in these genes are uncertain. With a total of 59,639 breast cancer cases and 53,165 controls from 44 studies including European and Asian women, we took a training (80%) and validation (20%) approach to analyse data on rare (frequency ATM (1,146 training variants), *BRCA1* (664), *BRCA2* (1,425), *CHEK2* (325) and *PALB2* (472). We evaluated risks according to five *in-silico* risk prediction algorithms (Align-GVGD, BayesDel, CADD, Helix and REVEL), functional protein domain and frequency. We evaluated breast cancer risks using empirical logistic regression models as well as mixture models in which a subset of variants were assumed to be risk associated. The most predictive *in-silico* algorithms were Helix (*BRCA1*, *BRCA2* and *CHEK2*) and CADD (*ATM*). Increased risks appeared restricted to functional protein domains for *ATM* (FAT and PIK domains) and *BRCA1* (RING and BRCT domains). For *ATM*, *BRCA1* and *BRCA2* the data were compatible with the majority of the risk coming from small subsets (approximately 7%, 2% and 0.6%, respectively) of rare missense variants conferring similar risk to those of PTVs in the same genes. In contrast, for *CHEK2*, the data were more consistent with a large fraction (approximately 60%) of rare missense variants conferring an increased risk but lower (OR 1.75, 95% CI (1.47-2.08)) than *CHEK2* PTVs. There was little evidence for an association with risk for missense variants in *PALB2*. The best fitting training models were well calibrated in the validation set. These results inform both the selection of candidate variants for functional assays and risk prediction models, and thus could contribute to the clinical reporting of results to women undergoing gene panel testing for breast cancer susceptibility.

PrgmNr 2342 - Copy number variation (CNV) analysis identifies variants in 1p36 in African American and Caucasian hereditary prostate cancer cases

View session detail

Author Block: **A. Williams**[1], K. W. Termine[1], J. Waldron[1], O. Sartor[2], J. E. Bailey-Wilson[3], D. M. Mandal[1]; [1]LSU Hlth Sci Ctr, Genetics, New Orleans, LA, [2]Tulane Med. Sch., New Orleans, LA, [3]NIH/NHGRI, Baltimore, MD

Prostate cancer (PCa) is a common malignancy which affects 1 in 8 men. There is a significant racial disparity and African American (AA) males are more at risk for developing such cancers, at a rate of almost double compared to the males of European ancestry (EA). So far, not much is known about the role of germline copy number variations (CNVs) in this health disparity. Our previous work has shown several genetic regions with CNVs in both AA and EA hereditary prostate cancer (HPC) cases. The goal of this project was to detect germline CNVs in the targeted resequencing data spanning 9 Mb region in 1p36, that was previously identified by microarray and whole exome sequencing analyses. For this study, a total of 50 individuals were used, 25 AA and 25 EA men from HPC families. We have used three CNV calling algorithms: XHMM, CANOES, and GATK4. First, we focused on four PCa associated genes: *NBPF1*, *NBL1*, *SRSF10*, and *RHD*, that were previously identified in our study. In the current CNV analysis, XHMM identified deletions in *NBPF1* in several samples in both AA and EA cases. GATK4 was unable to call any CNVs in this gene. *NBL1* had no identified deletions in any tool, despite previous microarray data to the contrary. XHMM identified full deletions of SRSF10 in most of the cases, while GATK4 identified partial deletion in several cases from both ancestries, but more frequently in AA cases. Finally, a deletion was detected in *RHD* in only a few cases, and the deletion was confirmed by both XHMM and GATK4 algorithms. Deletion in *RHD* was more common in the EA population than the AA population. CANOES was unable to identify any variants within our regions of interest. We then expanded our search to other identified variants to identify regions commonly detected by the CNV calling algorithms. A region of deletion was detected in the *CELA3A* gene (reported to be downregulated in pancreatic and prostate cancer) and a region between *AKR7L* and *AKR7A3* both of which are found to be frequently mutated in cancer cells. XHMM called the deletion of both of these regions at a much higher rate than GATK4: nearly in all our cases from the two ancestries, compared to only a few in GATK4 and CANOES. The few PCa cases who had deletions across all tools were always in the AA population. Altogether, this new analytical strategy establishes the usefulness of applying multiple CNV callers in identifying regions of potential interest, as well as verifying the results from previous studies of PCa. Results from this study may hold valuable information in finding potential biomarkers to address PCa health disparity in the future. Further validation of the identified variants is ongoing.

PrgmNr 2343 - Genetically Predicted Serum Insulin-like Growth Factor-1 (IGF-1) Levels and Risk of Multiple Primary Cancers in the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial

View session detail

Author Block: **S. He**, C. Breeze, W. Wong, M. Machiela, W-Y. Huang, N. Freedman, S. I. Berndt; Natl. Cancer Inst., Rockville, MD
Disclosure Block: **S. He:** None.
Objectives: Epidemiologic studies have reported positive associations between elevated levels of serum insulin-like growth factor-1 (IGF-1) and the risk of several common cancers, such as prostate and colorectal cancer, leading to speculation that IGF-1 may contribute to the risk of multiple primary cancers. Multiple primary cancers are estimated to occur in 2-17% of the population, but etiologic factors are not well understood. This study aims to investigate the causal relationship between the IGF-1 pathway and the risk of multiple primaries using a Mendelian randomization approach.
Methods: We conducted a trans-ancestry case-control study including 4,402 cases with multiple primaries and 76,419 controls from the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial. Using a previously derived polygenic risk scores (PRS) for serum IGF-1 levels based on 23,443 SNPs , we calculated scores for each subject using PRSice2. This PRS is estimated to explain approximately 22% of the variance in Europeans, but less in other populations (Sinnott-Armstrong N, et al. 2021). We used logistic regression to estimate the odds ratios (ORs) for the association with multiple primaries, adjusting for age, sex, genotype platform and ancestry-specific principle components. The PRS was analyzed both as a continuous measure and as quintiles, based on the distribution among controls. Analyses were conducted separately for European (EUR), African American (AA), and East Asian (EA) populations. We then meta-analyzed the ancestry-specific results using a fixed effects model.
Results: No significant associations were observed between genetically predicted IGF-1 levels and the risk of multiple primaries in either ancestry-specific analyses or the trans-ancestry meta-analysis (trans-ancestry OR (95%CI): 1.18 (0.82, 1.70) for the IGF-1 PRS as a continuous measure; 1.03 (0.93, 1.13)) for the highest PRS quintile compared to the lowest one). **Conclusions:** Our trans-ancestry study does not support an association between genetically predicted serum IGF-1 levels and multiple primaries. Further polygenic risk score analyses are planned to explore the relationship between other biomarkers and the risk of multiple primaries.

PrgmNr 2344 - Germline *PALB2* mutations found in NGS multigenetic panels from breast-ovarian cancer patients in Argentina

Disclosure Block: **A. Gonzalez:** None.

During the last decade, *PALB2* has been included as one of the most relevant high-risk breast cancer predisposing genes after *BRCA1/2*. *PALB2* variants have been scarcely described in Argentinian reports, mainly in the context of multi genetic panel (MP) testing along with other hereditary cancer genes (Cerretini R, et al.2019). In this study, we describe molecular and clinical characteristics of *PALB2* mutations found in 1276 MP from breast-ovarian cancer families in different institutions from Argentina. PALB2 pathogenic (PV) and probably pathogenic (PPV) variants were retrospectively identified and MP reports collected from one local reference lab, Heritas and SITHER public database, from 2017 to present. Geneticists in charge of the patients were contacted to provide anonymous clinical data. All patients were adequately counseled and met NCCN criteria for hereditary breast/ovarian cancer (HBOC) testing. MP were performed by different laboratories with Illumina NGS technology and the number of genes per panel ranged from 5 to 30. All MP included actionable genes associated with HBOC and all the variants were reviewed using the ACMG guidelines. VUS and familial mutations were excluded from this report. A total of 32 *PALB2* PV and 4 PPV were identified. Three of the PPV are novel. The frequency of *PALB2* mutations in the MP cohort is 2,8% (36/1276) similar to other reports. Regarding type of mutations 60% are nonsense, 33% frameshift and 7% large rearrangement. We found 3 double heterozygotes with a PV in *PALB2* and also in *TP53, ATM* and *BRCA2* genes. One recurrent PV (c.1653T>A,p.Tyr551*) was present in 47% (17/36) of carriers. Although previously reported , such a high recurrence mutation rate justifies further research. All patients were unrelated index cases, 32 (89%) with breast cancer (BC), 1 (3%) prostate cancer, 1 (3%) pancreatic cancer and 1 with BC and ovarian cancer concomitant diagnosis. One patient was unaffected at the time of testing (positive family history). BC cases were mainly ductal carcinoma (76%) , luminal (57%) and triple-negative (24%). The mean age at BC diagnosis was 43.5 years (23-60) and there were 5 (15%) cases of bilateral BC and 4 (12%) cases of second BC. Ethnic background is mainly of western European origin (53% of patients with Spanish ancestry and 36% Italian) and less than 10% native Amerindian. To our knowledge, this is the first report describing molecular and clinical characteristics of PALB2 carriers in Argentina. The frequency of PALB2 PV in families with HBOC suspicion is similar to other populations and Tyr551* is a recurrent mutation that seems to be responsible for almost 50% of the cases.

PrgmNr 2345 - Germline genetically predicted mammographic density is associated with breast tumor transcriptomic and proteomic features, CD8+ T cell infiltration, somatic mutational signatures, and tumor mutational burden in The Cancer Genome Atlas

High mammographic density (MD) is one of the strongest risk factors for breast cancer, the most common cancer in women globally, but the molecular underpinnings of this association are poorly understood. Tumor cohorts with multi-omic phenotyping currently do not have linked MD data at scale, making it challenging to define the genomic landscape of breast tumors arising on a background of high MD. We took a new approach to address this challenge by integrating MD genome-wide association study (GWAS) data with The Cancer Genome Atlas (TCGA) breast tumor data. We built a polygenic score for MD using effect size estimates and allele information for the lead variants at 17 independent loci (P -8) from a GWAS of percent MD in 24,192 women of European ancestry. We performed sample and genotype quality control and imputation into the 1000 Genomes reference panel on germline genetic data from 721 female breast cancer cases of genetically inferred European ancestry from TCGA. We assigned each woman in this TCGA cohort, which lacks measured MD, her genetically predicted MD based on the MD polygenic score. We evaluated the association between germline genetically predicted MD and breast tumor genome-wide transcriptomic, proteomic, genomic, epigenomic, and immune traits in TCGA using linear (default) and quasi-Poisson (for overdispersed count data) regression models adjusted for age and stage at diagnosis, estrogen receptor status, and 10 genetic principal components, reporting associations at FDR DLL1, an estrogen-dependent Notch ligand previously implicated in breast oncogenesis ($P = 2 \times 10^{-6}$; top gene of 20,530 genes profiled by RNA-Seq). High genetically predicted MD was associated with increased breast tumor CD8+ T cell infiltration (P = 0.004) in our evaluation of 22 tumor immune infiltrates profiled by the CIBERSORT algorithm. Genetically predicted MD had positive and inverse associations with breast tumor MAPK ($P = 3 \times 10^{-4}$) and XRCC1 ($P = 4 \times 10^{-4}$) protein levels, respectively, of the 281 tumor proteins profiled by reverse-phase protein array, suggesting roles for mitogen-activated protein kinase signaling and DNA repair. High genetically predicted MD was associated with the mitotic clock-like, aging-related single base substitution mutational signatures 1 (P = 0.001) and 5 (P = 0.002) and with high tumor mutational load (P = 0.006 for association with non-silent mutations/Mb). Thus, we combined germline and somatic data to identify breast tumor molecular features associated with genetically predicted MD, with potential implications for breast cancer development and progression.

PrgmNr 2346 - Identification of copy number variants in hereditary lung cancer families

Lung cancer is the most common cause of cancer mortality and the third most common cancer by incidence in the United States. While environmental factors (e.g. tobacco smoke) play an important role in its development, lung cancer risk also exhibits a high degree of heritability. Linkage analyses and genome-wide association studies have identified multiple loci associated with increased lung cancer risk; however, much of the heritability has yet to be explained by these loci. Structural mutations, including a gain or loss of DNA (copy number variants or CNVs), contribute to phenotypic diversity through dosage and/or cis-regulatory effects. CNVs are important sources of phenotypic variation and likely contribute a larger fraction of genomic variation among individuals than SNPs. Unbiased CNV mapping is only possible with the use of high-depth, short-read sequencing and remains much more complicated and prone to false positives than SNP detection. As a result, the contribution of CNVs to genetic variation is not as well understood as the impact of SNPs. As the tools necessary for CNV detection have improved, both somatic and germline CNVs have been shown to play an important role in disease, especially cancer. Although CNVs have been shown to be common and often benign, they account for a significant proportion of pathogenic variants. Little has been done to understand the role of germline CNVs in the biological pathways of hereditary lung cancer. The goal of the current project is to utilize the whole exome sequencing (WES) data in identifying the CNVs in the hereditary lung cancer (HLC) families (â¥3 LC/family) recruited by the Genetic Epidemiology of Lung Cancer Consortium (GELCC). This work uses germline WES data from 203 individuals (60 with a lung cancer diagnosis) from 25 HLC families. We limited our investigation to CNVs called by two independent tools using read depth to infer copy number changes and genomic breakpoints: GATK 4 (https://gatk.broadinstitute.org) and XHMM (https://atgu.mgh.harvard.edu/xhmm/). Those CNVs that segregate with disease, are consistent with Mendelian expectations, and appear to be uncommon in the general population, are subjected to bioinformatic annotation to detect the most probable causal variants in each family. The enrichment of rare variants in oncogenically associated genes that co-segregate with lung cancer provides specific mutations for future work and improves our understanding of the inheritance and pathogenesis of lung cancer. This work is ongoing.

PrgmNr 2347 - Immune-related intra-tumoral gene expression and survival by *BRCA1/2* mutation status in high grade serous ovarian cancer cases: an Ovarian Tumor Tissue Analysis (OTTA) study

Disclosure Block: **R. Vierkant:** None.

Background: The immune system appears to play an important role in determining outcome in women with high-grade serous ovarian cancer (HGSOC) and *BRCA1/2* mutated HGSOC tumors are prime candidates for immunotherapy combined with PARP inhibitors. However, little is known about the expression profile of immune-related genes in tumor tissue and the effect on prognosis for patients with and without *BRCA1/2* mutations. We investigated associations between intra-tumoral expression in nine immune-related genes and survival by *BRCA1/2* mutation status in a multi-site study of women with HGSOC from the Ovarian Tumor Tissue Analysis (OTTA) consortium.

Methods: Nine genes were examined in FFPE tissue containing >70% tumor using NanoString nCounter technology: *CD3E, CD8A, TLR4, MYD88, PD-1, PD-L1, CD68, TAP1 and CD7*4. Gene-specific individual expression values were standardized by subtracting the sample mean and dividing by the sample standard deviation. Associations of expression with 10-year survival, overall and by germline pathogenic *BRCA1* and *BRCA2* mutation status, were modeled using Cox proportional hazards regression adjusted for age, tumor stage and study site. Tests for interaction assessed differential associations between expression and survival by mutation status.

Results: Of 3,055 HGSOC cases included, 2,109 (69%) died within 10 years. Overall, higher expression of *CD3E* (HR 0.94, 95% CI 0.90-0.98); *CD8A* (HR 0.96, CI 0.92-1.00); *PD-1* (HR 0.92, CI 0.88-0.96); *PD-L1* (HR 0.90, CI 0.86-0.94) and *TAP1* (HR 0.85, CI 0.82-0.89) were associated with decreased risk of death. Subset analyses of 640 *BRCA1/2* mutation-negative individuals and 127 *BRCA1* mutation carriers revealed null or protective associations for each gene. In contrast, in 69 *BRCA2* mutation carriers, high expression was associated with increased risk of death for *PD-L1* (HR 1.52, CI 1.04-2.24, p-interaction=0.02) and *CD8A* (HR 1.35, CI 0.97-1.88, p-interaction 0.07). High *TLR4* expression was also associated with risk of death in BRCA2 carriers (HR 1.43, CI 0.98-2.08), but the interaction between TLR4 and mutation status was not statistically significant (p=0.40).

Conclusion: Herein, *BRCA2*-mutated HGSOC cases had different immune-related prognostic associations than those who were mutation-negative or had *BRCA1* mutations. This information may help inform future mutation-specific treatment modalities.

Notwithstanding the direct correlation between the level of asbestos exposure and the risk of malignant pleural mesothelioma (MPM), only a small proportion of individuals with a high asbestos exposure develop MPM. This observation, reports of familial MPM, and identification of germline pathogenic variants (PVs) in *BAP1* or other DNA repair genes in approximately 10% of MPM patients suggest the occurrence of inherited predispositions.

We aimed to search for new predisposing genes, assess the prevalence of PVs in DNA repair genes in MPM patients, and evaluate whether these patients could be sensitive to tailored treatments.

A total of 206 MPM patients (93 from Betti *et al.* 2017, 113 new) were screened by targeted-NGS for germline PVs in cancer-predisposing genes. Six further patients with family history of mesothelioma were analyzed by Sanger sequencing of *BAP1* and *CDKN2A*. Life-long cumulative asbestos exposure was quantified for 203/212 patients.

We identified 18 PVs in 17/206 patients (8.25%), most of them (14 PVs in 13 patients) were found in genes involved in the DNA repair pathway (i.e. *ATM, BRCA1, BRCA2, BRIP1, CHEK2, FANCC, FANCF, FANCI, PALB2, PMS1, SLX4, XPC*). PVs in *BAP1* and *CDKN2A* were identified in five and one patients with family history of mesothelioma, respectively. Carriers of PVs in DNA repair genes (18/212 patients) showed a statistically significant lower asbestos exposure than non-mutated patients (p=0.0001). These data suggest that patients with germline mutations in DNA repair genes are less proficient at repairing the DNA damage induced by asbestos and show increased susceptibility to asbestos-induced MPM.

According to the concept of BRCAness, MPM patients with germline PVs in DNA repair genes may respond to drugs that induce synthetic lethality, a mechanism by which two, otherwise non-lethal defects, become lethal when they are both present in a cell. Thus, we created a 3D-MPM cell model that had a defect in ATM, the master regulator of DNA repair, using a siRNA targeting *ATM* or a specific inhibitor (KU55933). Spheroids obtained using this model showed apoptosis induction when treated with an EZH2 inhibitor (tazemetostat) (p â□¤ 0.05). These data suggest that the subset of patients carrying PVs in DNA repair genes may benefit from this treatment that induces synthetic lethality.

PrgmNr 2349 - On cross-ancestry cancer polygenic risk scores

Polygenic risk scores (PRS) can provide useful information for personalized risk stratification and disease risk assessment, especially when combined with non-genetic risk factors. However, their construction depends on the availability of summary statistics from genome-wide association studies (GWAS) independent from the target sample. For best compatibility, it was reported that GWAS and the target sample should match in terms of ancestries. Yet, GWAS, especially in the field of cancer, often lack diversity and are predominated by European ancestry. This bias is a limiting factor in PRS research.

By using electronic health records and genetic data from the UK Biobank, we contrast the utility of breast and prostate cancer PRS derived from external European-ancestry-based GWAS across African, East Asian, European, and South Asian ancestry groups.

We highlight differences in the PRS distributions of these groups that are amplified when PRS methods condense hundreds of thousands of variants into a single score. While European-GWAS-derived PRS were not directly transferrable across ancestries on an absolute scale, we establish their predictive potential when considering them separately within each group. For example, the top 10% of the breast cancer PRS distributions within each ancestry group each revealed significant enrichments of breast cancer cases compared to the bottom 90% (odds ratio of 2.81 [95%CI: 2.69,2.93] in European, 2.88 [1.85, 4.48] in African, 2.60 [1.25, 5.40] in East Asian, and 2.33 [1.55, 3.51] in South Asian individuals).

Our findings highlight a compromise solution for PRS research to compensate for the lack of diversity in well-powered European GWAS efforts while recruitment of diverse participants in the field catches up.

PrgmNr 2350 - Rates of mutations in DNA repair genes are low in localized prostate cancer patients, particularly among non-White individuals

Background: The identification of germline mutations in DNA repair genes has significant implications for the personalized treatment of individuals with prostate cancer (PrCa). **Objective:** To determine DNA repair genes associated with localized PrCa in a diverse academic biobank cohort and to determine genetic testing burden. **Design, Setting and Participants:** Cross-sectional study of 2,391 localized PrCa patients. **Outcome Measurements and Statistical Analysis:** Genetic ancestry and mutation rates (excluding somatic interference) in 17 DNA repair genes was determined in 1,588 localized PrCa patients and 3,273 cancer-free male controls. Burden testing within individuals of genetically determined European ancestry (EUR) and African ancestry (AFR) was performed between biobank PrCa cases and cancer-free biobank and gnomAD controls. **Results and Limitations:** AFR individuals with localized PrCa had lower DNA repair gene mutation rates than EUR individuals (1.4% vs 3.7%, p=0.04). Mutation rates in localized PrCa patients was similar to biobank and gnomAD controls (EUR: 4.0% vs 2.8%, p=0.15; vs 3.1%, p=0.04; AFR: 1.4% vs 1.8%, p=0.79; vs 2.1%, p=0.52). Gene-based rare variant association testing revealed no gene had significantly enriched mutation rates between biobank PrCa cases and controls in either AFR or EUR. *BRCA2* mutations were significantly enriched compared to gnomAD controls in EUR (1.0% vs 0.3%, p=0.03). 19% and 13% met high-risk and very high-risk criteria; of those, 3.3% and 7.5% had any germline genetic mutation and 1.1% and 2.7% had a *BRCA2* mutation, respectively. Limitations of this study include analysis of a relatively small, single-institution cohort. **Conclusions:** DNA repair gene germline mutation rates are low in an academic biobank cohort of localized PrCa patients, particularly among individuals of AFR genetic ancestry. Only *BRCA2* mutations are enriched compared to non-cancer controls. Mutation rates exceed 5% in very-high risk localized PrCa patients. These findings highlight the importance of germline genetic testing for patients with localized PrCa.

PrgmNr 2351 - The IMPACT study Lynch Syndrome cohort - results after first round of screening

View session detail

Author Block: **E. K. Bancroft**[1], E. C. Page[2], The IMPACT Study Steering Committee and Collaborators, R. Eeles[3]; [1]Royal Marsden Hosp, Sutton, United Kingdom, [2]Inst. of Cancer Res., Sutton, United Kingdom, [3]The Inst. of Cancer Res., Sutton, Surrey, United Kingdom
Disclosure Block: **E.K. Bancroft:** None.
Introduction: Pathogenic variants in the mis-match repair genes (MMR) have been reported to increase the risk of early-onset aggressive prostate cancer (PrCa). The IMPACT study is prospectively evaluating Prostate Specific Antigen (PSA) screening in men with germline MMR pathogenic variants. Here we report the utility of PSA screening, PrCa incidence and tumour characteristics after the first screening round among men with and without these germline pathogenic variants.
Methods: Healthy men aged 40-69 years with germline pathogenic variants *in MLH1, MSH2, and MSH6 genes* and male controls testing negative for a familial pathogenic variant in these genes, were recruited over 90 months from 34 centres in 8 countries. Participants underwent PSA screening and if PSA >3.0ng/ml, were offered prostate biopsy. Screening outcome was assessed related to mutation status.
Results: 204 *MLH1* carriers, 199 *MLH1* non-carriers, 305 *MSH2* carriers, 210 *MSH2* non-carriers, 135 *MSH6* carriers, 177 *MSH6* non-carriers were recruited. Within the first round of screening 56 men had PSA>3.0ng/ml, 35 biopsies were performed, and 18 PrCas diagnosed (13 *MSH2* carriers, 1 *MSH2* non-carrier; 4 *MSH6* carriers). Zero cancers were detected in the *MSH6* non-carriers, and *MLH1* carrier and non-carrier cohort. Cancer incidence was higher in *MSH2* carriers than non carriers (4.3% vs 0.5%; p=0.01) and *MSH6* carriers than non-carriers respectively (3% vs 0%; p=0.04). *MSH2* carriers were diagnosed younger (60 vs 66 years) and more likely to have clinically-significant disease than non-carriers (85% vs 0%). *MSH6* carriers were diagnosed at 64 years (median age) and 75% had clinically significant disease.
Discussion: After the first screening round, carriers of *MSH2* and *MSH6* pathogenic variants had a higher incidence of PrCa, were diagnosed at a younger age and had more clinically significant disease compared with non-carriers. These findings support the use of targeted PSA screening in these men to identify clinically significant disease. Future study screening rounds will help determine the optimal frequency of PSA testing, the utility of PSA screening in *MLH1* carriers and provide further data on the value of annual screening in *MSH2* and *MSH6* carriers.

PrgmNr 2352 - Wood stove use interacts with genetic variants to alter risk of gastric cancer in a high altitude Central American population

View session detail

Author Block: **A. K. Miller**[1], S. B. Rifkin[2], R. L. Dominguez[3], E. Martinez[4], D. Norwood[3], E. E. Montalvan[4], T. Waterboer[5], M. Beasley[6], D. R. Morgan[6], S. M. Williams[1]; [1]Case Western Reserve Univ., Cleveland, OH, [2]Univ. of Michigan, Ann Arbor, MI, [3]Hosp. de Occidente, Copan, Honduras, [4]Hosp. Evangelico, Siguatepeque, Honduras, [5]German Cancer Res. Ctr., Heidelberg, Germany, [6]Univ. of Alabama at Birmingham, Birmingham, AL

Disclosure Block: **A.K. Miller:** None.

Gastric adenocarcinoma is the leading global cause of infection-related cancer mortality and the overall third leading cause of cancer death. In Central America, a disproportionate burden of disease is concentrated in the mountainous regions along the Pacific littoral, a phenomenon often described as the â□□Latin America Altitude Enigma.â□□ Wood stoves (â□□fogonsâ□□) are the predominant method for the heating of homes and cooking, and food preparation with these stoves may be linked to aero-digestive cancers, mediated by ingested and inhaled carcinogens. To assess whether wood stove use is associated with and/or modifies the genetics of gastric cancer, we conducted a population-based, case-control study (814 incident cases, 1,049 controls) in rural western Honduras, a high incidence region with a homogeneous diet, and endemic *H. pylori* infection, predominantly with the high-risk cagA genotype. We investigated the association between gastric cancer and physical and environmental factors including age, sex, *H. pylori* CagA serostatus, wood stove use, 15 variants from 6 heterocyclic amine (HCA) metabolizing genes, and interactions between wood stove use and the HCA-metabolizing gene variants. Age, sex, wood stove use, and *H. pylori* CagA infection were independently associated with gastric cancer in univariate analyses, as well as two SNPs in the gene *CYP1B1* (rs1800440 and rs1056836). Rs1800440 remained significant in models adjusting for combinations of variables age, sex, CagA serostatus, woodstove use, and rs1056836. When the interaction between rs1800440 and wood stove use was added to any model, rs1800440 as an independent predictor of gastric cancer was no longer significant, but the effect size of wood stove use increased by almost 2-fold when the interaction was included in the model. Lifetime wood stove use is associated with gastric cancer, independent of *H. pylori* CagA serostatus, in the high incidence regions of mountainous Central America where *H. pylori* infection is endemic. However, the impact of this exposure on disease risk is dependent on *CYP1B1* genotype, indicating the gene-environment interaction plays a significant role in the association with gastric cancer. Therefore, environment and genetic risk factors should be considered together in assessing risk and planning surveillance and prevention.

PrgmNr 2353 - ACSL VI:A Novel Variation Results in Structural Modification and Multiple Neoplasia in a 46-year-old Female

View session detail

Author Block: **I. Castillo**[1], E. E. Freire[1], V. Romero[1], K. Hosomichi[2], A. Tajima[2], B. Arias[3], C. Reyes[4]; [1]Univ. San Francisco de Quito, Quito, Ecuador, [2]Kanazawa Univ., Kanazawa, Japan, [3]Onelabt S.A, Ballenita, Ecuador, [4]Hosp. Eugenio Espejo, Quito, Ecuador

Disclosure Block: **I. Castillo:** None.

Multiple non-related neoplasia in one patient is a rare event and suggest an inherited pathological variant and a further loss of the normal allele. We analyzed a 46-year-old female patient diagnosed with frontotemporal astrocytoma (2010), papillary thyroid cancer (2013), and ductal breast cancer in 2017 and no family history. The general population risk for developing these three neoplasia within one lifespan is 0.000000000675 compared to 0.00000342 of winning the lottery.

We hypothesized a shared affected gene responsible for the conditions, not frequently associated with cancer. We performed whole-exome sequencing (WES) identifying a novel missense variant in the ACSL VI gene and no pathological variations in common neoplasia-associated genes. ACSL VI catalyzes long-chain fatty acids mainly in the brain (mainly expressed in the astrocytes), and in minor quantities in the breasts, thyroid, erythrocytes, leucocytes, and other tissues. Notably, the ACSL gene family has been shown to be implicated in the development and prognosis of different types of cancer.

Next, we modeled the mutant ACSL VI confirming the damaging effect in the secondary and tertiary structures. The details found in the ACSL VI gene allow us to interpret that the mutant protein (patient) presents a change in the secondary and tertiary structure important for anchoring to the membranes of the endoplasmic reticulum, mitochondria, and peroxisomes. As it is an evolutionarily conserved region, its function is essential for correct cell development and metabolism, making it an ideal candidate in the hypothesis that this is the gene associated with the patient's cancers.

Finally, our research suggests the importance of the study of non-conventional cancer-associated genes involved in lipidic metabolic processes. This can open the doors for the development of new personalized therapeutic approaches targeting the affected gene and potential metabolic pathways involved in neoplastic processes.

PrgmNr 2355 - Functional study of the 2q22 renal cancer susceptibility locus

View session detail

Author Block: **A. G. Souza**[1], L. Jessop[2], T. A. Myers[2], M. Machiela[2], K. Brown[2], S. Chanock[2], L. Colli[1,2]; [1]Dept. of Med. Imaging, Hematology, and Oncology, RibeirÃ£o Preto Med. Sch. - Univ. of SÃ£o Paulo, RibeirÃ£o Preto, Brazil, [2]Div. of Cancer Epidemiology and Genetics, Natl. Cancer Inst., NIH, Dept. Hlth.and Human Services, Bethesda, MD

Disclosure Block: **A.G. Souza:** None.

Renal cancer (RCC) tumorigenesis develops partly due to series of somatic genetic events such as mutations, deletions and epigenetic alterations in tumor suppressor genes. Genome Wide Association Study (GWAS) have identified 13 different genomic regions associated with the risk of developing RCC. We report on analyses of the 2q22 region, whose biological mechanisms related to the development of RCC are not well understood. Thus, the aim of this study was to identify the role of functional SNPs located in the 2q22 region based on the assessment of putative functional SNPs identified and prioritized using MPRA, ATAC-Seq, ChIP-Seq, Capture-HiC, eQTL, LDlink data and the validation of the SNP by electrophoretic mobility shift assays (EMSA) assays. Among the 14 SNPs evaluated, we selected the SNP rs72858496 that showed high linkage disequilibrium (R^2 = 0.93; Dâ = 1) with the SNP tag (rs12105918) with a *p-value* of 2.9 x 10^{-9}. We have shown that this SNP has a chromosomal loop that allows physical interaction with the promoter region of the *ZEB2* gene. EMSA analyses of this SNP revealed that the DNA fragments produced a specific shift with nuclear extracts from renal cancer cell line (RCC4). Thus, our initial results point to rs72858496 as a potential functional SNP in the 2q22 region, altering *ZEB2* expression and consequently contributing to the progression of renal cancer. Additional functional studies are now underway to understand the molecular and oncological mechanisms linked to the 2q22 region that may contribute to a better understanding of RCC, which could also impact the treatment and prognosis of patients with this disease.

PrgmNr 2356 - Inflammatory and oncological processes contributing to the increased susceptibility to Barrettâ□□s esophagus in adults born with esophageal atresia

View session detail

Author Block: **E. Brosens**[1], C. A. ten Kate[1], B. de Graaf[1], M. Doukas[1], A. Koivusalo[2], H. Nastiti[1], R. van der Helm[1], T. Brands[1], H. IJsselstijn[1], Y. van Bever[1], A. de Klein[1], R. M. H. Wijnen[1], M. C. Spaander[1], R. M. W. Hofstra[1]; [1]Erasmus Univ. Med. Ctr. â□□ Sophia Childrenâ□□s Hosp., Rotterdam, Netherlands, [2]Univ. of Helsinki, Children's Hosp., Helsinki, Finland, Helsinki, Netherlands
Disclosure Block: **E. Brosens:** None.
Introduction Adults born with esophageal atresia (EA) are more prone to chronic gastroesophageal reflux (GER), which can cause Barrettâ□□s esophagus (BE). The prevalence of BE in EA adults is 4-times higher than in the general population and presents at a younger age (34 versus 60 years). Given the overlap between genes and pathways involved in foregut development and risk loci and pathways for BE, we hypothesized that EA patients have a predisposition to develop BE.
Material and methods Blood and esophageal biopsies were collected during endoscopic surveillance. We compared risk loci and transcriptomes of 19 EA patients with BE (EA/BE); 44 EA patients without BE (EA only); 10 BE patients without EA (BE only) and 730 unaffected controls. Subsequently, we simulated a reflux episode by exposing fibroblasts of 3 EA patients and 3 unaffected controls to acid medium, and compared their response.
Results We found a median polygenic risk score of 3.24 (range 1.39-4.68) in EA/BE patients versus 2.63 (1.85-3.53) in BE only patients. Pathway enrichment analysis revealed differences in retinoic acid signaling and downstream pathways as well as inflammatory, stress response and oncological processes in EA/BE patients relative to BE only patients. In-vitro experiments in fibroblasts confirmed the effect on retinoic acid signaling and immune response in EA patients upon acid exposure.
Conclusion The contribution of risk loci seems elevated, although sample sizes are insufficient to draw definite conclusions. Epithelial tissue homeostasis is more prone to disturbances in EA patients. This intrinsic susceptibility could potentially explain the earlier age of onset of BE in these patients.

PrgmNr 2358 - Utility of altered nuclear expression of the *BAP1* for assessment of pathogenicity of Variants of Unknown Significance

View session detail

Author Block: **P. Hanpude**[1], D. Etia[1], J. B. Massengill[1], F. H. Davidorf[1], L. Byrne[2], C. M. Cebulla[1], M. H. Abdel-Rahman[3]; [1]Ophthalmology, The Ohio State Univ., Columbus, OH, [2]Div. of Human Genetics, The Ohio State Univ., Columbus, OH, [3]The Ohio State Univ., Columbus, OH
Disclosure Block: **P. Hanpude:** None.
Purpose- Germline mutation in the tumor suppressor gene *BAP1* is associated with the hereditary tumor predisposition syndrome, *BAP1*-TPDS (OMIM 614327), which is associated with predisposition mainly to four cancers: uveal melanoma, mesothelioma, cutaneous melanoma, and renal cell carcinoma. A growing number of variants are being deposited in ClinVar, including 706 variants of uncertain significance (VUS). It has been reported that variants with loss of deubiquitinase function of BAP1 are associated with loss of nuclear BAP1 (nBAP1) localization. We hypothesized that detection of loss of nBAP1 would help to characterize the pathogenesis of VUSs.
Methods- Flag-tagged full-length *BAP1* was sub-cloned in p3xFLAG-CMV-10 vector. Mutations were generated by site-directed mutagenesis and confirmed by Sanger sequencing. We transiently overexpressed empty vector, wild type and mutant BAP1 in NCI-H226 cell line with no endogenous BAP1 and BAP1 knock out (KO) SNU449 cells. Localization of all the mutant proteins was explored by immunofluorescence (IF) staining with anti-BAP1 and anti-Flag antibodies. Samples were analyzed by a confocal microscope.
Results- We selected four VUSs (L14H, N78S, Q85H and W202R), three truncating variants (Q267*, Q393* and Q573*), a benign variant; G41S, catalytic inactive pathogenic variantC91A and an NLS (Nuclear Localization Signal) mutant. *BAP1* deletion and loss of expression in NCIH226 and SNU449 BAP1 KO cells were confirmed by sequencing and western blot, respectively. Wild type BAP1 as well as the benign G41S variant showed both nuclear and cytoplasmic expression. NLS and truncating variants showed complete loss of nuclear expression. Catalytic inactive C91A variant showed perinuclear accumulation along with decrease nuclear expression confirming the importance of auto-deubiquitination for the nuclear localization of BAP1. Among the tested VUSs, W202R, Q85H and N78S showed loss of BAP1 nuclear localization. Interestingly, the VUS L14H showed partial loss of nuclear localization. Segregation studies of the W202R variant suggest that it is a likely pathogenic variant.
Conclusions- Our results suggest that BAP1 nuclear localization might be used to assess the pathogenesis of *BAP1* missense VUSs. Validation studies in a larger cohort of well-characterized missense *BAP1* VUSs is warranted.

Background: Ovarian clear cell carcinoma (OCCC) is rare and tends to respond poorly to standard platinum-based chemotherapies, the mainstay of ovarian cancer. Tumor methylation profiles differ between OCCC and other histotypes; but studies have been too limited in sample size to evaluate variation within the OCCC histotype. Here, we sought to define the role of DNA methylation and prognostic subclassification of a large series of OCCC.

Methods: To better understand the role of DNA methylation in the biological and prognostic subclassification of OCCC, we used Illumina Infinium MethylationEPIC and HumanMethylation450k Beadchips to interrogate methylation in tumor DNA from 271 fresh frozen OCCC tumors from ten study sites.

Results: Non-smooth non-negative matrix factorization clustering revealed two approximately equally sized clusters defined by the most variable 2,437 CpGs. Cluster membership was associated with several clinical features: compared to Cluster 2 (N=137), Cluster 1 OCCCs (N=134) presented at a more advanced stage, were less likely to be of Asian ancestry, and tended to have poorer outcomes including macroscopic residual disease following primary debulking surgery (p-values Conclusion: This work serves as a foundation for integrative analyses to better understand the complex biology of OCCC in an effort to facilitate development of targeted therapeutics.

PrgmNr 2361 - From genetics to immune system: the dynamic crosstalk in a wide cohort of completely resected Gastrointestinal Stromal Tumors (GISTs)

Disclosure Block: **L. Incorvaia:** None.
The exon 11 mutations are the most frequent *KIT* mutations, but represent a heterogeneous subgroup in terms of biological and clinical behavior. The exact pathogenic variant (PV) type and codon location, and other biological factors, could affect the Recurrence-Free Survival and the development of an organ-selective pattern of tumor metastasis to relapse. 116 GIST patients completely resected were included in the study between January 2005 and September 2020. The association between Exon 11 PV type with RFS was evaluated. In relapsed patients, metastatic sites were described, Neutrophil-Lymphocyte Ratio (NLR) was calculated, and plasma PD-1, PD-L1, BTN3A1 and BTN2A1 levels have been measured using homemade ELISA assays not yet commercially available. Deletions (del) of the codons 557/558 showed more aggressive tumor behavior and a higher risk of recurrence compared to other exon 11 del, or duplication/insertion/SNV (7-year RFS: 48.6% vs 73.1% vs 87.9%; pKIT p.W557_K558del); when 557 and 558 deletions were analyzed separately, only 22.2% showed a tumor relapse, miming the prognostic behavior of tumor carrying del outside 557/558 position. In contrast to previous findings, in relapsed patients with 557/558 del, the peritoneum is the most frequent metastatic site (72.2%). Using thresholds by ROC analysis and multivariate analysis, we found that the patients with a tumor harboring del outside 557/558 and prevalent peritoneal metastasis, had NLR significantly lower compared to the relapsed patients with other exon 11 PVs (median 2.3 vs 3.1 G/L; p=0.029), and lower baseline levels of plasma PD-1 (>7.9 ng/mL), PD-L1 (

In recent years, molecular profiling of cancer patients using next generation sequencing (NGS) has become a crucial clinical tool for cancer care, via the ability to detect clinically actionable variants including single nucleotide variants (SNVs), small InDels, copy number variants (CNVs) and structural variants(SVs). This collection of variants and mutations plays an important role in cancer diagnosis and therapeutic selection. To further improve the effectiveness of NGS data in cancer care, the integration of multi-omics datafrom whole genome, exome, transcriptome, methylome, and clinical data, this provides a more comprehensive molecular profile of the cancer genome. Currently, the major bottlenecks appear to be the processing and integration of multi-omic data, often taking weeks to months to complete, which will only grow as longitudinal multi-omic assessments for the same patient become the clinical standard. By using an accelerated framework, it is possible to iterate the data analysis to reduce the complexity of this computational puzzle while simultaneously identifying those clinically actionable signatures to improve cancer therapy outcomes.
We implemented an accelerated framework that provides 15-50x faster run times for a series of somatic callers including Mutect2, Somatic Sniper, MuSE, and VarScan algorithms, allowing more variants to be identified from a data set. First, we assessed the performance of the individual baseline variant calling algorithms on the SEQC-II 50x WGS data set. For somatic SNV detection, Strelka2 had the highest F1 score, and recall (0.9435, 0.9425) while MuSE had the highest precision (0.9966). For somatic InDel detection, Mutect2 and Strelka2 performed similarly with Mutect2 higher recall, but Strelka2 had higher F1 score and precision.
Here, we apply the Clara Parabricks accelerated framework to 458 samples from leukemia patients treated on the same phase III randomized clinical trial. Analyses focused on variant calling, copy number analysis and fusion calling from genome, transcriptome and targeted DNA or RNA deep sequencing panels, providing the basis for a multi-omics approach to identify those genetic signatures that correlate with disease.

PrgmNr 2364 - Germline variants associate with the presence of somatic *TP53* and *PIK3CA* mutations in breast tumors

View session detail

Author Block: **A. E. Toland**, N. Pollock, J. Ramroop, P. Stevens, J. McElroy; The Ohio State Univ., Columbus, OH
Disclosure Block: **A.E. Toland:** None.
Somatic mutations in *TP53* and *PIK3CA* in breast tumors have unequal prevalence among racial and ethnic groups. Some of the factors leading to somatic mutations in specific genes can be attributed to socioeconomic and environmental exposures, but studies by our group and others suggest that inherited genetic variants also impact selection of mutations in specific genes. To test the hypothesis that germline variants could contribute to selection of somatic *TP53* and *PIK3CA* mutations in breast tumor development, we performed a genome-wide association study of ~776,800 single nucleotide variants in 2850 women with breast cancer using existing germline genotypes and somatic tumor mutation data from The Cancer Genome Atlas, METABRIC, and the Welcome Trust. For initial discovery studies, only data from non-Hispanic whites, defined by principle component analyses, were used. Five SNVs associated with *TP53* somatic mutations were identified with p-values -6 and 34 with p-values -5. Some variants associated with the presence of *TP53* mutation of any type; others were exclusively associated with loss-of-function or gain-of-function *TP53* mutations. Some significant variants were previously associated with estrogen receptor negative breast cancer in GWAS. This includes rs9397437 that maps to the estrogen receptor 1 locus and was shown in previous studies to affect expression of *ESR1*, *RMND1* and *CCDC170*. We identified 44 SNVs associated with *PIK3CA* mutations with p-values -5. Some variants were associated with the presence of any *PIK3CA* somatic mutation and others only with a hotspot mutation (e.g. H1047R, E542K or E545K). These studies suggest that germline variants can shape a cellular environment which promotes selection of somatic mutations in specific genes and provide insight into which genes/pathways may be important for the cellular context that supports tumors with these specific mutations. Interestingly, some of these variants map to previous GWAS loci for breast cancer risk, specifically triple negative breast cancer risk, suggesting that there may be overlap of variants associated with risk of tumor subtypes and specific mutations. Ongoing studies are evaluating these variants for association with *TP53* and *PIK3CA* somatic mutations using more diverse study populations.

PrgmNr 2365 - Identify non-mutational TP53 loss of function in human cancers

View session detail

Author Block: **L. WANG**[1], Q. Li[2], Y. Zhang[2], L. Ma[2], Z. Zhang[2]; [1]Mayo Clinic, ROCHESTE, MN, [2]Beijing Inst. of Genomics, Beijing, China
Disclosure Block: **L. Wang:** None.
Background: A gene with an intact DNA sequence can compromise its function by epigenomic, transcriptomic, and proteomic level dysregulations. Such non-mutational inactivations are prevalent in cancers but, due to the heterogenetic causes, cannot be detected by the DNA-sequencing, immunohistochemical staining, or any other single assay alone. Therefore, they would become a significant impediment for molecular diagnostics, clinical management, and treatment selection for cancer patients. **Approach**: We hypothesized that when a transcription factor (TF) is functionally impaired, either due to genetic or non-genetic causes, the expression of downstream target genes would be significantly altered and that such expression alteration, in turn, can be used to predict the functional status of the TF. Here we used p53 as an example; we first define the p53 target genes through a comprehensive literature review and meta-analysis. Then, we build an SVM model using the composite expression scores of these target genes as features and using the â□□normal tissuesâ□□ (assuming p53â□□s tumor suppressor function is normal in this group) and â□□*TP53* truncating tumor samplesâ□□ (assuming p53â□□s tumor suppressor function is lost in this group) as training datasets. **Results**: Using 5-fold cross-validation, we demonstrated the superior performance of our SVM model (average AUC = 0.995, F1-score = 0.989, recall = 0.992) in TCGA LUNG and BRCA cohorts. When applying our SVM model to *TP53*^{WT} tumor samples, we found 87% of BRCA and 94% of LUNG samples were predicted to be LoF (termed as *TP53*^{WT}-LoF). These *TP53*^{WT}-LoF patients exhibited distinct genomic and clinical characteristics from the other *TP53*^{WT} patients. Specifically, *TP53*^{WT}-LoF patients have significantly higher tumor mutation burden, the fraction of genome with copy number variations, aneuploidy score, and hypoxia score, consistent with p53â□□s function as a central regulator of DNA damage repair and cellular stress response. In addition, *TP53*^{WT}-LoF patients with lung cancer have significantly shortened overall survival compared to those real *TP53*^{WT} patients. Further analyses revealed that *MDM2*/*MDM4* amplifications are significantly enriched in *TP53*^{WT}-LoF patients, partially and mechanistically explained the p53 loss-of-function.

PrgmNr 2366 - Integrated Transcriptomic Profiling with Deep Learning Classification Applied to Prostate Cancer Tissue Images

Disclosure Block: **D. Van Booven:** None.

Introduction : Prostate cancer (PCa) diagnosis starts with PSA level detection, which if above the normal range, the patient is subjected to genomic tests like 4K scores, PCA3 or PHI test. After confirmation, MRI is used to identify potential areas of PCa. The biopsy is extracted by the clinicians, inspected by the pathologist and are further subjected to genomic testing. Typically, a single worst area is selected for the test, leaving a large area from consideration. In case of false outcome, patients are subjected to the same steps making it financially cumbersome for the patients and increasing time/accuracy for treatment. We propose a multi-tiered approach using machine learning to analyze the entire section and integrate gene signatures in real time. This allows us to A) identify/characterize the areas of cancer, B) monitor the areas more precisely enabling us to study the therapy response in a longer run. **Methods :** Prostate slide tissues from 500 individuals in the PRAD study contained in TCGA were downloaded and evaluated. We used multiple deep learning algorithms before selecting the Xception model. We selected 107 random images across all Gleason scores (GS) that were then scored by 3 pathologists as a basis for training images to create the network to automate GS grading. This automation identified cancer regions of interest on test training slides with minimal hyperparameter manipulation. Additionally, we created gene expression profiles by taking RNAseq data and combining patients within a specific GS. To reduce variance, these profiles were then put through a rigorous analysis pipeline to identify and remove variability and potential confounding factors. Finally, these profiles were analyzed for differential expression to obtain genes that are uniquely different at a given Gleason grade. **Results :** Heterogeneity is seen when evaluating all 107 images and requiring all 3 pathologists, the AI as well as TCGA agree with only 25% accuracy. When requiring only 2 of 3 pathologists, the AI, and TCGA to agree this rises to 53% accuracy. However, using more generic classification system including normal tissue, low grade tumor (GS6 or GS7), and high grade tumor (GS8 or GS9) this accuracy is improved to 71%. Finally, integration with the transcriptome classifier this was further enhanced to 81%. **Conclusions :** ML can be applied to determine severity of tissue images. We are hopeful that future modifications will improve the accuracy of our current model and will aid in identifying tumor areas, accessing their severity, and enhance treatment decisions.

PrgmNr 2367 - Integrative genomic analysis reveals new insights on complex mutational landscape in T-cell prolymphocytic leukemia

View session detail

Author Block: **S. Tian**[1], H. Zhang[2], H. Jin-Lee[1], P. Hampel[2], E. Klee[1], H. Yan[1], W. Ding[2]; [1]Div. of Computational Biology, Mayo Clinic, Rochester, MN, [2]Div. of Hematology, Mayo Clinic, Rochester, MN
Disclosure Block: **S. Tian:** None.
T-cell prolymphocytic leukemia (T-PLL) is a rare mature T-cell malignancy with aggressive clinical course and poor prognosis. Cytogenetic, whole-exome and whole-genome analysis have identified major structural variations in T-PLL, including inv(14) (q11q32) and t(14;14)(q11;q32) that activated the oncogenic expression of TCL1A as a hallmark. In addition, recurrent somatic mutations were identified in epigenetic regulators, tumor suppressors and genes from the JAK-STAT signaling pathway. However, T-PLL demonstrates a strong heterogeneity, and our understanding of the molecular events driving T-PLL pathogenesis is mostly from small cohort studies and thus remains incomplete. This study analyzed whole-exome and transcriptome data from a cohort of 14 cases. We identified recurrent mutations previously known in T-PLL, such as ATM (57%), STAT5B (28.6%), and JAK3 (21.5%), along with novel recurrent mutations that may play critical roles in T-PLL. Specifically, the latter include genes in cancer initiation and proliferation (PABPC3/71.4%, HRNR/64.3%, AK2/50%, LRP1/35.7%, and NOTCH2/14.3%), activators of ERK/JNK kinase pathway (MAP3K1/50% and MAP3K4/35.7%), key epigenetic regulators (KDM6B/21.4% and HDAC8/14.3%), and immune surveillance (MAGEC1/64.3% and HLA-DQA2/57.1%). In addition, we identified many recurrent arm-level or large-scale focal events across over 13 chromosomes (15.4-100%). These somatic copy number alterations (SCNAs) were manually inspected through coverage profiles. The most significant arm-level SCNAs were on 8p (9/14) and 8q (7/14). Other significant SCNAs were observed on chr 7 (14/14), followed by chr22 (61.5%), chr12 (53.8%), chr14 (53.8%), chr11 (46.1%) and chr20 (46.1%). The genes targeted by SCNAs are highly associated with cell cycle and chromosome maintenance. Finally, analysis of transcriptome data identified 281 down- and 282 up-regulated genes in T-PLL cases compared to those of healthy controls. As expected, TCL1A and TCL1B were significantly overexpressed (>10 fold). The down-regulated genes are enriched in the cellular defense response, regulation of immune response, chemokine receptor activity, and regulation of T cell proliferation, while up-regulated genes are involved in the regulation of MAPK cascade, MAP kinase activity, and protein kinase binding. In summary, our integrative analyses of genomic and expression data provided new insights into T-PLL complex mutational landscape. Further analysis of the altered key genes and pathways could help elucidate the molecular mechanisms of T-PLL pathogenesis.

PrgmNr 2368 - Investigating associations of common *ATM* missense variants with neoplasms in the UK Biobank exome sequencing data - a conditional analysis

View session detail

Author Block: **X. Jiang**[1], A. O'Neill[1], K. R. Smith[2], Z. Lai[3], K. J. Carss[2], Q. Wang[4], S. Petrovski[1]; [1]Ctr. for Genomics Res., AstraZeneca, Melbourn, United Kingdom, [2]AstraZeneca, Melbourn, United Kingdom, [3]Astra Zeneca, Waltham, MA, [4]Ctr. for Genomics Res., AstraZeneca, Waltham, MA
Disclosure Block: **X. Jiang:** None.
As an essential regulator of DNA damage, Ataxia-telangiectasia mutated (*ATM*) gene has been widely studied in oncology. However, the independent effects of *ATM* missense variants and protein-truncating variants (PTVs) on neoplasms have not been heavily studied in large population biobank settings. Whole-exome sequencing data and the clinical health records of ~400K UK Biobank participants of European ancestry were used in this analysis. We mined genetic associations from variant-level and gene-level phenome-wide association studies and conducted a variant-level conditional association study to test whether the effects of *ATM* missense variants on neoplasms were independent of *ATM* PTV carrier status.

Of 773 distinct protein-coding variants in *ATM*, variant-level association analysis revealed three missense variants significantly (P-8) associated with at least one of 12 phenotypes relating to six different neoplasms. Remarkably, none of the phenotypes significantly associated with these three *ATM* missense variants were among established *ATM* PTV-linked malignancies. Whereas our gene-level PTV collapsing analysis was consistent with established *ATM* PTV literature showing that the aggregated impact of 286 *ATM* PTVs significantly (p-9) associated with 17 malignant neoplasm phenotypes. A subsequent conditional analysis identified that the missense signals were acting independently of the known clinically relevant *ATM* PTVs.

PrgmNr 2369 - JBrowse 2: an extensible open-source platform for modern genome analysis

Introduction
Genome browsers are useful tools for research in human genetics, able to display and integrate biological information such as long and short read sequencing data, variant calls, and annotations. While traditional linear genome browsers have demonstrated broad utility for many applications, there is an increasing need for visualizing complex structural variants (SVs) beyond the linear view. To meet these challenges, we created JBrowse 2: an extensible open-source platform for visualizing and integrating genomic data.
Results
JBrowse 2 is a flexible platform that provides the foundation for the development of applications and web dashboards that combine novel views and representations extending beyond linear displays in genomic reference coordinates. For example, a flagship JBrowse 2 application is the SV Inspector, which lets users open a list of structural variants in a data table and see the results in a whole-genome circular view. Clicking on a given variant in the table or circular view opens up a linear view that displays the read evidence supporting the SV, even across complex breakpoints like translocations. Dotplot and synteny views are built-in, enabling â□□long read vs referenceâ□□ dotplot visualizations, or alignments of de-novo assembled contigs to the genome. These views are integrated with each other, so that (for example) a long read is just a few clicks away from the corresponding dotplot.
In addition to including these new views, the JBrowse 2 platform is designed from the ground up to enable third-party plugins to add new views, data adapters, and track types, which has facilitated the creation of new plugins that address some very specific use cases. These include our MSA view plugin for viewing multiple sequence alignments, data adapters that download data from UCSC and CIVIC APIs, and the Quantseq plugin for viewing quantitative motif scores as a genome browser track.
JBrowse 2 is available as both a web app or a local desktop app. We also offer re-usable components on NPM, and users of R can programmatically create an instance of JBrowse 2 with the JBrowseR package on CRAN. JBrowse 2 can also generate high quality SVG snapshots from inside the app, and we also created a CLI tool called jb2export to perform automated or bulk exports of JBrowse 2 visualizations. We anticipate that JBrowse 2 will better serve genome scientists with its structural variant visualization capabilities, and will provide the flexibility to adapt to new visualization and analysis challenges as they emerge in the coming years.

PrgmNr 2370 - Oncogenic mutations in the normal human brain

View session detail

Disclosure Block: **J. Ganz:** None.

Oncogenic mutations have been found in non-diseased, proliferative tissues such as skin, blood, and esophagus, showing an age-related increase in most cases. However, the prevalence of such mutations in the normal brain, a low-proliferating organ, is unknown and remains challenging due to the abundance of non-proliferating neurons concentrated in the grey matter. Thus, targeting the white matter for sequencing, which is rich in glial cells, and analyzing data from large cohorts would allow for enhanced power to detect oncogenic events in the non-diseased brain. We evaluated genes implicated in brain tumors by deep sequencing in over 418 normal brain samples derived from 110 individuals of varying ages, without tumor diagnosis, and separately analyzing white and grey matter and other brain regions. We detected predicted and reported pathogenic oncogenic variants in cancer driver genes such as *IDH1, PTPN11, NF1,* and *PTEN*. These mutations were predominantly present in the subcortical white matter (p=0.029) and, surprisingly, were less common in older individuals (p=0.025). In addition, we identified the recurrence of glioma driver variants and their enrichment in glial cells. These findings were replicated using 1,640 non-diseased bulk RNA-seq brain samples from the GTEx consortium, confirming the existence of oncogenic variants and depletion of protein disruptive variants with age. The normal brain exhibits enrichment of mutational signatures present in brain tumors (p=0.00018), suggesting that mutational processes of the normal brain drive early oncogenesis. Our study helps understand the origin and early evolution of brain tumors and opens avenues for early interventions and more accurate diagnosis baselines.

PrgmNr 2371 - Paired DNA and RNA genetic testing improves variant detection and classification independently of personal history of cancer

View session detail

Author Block: **S. Campian**, K. Burgess, C. Horton, L. Hoang, R. Pilarski, J. Profato, H. Zimmerman, E. Chao, R. Karam; Ambry Genetics, Aliso Viejo, CA
Disclosure Block: **S. Campian:** Salary/Employment; Ambry Genetics.
Introduction: Recent advances in germline hereditary cancer testing include concurrent analysis of mRNA (RNA genetic testing, or RGT) in conjunction with DNA genetic testing (DGT). RGT can provide an additional line of evidence for variant interpretation, leading to fewer variants of unknown significance (VUS) and increased detection of deep intronic pathogenic/likely pathogenic variants (PVs) that previously were undetected by DNA testing alone.As healthcare providers navigate these new technologies, data on which populations would benefit the most may be critical to inform the most appropriate test for their patient. This study aims to determine whether personal cancer history impacts the rate of detection of PVs that would have been misclassified or undetected with DGT alone.
Methods:Proband clinical history data were curated for all patients undergoing paired DGT/RGT from October 2019 through April 2020. Family history information was not available for this study. We then identified patients meeting National Comprehensive Cancer Network testing criteria based on personal history of cancer alone: breast =Results:Clinical history was provided for 43,145 individuals who underwent concurrent DGT/RGT during the study period. Of these, 4,807 individuals had a PV in one of the 18 genes included in the RNA analysis, 3.2% (n=153) of whom had an RNA-impacted PV. For individuals who met personal history testing criteria (n=10,882), 13.1% had a PV compared to 10.5% of those who did not meet criteria (n=32,263) (OR 1.3; 95% CI 1.2-1.4; pDiscussion:Our findings reveal no difference in the proportion of PVs impacted by RNA evidence in those meeting personal history testing criteria and those who do not. Though further study incorporating family history is needed, these observations suggest that RGT is equally beneficial in patients undergoing DGT regardless of personal history.

PrgmNr 2372 - Role of circulating immune checkpoints in *KIT*-mutated metastatic gastrointestinal stromal tumor (GIST) patients

View session detail

Author Block: **C. Brando**[1], D. Fanale[1], L. Incorvaia[2], L. Algeri[1], A. Bonasera[1], N. Barraco[1], L. Corsini[1], A. Cucinella[1], A. Dimino[1], C. Filorizzo[1], A. Fiorino[1], V. Gennusa[1], G. Madonia[1], L. Magrin[1], E. Pedone[1], M. Ricciardi[1], S. Sammataro[1], R. Sciacchitano[1], R. Scalia[1], G. Badalamenti[1], V. Bazan[2], A. Russo[1]; [1]Dept. of Surgical, Oncological and Oral Sci., Section of Med. Disclosure Block: **C. Brando:** None.

Circulating immune checkpoints and type of *KIT* mutations have recently been shown to correlate with shorter survival in gastrointestinal stromal tumor (GIST). Our study was aimed to understand if soluble forms of immune checkpoints, such as sPD-1, sPD-L1, sBTN3A1, and pan-sBTN3As, and type of *KIT* mutations may be predictors of survival for metastatic GIST (mGIST) patients, in order to obtain useful information about the clinical evolution of disease.We performed a retrospective study including a cohort of 30 mGIST patients enrolled from February 2015 to June 2017. All patients harboring a KIT exon 11 pathogenic variant (PV) were treated with first-line imatinib 400 mg/day: 16 patients (53.3%) harbored KIT exon 11 deletion or delection/insertion, and 14 (46.7%) carried other PV types (duplication, insertion, or single nucleotide variant). The plasma PD-1, PD-L1, BTN3A1, and panBTN3As concentrations were measured in peripheral blood by specific ELISAs, not yet commercially available.Plasma levels of sPD-1, sPD-L1, sBTN3A1, and pan-sBTN3As, age at diagnosis, and type of *KIT* exon 11 PV were found to be statistically significantly associated with progression-free survival (PFS) in univariable analyses, while in the final multivariable Cox regression model, only the plasma levels of sPD-L1 â¤ 0.7 ng/mL (HR: 0.01; 95% CI: 0.001 to 0.18; p = 0.001) and pan-sBTN3As â¤ 5.0 ng/mL (HR: 4.45; 95% CI: 0.96 to 20.5; p = 0.05), and the absence of *KIT* exon 11 Del or Delins at codons 557 and/or 558 (HR: 0.05; 95% CI: 0.007 to 0.31; p = 0.003) were statistically significant. The absence of *KIT* exon 11 deletions or delins at codons 557 and/or 558 and expression levels of sPD-L1 â¤0.7 ng/mL and pan-sBTN3As â¤ 5.0 ng/mL were independent prognostic factors associated with a longer PFS in mGIST patients harboring a *KIT* exon 11 PV prior to imatinib therapy.Our study revealed that sPD-1, sPD-L1, sBTN3A1, and pan-sBTN3As could be used as prognostic factors in mGIST patients because individuals treated with imatinib with baseline immune checkpoint expression values below the respective thresholds showed improved clinical outcome and longer PFS than those with plasma levels above the cut-offs.

PrgmNr 2373 - Single cell consensus clustering (SC3) with REVEAL™: SingleCell on neuroblastoma and fetal gene expression data

View session detail

Author Block: **S. Sarangi**[1], K. S. Sharma[1], G. Kildisiute[2], Z. Pitluk[1], J. Kinchen[1]; [1]Paradigm4, Waltham, MA, [2]Wellcome Sanger Inst., Cambridge, United Kingdom
Disclosure Block: **S. Sarangi:** Salary/Employment; Paradigm4.
Single-cell RNA sequencing (scRNA-seq) is a crucial technology for dissecting the heterogeneity associated with cancer. Profiling the transcriptome at single-cell resolution enhances identification and characterization of distinct subpopulations of tumor cells for the precision treatment of cancer. Additionally, the relatively recent compilation of reference single-cell atlases such as the Human Cell Atlas of Fetal Gene Expression (HCA-FGE), and the Human Cell Atlas (HCA) provides researchers with an invaluable resource for comparing cells from diseased and normal patients and tissues. Consequently, this can create personalized and more effective interventions by understanding the co-distribution of therapeutic targets. As with any rapidly developing technology, scRNA-seq also faces a number of issues, a couple of which we will address in this study - a) validation of analysis tools such as clustering algorithms, and b) computational platform to perform population-scale analyses. Growth in the number of available scRNA-seq analysis tools has mirrored the growth in sequencing efforts. A critical part of the analysis workflow is clustering of cells into different cell types, and one of the algorithms used is called single-cell consensus clustering (SC3) - noted for its high accuracy. One of the limitations in SC3 is its inability to scale to population-scale datasets due to computational complexity. In this study, we demonstrate implementation of SC3 in our software platform REVEAL™: SingleCell, and apply it to data from a recent publication, which looked at differences and similarities between human neuroblastoma cells and a reference of normal human fetal medullary cells. We also show comparison of the tumor dataset in the aforementioned publication to the HCA-FGE, as well as an HCA dataset on maternal-fetal interface. Our objectives in this study are to address the need for consensus-driven benchmarks for single-cell data and demonstrate the ability of our computational platform to perform population-scale analyses.

PrgmNr 2374 - Targeted NGS-based molecular profiling of conjunctival squamous cell carcinomas

View session detail

Author Block: **F. Y. Demirci**[1], Y-M. Wu[2], A. Bernard[2], L. Axenol[2], A. Chinnaiyan[2], D. R. Robinson[2], H. Demirci[2]; [1]Univ. of Pittsburgh, Pittsburgh, PA, [2]Univ. of Michigan, Ann Arbor, MI
Disclosure Block: **F.Y. Demirci:** None.
Squamous cell carcinoma (SCC) can rarely occur in conjunctiva, and unlike its common and well-characterized cutaneous counterpart, conjunctival SCC remains understudied and not well understood molecularly. In this study, we conducted targeted next-generation sequencing (NGS)-based genomic and transcriptomic analyses of DNAs and RNAs isolated from fresh-frozen tumor samples obtained from 24 eyes with invasive conjunctival SCC during surgical excision. While our in-depth evaluation of the generated high-throughput data is still underway, our initial findings have shown that the majority of conjunctival SCCs harbored somatic *TP53* mutations, similar to that observed in SCCs affecting other anatomic sites, whereas the *CDKN2A, RB1, NOTCH1/2,* and *PIK3CA* mutations were present less commonly. The most frequently observed outlier gene expression involved *TP63*. While a subset of conjunctival SCCs demonstrated *PD-1/PD-L1* expression, tumor mutation burden was more than 20 Mut/Mb in about half of the cases, suggesting a potential benefit from immunotherapy. Our initial observations suggest that conjunctival SCCs show a number of similar and also some different molecular features as compared to cutaneous SCCs. An improved molecular understanding of conjunctival SCC may facilitate our ability to identify the best targets for precision therapy and improve the clinical outcomes in patients suffering from this invasive malignancy.

PrgmNr 2375 - The landscape and clinical relevance of somatic mutations in a cohort of patients with myelodysplastic syndrome

View session detail

Author Block: **T. Zhang**[1], P. Auer[2], S. Spellman[1], W. Saber[3], Y-T. Bolon[1]; [1]Ctr. for Intl. Blood and Marrow Transplant Res., Natl. Marrow Donor Program/Be The Match, Minneapolis, MN, [2]Natl. Marrow Donor Program/Be The Match, Minneapolis, MN, [3]Ctr. for Intl. Blood and Marrow Transplant Res., Dept. of Med., Med. Disclosure Block: **T. Zhang:** None.

Myelodysplastic syndromes (MDS) represent a heterogeneous group of myeloid malignancies characterized by diverse genetic alterations in hematopoietic stem cells (HSCs). Although several recent studies have characterized the genomic landscape of patients with MDS, there has yet to be a comprehensive genome-wide survey of somatic mutations and their clinical implications in a sizable cohort. To address this gap, whole blood from 494 patients with MDS was subjected to whole-genome sequencing (at 60X depth) and analysis. We utilized the Octopus pipeline to call somatic variants without matched normal and built a reusable germline variant filtering strategy with a custom user interface. Multiple filters allowed for selection and fine-tuning of criteria, including removal of variants with Gnomad allele frequency above 10x10-06, and removal of noncoding variants in low complexity and repetitive regions, those with no functional indications from ANNOVAR annotations, CADD conservative score under 15, and absence in HGMD or COSMIC database. Across all somatic variants, we observed a mean clone number of 3 (range=1-6) with mean variant allele frequency (VAF)= 25.9%. Recurrent somatic mutations demonstrated lower clonal fractions (mean clone number of 1.5 (range=1-3), mean VAF=19.6%). Among 52 recurrently mutated genes in 252 of 494 MDS cases, *TP53*, *TET2*, *RUNX1*, *DNMT3A*, and *ASXL1* were the most frequently mutated genes in our MDS cohort. We used K-means clustering to stratify our cohort into clinically meaningful sub-groups. Six clusters were identified, including one reference cluster with no recurrent somatic mutations or cytogenetic abnormalities. Two other clusters contained samples with *TP53* mutations and the deletion 5q or monosomy 7 cytogenetic abnormalities. We tested whether the distribution of known risk factors for mortality from MDS differed between these two clusters and the reference sub-group. MDS sub-type was strongly associated with cluster membership (p=3.51e-07), as was presence of complex karyotype (p

PrgmNr 2377 - Using single-cell transcriptomics to fit a multi-level computational model of cancer

View session detail

Author Block: **P. Victori**, F. M. Buffa; Univ. of Oxford, Oxford, United Kingdom
Disclosure Block: **P. Victori:** None.

Computational models can provide mechanistic explanations of biological phenomena and improve data integration and interpretation. In cancer, they can help predict response to targeted and combination therapy. In this project, we focused on triple negative breast cancer (TNBC), a cancer of unmet need.

We have developed an agent-based, multi-level model of tumour spheroid growth where genes, cells and diffusible substances have defined properties and a set of possible actions. Each individual cell in the model contains a gene regulatory network (GRN) that receives inputs from the microenvironment and other cells. This GRN outputs a cell fate such as growth arrest, proliferation or apoptosis. This integration of three different modelling levels - intracellular, intercellular and microenvironment - makes our model capable of robust predictions.

We aimed to use the many publicly available single-cell RNA-seq data to fit our model, which will help predict targets for therapy and elucidate mechanisms of resistance to certain drugs. In particular, we are interested in how TNBC resists EGFR targeted therapy.In order to do that, we imported these datasets into our model by building a probabilistic boolean network where the likelihood of each node being active is relative to the computed enrichment score for each gene/protein, not only to the upstream regulation. After importing the regulatory profile of each cell to fit our model, we observed that the general 'phenotype' of each subpopulation (scRNA-seq cluster) is faithfully reproduced in the model, with the proliferative cluster being the one growing the most, which supports the translatability of the model.

We also imported spatial transcriptomic data produced with several technologies. Our model is capable of importing both the expression data and the spatial data, placing each starting cell in the same position within the model as one cell or spot from the spatial dataset. This way we can simulate clonal competition within the tumour paying attention to its topology and composition.

A next step will be to compare the results of simulating targeted drug treatments with our before and after treatment patient data. We are also working in a way to import pseudotime analyses into our model, by defining a differentiation tree for each subpopulation. Then we will check how mutations and targeted drugs affect these differentiation paths, which is something that has already been observed for some of the patient datasets we are using. We hope that this will provide us with novel mechanistic explanations of drug resistance and tumour growth.

PrgmNr 2379 - WGTS insights in a cancer patient: a tale of two primaries

Sequencing is increasingly used in cancer to guide therapy selection and provide prognostic information. Whole genome sequencing provides a comprehensive view of somatic and germline variants, which may provide clinical benefit and improve patient outcomes. Parallel transcriptome analysis enables investigation of the impact of genomic alternations on gene expression, cancer progression prediction and expression signature-based subtyping.
Here, we describe the genomic and transcriptomic profiling of a patient who was treated for two anatomically distant tumours in an 11-month period. The first was a clear cell renal cell carcinoma (ccRCC). We received resected tumour tissue, as well as adjacent non-malignant tissue, from which we carried out high-depth whole genome (~120x) sequencing on four independent sections and transcriptome sequencing (average of 370 million reads per library) on three sections. We identified somatic small variants, copy number alterations and structural rearrangements characteristic of renal carcinomas, including loss of the chromosome 3p. We also observed intra-tumour heterogeneity, including a *BAP1* mutation with an allele frequency ranging from 0.04 to 0.47. Differential gene expression identified upregulated negative prognostic markers of renal carcinomas.
Shortly afterwards the patient had a bowel resection in management of colorectal cancer, from which we received two spatially separated samples of the tumour and adjacent normal tissue. We again applied high-depth whole genome and transcriptome sequencing and observed somatic variants that have been shown to be frequently mutated in colon adenocarcinomas, including *APC* loss of function mutations. No pathogenic germline variants in mismatch-repair genes were observed, nor were microsatellite instability or signatures of mismatch repair deficiency.
We considered the possibility that the two tumours had a common origin. We found, however, that the genomic rearrangements and characteristic mutations were not shared. Similarly, analysis of the whole transcriptome data in comparison to The Cancer Genome Atlas (TCGA) revealed that the patientâ□□s ccRCC samples clustered with 538 kidney renal clear cell carcinoma (KIRC) samples, and the colon cancer samples clustered with 429 colon adenocarcinoma (COAD) samples. These results confirmed that the patient was suffering from two independent synchronous tumours.
This analysis shows that whole genome and transcriptome sequencing (WGTS) can provide insight into tumour origin and development, and supports its use to guide clinical decision making.

PrgmNr 2380 - Whole-genome sequencing of phenotypically distinct inflammatory breast cancers reveals similar genomic alterations to non-inflammatory breast cancers

Background: Inflammatory breast cancer (IBC) has a highly invasive and metastatic phenotype. However, little is known about its genetic drivers. To address this, we report the largest cohort of whole-genome sequencing (WGS) of IBC cases.
Methods: We performed WGS of 20 IBC samples and paired normal blood DNA to identify genomic alterations. For comparison, we used 23 matched non-IBC samples from the Cancer Genome Atlas Program (TCGA). We also validated our findings using WGS data from the International Cancer Genome Consortium (ICGC) and the Pan-Cancer Analysis of Whole Genomes (PCAWG) Consortium. We examined a wide selection of genomic features to search for differences between IBC and conventional breast cancer. These include (i) somatic and germline single-nucleotide variants (SNVs), in both coding and non-coding regions; (ii) the mutational signature and the clonal architecture derived from these SNVs; (iii) copy number and structural variants (CNVs and SVs); and (iv) non-human sequence in the tumors (i.e., exogenous sequences of bacterial origin).
Results: Overall, IBC has similar genomic characteristics to non-IBC, including specific alterations, overall mutational load and signature, and tumor heterogeneity. In particular, we observed similar mutation frequencies between IBC and non-IBC, for each gene and most cancer-related pathways. Moreover, we found no exogenous sequences of infectious agents specific to IBC samples. Even though we could not find any strongly statistically distinguishing genomic features between the two groups, we did find some suggestive differences in IBC: (i) The *MAST2* gene was more frequently mutated (20% IBC vs. 0% non-IBC). (ii) The TGF *Î²* pathway was more frequently disrupted by germline SNVs (50% vs. 13%). (iii) Different copy number profiles were observed in several genomic regions harboring cancer genes. (iv) Complex SVs were more frequent. (v) The clonal architecture was simpler, suggesting more homogenous tumor-evolutionary lineages.
Conclusions: Whole-genome sequencing of IBC manifests a similar genomic architecture to non-IBC. We found no unique genomic alterations shared in just IBCs; however, subtle genomic differences were observed including germline alterations in TGFÎ² pathway genes and somatic mutations in the *MAST2* kinase that could represent potential therapeutic targets.

Blood lipid levels are well documented risk factors for cardiovascular disease but pleiotropic associations might exist for other conditions. Within a trans-ancestry genome-wide association study involving 1.65 million individuals, we identified 2,399 index lipid-associated variants and used the results to develop best performing polygenic risk scores (PRS) for each of the 5 blood lipid traits, including low density lipoprotein (LDL-C), high density lipoprotein (HDL-C), total cholesterol (TC), triglycerides (TG), and non-high density lipoprotein cholesterol (non-HDL-C). We then investigated the association between genetically increased blood lipids and many health-related traits in two large-scale cohorts with deep phenotyping; UK Biobank and the Million Veteran Program. We performed study-wise phenome-wide (PheWAS) scans for each of the lipid PRSs and combined the two datasets via inverse-variance weighted meta-analysis. Our combined dataset for the PRSs scans included results for 739 phecodes and 34 biomarkers. We detected 38 phenotypes associated with the LDL-C PRS at a level of genome-wide significance (GWS), 114 with the HDL-C PRS, 38 with the total cholesterol PRS, 100 with the triglycerides (TG) PRS, and 49 with the non-HDL-C PRS. As expected, multiple coronary and non-coronary atherosclerosis-related phenotypes, as well as hypertension and aortic aneurysm were associated with all five lipid PRSs. All lipid PRSs were also associated at GWS with decreased levels of direct bilirubin; the strongest association was detected for the TC PRS (beta=-0.049 umol/L, SE=0.001, p=1.06e-260). Similarly, all lipid PRSs were associated with low risk for cholelithiasis, apart from the TG PRS, where the direction of effect was reversed. The inverse association between LDL PRS and cholelithiasis had a magnitude of OR=0.937 (95% CIs= 0.923-0.950, p=1.90e-20) in a total of 21,337 cases and 454,050 controls and we further replicated this association in the Michigan Genomics Initiative. In our single-variant by variant PheWAS scan in the UK Biobank, we found 30 unique variants, corresponding to 17 loci, associated with cholelithiasis at GWS. These included variants in four genetic loci (GCKR, ABCG8, CYP7A1 and SULT2A1) previously reported in association with gallstone disease. Our results suggest a substantially larger fraction of lipid-related loci influence the risk of gallstone disease through blood lipid levels than previously

anticipated and may help stratify the risk of subclinical and/or clinical cholelithiasis.

PrgmNr 2382 - Assessing the contribution of rare variants to human complex traits by whole-genome sequencing

Disclosure Block: **K. Kundu:** None.
As part of the INTERVAL study (http://www.intervalstudy.org.uk) we have generated whole-genome sequence data (WGS) at 15X coverage for 12,354 samples and whole-exome sequence data (WES) at 50X coverage for 4,070 samples. INTERVAL is a cohort study of approximately 50,000 healthy blood donors, aged 18 years and older, who were consented and recruited from 25 National Health Service Blood and Transplant donor centres across England between 2012 and 2014. WGS and WES data enable the direct calling of rare variants with allele frequencies AFP -8. In the future, we would like to investigate the functional impact on the non-coding, regulatory part of the genome to further enhance our insight into the genetic architecture of complex traits. Mendelian randomization approaches will be employed to establish the causal relationship between the intermediate phenotypes found to be associated in the INTERVAL study and disease outcomes from the PheWAS study.

PrgmNr 2383 - Assessing the role of rare pathogenic variants in heart failure progression in the UK Biobank

View session detail

Author Block: **O. Chazara**[1], Q. Wang[1], S. V. V. Deevi[1], D. S. Paul[1], J-C. Tardif[2,3], M-P. Dube[2,3,4], C. Haefliger[1], K. J. Carss[1]; [1]Ctr. for Genomics Res. Disclosure Block: **O. Chazara:** Salary/Employment; Astrazeneca.
Heart failure affects ~40 million individuals around the world. In age and sex-adjusted analyses, the relative risk of developing heart failure is 1.69 if one parent is affected and 1.92 if both parents have heart failure, suggesting a genetic component [1].
The majority of heart failure cases are attributed to ischemic heart disease, hypertension, or cardiomyopathy. The latter can be caused by rare, high-impact variants in genes encoding proteins expressed in the heart. Recently, a study highlighted that these rare variants also contribute to the development of heart failure in patients with ischemic heart disease [2]). The role of rare variants in heart failure progression remains to be investigated.
In this study, we tested the hypothesis that rare variants have an impact on heart failure progression using exome sequencing data of ~455,000 participants in the UK Biobank prospective cohort study. We identified up to 11,076 individuals with heart failure and/or cardiomyopathy (based on ICD-10 codes from hospital in-patient diagnoses [3]). We defined â□□progressionâ□□ as cardiovascular death or a composite of cardiovascular death and heart failure hospitalisation. We used Cox Regression with Firth's penalized likelihood to assess the contribution of rare pathogenic variants (collapsed to gene-level) in heart failure progression.
For an endpoint defined as cardiovascular death, highly ranked associations include *KDM3B* (p = 6.89x10-7), *ARHGEF17* (p = 2.0x10-6), and *TTN* (p = 1.04x10-4), but none of these reach the stringent threshold for statistical significance set at p = 2.7x10-7. As these results did not pass the significance threshold, they will need further validation and investigation. We will explore the differences between heart failure patients with and without diagnosed cardiomyopathy, and between patients with and without a diagnosis at the time of enrolment in the UK Biobank.

Author Block: **A. L. Roberts**[1], A. Morea[2,1], M. Tomlinson[1], J. S. El-Sayed Moustafa[1], C. Christiansen[1], C. C. Y. Wong[1], T. J. Vyse[1], K. S. Small[1]; [1]King's Coll. London, London, United Kingdom, [2]The FIRC Inst. of Molecular Oncology, Milan, Italy
Disclosure Block: **A.L. Roberts:** None.
Chromosome X inactivation (XCI) is a dosage compensation mechanism which transcriptionally silences one X chromosome to equalise the gene expression of XX females and XY males. The XCI status of a cell is clonally inherited, and though XCI is typically a random process resulting in an equal mosaicism across a tissue, females can display XCI-skew which is the preferential silencing of one X chromosome. XCI-skew has a heritable basis and becomes more prevalent with increasing age in blood tissues; XCI-skew is observed in ~25% of females over 50. XCI-skew is associated with clonal haematopoiesis, which itself has been linked to increased risk of cardiovascular disease, cancer, and all-cause mortality. However, the health risks associated with XCI-skew have not been robustly established. Similarly, mosaic loss of chromosome Y (mLOY) is a heritable cellular phenotype associated with health outcomes in ageing males. Yet it is unknown whether there is a shared genetic susceptibility between these two age-associated traits of sex chromosome dysregulation. We measured XCI cross-sectionally in 1,575 samples from the deeply-phenotyped twin cohort TwinsUK to identify associations with cardiovascular disease risk and genetic susceptibility to mLOY. XCI-skew was assayed from blood-derived DNA (median age = 61) using the Human Androgen Receptor Assay. The Atherosclerosis and Cardiovascular Disease (ASCVD) risk score was calculated, and date-matched full blood count data were available. A polygenic risk score for mLOY was calculated from publicly available summary statistics (Thompson, 2019). Associations were tested using linear mixed effects models, controlling for relatedness and family structure, and relevant covariates including cell-type composition. Similar to clonal haematopoiesis, XCI-skew was positively associated with ASCVD risk score (P=0.01). This was confirmed in XCI-skew discordant twin pairs (N=34), where higher XCI-skew was associated with higher ASCVD risk score (Wilcox paired-test P=0.009) suggesting the association is not driven by shared genetic susceptibility to both traits. XCI-skew was also associated with increased monocyte abundance (P=0.004), an immune cell involved in the inflammatory pathophysiology of cardiovascular disease. However, no association was observed between XCI-skew and the polygenic risk score for mLOY (P=0.89), suggesting limited shared genetic susceptibility between these two traits. Our study is the first to demonstrate an association between cardiovascular disease risk and XCI-skew. Further data from TwinsUK will enable the identification of other age-related health consequences linked to XCI-skew.

PrgmNr 2385 - Discovery of rare variants associated with resting heart rate

View session detail

Author Block: **L. T. Sooriyabandara**[1], J. RamÃrez[2], S. Van Duijvenboden[1], A. Tinker[2], P. B. Munroe[3]; [1]Queen Mary Univ. of London, London, United Kingdom, [2]William Harvey Res. Inst., London, United Kingdom, [3]Queen Mary Univ. of London, London, United Kingdom
Disclosure Block: **L.T. Sooriyabandara:** None.
Resting heart rate (RHR) is an important marker associated with cardiovascular disease, and genome-wide association studies (GWAS) have identified common variants at more than 437 loci. For most loci, the effector genes and relevant biological processes through which HR associations are mediated are not yet fully characterised, identification of rare variants may help to pinpoint candidate genes and explain additional percentage variance of this trait. We performed a rare variant GWAS (RV-GWAS) in 388,223 individuals and whole exome sequencing (WES) analysis in 161,539 individuals for RHR using BOLT-LMM v2.3.5 and determined the functional impact of rare variants using Variant Effect Predictor. All participants were of European ancestry from UK Biobank. We used PLINK 2.0 to perform genotype quality control, including a minor allele frequency (MAF) > 6.2×10^{-6} and -12. We first estimated the heritability of RHR in the RV-GWAS dataset, rare variants contributed 1.95% of trait variance. This is approximately $1/10^{th}$ of the heritability estimated from common variants. The RV-GWAS identified rare variants at 29 loci, 20 at novel loci and nine at previously reported RHR loci. The effect sizes ranged between 0.81 and 5.75 beats per minute per allele (a variant at the *NEO1* locus had the largest effect size, variants in this gene have suggestive association with heart rate variability). At novel loci, we observe three missense variants in the genes *AKTIP*, *TBX5* and *DBH*. *AKTIP* encodes an *AKT* interacting protein, and a knockout mouse model has heart abnormalities. The rare variants at *TBX5* and *DBH* are identical to rare variants recently reported for blood pressure traits. Rare variants at previously reported RHR loci include several well-established cardiovascular genes (*MYH6*, *CACNA1D*, *GJA1*). Mutations in these genes may cause deficits in autonomic and cardiovascular function, leading to sinoatrial node dysfunction and cardiomyopathy. The WES analysis identified rare variants at seven loci. Five loci do not overlap results from the RV-GWAS, 3 are novel and 2 are at previously reported loci. At novel loci, there are two missense variants in genes *SPATA31A1,* and *HIGD1B*. There are no prior associations described with cardiovascular phenotypes for both genes. At the third novel locus, the nearest gene is *TBC1D32*. Several cardiovascular abnormalities have been observed in a knockout mouse model supporting its candidature. In summary, we found 34 rare variants associated with RHR, our findings provide new biological mechanisms mapping to cardiovascular risk and novel candidates for functional experimentation.

PrgmNr 2386 - Epigenetics of Single and Multisite Atherosclerosis in African Americans from the Genetic Epidemiology Network of Arteriopathy (GENOA)

View session detail

Author Block: **F. Ammous**[1], W. Zhao[1], L. Lin[1], S. Ratliff[1], T. Mosely[2], L. Bielak[1], X. Zhou[3], P. peyser[4], S. L. Kardia[4], J. A. Disclosure Block: **F. Ammous:** None.
Background: DNA methylation, an epigenetic mechanism modulated by lifestyle and environmental factors, may be an important biomarker of complex diseases including cardiovascular diseases (CVD) and subclinical atherosclerosis. **Methods:** DNA methylation in blood samples from 391 African Americans from GENOA was assessed at baseline and atherosclerosis was assessed five and 12 years later. Using linear mixed models, we examined the association between previously-identified CpGs for coronary artery calcification (CAC) and carotid plaque in another study, both individually and aggregated into methylation risk scores (MRS_{CAC} and $MRS_{cartoid}$), and four measures of atherosclerosis (CAC, abdominal aorta calcification (AAC), ankle brachial index (ABI), and multisite atherosclerosis based on gender-specific quartiles of the single site measures. We also examined the association between four epigenetic age acceleration measures (IEAA, EEAA, PhenoAge acceleration, and GrimAge acceleration) and the four atherosclerosis measures. Finally, we characterized the temporal stability of the epigenetic measures using repeated DNA methylation at five years from baseline (N=193). **Results::** After adjusting for traditional CVD risk factors, one and six CpGs were associated with AAC and multisite atherosclerosis at false discovery rate $_{carotid}$ was associated with 1.6-fold increase in the Agatston score of CAC (95%CI 1.09-2.40) and AAC (95%CI 1.13-2.68), and a 0.7 units (95%CI 0.21-1.13) increase in multisite atherosclerosis, after adjusting for CVD risk factors. MRScarotid explained 5.3%, 2.7%, and 5.5% of the variability of CAC, AAC, and multisite atherosclerosis. A 5-year increase in GrimAge acceleration (~1 SD) was associated with a 1.6-fold (95%CI 1.11-2.25) increase in the Agatston score of AAC and 0.7 units (95%CI 0.33-1.07) increase in multisite atherosclerosis, all after adjusting for CVD risk factors. All epigenetic measures were relatively stable over five years, with the highest intraclass correlation coefficients observed for $MRS_{carotid}$ and GrimAge acceleration (0.82 and 0.89, respectively). **Conclusions:** We found evidence of an association between DNA methylation and atherosclerosis at multiple vascular sites in a sample of African Americans. These findings deepen our understanding of the relationship between biological aging and atherosclerosis and suggest that further evaluation of these potential biomarkers is warranted.

PrgmNr 2387 - Estimating the causal effects of cardiometabolic factors on coronary artery disease in British Pakistanis and Bangladeshis: A trans-ancestry Mendelian Randomisation study

View session detail

Author Block: **D. Dunca**[1], Q. Huang[2], N. Sallah[1], H. Martin[2], T. Lumbers[1], K. Kuchenbaecker[1]; [1]Univ. Coll. London, London, United Kingdom, [2]Wellcome Sanger Inst., Cambridge, United Kingdom

British people with South Asian (SAS) ancestry have a higher risk of coronary artery disease (CAD) than other ancestry groups. However, genetic research into the causes of CAD has focused on primarily European (EUR) ancestry individuals. Statistical power can be the limiting factor when extending Mendelian Randomisation (MR) analyses to non-European populations because independent ancestry matched GWAS for risk factors of interest might not be sufficiently large. Here we compared different strategies for trans-ancestry MR and used them to assess the causal effect of cardiometabolic risk factors (BMI, triglycerides, HDL-cholesterol, LDL-cholesterol, systolic and diastolic blood pressure) on the risk of CAD in 22,000 British Pakistani and Bangladeshi (BPB) individuals from the Genes&Health (G&H) cohort. First, we followed the standard MR approach of using an independent ancestry matched sample to derive instruments: a two-sample MR of CAD in G&H with summary statistics for risk factors from the SAS group in UK Biobank. However, insufficient numbers of genome-wide significant instruments were identified for the exposure variables in the UK Biobank SAS population for a well powered MR analysis, due to limited sample size (~8,000). We assessed different strategies to address this. First, we used a less stringent p-value threshold (p

PrgmNr 2388 - Exploring causal relationships between cardiometabolic traits and cancers using pathway-specific genetic instruments

Introduction: Epidemiological studies suggest that people with type 2 diabetes (T2D) are at increased risk for various cancers. T2D and postmenopausal breast (BrC), colorectal, prostate and pancreatic cancers share many risk factors, but potential biological links between them are incompletely understood. We aimed to investigate causality between biological pathways underlying T2D, glycaemic traits and cancers using clustering and Mendelian Randomization (MR). Materials and Methods: We first used agglomerative hierarchical clustering to group 1,083 genetic variants associated with T2D, glycaemic traits and four cancers based on their effects on 35 metabolic/inflammatory/tumour- and obesity-related phenotypes. We obtained 5 groups in total. The adiposity cluster comprised 464 variants, including 36 with pronounced effects on triglycerides and age at menarche, respectively. The beta-cell function cluster grouped 96 variants with shared effects on hormone and lipid levels. The sex hormones cluster included 409 variants with lower levels of sex hormone binding globulin and testosterone. The metabolic syndrome cluster comprised 78 T2D SNPs with higher insulin resistance.We then applied a two-sample MR framework to investigate the role of these four pathways in cancer development. Effect estimates for the same or proxy variants (r^2>0.8) on T2D and cancers were obtained from largest-to-date GWAS.Results: The adiposity pathway showed evidence of a negative causal relationship between BMI and BrC (OR_{MR}=0.66, P-value=4.22x10^{-5}) mediated by later age at menarche. Further analysis using 409 BMI variants as instruments also suggested a causal relationship between adiposity and BrC ($\hat{I}^2_{MR}$=0.88, P-value= 5.59x10^{-5}).Conclusions: Dissection of T2D risk variants into distinct pathways improved our ability to detect causal relationships between specific T2D pathways and cancers. Adiposity and age at menarche were intermediate traits underlying the observed relationship between BrC and T2D.

PrgmNr 2389 - Gene-SCOUT: gene-based biomarker signatures can assist identification of novel genes from phenome-wide association analyses

View session detail

Large-scale PheWAS, performed using densely-phenotyped cohorts such as the UK Biobank (UKB), reveal many statistically robust gene-phenotype relationships. We hypothesised that we can leverage these association statistics to construct â□□quantitative trait fingerprintsâ□□ per human gene to reflect an individual geneâ□□s biomarker statistics and then identify gene groups in the human exome on the basis of similar fingerprints to achieve a holistic view of their impact on human biomarkers. Here, we present Gene-SCOUT (Gene-Similarity from COntinUous Traits), a tool that identifies genes with similar quantitative trait fingerprints to a gene of interest. A fingerprint reflects the collection of biomarkers identified to be statistically associated with a gene of interest (hyperparameter recommended setting at p-5) across multiple qualifying variant models and with similar effect directions (cosine similarity measure). These similarity metrics allow highly similar genes to be clustered together. The underlying gene-biomarker population-scale association statistics were obtained from a gene-level rare variant collapsing analysis performed on ~1500 quantitative traits using ~455K UK Biobank exomes, including the recently released Nightingale metabolomic features, available for ~120K of the UKB individuals.
This novel similarity score both helps to expand our understanding of the key biological systems a gene is involved in, and can also suggest alternative drug targets for known non-tractable genes. Using *APOB* as an exemplar, within the top ten ranked genes identified to have the most comparable fingerprint to *APOB*, five are **known cholesterol-lowering** targets **(*PCSK9, ANGPTL3, APOC3, PDE3B and ABCA1)***, thereby demonstrating the robustness of the approach while also suggesting alternative genes that when genetically aberrated in humans have similar biomarker fingerprints. To support the resulting similarities, we provide enrichment analyses based on neighbouring genes to establish whether gene clusters are significantly enriched for Gene Ontology biological processes or human disease traits.
Gene-SCOUT can facilitate the discovery of novel genes beyond those reported in conventional PheWAS analyses and enables them to be assessed against established disease targets. We also developed a web resource to allow users to either prespecify a query gene and visually explore a network of similar genes, according to their quantitative trait fingerprints, or define a list of specific traits and directionalities to retrieve genes satisfying the desired multi-biomarker fingerprint.

PrgmNr 2391 - Polygenic risk and its interaction with lifestyle for cardiovascular mortality

View session detail

Hosp., Boston, MA, [7]Sungkyunkwan Univ, Seoul, Korea, Republic of
Disclosure Block: **J. Yun:** None.
Background Previous studies primarily targeted the ability of polygenic risk scores (PRSs) to predict a specific disease, and only a few studies have investigated the association between genetic risk scores and cardiovascular (CV) mortality. We assessed PRSs for coronary artery disease (CAD) and type 2 diabetes (T2D) as predictive factors for CV mortality. **Methods** We used genetic and phenotypic data from UK Biobank participants aged 40-69 years at baseline, collected with standardized procedures. Genome-wide PRSs were constructed using >6 million genetic variants. Cox proportional hazard models were used to analyze the relationship between PRS and CV mortality with stratification by age, sex, disease status, and lifestyle behavior. **Results** Of 377,909 UK Biobank participants, 3,210 (0.8%) died due to CV disease during a median follow-up of 8.9 years. CV mortality risk was significantly associated with CAD PRS (low vs. very high genetic risk groups, CAD PRS hazard ratio [HR] 2.61 [2.02-3.36]) and T2D PRS (HR 2.08 [1.58-2.73]), respectively. These relationships remained significant even after adjustment for demographic and clinical factors. In the very high genetic risk group, adherence to an unfavorable lifestyle was further associated with a substantially increased risk of CV mortality (favorable versus unfavorable lifestyle with very high genetic risk for CAD PRS, HR 8.31 [5.12-13.49]; T2D PRS, HR 5.84 [3.39-10.04]). There was no evidence of significant interaction between PRSs and age, sex, or lifestyle behavior in predicting the risk of CV mortality. **Conclusions** PRSs for CAD or T2D and lifestyle behaviors are independent predictive factors for future CV mortality in the white, middle-aged population. PRS-based risk assessment could be useful to identify individuals who need intensive behavioral or therapeutic interventions to reduce the risk of CV mortality.

PrgmNr 2392 - Polygenic score from a large GWAS predicts cases of heart failure with reduced ejection fraction (HFrEF) but not preserved ejection fraction (HFpEF)

View session detail

Author Block: **K-H. Wu**[1], N. J. Douville[2], B. N. Wolford[1], I. Surakka[1], W. E. Hornsby[1], M. C. Konerman[2], M. R. Mathis[2], M. J. Daly[3], B. M. Neale[3], C. J. Willer[1], W. Zhou[4], the Global Biobank Meta-analysis Initiative; [1]Univ. of Michigan, Ann Arbor, MI, [2]Michigan Med., Ann Arbor, MI, [3]Massachusetts Gen. Hosp., Boston, MA, [4]Massachusetts general Hosp., Broad Inst., Boston, MA
Disclosure Block: **K. Wu:** None.
Introduction Heart failure (HF) is a complex disease with multiple subtypes that have distinct etiologies, pathophysiologies, and genetic risk. The performance of a heart failure polygenic score (PGS), derived from a new genome-wide association study (GWAS), was tested to predict cases of heart failure with reduced ejection fraction (HFrEF) and preserved ejection fraction (HFpEF). **Methods** GWAS was performed within the Global Biobank Meta-analysis Initiative (GBMI) â a global collaboration among 13 biobanks across the world with diverse ancestries. GWAS summary statistics were then used to generate a PGS in a combined cohort from the Michigan Genomics Initiative and Cardiovascular Health Improvement Project (MGI/CHIP). Heart failure cases in the GBMI training dataset were defined based upon ICD codes, which did not distinguish between HF subtypes. Electronic health record data available within MGI/CHIP enabled further classification of patients into HFrEF and HFpEF, using a previously validated methodology incorporating ICD diagnoses, free-text language processing, and left ventricular ejection fraction (LVEF). Twenty percent of the cases derived with this method were further adjudicated by clinicians to confirm the phenotype. To compare the predictive ability of PGS, we evaluated logistic regression models with PGS adjusted for age, sex, and principal components derived from genotype data separately for both HFrEF and HFpEF phenotypes. **Results** In the GBMI training dataset, genetic data was analyzed from a total of 67,049 HF patients from 1,305,592 samples from 6 ancestral populations: 25.4% of the samples were of non-European ancestry. The GWAS identified 22 index variants that reached genome-wide significance. The MGI/CHIP validation dataset contained: 360 HFrEF patients, 232 HFpEF patients, and 24,313 healthy controls. The genome-wide PGS is a significantly better predictor of HFrEF compared to HFpEF in the MGI/CHIP cohort. In the HFrEF model, the PGS had an adjusted odds ratio (aOR) of 1.40 (95% CI: 1.25-1.57; p-value: 1.25×10^{-8}) compared to an aOR of 1.08 (95% CI: 0.93-1.24; p-value: 0.30) in the HFpEF model. **Conclusion** Our analyses showed that a PGS for heart failure derived from GBMI data is useful in predicting HFrEF in an independent dataset. The difficulty in predicting HFpEF could result from: (i) the GBMI HF phenotype preferencing HFrEF over HFpEF, (ii) increased diagnostic accuracy in HFrEF in the evaluation cohort (due to inclusion of decreased LVEF), or (iii) greater genetic heterogeneity in the HFpEF population. Future studies focused on a GWAS for HFpEF may create a more useful polygenic score, if the trait is sufficiently heritable.

PrgmNr 2393 - The impact of polyunsaturated fatty acids biosynthesis on the risk of cardiovascular diseases: A Mendelian randomization study in up to 1,153,768 European ancestry individuals

View session detail

Author Block: **M. Borges**[1], P. Haycock[1], J. Zheng[1], G. Hemani[1], L. Howe[1], A. D. Hingorani[2], D. A. Lawlor[1]; [1]Univ. of Bristol, Bristol, United Kingdom, [2]Univ. Coll. London, London, United Kingdom
Disclosure Block: **M. Borges:** None.
Background: Despite early interest in the cardiovascular effects of polyunsaturated fatty acids (PUFA), the evidence linking PUFA to cardiovascular diseases (CVDs) is still controversial. Genetic variants regulating fatty acid desaturases genes (e.g. *FADS1*), coding for rate-limiting enzymes in PUFA biosynthesis (e.g. D5D), can be used as causal anchors to investigate the involvement of PUFA in CVD aetiology.
Aims: We used Mendelian randomization (MR) to explore the effect of higher D5D activity on a wide range of CVDs in up to 1,153,768 European ancestry individuals. In addition, we explored the three key scenarios that could lead to spurious MR findings (i.e. horizontal pleiotropy, population structure, and selection bias).
Methods: We used summary-data MR to investigate the effect of higher D5D activity (proxied by the ratio of arachidonic acid to dihomo-gamma-linolenic acid) on CVDs risk using rs174546 as the genetic instrument. To assess the plausibility of bias by horizontal pleiotropy, we used genetic colocalization and multivariable Mendelian randomization jointly modelling the expression of multiple genes within the *FADS1* locus. To assess confounding by residual population structure, we compared the association of rs174546 with established CVDs risk factors (i.e. LDL-cholesterol, triglycerides, systolic blood pressure, glycated haemoglobin, smoking, and body mass index) between unrelated individuals and within-siblings (up to 68,691 sibships). To explore selection bias, we carried out a positive control Mendelian randomization analyses of established risk factors on CVDs risk.
Results: Our main findings suggest that higher D5D activity is related to higher risk of coronary artery disease, ischemic stroke, heart failure, atrial fibrillation, peripheral artery disease, venous thromboembolism, and aortic valve stenosis. Multivariable MR confirmed that main findings were driven by higher *FADS1* expression (rather than by the expression of other genes in the region) in multiple tissues and genetic colocalization pointed out a shared genetic variant between genetic signals for D5D activity and LDL-cholesterol. The association of rs174546 with CVDs risk factors was broadly similar when comparing unrelated individuals and siblings. In the positive control analyses, we observed the expected effect of risk factors on CVDs risk.
Conclusions: MR findings indicate that lifelong exposure to higher D5D activity is related to higher risk of several CVDs among Europeans. Sensitivity analyses support this interpretation and indicate LDL-cholesterol as a potential mediating trait between PUFA biosynthesis and CVDs risk.

PrgmNr 2394 - The transcriptional landscape of human atria and its role in atrial fibrillation: the RACE-V Consortium

View session detail

Author Block: **A. Isaacs**[1], B. Mulder[2], M. Gilbers[1], M. Kawczynski[1], E. Bidar[1], B. Maesen[1], J. Maessen[1], J. Winters[1], E. Dâ□□Alessandro[1], B. Scaf[1], M. Rienstra[2], I. C. Van Gelder[2], H. J. G. Crijns[1], M. Stoll[1], U. Schotten[1], RACE-V Consortium; [1]Maastricht Univ., Maastricht, Limburg, Netherlands, [2]Univ. of Groningen, Groningen, Netherlands
Disclosure Block: **A. Isaacs:** None.
Atrial fibrillation (AF), a complex, multifactorial disease, is the most common form of arrhythmia and predisposes patients to several adverse outcomes. Heterogeneity in individual characteristics (e.g., surgical indication and comorbidities) can confound associations between AF and atrial expression. To counter this, carefully matched groups (n = 15 per group; SR: no history of AF; parAF: paroxysmal AF; and persAF: persistent AF) were selected from the RACE-V study and utilized to study atrial expression levels. Unmatched samples were used for replication.
Left (LA) and right atrial (RA) appendages were biopsied and detailed phenotypic information was collected. RNA was extracted and poly-A tailed molecules were sequenced (paired-end, 75 base pair, with Illumina chemistry on a NextSeq500). Raw data was aligned to the human genome (GRCh38p13) and quantified using STAR. Differential expression (DE) analyses were performed with DESeq2. All other statistics were implemented in R.
In total, 29 DE transcripts were observed in LA and 16 in RA for the comparison of persAF and SR. Seven of these were present in both atria. In the replication sample (n = 68 LA and n = 63 RA), most effects were concordant in direction (LA: 29/29, 100%; RA: 15/16, 94%) and were nominally significant (LA: 24/29, 83%; RA: 15/16, 94%). Majorities were replicated at transcriptome-wide significance (LA: 19/29, 66%; RA: 13/16, 81%). No DE was observed for parAF vs. SR or persAF vs. parAF.
DE persAF transcripts were also investigated in parAF. They were greatly enriched for both concordant effect directions (LA: 28/29, 97%, $P = 1.1 \times 10^{-7}$ and RA: 16/16, 100%, $P = 3.5 \times 10^{-5}$) and nominal significance levels (LA: 22/29, 76%, $P = 2.6 \times 10^{-23}$ and RA: 10/16, 63%, $P = 5.9 \times 10^{-10}$). Typically, effects for parAF were in between those for persAF and SR.
In the persAF vs. SR comparison, 100% of significant LA and RA transcripts had a concordant effect direction in the other tissue. LA DE transcripts were highly enriched for nominal significance in RA (25/29, 86%, $P = 5.8 \times 10^{-29}$), and vice versa (14/16, 88%, $P = 6.7 \times 10^{-17}$), with highly correlated effect estimates.
Although poly-A tailed RNA does not capture all non-coding RNA, many such transcripts were identified, suggesting that transcriptional regulation plays an important role in AF. Two of these were anti-sense transcripts for crucial calcium handling molecules *CALM1* and *CALM3*. Also of note is the finding that persAF DE transcripts showed substantial evidence of association with parAF. These effects were typically between persAF and SR, in line with the broadly accepted notion of AF as a progressive disease. Other transcripts identified include *RALGPS1*, *MDM1*, and *PPIB*.

PrgmNr 2395 - A glomerular transcriptomic landscape of *APOL1* in Black patients with focal segmental glomerulosclerosis

View session detail

Author Block: **M. T. McNulty**[1], D. Fermin[2], F. Eichinger[2], D. Jang[3], N. P. Burtt[3], M. Kretzler[2], M. Pollak[4,5], J. Flannick[1,3], D. Friedman[4,5], M. Sampson[1,5,3]; [1]Boston Children's Hosp., Boston, MA, [2]Univ. of Michigan - Michigan Med., Ann Arbor, MI, [3]Broad Inst., Cambridge, MA, [4]Beth Israel Deaconess, Boston, MA, [5]Harvard Med. Sch., Boston, MA

Disclosure Block: **M.T. McNulty:** None.

Apolipoprotein L1 (*APOL1*)-associated focal segmental glomerulosclerosis (FSGS) is the dominant form of FSGS in Black people. There are no targeted therapies for this condition, in part because the molecular mechanisms underlying *APOL1*â□□s pathogenic contribution to FSGS are incompletely understood. Studying the transcriptomic landscape of *APOL1* FSGS in patient kidneys is an important way to discover genes and molecular behaviors that are unique or most relevant to the human disease. With the hypothesis that the pathology driven by the high-risk (HR) *APOL1* genotype is reflected in alteration of gene expression across the glomerular transcriptome, we compared expression and co-expression profiles of 15,703 genes in 16 Black FSGS patients with a HR vs 14 with a low-risk (â□□LRâ□□) *APOL1* genotype. Expression data from *APOL1*-inducible HEK293 cells and normal human glomeruli were used to pursue genes and molecular pathways illuminated in these studies. We discovered (1) increased expression of *APOL1* in HR and nine other significant differentially expressed genes, including stanniocalcin (*STC1*), which has a role in mitochondrial and calcium-related processes, (2) differential correlations between HR and LR *APOL1* and metabolism pathway genes, but similar correlations with extracellular matrix- and immune-related genes, (3) significant loss of co-expression of mitochondrial genes in HR FSGS, and (4) an NF-kB -down-regulating gene, *NKIRAS1*, as the most significant hub gene with strong differential correlations with NDUF family and immune-related genes. Overall, differences in mitochondrial gene regulation appear to underlie many differences observed between HR and LR FSGS. All data are available for secondary analysis through the â□□*APOL1* Portalâ□□ (http://APOL1portal.org).

PrgmNr 2396 - Assessment of the Genetic Risk Scoring Algorithm GRS2 for Type 1 Diabetes in African American Children

View session detail

Author Block: **J. Qu**[1], H-Q. Qu[2], Y. Liu[3], F. D. Mentch[4], J. Glessner[5], X. Chang[6], M. March[7], J. Li[2], J. J. Connolly[2], J. D. Roizen[8], P. M. Sleiman[6], H. Hakonarson[7]; [1]Childrenâ□□s Hosp. of Philadelphia, Philadelphia, PA, [2]Children's Hosp. of Philadelphia, Philadelphia, PA, [3]The children's Hosp. of philadelphia CHOP, Philadelphia, PA, [4]Childrens Hosp. of Philadelphia, Philadelphia, PA, [5]Children s Hosp. of Philadelphia, Philadelphia, PA, [6]CHOP, Philadelphia, PA, [7]Children S Hosp. of Philadelphia, Philadelphia, PA, [8]The Children S Hosp. of Philadelphia, Philadelphia, PA
Disclosure Block: **J. Qu:** None.

Type 1 diabetes (T1D) is caused by autoimmune destruction of pancreatic Î²-cells, which is most prevalent in children with European ancestry, but also presents a serious burden among African American (AA) children (Mayer-Davis, Beyer et al. 2009). Once diagnosed, the disease progress is irreversible, and the patients will depend on insulin therapy. Precise risk prediction to enable prevention or early intervention is therefore warranted. The genetic risk scoring (GRS) system for T1D, i.e. T1D-GRS2 (Sharp, Rich et al. 2019), using 67 SNPs from known autoimmune loci, demonstrated excellent performance for the prediction of T1D in European children. With genetic susceptibility of T1D varying significantly across human populations, our study aimed to assess the performance of T1D-GRS2 in AA children. We investigated 168 T1D AA cases versus 1366 non-diabetes AA controls. In comparison, 361 T1D cases of European American (EA) versus 1943 non-diabetes EA controls were also studied. The patients were recruited by the Center for Applied Genomics (CAG) at CHOP, which has established a large pediatric biobank coupled to comprehensive electronic medical record (EMR). The genotyping was done with the Illumina Genotyping BeadChips with at least 550,000 SNPs genotyped. Genome-wide imputation was done with the TOPMed Imputation Server using the TOPMed (Version R2 on GRC38) Reference Panel. The *HLA* region was additionally imputed, using the SNP2HLA software (Jia, Han et al. 2013). The population ancestry of each individual was validated by principal component analysis (PCA) with genome-wide SNP markers. As shown by our results, the T1D AA cases had lower GRS2 scores than the EA cases (8.13Â±2.33 *vs.* 10.52Â±2.20, *P*=3.62E-27), while the AA controls had also lower GRS2 scores than the EA controls (5.24Â±2.32 *vs.* 7.41Â±2.53, *P*= 8.86E-127). The GRS2 had AUC (95% CI)=0.807 (0.779, 0.835) to predict T1D in the CAG AA cohort, compared to AUC (95% CI)=0.823 (0.804, 0.842) in the CAG EA cohort. The prediction of T1D has a sensitivity of 0.613 and a specificity of 0.834 with the maximum Matthews correlation coefficient (MCC) at the cutoff of GRS2=7.43 in AA, compared to a sensitivity of 0.623 and a specificity of 0.833 at the cutoff of GRS2= 9.75 in EA. Furthermore, we attempted to improve the GRS2 performance in AA by including 4 more SNPs (GRS2â□□, *HLA-DQ*: rs9273363; non-*HLA*: rs926169, rs10788599, and rs56380902) identified with T1D association in AA. The GRS2â□□ has an improved AUC (95% CI)= 0.826 (0.800, 0.852) in the CAG AA cohort. Our study suggests that the T1D GRS2 is applicable to the AA population, and could be further improved by including more SNP markers associated with AA T1D.

PrgmNr 2397 - Causal association between circulating metabolites and age at menarche: A two-sample Mendelian randomization study

View session detail

Author Block: **M. Yazdanpanah**[1], N. Yazdanpanah[1], D. Manousaki[1,2]; [1]Res. Ctr. of the Sainte-Justine Univ. Hosp., Univ. of Montreal, Montreal, QC, Canada, [2]Dept.s of Pediatrics, Biochemistry and Molecular Med., Univ. of Montreal, Montreal, QC, Canada
Disclosure Block: **M. Yazdanpanah:** None.
Pubertal timing, as reflected in the age at menarche (AAM) in girls, has a multifactorial etiology and a polygenic basis, but the biological mechanisms underlying variation in the AAM are not completely understood. It has been suggested that earlier pubertal maturation may be associated with adverse health outcomes. Thus, recognizing early predictors of precocious puberty could enhance our understanding of its pathophysiology and identify potential biomarkers for screening and diagnosis. Here, we applied a two-sample Mendelian Randomization (MR) study to screen thousands of previously measured circulating metabolites for a causal association with AAM. We identified 903 unique circulating metabolites with genome-wide significant single nucleotide polymorphisms (SNPs) in four large scale metabolomic genome-wide association studies (GWAS), as instruments in our MR study. Among these 903 molecules, genetically altered levels of 17 metabolites were associated with AAM in ~370,000 women from the ReproGen Consortium GWAS, after correction for multiple testing: specifically, 4 amino acids (isolucine threonine, glutamate, and histidine); 8 lipids (phosphatidylcholines and lyso-phosphatidylcholines), 3 carbohydrates (mannose, Inositol, myo-inositol) and 2 metabolites of unknown class (all Wald ratio p-values -3). Two metabolites with multiple SNPs showed evidence for causal relationships with AAM in the main analysis and in pleiotropy-robust sensitivity MR analyses, namely lyso-phosphatidylcholine and imidazole lactate (p-value inverse variance-weighted (IVW) MR $=1.23x10^{-3}$, and $5.10x10^{-2}$, respectively). Further, we tested whether the prioritized metabolites from our MR study for AAM was also associated with the Tanner stage for breast or testicular development or time of pubertal growth spurt in children from the Early Growth Genetics Consortium GWAS (N= 6,147 females and N= 3,769 males). 2-methylmalonyl carnitine was significantly associated with Tanner stage in males (Wald ratio p-value= $8.16 x10^{-7}$), while glutamate showed an association with both Tanner stage and pubertal growth (Wald ratio p-value for both = $4.0 x10^{-3}$). Our MR study provides evidence supporting a causal role of genetically altered levels of specific blood metabolites in pubertal timing. Our results are in line with previous studies that have linked blood glutamate levels with plasma estrogen and progesterone levels. Our findings support the presence of differences in the metabolic profile of children with altered pubertal timing, while they pinpoint promising biomarkers and/or potential therapeutic targets for early puberty.

PrgmNr 2398 - Discovery of Type 2 Diabetes genes using an accessible tissue

Introduction

Transcriptome Wide Assocation Study (TWAS) methods use reference expression datasets to link genes to disease. Ideally, the reference dataset should use samples from a tissue relevant for the disease, but many relevant tissues are difficult to collect, limiting sample size. However, from projects such as GTEx we have observed that many genetic signals are shared across multiple tissues. Here we investigate the power to discover Type 2 Diabetes (T2D) relevant genes using a well powered whole blood expression reference.

Materials and Methods

Genotypes, gene expression and protein levels data from DIRECT consortium (n = 3029 pre-diabetics and diabetics, 16,205 genes and 452 proteins) from whole blood samples were used to train predictive models using the PrediXcan, Elastic Net approach. These models were then combined to GWAS summary statistics from the DIAGRAM consortium (n = 898,130) and used to calculate gene-trait association scores with S-PrediXcan. We compared our results to the publicly available GTEx v8 PrediXcan results (49 tissues, maximum sample size 706).

Results

We found 160 significant associations between T2D and predicted gene expression levels and 4 with predicted protein levels. We recapitulate known T2D genes such as *HHEX, PAM*, and *CKDN1C*, as well genes where the relevant tissue of action is not whole blood but pancreas or liver (*HNF1A, KCNJ11*). Among the 4 protein associations, gene expression of PAM and ST6GAL1 was also associated with T2D, suggesting a putative continuity from genetic variants to phenotype. Compared to the GTEx v8 results, we find more associations using the larger reference dataset (~0.95% significant associations in DIRECT and from 0.07% to 0.55% in GTEx, depending on tissue). We also find DIRECT implicated genes to be enriched around multiple GWAS loci compared to GTEx tissue derived genes, (odds ratio from 2.2 to 3 in a European GWAS and from 1.4 to 2 in an East Asian GWAS), demonstrating that a higher proportion of DIRECT genes have supporting genetic evidence.

Conclusion

Our findings indicate that large studies can improve the identification of disease causal genes even if a non-relevant tissue is used as a reference panel.

PrgmNr 2399 - Evaluation of genetic prediction and differential expression of genes in non-alcoholic fatty liver disease (NAFLD)

View session detail

Author Block: **T. Kolvekar**[1], W. Li[2], P. Deloukas[1,3], W. Alazawi[2], S. Kanoni[1,3]; [1]Clinical Pharmacology, William Harvey Res. Inst., Barts and the London Med. Sch., Queen Mary Univ. of London, London, United Kingdom, [2]Liver Unit, Blizard Inst., Queen Mary Univ. of London, London, United Kingdom, [3]Ctr. for Genomic Hlth., Queen Mary Univ. of London, London, United Kingdom
Disclosure Block: **T. Kolvekar:** None.
NAFLD is the most common cause of chronic liver disease associated with obesity and metabolic syndrome. It is a disease spectrum ranging from steatosis to non-alcoholic steatohepatitis (NASH) that can progress without symptoms towards end stage liver disease and liver cancer.
Over 11 genetic loci have been associated with NAFLD so far, explaining 10-20% of the heritability. We selected 5,363 patients with NAFLD and 383,165 controls from UK Biobank, all of European ancestry and performed a genome-wide association study (GWAS) analysis. We meta-analysed results with two publicly available summary statistics datasets (1,483 NAFLD cases / 17,781 controls from the EPoS Consortium and 1,106 cases / 8,571 controls from the eMERGE Network). We detected 7 known genetic loci associated with NAFLD at genome-wide significance level and a novel locus, *APOE* (rs429358-T, OR: 1.17, p=7e-11). This missense *APOE* variant was previously associated with CT-measured liver attenuation at exome-wide significance.
We also computed the Fatty Liver Index (FLI) and Fibrosis-4 (FIB-4) and performed separate GWAS analyses in UK Biobank. We used the summary statistics to compute a weighted polygenic risk score (PRS) for each of these indexes, using an optimised pruning and thresholding approach. The best performing PRS for each index was applied to predict classification among NAFLD cases and controls in UK Biobank. Both FLI and FIB-4 were significantly associated with the disease risk but only the FLI-PRS was significantly associated with NAFLD (OR: 1.002 per SD increase, p= 5.66e-85). All quintiles of the FLI-PRS were significantly associated with the risk for NAFLD, compared to the middle quintile. Individuals at the highest 10% of the FLI-PRS had 1.01 higher risk of having NAFLD compared to those at the lowest 10% of the FLI-PRS (p=8.27e-11). The FLI-PRS might be a useful tool to identify individuals at high risk for NAFLD earlier in life.
Finally, we performed RNA-Seq analysis in matched liver and adipose tissue of 25 patients undergoing bariatric surgery (10 NAFLD cases with NASH, 10 NAFLD cases with no NASH and 5 obese controls with normal liver). We identified several differentially expressed genes among the disease states and tissue types implicated in liver injury, fibrosis, inflammation, and metabolism. We found more differentially expressed genes between cases and controls in the adipose tissue, compared to the liver tissue. Simultaneous transcriptomic analysis of liver and fat in NAFLD fibrosis might help disentangle the complex pathophysiology of the disease.

PrgmNr 2400 - Gene-based analyses in population based data identify *MTTP* as associated with nonalcoholic fatty liver disease

View session detail

Author Block: **X. Du**, L. Stetson, Y. Chen, A. Kuppa, GOLD Consortium Groups, E. K. Speliotes; Univ. of Michigan, Ann Arbor, MI
Disclosure Block: **X. Du:** None.
Introduction: Nonalcoholic fatty liver disease (NAFLD) is caused by excess fat (steatosis) deposition in liver, is the most common liver disease worldwide, and has no effective treatments. Hepatic steatosis can be measured using Magnetic Resonance Imaging or Computed Tomography (CT) which correlates with the histologic presence of steatosis with a correlation of 0.78-0.92. NAFLD is heritable/genetic. We and others have identified multiple common single genetic variants that associate with NAFLD; rare variants with effects on NAFLD may be missed by such single variant analyses as they are underpowered. Gene-based analyses which aggregate the effects of rare variants in a gene help to amplify rare variant association signals and can identify genes that when perturbed have effects on NAFLD.
Methods: We used SeqMeta to carry out gene specific association analyses for CT measured liver attenuation which correlates with the presence of liver steatosis in 24,450 multiethnic individuals from the GOLD Consortium. We created SeqMeta objects of 200 KB widths with 100 KB of overlap with neighboring windows and carried out association analysis with inverse normal transformed liver attenuation controlled for age, age2, PCs 1 - 10, alcohol intake as well as kinship structure for family based studies. We filtered for missense and stop-gain variant and performed meta-SKATO analysis. We carried out a similar gene based analysis in UK Biobank where we had liver steatosis measured using magnetic resonance imaging.
Results: In GOLD, *MTTP* (p-value = 2.30E-3) had significant (p-value Conclusions: We can identify genes in population-based studies through gene-based analyses (*MTTP*) that are not captured in single variant analyses. *MTTP* transfers phospholipids and triacylglycerols to nascent apoB for the assembly of lipoproteins. Severe mutations in *MTTP* cause the Mendelian disease abetalipoproteinemia which causes malabsorption in the digestive track and NAFLD due to problems in packaging lipids to be secreted from intestinal or liver cells. Therefore, gene based analyses within large population based studies can now identify bonafide disease genes with rare coding mutations that previously would have been only identifiable with family based analyses, mapping and sequencing.

PrgmNr 2401 - Genetics of osteopontin in patients with chronic kidney disease: the German Chronic Kidney Disease study

View session detail

Author Block: **U. Schultheiss**; Inst. of Genetic Epidemiology, Freiburg, Germany
Disclosure Block: **U. Schultheiss:** None.
Background Osteopontin (OPN), encoded by the *SPP1* gene, is a phosphorylated glycoprotein synthesized predominantly in kidney tissue. OPN levels are known to be associated with adverse kidney outcomes, but the genetic underpinnings of this kidney-enhanced protein are not fully understood. We therefore conducted a genome-wide association study (GWAS) of OPN in a chronic kidney disease (CKD) population, a setting in which the transcription of kidney-specific genes may be altered in comparison to the general population. **Methods** Using genetic data and serum OPN levels quantified via ELISA from CKD patients of European ancestry enrolled into the German Chronic Kidney Disease (GCKD) study, we performed a GWAS of common variants (minor allele frequency [MAF]>1%, additive model), and conducted aggregated rare variant tests (MAFResults Within the GCKD study, data of 4897 participants with a mean age of 60 years (SD 12), median eGFR of 46 mL/min/1.73mÂ² (p25: 37, p75: 57) and median UACR of 50 mg/g (p25: 9, p75: 383) was available. Common variant GWAS revealed index SNPs at 3 loci, two of which replicated in YFS: rs10011284, located downstream of *SPP1*, and rs4253311, mapping into *KLKB1* encoding the protein prekallikrein. The *SPP1* gene was also identified by aggregated rare variant analysis (SKAT p=2.5E-8), comprising 7 variants. The splice acceptor variant (rs139555315) drove the association, with other variants being missense. Using GTEx tissue expression data, colocalization of the association signal with OPN at *SPP1* with pancreas tissue was detected amongst others. SNPs at *KLKB1* showed colocalization of association statistics between serum OPN and various plasma proteins such as SPARC-like and MMP-2 in *trans*, as well as with various phenotypes such as bone disorder and deep venous thrombosis. **Conclusion** This GWAS of OPN levels revealed two replicated associations. The *KLKB1* locus connects the function of OPN with prekallikrein, suggestive of inflammatory functions of the kallikrein-kinin system and theoretically kidney fibrosis. Further studies are needed to elucidated the complexity of OPNâ□□s role within human (patho)physiology.

Opioid consumption leads to contradictory effects on metabolic homeostasis, by increasing hyperglycemia but improving lipid profile and adiposity. However, the mechanisms linking opioids and metabolism are unknown. RNA sequencing data showed that *OPRD1* encoding Î´ opioid receptor (DOP) is expressed in human islets, especially in Ã□ cells. DOP is an inhibitory G-protein coupled receptor. Based on *OPRD1* resequencing and functional experiments, we aimed to decipher the putative link between *OPRD1* mutations and metabolic disorders.

OPRD1 was sequenced in 6,971 individuals. The effect of each detected variant was assessed via luciferase experiments, in response to increasing concentrations of two DOP agonists (DII or DPDPE). We categorized these variants as gain-of-function (GoF) or loss-of-function (LoF). In parallel, expression and localization of each variant were assessed by western blotting and immunofluorescence assays. Association studies between GoF or LoF variants and various metabolic traits were assessed in our cohort, and in further 34,812 individuals from the T2D Knowledge Portal for the study of the frequent GoF variant encoding p.I52V. Finally, we performed glucose-stimulated insulin secretion (GSIS) in the human Ã□-cell model EndoCÃ□H1 overexpressing *OPRD1* and treated with DII DOP agonist.

In 6,971 individuals, we detected 31 rare variants and 3 frequent variants of *OPRD1*. Luciferase assays highlighted 7 GoF variants, including the frequent variant encoding p.I52V, and 12 LoF variants. Immunofluorescence assays showed that all the mutants were effectively expressed and localized at the plasma membrane, except for two LoF mutants (p.P14R and p.G36E). Western blots showed that these two mutants tended to have a lower expression than wild-type DOP. Association analyses revealed that rare LoF variants increased overweight and obesity risk (P=0.0054; OR=11) but decreased hyperglycemia risk (P=0.054; OR=0.23), while rare GoF variants significantly improved lipid profile. Besides, the frequent GoF p.I52V variant was associated with increased type 2 diabetes risk ($P=3.6Ã□10^{-6}$; OR=2) but decreased body mass index (P=0.0038; Ã□=-0.37) and improved lipid profile, confirming this mirror effect. Finally, we showed that DOP significantly inhibited insulin secretion from Ã□ cells.

This study highlights DOP as a major link between opioids and metabolic disorders. DOP agonists and/or antagonists should be considered as new tools to improve metabolic homeostasis.

PrgmNr 2404 - Mutation Burden Analysis Reveal Genetic Differences between Obesity and non-Obesity Asthma patients in African American Population

View session detail

Author Block: **Y. Liu**[1], J. Qu[2], H-Q. Qu[3], X. Chang[4], F. D. Mentch[5], K. Nguyen[6], J. Glessner[7], P. M. Sleiman[4], H. Disclosure Block: **Y. Liu:** None.

Asthma is a complex condition largely attributed to the interactions among genes and environments with a heterogeneous phenotype. Hundreds of asthma-associated genes have been reported, but insufficient replication have made conclusions difficult to draw. Obesity is significantly associated with asthma development, and obesity asthma subjects have more frequent/severe exacerbations while reduced response to asthma medications. In other hands, genetic studies for obese asthma were lacks due to the nature of the complex syndrome. To explore the genetics and potential drug target genes for asthma, especially obese asthma in minority population, we applied blood-derived whole genome sequencing (WGS) data from 4289 African American (AA) individuals. The data include 2226 diagnosed asthma patients, and 1364 subjects who also diagnosed with obesity. The mutation burden analysis was applied using deleterious genomic variants for asthma versus controls, and obese asthma versus non-obese asthma, respectively, based on multiple computational prediction tools. Previously reported asthma associated genes, include *TSLP, RAB6B, SF3B4, RGS7* were identified in asthma/control analysis. For obese asthma comparisons, two gene modules were identified either with significantly adjust p value and/or exclusively occurrences in obese asthma. First group is a list of olfactory receptors genes, second group is immune system related genes that enriched in HDACs deacetylate histones pathway (adjust p value = 7.97E-06), Wnt signaling pathway (5.65E-05), RUNX1 transcription factors pathway (8.22E-05), HATs acetylate histones pathway (1.44E-04), and genomic locus chr6p22.2, which highlighted as contribution of immune system pathways to the genetic architecture of asthma in the most recent genome-wide analysis. As a result, the genes with significantly mutation burden would be the potential drug targets for obese asthma in AA.

PrgmNr 2405 - N6-methyladenosine methylation regulatory genes modified the effect of APOL1 risk genotype on progression of chronic kidney disease

View session detail

Author Block: **C. Li**[1], A. Westbrook[1], R. Zhang[1], L. Hamm[1], J. Chen[1], J. He[1], T. N. Kelly[2]; [1]Tulane Univ. Sch. of Publ. Hlth.and Tropical Med., New Orleans, LA, [2]Tulane Univ, New Orleans, LA
Disclosure Block: **C. Li:** None.
Background: The *APOL1* risk genotype is a major cause of chronic kidney disease (CKD) and CKD progression among African Americans. N(6)-methyladenosine (m6A) is the most abundant modification in mammalian mRNA and regulates all stages of the RNA life cycle. M6A is modified by 10 writer genes which encode m6A methyltransferase enzymes, 9 reader genes which encode m6A binding proteins to stabilize, splice and translate mRNA, and 2 eraser genes encoding m6A demethylase enzymes. We aimed to evaluate whether expression quantitative trait loci (eQTLs) of m6A regulatory genes modify the effect of *APOL1* risk alleles on CKD progression.
Methods: A total of 666 independent (r^2â¤0.3) eQTLs of m6A regulatory genes (Writer genes: *METTL3*, *METTL14*, *WTAP*, *VIRMA*, *HAKAI*, *ZC3H13*, *RBM15*, *RBM15B*, *METTL16*, *PCIF1*/*CAPAM*; Reader genes: *YTHDC1*, *YTHDF1*, *YTHDF2*, *YTHDF3*, *YTHDC2*, *HNRNPA2B1*, *FMR1*/*FMRP*, *HNRNPC*, and *HNRNPG*; and Eraser genes: *FTO* and *ALKBH5*) were retrieved from the GTEx portal. The variants were tested for interactions with *APOL1* risk allele status on CKD progression among 1,224 African American participants of the Chronic Renal Insufficiency Cohort (CRIC) in Cox regression models. We adjusted for age, sex, study site, and the first 10 ancestry principal components (PCs) in a base model and additionally adjusted for baseline kidney function in a full model. We also performed stratified analyses to evaluate *APOL1* risk allele effects on CKD progression according to genotypes of the significant variants.
Results: After Bonferroni correction, a cluster of four variants at the *LAMTOR5* locus (lead SNP: rs6671673, P=6.58Ã10^{-5}) modified the effect of *APOL1* risk alleles on CKD progression. The rs6671673 variant is an eQTL for the writer gene *RMB15*, with the major T allele increasing expression of *RMB15* in whole blood (P=5.4Ã10^{-5}). In stratified analyses, effects of *APOL1* risk alleles on CKD progression decreased with the number of T alleles of rs6671673. Hazard ratios and the corresponding 95% confidence intervals associated with the *APOL1* risk alleles were 1.87 (1.18-2.97), 1.39 (1.13-1.71) and 0.85 (0.67-1.07), respectively, for participants carrying 0, 1, and 2 T alleles at rs6671673.
Conclusion: An eQTL for the m6A writer gene *RMB15* reduced the detrimental effects of the APOL1 risk alleles on CKD progression.

PrgmNr 2406 - Random glucose GWAS in 493,036 individuals provides evidence for reduced lung function as a novel complication of type 2 diabetes

Disclosure Block: **A. Ulrich:** None.

Introduction: Blood glucose and T2D are highly heritable traits (hÂ²â□□30%-60%) with large genome-wide association studies (GWAS) reporting hundreds of associated variants for T2D and over one hundred for fasting glucose. Blood glucose is frequently measured at different times throughout the day (random glucose; RG). Through meta-analysis of RG variant effects in 493,036 non-diabetic individuals from 17 studies, we have expanded by 58 the number of loci associated with glycaemic traits. Previous observational studies have highlighted worsening lung function, as defined by forced vital capacity (FVC), in T2D patients. More recently, it was shown that patients with diabetes are at an increased risk of death from the viral infection COVID-19, with pulmonary dysfunction contributing to mortality. However, confounding and reverse causation inherent to the design of observational studies makes causal inference difficult. Materials and Methods: To quantify the shared genetic contribution between RG and other phenotypes, we estimated their genome-wide genetic correlations using linkage-disequilibrium score regression analyses. We tested causality between RG and correlated traits via bi-directional Mendelian Randomization (MR) analyses using summary level data from non-overlapping samples. Horizontal pleiotropy was tested using the Egger intercept test while heterogeneity was assessed by the Q-statistic. Results: We detected positive genetic correlations between RG, squamous cell lung cancer (rg=0.28, P=0.0015), and lung cancer (rg=0.12, P=0.037); as well as inverse genetic correlations with lung function related traits, such as forced vital capacity (FVC, rg=-0.090, P=0.0059) and forced expiratory volume in 1 second (FEV1, rg=-0.054, P=0.017).MR suggested a causal effect of RG on lung function, including FEV1 ($Î²_{MR-RG}$=-0.60, P=0.0015) and FVC ($Î²_{MR-RG}$=-0.61, P=$3.5x10^{-4}$), but not vice versa. In agreement with this, MR analysis using 413 T2D susceptibility variants suggested T2D as a possible causal factor for declining lung function (FEV1: $Î²_{MR-T2D}$=-0.049, P=$1.27x10^{-13}$; FVC: $Î²_{MR-T2D}$=-0.062, P=$1.42x10^{-21}$). We found no evidence for marked horizontal pleiotropy for the RG-FVC and RG-FEV1 or the T2D-FEV1 MR analyses. We observed no heterogeneity between individual causal estimates for the RG-FVC test (P_{Q-stat}=0.053), while there was some heterogeneity observed for RG-FEV1 (P_{Q-stat}=$6.6x10^{-4}$), and marked heterogeneity for T2D-FVC (P_{Q-stat}=$4.2x10^{-228}$) and T2D-FEV1 (P_{Q-stat}=$7.7x10^{-240}$). Conclusions: Our data suggest a causal effect of glycaemic dysregulation on a decline in lung function as a novel complication of diabetes.

Background and objectives. While sugary drinks intake is decreasing in rich countries, the opposite trend is seen in developing countries; currently the Chilean population presents the highest per-capita consumption world-wide. Consumption of sugar-sweetened beverages alters fasting glucose and other cardiometabolic risk factors. However, it is unclear what effects these lifestyle trend will have among populations of diverse genetic composition. Our goal was to investigate an association between consumption of sugar-sweetened beverages and genetic susceptibility to Type 2 Diabetes (T2D) on fasting glucose in a Chilean population. **Methods.** We calculated a weighted genetic risk score (w-GRS) based on 16 T2D risk SNPs that where genotyped in 2895 non-diabetic participants of the MAUCO cohort by custom targeted sequencing assays. Sugar-sweetened beverage consumption (SSB) was measured with a food frequency questionnaire and classified into 4 levels (0, 1, 2, and >2 servings/day). Log fasting glucose was regressed on SSB and w-GRS tertiles while accounting for socio-demography, lifestyle, and Amerindian ancestry. **Results.** We found that glycemia level increased by SSB (Î²=0.007Â±0.002, p= 0.005) and w-GRS (Î²=0.04Â±0.008, p=0.0001). We also found a significant interaction between sugar consumption and the higher tertile of w-GRS (Î²=0.05Â±0.02, pTCF7L2 (rs7903146, Î²=0.16Â±0.05, pJAZF1 (rs849135, Î²=0.05Â±0.02, pDUSP9 (rs5945326, Î²=0.07Â±0.02, pConclusions. We conclude that association between SSB intake and fasting glucose in a Chilean population is modified by genetic susceptibility to T2D in a non-obesity-mediated manner.

PrgmNr 2408 - The genetic architecture of BMI in infancy and early childhood is characterized by age-specific effects and overlap with pathways involved in Mendelian obesity

We performed genome-wide association studies across 12 time points on BMI from birth to eight years of age in 28,681 children and their parents (27,088 mothers and 26,239 fathers) in the Norwegian Mother, Father and Child Cohort Study (MoBa). We identify 46 distinct loci associated with infant and early childhood BMI at specific ages of which 30 have not previously implicated in birthweight or adult BMI. The loci show striking age-dependency in effect sizes that we can model into four main trajectory clusters that align well with the known growth patterns of infancy and early childhood. A total of 21 loci show peak effect between six months and three years, making these discoverable only at early age. Several of the variants reside in/near genes previously implicated in severe forms of early-onset obesity, and monogenic obesity genes are enriched in the vicinity of the 46 loci. Four loci demonstrate evidence of several independent association signals for BMI development near *LEPR*, *GLP1R*, *PCSK1*, and *KLF14*, all central to appetite and energy balance. At the *KLF14* locus, we detect evidence of two distinct regions with imprinting effects. In conclusion, our results provide the most comprehensive map of common genetic influences on early growth to date.

Diabetic nephropathy (DN) is a major public health challenge, posing substantially increased risks of end-stage-renal disease, cardiovascular disease, and death. Although established as a polygenic condition, the genomic mechanisms underlying DN remain largely unknown. To reveal novel genes and variants associated with DN, we conducted a whole-exome sequencing study among -4) from single variant and aggregate rare variant analyses of multi-ancestry and ancestry-specific participants were replicated leveraging whole-genome sequencing data from 11,487 multi-ancestry Trans-Omics for Precision Medicine (TOPMed) participants. In single variant analyses, two novel variants achieved exome-wide significance (P-7) in discovery and replication stage meta-analyses comparing DN cases to healthy controls. A rare inframe insertion (MAF=0.0021) at the novel *DIS3L2* locus was associated with increased risk of DN in multi-ancestry (OR=193, P=3.59Ã□10^{-9}) and white (OR=100, P=3.01Ã□10^{-8}) participants. In addition, a low-frequency variant (MAF=0.038) at the novel *KRT6B* locus strongly associated with DN in whites (OR=5.31, P=2.72Ã□10^{-9}). Furthermore, we identified aggregate associations of rare predicted loss-of-function variants in *ERAP2* (P=4.03Ã□10^{-8}) and *NPEPPS* (P=1.51Ã□10^{-7}) among multi-ancestry participants at exome-wide significance (P-6) in meta-analyses comparing those with DN to healthy controls and kidney disease controls, respectively. In general, reported signals were consistent across analyses of the three control groups. In summary, we identified and replicated novel signals with large effects in exonic regions, providing empirical evidence of rare variants with large effects on DN and highlighting the utility of aggregate tests to complement single marker analyses for rare variant association discoveries.

PrgmNr 2411 - Defining the Regulatory Mechanism for Helios in Autoimmune Disease

Systemic Lupus Erythematosus is a complex autoimmune disease of which the mechanism is unclear. Our group has completed a large genome-wide genetic association study in SLE. One of the genes we identified was IKZF2 (Helios) - a member of the Ikaros family of Kruppel zinc finger transcription factors (TF). Studies have implied the important role of IKZF2 (Helios) in the development and function of the immune system. In the current project, we aim to elucidate the function of Helios in different T cell types by defining its binding sites and related target genes and enriched pathways Jurkat T cells, regulatory T cells with combinatory use of several bioinformatics tools multiple large-scale of high throughout sequencing datasets and obtain an implication about the role of IKZF2 in development of SLE. Up until the date of this submission, we explored for the first time the genome-wide binding sites and direct target genes and regulatory network of IKZF2 in Jurkat T cell by combining chip-seq data with gene expression data. The differential expression between Jurkat T cell with a Helios knockdown and wild-type Jurkat T cells were analyzed. 415 genes (115 upregulated and 300 downregulated) 4 were found to be differentially expressed between Helios knockdown Jurkat T cell and wild type Helios Jurkat T cell (with the cutoff of |log2FC|>1.0, adjust P value

PrgmNr 2412 - Evaluate mitophagy/autophagy modulators and FDA-approved drugs to prevent or ameliorate the autoimmune, lipodystrophic and neurodegenerative phenotypes observed in *Clec16a* KO mice

View session detail

Author Block: **R. Pandey**, B. Strenkowski, M. Bakay, H. Hakonarson; Children's Hosp. of Philadelphia, Philadelphia, PA
Disclosure Block: **R. Pandey:** None.
Abstract: CLEC16A is implicated in multiple autoimmune diseases. We generated an inducible whole-body knockout (KO), Clec16aî UBCâ¯ mice to address the role of CLEC16A loss of function. Preliminary data from our inducible *Clec16a* KO mice suggests a derailed functional link between mitophagy/autophagy/lipophagy, SOCS signaling and CLEC16A, predisposing to the immune dysregulation and the risk of developing resulting in an inflammatory phenotype and/or neurodegeneration. We propose to examine if treatment with drugs targeting mitophagy/autophagy/lipophagy/SOCS will rescue the phenotypic defects and prevent the onset of the autoimmune, inflammatory and neurodegenerative phenotypes observed in CLEC16A KO mice.
Methods: We generated *Clec16a* inducible knockout (KO) mice to address the role of CLEC16A loss of function in autoimmune inflammatory disorders. Turning off *Clec16a* in adult mice leads to dysregulated mitophagy, severe weight loss, robust autoimmune inflammatory responses, severe neurological symptoms with neuroinflammation and progressive neurodegeneration resembling spinocerebellar ataxia. Here, we examined if the observed perturbations in mitophagy/autophagy, cytokine expression, release and signaling, can be rescued by interventions targeting the mitophagy/autophagy with or without anti-inflammatory therapy, using, JAK-STAT pathway inhibitors, such as SOCS1 and tofacitinib. **Results:** Treatment with a JAK/STAT inhibitor (tofacitinib) partially rescued the inflammatory lipodystrophic phenotype and improved survival of *Clec16a* KO mice by modulating ER stress, lipolysis, mitophagy and autophagy. Our results provide evidence in support of phenotype rescue from targeting autophagy/mitophagy and in combination with SOCS1. In patient populations harboring variants that result in CLEC16A hypofunction, drugs with modulatory effects on mitophagy/autophagy in combination with JAK-STAT signaling inhibition, could compensate for the attenuated CLEC16A activity and present formidable candidates for targeted interventions.
Conclusion: Our mouse model serves as a valuable tool for assessing therapeutic interventions that may and will prevent/delay the phenotype occurrence and progression in autoimmune disease patients and improve the outcome in patient populations harboring variants that result in CLEC16A hypofunction.

PrgmNr 2413 - Expanded genome-wide association study of IBD identifies novel loci and implicates new genes in disease susceptibility

View session detail

Author Block: **L. Fachal**, International IBD Genetics Consortium; Wellcome Sanger Inst., Hinxton, United Kingdom
Disclosure Block: **L. Fachal:** None.
Background: Genome-wide association studies (GWASs) have identified 241 loci associated with inflammatory bowel disease (IBD). However, the mapping of additional disease loci and fine-mapping causal variants is still limited by sample size. Larger GWASs can provide further insights into causal IBD biology.
Methods: We performed a GWAS meta-analysis of 33 cohorts, totalling 54,439 IBD patients (30,574 with Crohnâ□□s disease (CD) and 21,193 with Ulcerative Colitis (UC)) and 37,054 European population controls. Genotype imputation was undertaken using the TOPMed diverse population panel and logistic mixed model association tests were performed using REGENIE.
Results: We identified 78 novel genome-wide significant (p1Mb from any known loci. Five new loci contain genes implicated in monogenic autosomal recessive syndromes that include colitis: *CARMIL2*, *DOCK8*, *G6PC3*, *HPS4*, *NCF1*. Many new loci causally alter the expression of nearby genes (ie *DOCK8*, *ITPKC*, *SDCBP2, STK10*) in relevant cell types and tissues, suggesting that aberrant expression of these genes underpins the IBD association. Fine-mapping analyses identified likely causal missense variants at three new loci. *DOK2* (OR_{CD}=1.24 p=7.4x10-9) encodes a cytoplasmic signalling protein highly expressed in macrophages and T cells in the terminal ileum. Loss of Dok2 in mice causes severe DSS-induced colitis with reduced IL17A and IL22 expression. *SHARPIN* (OR_{CD}=1.25 p=6.7x10-17) forms part of the linear ubiquitin chain assembly complex that modulates activation of the NF-ÎºB signalling pathway. Loss-of-function (LOF) mutations in other proteins in the complex are associated with both combined immunodeficiency and systemic autoinflammation. *CARMIL2* (OR_{UC}=1.23 p=1.1x10-9) is required for NF-ÎºB signalling in both B and T cells, and is expressed in these cell populations in the terminal ileum. LOF mutations are associated with primary immunodeficiencies and paediatric forms of IBD.
Discussion: We performed the largest GWAS meta-analysis of IBD to date, which enabled us to identify low frequency variants with larger effects on IBD susceptibility than the more common variants typically identified via GWAS. The biological overlap between Mendelian and more complex forms of IBD is demonstrated by the identification of common non-coding variants associated with complex forms of IBD that dysregulate the function of a Mendelian gene. At the meeting we will present results of our fine-mapping and pathway analyses, with a view to identifying candidate drug targets for IBD.

PrgmNr 2414 - Risk HLA alleles in South America and potential new epitopes for SARS-CoV2

View session detail

Author Block: **S. SAENZ**[1], V. I. Romero[2]; [1]UNIVERSIDAD SAN FRANCISCO DE QUITO, QUITO, Ecuador, [2]Univ. San Francisco de Quito, Quito, Ecuador
Disclosure Block: **S. Saenz:** None.
HLA alleles are associated with the bodyâ□□s response to infection, such as SARS-CoV2. We asked which HLA alleles were associated with protection or susceptibility to SARS-CoV2 infection and the prevalence of these HLA alleles in South America. We performed a literature review which found that previous reported HLA protective/susceptible allele, obtained the prevalence of those HLA in South America, as well as the most common HLA alleles in this region. Also, we calculated binding prediction of the most common HLA alleles in this continent to SARS-CoV2 immunogenic regions. We identified that the previously reported protective/susceptible alleles are not frequent in South America, confirmed that the spike protein is the most immunogenic protein of SARS-CoV2, and detected new immunogenic epitopes that bound to protective HLA alleles and to HLA alleles common in South America (binding score>0.90). The epitopes found in our study could be used as vaccine targets. Information related to regional HLA frequency databases in South America is limited; therefore, our study reinforces the importance of researching HLA variants in different populations and encourages the creation of a South America HLA variant database.

PrgmNr 2415 - SARS-CoV-2 as a trigger of autoimmune diseases: brazilian experience

Author Block: **M. C. Silva**[1], G. F. S. Carvalho[1], V. C. QuintÃ£o[1], Y. G. Oliveira[1], V. T. Almeida[1], A. M. Nascimento[1], B. M. Wolff[1], L. L. Vieira[1], C. S. Faria[1], L. Antonangelo[1], L. D. Kulikowski[2]; [1]Univ. of SÃ£o Paulo, SÃ£o Paulo, Brazil, [2]Univ. de Sao Paulo, Sao Paulo, Brazil
Disclosure Block: **M.C. Silva:** None.
The infection by the new virus SARS-CoV-2, responsible for causing the coronavirus disease 2019 (COVID-19), has been reported as a trigger for several different autoimmune diseases, which are characterized by an abnormal reaction from the immune system against the body's healthy cells. These diseases have a complex activation mechanism including genetic factors associated with susceptibility. Different genome-wide association studies and meta-analysis identified single nucleotide polymorphisms (SNPs) possibly related, which represents a genetic susceptibility in some individuals to develop autoimmune diseases. In the present study, we purpose to investigate the impact of 10 SNPs, for each disease, who increase the susceptibility for the development of diabetes mellitus type 1, psoriasis, Hashimotoâ□□s thyroiditis, asthma, multiple sclerosis, systemic lupus erythematosus and rheumatoid arthritis, which represents seven of the most important autoimmune diseases previously observed in clinic practice and reported as triggered by the SARS-CoV-2 infection. We evaluated 24 DNA samples from patients previously infected by the SARS-CoV-2 virus using the SNP-array technique with the Infinium ImmunoArray-24 v2 BeadChip Kit. The analyses of the SNPs and genomic regions were obtained from GenomeStudio 2.0 and RStudio softwares and the variants were selected using the following databases: GWAS Catalog, dbSNP, Database of Genomic Variants (DGV) e UCSC Genome Bioinformatics. The results allowed us to identify two patients, who developed multiple sclerosis after the SARS-CoV-2 infection, with allelic compatibility for six of the ten selected genomic variants associated with the disease (rs1077667, rs12927355, rs1323292, rs1738074, rs1800693 e rs2104286). The patient 1 has 4 SNPs in homozygosis for the impact allele, while the patient 2 has two of them in homozygosis. Furthermore, both patients have an allelic homozygosis to the same variant rs2104286 in the *IL2RA* gene, showing a strong association genotype-phenotype. In the current scenario, COVID-19 represents a global challenge for health policies, including many diseases reported in post-COVID. Thus, investigation of specific SNPs can directly contribute to improve the understanding of genomic variants considered as a potential trigger for important autoimmune diseases such as multiple sclerosis.

PrgmNr 2416 - Whole-exome sequencing of hundreds of microbiopsies reveals the somatic evolutionary landscape of psoriatic skin

View session detail

Author Block: **S. Olafsson**[1], E. Rodriguez[2], Y. Hooks[1], I. Martincorena[1], S. Weidinger[2], P. J. Campbell[1], C. A. Anderson[1]; [1]Wellcome Trust Sanger Inst., Hinxton, Cambridgeshire, United Kingdom, [2]Dept. of Dermatology and Allergy, Univ. Hosp. Schleswig-Holstein, Campus Kiel, Kiel, Germany
Disclosure Block: **S. Olafsson:** None.
Recent studies of somatic evolution have revealed that normal tissues are a mosaic of cellular clones competing for limited space within the body. In some instances, clones carrying favorable mutations may transform into cancers. However, it is becoming increasingly clear that somatic evolution may also contribute to non-neoplastic disease, for example cardiovascular disease and inflammatory bowel disease. Here we study somatic evolution in psoriasis, a chronic inflammatory disease of the skin affecting about 2% of Europeans. We have used laser capture microscopy to isolate samples of keratinocytes, 2 in size, from psoriatic lesions and adjacent non-lesional skin. By whole-exome sequencing hundreds of microbiopsies from dozens of donors, we compare the psoriatic and normal epidermis in terms of its clonal structure, mutation burden, mutagen activity and selection landscape. Results from the first 140 exomes indicate that in the absence of cytotoxic treatment, the clonal structure of psoriatic skin is similar to that of non-lesional skin, with clones rarely expanding over large distances. As in non-lesional skin, most mutations in psoriatic skin result from UV-light exposure, but we reveal a large heterogeneity in UV-associated mutation burden between cells separated by less than 1mm in the tissue. We identify genes under selection in the skin and compare their mutational frequencies in diseased and healthy tissue. Preliminary results replicate earlier findings of frequent mutations in *NOTCH1*, *FAT1* and *PPM1D* in the skin and additionally suggest positive selection of mutations in *GXYLT1*. The encoded protein is involved in the glycosylation of epidermal growth factor motifs of proteins such as NOTCH1 and the mutations likely represent another mechanism for disrupting NOTCH signaling. Finally, we describe one patient with a history of phototreatment with psoralens. This cytotoxic treatment left a characteristic mutational signature, caused hundreds of thousands of mutations in the genomes of exposed cells and enabled the expansion of heavily mutated clones in the skin. Results from an expanded cohort of over 1000 exomes will be presented at the meeting.

De novo mutations (DNMs) are known to play a prominent role in many sporadic disorders with reduced fitness and genetic heterogeneity. Due to this strong effect on fitness, we hypothesize that DNMs play a prominent role in male infertility and explain a significant proportion of the genetic causes in this understudied disorder, where large-scale studies have to yet been published. In our study, we performed trio-based exome sequencing in a unique cohort of 185 males with unexplained cases of azoospermia or oligozoospermia and their unaffected parents. In total, 145 rare protein-altering *de novo* SNVs and 2 *de novo* CNVs were identified in these patients. Following a systematic analysis assessing mutational impact and protein function, 29 DNMs were classified as possibly causative of the male infertility phenotype observed in the affected patients. Additionally, a significant enrichment was detected in the number of Loss-of-Function (LoF) DNMs in LoF-intolerant genes ($p=1.00x10^{-5}$) and in predicted pathogenic missense DNMs in missense-intolerant genes ($p=5.01x10^{-4}$). Overall, a significant increase was found in the number of protein-protein interactions amongst genes affected by these DNMs ($p=2.35x10^{-2}$). Among the new candidate genes identified was *RBM5*, an essential regulator of male germ cell pre-mRNA splicing. Besides the patient carrying

the DNM in *RBM5*, 6 additional infertile men were found carrying a distinct rare pathogenic missense mutation in *RBM5* in an international cohort of patients (n=2,506), a significant enrichment when compared to the number of mutations found in *RBM5* in a cohort of confirmed fertile men (n=5,784; p=0.03).Taken together, our results provide strong evidence for the role of DNMs in severe male infertility and identify a number of new candidate genes affecting human male fertility.

PrgmNr 2418 - Analysis of transcriptional changes associated with pubertal development

Author Block: **J. Resztak**[1], J. Choe[2], R. Bruinsma[1], R. Houpt[3], R. B. Slatcher[4], S. Zilioli[1], R. Pique-Regi[5], F. Luca[5]; [1]Wayne State Univ., Detroit, MI, [2]New York Univ., New York, NY, [3]Arizona State Univ., Tempe, AZ, [4]Univ. of Georgia, Athens, GA, [5]Wayne State Univ, Detroit, MI
Disclosure Block: **J. Resztak:** None.
Puberty is an important developmental period marked by hormonal, metabolic, immune and physiological changes, which have been implicated in predisposition to immune disease later in life. Yet little is known about the immune gene expression changes accompanying pubertal development. We studied a cohort of 251 children (103 girls, 148 boys, 10-17 years old), assessing their pubertal development and leukocyte gene expression changes between two time points (1-2 year interval). We identified gene expression changes over this time interval for 3240 genes in boys and 3187 genes in girls, which were largely overlapping (Pearsonâ□□s correlation=0.9, p-valueDSC1 and *TRBV30* in females and *HLA-H* and *PGAP1* in males (10% FDR). *HLA-H* was previously associated with auto-immune disease risk, including rheumatoid arthritis and multiple sclerosis in transcriptome-wide association studies. Overall, we demonstrated that changes in leukocyte gene expression reflect the physiological changes associated with pubertal development. Insight into immune gene expression processes accompanying puberty can help us understand their contributions to immune disease later in life.

PrgmNr 2419 - Construction of copy number variation map identifies small regions of overlap and candidate genes for atypical female genitalia

View session detail

Author Block: **A. Amukamara**[1], I. E. Amarillo[2]; [1]Washington Univ. Sch. of Med., St. Louis, MO, [2]Washington Univ in St Louis Sch. of Med., St. Louis, MO
Disclosure Block: **A. Amukamara:** None.
Copy number variations (CNVs) have been implicated in various conditions of differences of sexual development (DSD). Generally, larger genomic aberrations are more often considered disease-causing or clinically relevant, but over time, smaller CNVs have been associated with various forms of DSD. The main objective of this study is to identify small CNVs and smallest regions of overlap (SROs) in patients with atypical female genitalia (AFG) and build a CNV map of AFG. We queried the DECIPHER database for recurrent duplications and/or deletions detected across the genome of AFG individuals. From these data, we constructed a chromosome map consisting of SROs and investigated such regions for genes that may be associated with the development of atypical female genitalia. Our study identified 180 unique SROs (7.95-45,338.26 kb) distributed among 22 chromosomes. The most SROs were found in chromosomes X, 17, 11, and 22. None were found in chromosome 3. From these SROs, we identified 22 genes as potential candidates. Although none of these genes are currently associated with AFG, literature review indicated that almost half were potentially involved in the development and/or function of the reproductive system, and only one gene was associated with a disorder that reported an individual patient with ambiguous genitalia. Our study further demonstrates the clinical significance of small CNVs, and additional downstream functional investigations will provide better understanding of the genetic etiology of AFG. Data from this investigation may also aid in genetic counseling, genetic diagnosis, and management of patients with AFG.

PrgmNr 2420 - Genetic architecture of severe spermatogenic failure and male infertility: time to advance standard of care

Author Block: **C. Friedrich**[1], M. J. Wyrwoll[1], A-K. Dicke[1], E. Pohl[1], N. KÃ¶ckerling[1], N. Rotte[1], J. Emich[1], M. Vockel[2], M. WÃ¶ste[3], C. Ruckert[2], J. Seggewiss[2], S. Ledig[2], A-C. Tewes[2], Y. Stratis[2], J. Wistuba[4], C. Krallmann[4], S. Kliesch[4], A. RÃ¶pke[2], B. Stallmeyer[1], F. TÃ¼ttelmann[1]; [1]Inst. of Reproductive Genetics, Univ. of MÃ¼nster, MÃ¼nster, Germany, MÃ¼nster, Germany, [2]Inst. of Human Genetics, Univ. of MÃ¼nster, MÃ¼nster, Germany, MÃ¼nster, Germany, [3]Inst. of Med. Informatics, Univ. Hosp. MÃ¼nster, MÃ¼nster, Germany, MÃ¼nster, Germany, [4]Ctr. of Reproductive Med. and Andrology, Univ. Hosp. MÃ¼nster, MÃ¼nster, Germany, MÃ¼nster, Germany
Disclosure Block: **C. Friedrich:** None.

Half of all infertility cases, affecting 10-15% of couples, arise from male factors like crypto- and azoospermia (very few or no sperm in the semen). The only well-established genetic causes include Klinefelter syndrome (KS, karyotype 47,XXY), Y-chromosomal AZF microdeletions for quantitative spermatogenic failure (SPGF), and *CFTR* mutations for obstructive azoospermia (OA). However, although gene mutations are expected to explain most remaining cases, no respective analyses have yet informed clinical practice.

To address this, since 2017, we prospectively included crypto- and azoospermic men attending the Centre of Reproductive Medicine and Andrology (CeRA, MÃ¼nster, Germany) into our Male Reproductive Genomics (MERGE) study. After excluding known conditions leading to SPGF (e.g., testicular tumors and/or previous chemotherapy) and ruling out chromosomal aberrations and AZF deletions, we offered exome sequencing, analyzed 62 genes with at least limited clinical validity to be associated with crypto-/azoospermia based on our recent review of overall 596 genes, and strictly assessed variants according to ACMG-AMP guidelines.

Chromosomal aberrations (mostly KS) and AZF deletions were identified in 15.9% and 2.8% of cases. In 682 men without such conditions, 18 patients (2.6%) with OA carried causal variants in *CFTR* or *ADGRG2*. In 40 patients (5.9%) with SPGF, variants in 21 genes were identified as (likely) pathogenic. The most commonly affected genes were *TEX14* (5 cases), *NR5A1* (4 cases), and *AR*, *M1AP*, *SYCP2* (each 3 cases). Segregation analyses helped in assessing the pathogenicity of some variants, highlighted by a de novo variant in *DMRT1*.

The sequencing performed here offers a substantial diagnostic yield on top of that of current genetic tests. Further, some findings are immediately relevant for infertility counselling/treatment, as they indicate the success of treatments like testicular biopsy with the aim of sperm extraction (TESE). Overall, panel/exome sequencing provides strong enough evidence to be included in diagnostic workups of men with crypto- and azoospermia. Including more genes and additional functional assessments of variants of uncertain significance will quickly increase relevant diagnostic findings and improve patients care.

PrgmNr 2421 - Idiopathic hypogonadotropic hypogonadism in the Maltese island population: A spectrum of phenotypes and genotypes

View session detail

Author Block: **C. Axiak**[1], A. Pleven[1,2], F. Borg Carbott[1], R. Attard[1], K. Cassar[3], M. Gruppetta[3,4], J. Vassallo[3,4,5], S. Bezzina Wettinger[1,5], R. Farrugia[1,5]; [1]Dept. of Applied BioMed. Sci., Faculty of Hlth.Sci., Univ. of Malta, Msida, Malta, [2]Clinical Chemistry Section, Dept. of Pathology, Mater Dei Hosp., Msida, Malta, [3]Dept. of Med., Faculty of Med. and Surgery, Univ. of Malta, Msida, Malta, [4]Div. of Endocrinology and Diabetes, Dept. of Med., Mater Dei Hosp., Msida, Malta, [5]Ctr. for Molecular Med. and Biobanking, Faculty of Med. and Surgery, Univ. of Malta, Msida, Malta

Disclosure Block: **C. Axiak:** None.

Idiopathic Hypogonadotropic Hypogonadism (IHH) is a rare, genetically heterogeneous infertility disorder characterized by absent or incomplete sexual maturation by age 18. This is due to a deficiency or absence of either pulsatile hypothalamic secretion of gonadotropin-releasing hormone (GnRH) and/or gonadotropins from the anterior pituitary in the presence of low serum sex steroids. IHH diagnosis is only conclusive if there are no other abnormalities to hypothalamic and pituitary morphology and function.

Here, we report findings from a targeted gene panel of 17 IHH genes (*CHD7, EBF2, FGF8, FGFR1, GNRH1, GNRHR, HS6ST1, KAL1 (ANOS1), KISS1, KISS1R, NSMF (NELF), PROK2, PROKR2, TAC3, TACR3, TSHZ1,* and *WDR11*) on 15 probands with IHH. Causative variants explaining the phenotype were identified in 4 cases. These comprise (i) oligogenic inheritance of autosomal dominant *FGFR1* p.Y132C and autosomal recessive *TACR3* p.K286R in a male with cryptorchidism and a micropenis, (ii) a novel autosomal dominant *CHD7* p.Q78X stop variant in an anosmic male with 2 CHARGE characteristics and cryptorchidism, (iii) compound heterozygosity for *GNRHR* p.Q106R and the novel *GNRHR* p.N298KfsTer22 in a female, and (iv) homozygosity for a novel autosomal recessive *KISS1R* p.Y190_A199del deletion in a male. Four other probands were found to have only variants with partial or complete loss of function in heterozygosity and are thus only partially solved. Of these, 2 were females who presented with secondary amenorrhea. The first had an accumulation of heterozygous kisspeptin variants including *KISS1R* p.Q36R that is reported to contribute to pathogenicity. The second had an autosomal recessive *GNRHR* p.Q106R heterozygote variant. Exome sequencing on this latter case and her hyposmic father, who was diagnosed with IHH and took human chorionic gonadotropin treatment to achieve fertility, showed that the father was also heterozygous for *GNRHR* p.Q106R and had an additional novel heterozygous *CCDC141* p.E905K variant within a highly conserved region. Pathogenic variants in this gene are suspected to cause decreased embryonic GnRH cell migration that precedes formation of the hypothalamic neuronal network that secrets GnRH.

We also found *GNRHR* p.Q106R in heterozygosity to be a recurring variant in 4 unrelated individuals from the cohort. The local allele frequency was found to be 0.029 in a population study using 493 cord blood DNA samples of neonates with at least 1 ethnically Maltese parent. For a variant that is reported to contribute to IHH pathogenicity in multiple literature accounts, the variant frequency in the local population is higher than expected and suggests a founder effect.

PrgmNr 2422 - Challenging diversity in precision medicine through large-scale exome sequencing and genome wide genotyping in South Asians: Analyses of quantitative red blood cell traits

View session detail

Author Block: **S. Tuna**[1], W. McLaren[1], N. England[1], N. S. Roy[2], A. Shah[3], J. L. Rodriguez-Flores[4], M. Kapoor[4], Y. Turpaz[5], S. Jamuar[5], A. R. Schuldiner[4], J. Picker[6]; [1]Global Gene Corp, Cambridge, United Kingdom, [2]Global Gene Corp, Mumbai, India, [3]Global Gene Corp, Ahmedabad, India, [4]Regeneron Pharmaceuticals, Inc., Tarrytown, NY, [5]Global Gene Corp, Singapore, Singapore, [6]Global Gene Corp, Boston, MA
Disclosure Block: **S. Tuna:** None.
Background: Red blood cells (RBC) are essential for oxygenation and when disrupted can cause significant health problems. India has a high prevalence for RBC disorders including thalassemias, sickle cell anemias and others. Most genetic analyses of RBC traits report findings from European populations. As genomic architecture differs among populations, e.g., linkage disequilibrium (LD) structure and allele frequency, this bias can cause studies to miss significant variants that are not seen in European populations.
Methods: With the goal of increasing diversity in genomic studies and to better understand correlation between these markers and RBC disorders, we collected and sequenced (whole exome sequencing and chip array) >15,000 South Asian samples to date and ascertained complete blood count that included standard red blood cell indices (haemoglobin, mean corpuscular volume (MCV), hematocrit). We performed exome and genome wide association analyses of both common and rare (AF **Results**: MCV, a measurement of the size of the RBC, had the most significant results in our study. We identified several known and novel MCV-associated loci specific to South Asian populations, including *CLCN6* (leading variantâ□□s beta = -1.21(0.17), p-value = 1.4e-12), HBB (leading variantâ□□s beta = -2.15(0.26), p-value=3.7e-16), *LUC7L* (leading variantâ□□s beta = -5.07(0.42), p-value = 2.0e-33), and *SCO2* (leading variantâ□□s beta = -0.91(0.14), p-value=1.2e-10). Using a rare variant gene burden test approach we replicated *HBB* (beta = -19.20(1.10), p-value = 1.8e-68) and *SH3PXD2A* (beta = -6.29(1.16), p-value=6.4e-08.
Conclusion: Our study identified novel and known variants associated with RBC traits in South Asians. It is possible that some of these associations reflect adaptation or susceptibility to blood disorders. Better understanding of the correlation between these markers and RBC disorders within the population will lead to improved understanding of disease burden. Furthermore, a better understanding of complex traits and diseases through genetic studies of diverse populations will lead to novel drug targets, biomarker identification for patient stratification, and the promise of precision medicine for all.

PrgmNr 2423 - Clonal myelopoiesis and risk of adverse events in chronic kidney disease

View session detail

Author Block: **A. Dawoud**[1], W. Tapper[1], N. Cross[2,1]; [1]Univ. of Southampton, Southampton, United Kingdom, [2]Salisbury NHS Fndn. Trust, Salisbury, United Kingdom
Disclosure Block: **A. Dawoud:** None.
Background: Age-related clonal haematopoiesis (CH) is a risk factor for atherosclerotic cardiovascular disease (CVD) and all-cause mortality. Chronic kidney disease (CKD) is a worldwide health problem associated with an elevated risk of CVD, but the relationship between CH and CKD is unknown. We sought to assess (i) the relationship between CH, defined by mosaic chromosomal alterations (mCA) or somatic driver mutations, and Glomerular Filtration Rate scores estimated from cystatin-C (eGFR.cys), or creatinine (eGFR.creat) used in managing CKD and (ii) the effect of CH on developing adverse outcomes defined by myocardial infarction, stroke and mortality in CKD. Methods: We focused on subjects with both SNP array, and WES in the absence of End Stage kidney Disease (ESKD) in UK Biobank (n=190,487; median age = 58y). Array allelic intensities were used to infer mCA, which were categorized as myeloid, lymphoid, or other. Likely somatic driver mutations were extracted from WES variant calls based on recurrency in Catalogue of Somatic Mutations in Cancer, pathogenicity score, and a binomial test against mean VAF. Linear and logistic regression models were used with eGFR scores as continuous trait and CKD as binary trait (eGFR 2). A Cox proportional hazard model was used to assess the risk of developing adverse outcomes. Results: CH was identified in 5,449 (2.9%) eligible subjects. CH was negatively associated with eGFR.cys ($\hat{I}^2$=-0.82, P=6.05x10^{-5}), but not other eGFR scores, and was specifically associated with CKD (n=5,449/185,038, OR=1.02, P=1.2x10^{-8}). In participants without prevalent myeloid neoplasms, eGFR.cys was associated with myeloid-related mCA (n=148, $\hat{I}^2$=-3.37, P=6.75x10^{-3}), driver mutations in myeloid neoplasia-related genes (n=3241, $\hat{I}^2$=-1.11, P=2.78x10^{-5}), and specifically *CBL, TET2, JAK2, PPM1D* and *GNB1* but not *DNMT3A* or *ASXL1*. Excluding any prior history of CVD, we confirmed the risk of adverse outcomes in myeloid CH (HR=1.57, n=338/3,078, P=1.1x10^{-12}) compared to myeloid CH-free participants (n=9174/176,944), and the higher risk in CKD: HR=2, n=1,186/6,991 P=7.6x10^{-78} compared to CKD free participants (n=8326/173,031). Within the CKD group, the risk was further increased for subjects with myeloid CH (HR=1.62, n=59/226, P=1.5x10^{-3}) compared to those who were myeloid-CH free (n=1,127/6,765). Summary/Conclusion: CH, and specifically myeloid CH, is associated with the decrease in kidney function measured by eGFR.cys. Myeloid CH stratifies the risk of adverse outcomes in CKD.

PrgmNr 2424 - A Haptoglobin (HP) Exon Deletion Polymorphism Associates with Alzheimerâ□□s Disease Status with Stratification of *APOEe4* Status

View session detail

Author Block: **H. Bai**[1], W. S. Bush[2]; [1]System Biology and Bioinformatics, Dept. of Nutrition, Case Western Reserve Univ., Cleveland, OH, [2]Case Western Reserve Univ., Cleveland, OH
Disclosure Block: **H. Bai:** None.

The free hemoglobin capturing protein - haptoglobin (HP) is distinguished into two alleles, *HP2* and *HP1*, which has a two-exon deletion. We have previously demonstrated their association with HIV-associated neurocognitive impairments. We further hypothesize that this structural variation is also associated with dementia related disorders such as Alzheimerâ□□s disease (AD). To investigate this, we first pre-imputed chromosome 16 for every participant from the Alzheimerâ□□s Disease Genetics Consortium (ADGC) that passed genotyping quality control to the TOPMed genotype marker set by cohort, followed by a subsequent imputation for the *HP* genotypes using a custom reference panel, again respectively within each cohort from ADGC. Finally, we evaluated the association between HP genotype and the AD case/control status for all the cohorts jointly by using logistic regression, adjusting for sex. We also performed analyses stratified by the apolipoprotein E (*APOE)* e*4* allele status to account for the strong effect of *APOE* on AD. In the *APOE e4* dominant group, *HP2* additively decreased the risk of AD [OR=0.943, CI=(0.916, 0.970), p=0.042, n=10,054] and this effect was not present in the non-*APOE e4* group (n=12,631) suggesting the effect may depend on an *APOE e4* context. This conclusion was also supported by congruent analyses examining the effect of *APOE e4* on AD stratified by *HP2* status, which shows a decrease in *APOE e4* effect as the *HP2* allele count increased. The *HP2* effect was observed to be larger within the more phenotypically aligned National Alzheimer's Coordinating Center (NACC) cohorts only [OR=0.921, CI=(0.890, 0.953), p=0.017, n=7,448] while the *HP1* showed a detrimental effect [OR=1.129, CI=(1.076, 1.184), p=0.013, n=7,448]. We also considered the onset of AD as an event and conducted a time-to-event study over age with a Cox proportional hazard regression model in the NACC cohorts. *HP2* alleles additively decreased the hazard of AD (Î² =-0.062Â±0.023, p=6.85e-3, n=7,448) and *HP1* dominantly increased the hazard (Î² =0.089Â±0.033, p=7.9e-3, n=7,448). The *HP1* dominant effect remained after adjusting for the *APOE e4* additive effect while the *HP2* additive effect became marginal. These results are somewhat consistent with our prior findings for neurocognitive impairment in people living with HIV (though there are obvious differences in the phenotype and age effects). Based on these analyses, the HP protein may be an imminently translatable therapeutic target for neurocognitive impairment.

PrgmNr 2425 - Deep learning-based feature extraction in neuroimaging genetics for Alzheimerâ□□s Disease

View session detail

Author Block: **D. Chakraborty**[1], H. Xue[2], Z. Zhuang[3], W. Pan[4], ADNI; [1]Sch. of Publ. Hlth., Univ. of Minnesota, Minneapolis, MN, [2]Univ. of Minnesota, Twin Cities, St Paul, MN, [3]Univ. of Minnesota, Minneapolis, MN, [4]Univ Minnesota, Minneapolis, MN
Disclosure Block: **D. Chakraborty:** None.
The prognosis and treatment of the patients suffering from Alzheimerâ□□s disease (AD) have been one of the most important and challenging problems over the last few decades. To better understand the mechanism of AD, it is of great interest to identify genetic variants associated with brain atrophy. Commonly in these analyses, neuroimaging features are extracted based on one of many possible brain atlases with FreeSurf and other popular softwares, which however may lose important information due to our incomplete knowledge about brain function embedded in these suboptimal atlases. To address the issue, we propose convolutional neural network (CNN) models applied to both three-dimensional whole-brain structure MRI data and divided multi-branch data structures to perform automatic feature extraction. These image-derived features are then used as endophenotypes in Genome-Wide Association Studies (GWAS) to identify associated genetic variants. When applied to the ADNI data, we identified several associated SNPs which have been previously shown to be related to several disorders such as depression, schizophrenia and dementia. For example, we found SNP rs2075650 which is located close to *ApoE4*, yet may independently influence risk of AD; SNP rs2196315 (P value=8.02 x 10^{-8}) corresponding to gene *ADCY8* which is known to be associated with Dissociative Amnesia; SNP rs2395095 from the *ADK* gene, known to be responsible for triggering cognitive impairment and seizures. Furthermore, the results include SNP rs173754 (P value=3.33x10^{-6}) which has been shown responsible for Attention Deficit Hyperactivity Disorder and rs9257694 (P value= 1.55 x 10^{-6}) associated with *OR14J1* (olfactory receptor family 14 subfamily J member 1) responsible for abnormalities and impaired functions of the olfactory system which are seen to appear earlier than other AD symptoms. Overall, our work suggests a novel idea of automated feature extraction and the subsequent GWAS study focusing on the entirety of brain structure, thus identifying the genes associated with Alzheimerâ□□s Disease.

PrgmNr 2426 - Evaluation of the role of common variant burden in the familial aggregation of epilepsy

View session detail

Author Block: **V. Smuk**[1], C. Leu[1], J. A. LÃ³pez-Rivera[1], L. Ferguson[2,3], L. Jehi[2], I. M. Najm[2], R. M. Busch[2,3], D. Lal[1,4]; [1]Genomic Med. Inst. & Epilepsy Ctr., Cleveland Clinic, Cleveland, OH, [2]Epilepsy Ctr., Neurological Inst., Cleveland Clinic, Cleveland, OH, [3]Dept. of Psychiatry & Psychology, Neurological Inst., Cleveland Clinic, Cleveland, OH, [4]Stanley Ctr. of Psychiatric Res., Broad Inst. of Harvard and MIT, Cambridge, MA

Disclosure Block: **V. Smuk:** None.

Rationale: Polygenic risk scores (PRS) have proven to help predict the genetic risk of developing a disease phenotype. We previously showed that common genetic risk associated with epilepsy is significantly enriched in patients with focal and generalized epilepsy. For several neurological disorders such as schizophrenia, migraine, and autism, it has been shown that patients with a known family history of the disease carry a significantly higher polygenic risk than those with no family history. However, the relationship between family history and the polygenic burden has not been established for epilepsy. Our aim was to quantify the genetic burden in epilepsy cohorts to assess if the genetic risk is further enriched in cases of familial epilepsy.

Methods: Using genome-wide genotyping data generated with the Illumina Global Screening Array-24 with Multi-disease drop-in (GSA-MD v1.0), we quantified the common genetic burden in individuals with FE or GE from a single clinical center, the Cleveland Clinic Epilepsy Center. Quality-filtered genotyping data of all individuals was imputed to the TOPMed Reference panel r2 using Minimac4 and reference-based phasing with Eagle-v2.4, as implemented on the TOPMed Imputation server. PRS were derived from summary statistics of the ILAE Consortium on Complex Epilepsies European ancestry GWAS for generalized and focal epilepsy.

Results: After quality control, we identified 336 individuals of European ancestry with FE or GE and a known family history of epilepsy (FE, 40 out of 289 individuals with FE and at least one first-degree relative; GE, 15 out of 47 individuals). Overall, we found that individuals with FE or GE and first-degree relatives with epilepsy had higher FE-PRS or GE-PRS, respectively than individuals without a family history. At the time of the conference, we will present the results of a validation cohort and the combined cohort of all individuals with FE or GE and a known family history of epilepsy.

Conclusions: Our findings demonstrate that common polygenic risk for epilepsy contributes to the familial aggregation of epilepsy. Thus, our results could be used to inform future genetic studies with a specific focus on familial cases.

PrgmNr 2427 - Exploring genome wide association signals in mesial temporal lobe epilepsy

View session detail

Author Block: **P. Mello MagalhÃ£es**[1], E. Bruxel[2], M. C. P. Athie[1], M. K. M. Alvim[1], R. Secolin[3], C. L. Yasuda[1], F. Cendes[1], I. Lopes-Cendes[4]; [1]UNICAMP, Campinas, Brazil, [2]Univ. of Campinas, Campinas, Brazil, [3]Univ. of Campinas - UNICAMP, Campinas, Brazil, [4]Univ Campinas - UNICAMP, Campinas, Brazil
Disclosure Block: **P. Mello MagalhÃ£es:** None.
Introduction: Mesial temporal lobe epilepsy (MTLE) is the most common form of focal epilepsy. MTLE is a genetically complex disease for which the identification of predisposing genes is still elusive. Recent GWAS point to a few genomic regions that may harbor genetic variants predisposing to MTLE. These regions include a locus on chromosome (ch) *2q24.3*, detected in multiple association studies. The ch *2q24.3* region includes the *SCN1A* gene and several other genes that encode ion channel subunits, which could be involved in the predisposition to MTLE. More recently, two additional loci have also been associated with MTLE: *3q25.31* and *6q22.31*. This project aims to look deeper into these candidate loci in a large cohort of patients with MTLE.
Materials and Methods: We analyzed SNPs located within the three candidate regions previously identified on chs *2q24.3*, *3q25.31*, and *6q22.31*. The p-values were adjusted for multiple comparisons.
Results: We studied 472 patients and 415 controls and identified a significant association only at the candidate locus on ch *2q24.3* (p=0.03301). Target re-sequencing of such locus is underway, and new data is expected to be available soon.
Conclusion: We found a significant genetic association for MTLE on ch *2q24.3* in our cohort of patients with MTLE. We also achieved a fine genetic mapping of the candidate region, which is being sequenced to identify putative causative variants. Our study contributes to the ongoing worldwide efforts to unravel the genetics of complex epilepsies.
Supported by: FAPESP, Brazil; CAPES, Brazil.

PrgmNr 2428 - Investigating the contribution of common variants to neurodevelopmental disorders: Expression-modifying variants and polygenic scores

View session detail

Author Block: **E. Wigdor**, E. Arciero, Q. Huang, K. E. Samocha, V. Chundru, M. E. Hurles, H. C. Martin; Wellcome Sanger Inst., Hinxton, United Kingdom
Disclosure Block: **E. Wigdor:** None.
Work from the Deciphering Developmental Disorders (DDD) study has demonstrated an excess of rare, inherited coding variants among â¼5,500 undiagnosed probands with unaffected parents and that such variants are over-transmitted to probands. This suggests these variants contribute to patientsâ disorders but are incompletely penetrant. As common variants explain 7.7% of the variance in risk for rare neurodevelopmental disorders (NDDs) (Niemi *et al*., 2018), we hypothesised that these common variants may modify penetrance of rare coding variants.
Castel *et al*. (2018) have shown that common cis-expression quantitative trait loci (cis-eQTLs) modify the penetrance of deleterious coding variants and contribute to disease risk in cancer and autism cohorts. We investigated whether common cis-eQTL increase the penetrance of inherited rare (MAF
Similarly, we investigated the role of polygenic scores (PGS) in the penetrance of rare coding variants in DD genes in probands and their parents. We found that PGS for cognitive performance, educational attainment and schizophrenia explain a small but significant (p -20) amount of the variance in risk for NDDs (on the liability scale): 0.49%, 0.61% and 0.15%, respectively, 0.85% when combined (N = 6,987 cases; 9,270 controls). We then tested whether these PGS are over-transmitted from unaffected parents to probands with rare coding variants in DD genes (MAF -11 for all comparisons).
Overall, in a large sample size (N = 3,172) of NDD patients, we see no evidence to date that cis-eQTLs or PGS modify penetrance of rare coding variants. Our power is limited by pooling variants across genes (many of which will not be pathogenic) and the low variance currently explained by multi-eQTL models and PGS. We will extend our analysis to ~10K NDD trios in Genomics England to increase our power to detect modifying effects.

PrgmNr 2429 - Mendelian Randomization analysis reveals a potential causal relationship for lipids in amyotrophic lateral sclerosis risk

View session detail

Author Block: **D. Baird**[1], W. van Rheenen[2], Y. Huang[1], M. Bakker[2], C-Y. Chen[1], J. H. Veldink[3], H. Runz[1], E. A. Tsai[1]; [1]Biogen, Cambridge, MA, [2]Univ. Med. Ctr. Utrecht, Utrecht, Netherlands, [3]Univ Med Ctr Utrecht, Utrecht, Netherlands

Disclosure Block: **D. Baird:** Salary/Employment; Biogen Inc.

Deciphering the lipid fractions involved in disease risk is challenging due to the high correlation between the different lipid measures. Multivariable Mendelian randomization (MVMR), which models exposures together, can be used to help resolve the independent causal effects. Therefore, we applied MVMR to lipid and amyotrophic lateral sclerosis (ALS) GWAS data to investigate the role of lipids in ALS aetiology. For the lipid exposures, we used the summary statistics from UK BioBank GWAS conducted by Richardson et al 2020 on low-density (LDL-C) and high-density (HDL-C) lipoprotein cholesterol, triglycerides (TG), apolipoprotein A (ApoA) and apolipoprotein B (ApoB) measures. For the ALS outcome, we used the summary statistics from van Rheenen et al 2021 European GWAS (27,460 cases and 112,018 controls). To obtain the genetic instruments, we selected all genetic associations at P-8 across the lipid measures (after LD clumping). Instrument outliers were identified using radial analysis (Q-8 cut-off, there were 313 independent SNPs available for HDL-C, 145 for LDL-C, 264 for TG, 260 for ApoA and 168 for ApoB, from which 31 SNPs were removed as outliers from the HDL-C, 15 for LDL-C, 22 for TG, 24 for ApoA and 13 for ApoB MR analyses. Before outlier removal, the univariate MR (Inverse Variance Weighted method) suggested a relationship between increased ApoB (OR=1.09, P=0.014) and ALS risk, while other univariate results did not show significant effects (p-values: ApoA 0.144, HDL-C 0.045, LDL-C 0.053, TG 0.519). After outlier removal, evidence for a relationship between increased LDL-C and ALS also emerged (OR=1.10, P=0.0078). However, in the subsequent MVMR analysis, increased levels of ApoA (OR=1.21, P=0.21) rather than ApoB (OR=1.01, P=0.94) showed stronger evidence for an independent effect on ALS risk albeit with nonsignificant p-values. Our MR analysis suggests that lipids may have a causal role in ALS, but we are unable to reliably pinpoint the causative lipids (as the MVMR is underpowered therefore findings inconclusive). We also observed high heterogeneity in the instrument effects so further work will be needed to assess the impact of horizontal pleiotropy on all the MR findings.

PrgmNr 2430 - Polygenic risk score in Multiple Sclerosis: understanding the challenges of the post-GWAS era for complex diseases

View session detail

Author Block: **I. Charles**[1], S. Limou[1], O. Rousseau[1], V. Douillard[1], V. Mauduit[1], P-A. Gourraud[1], N. Vince[2]; [1]CRTI, UniversitÃ© de Nantes, Nantes Cedex 01, France, [2]UniversitÃ© de Nantes, Nantes Cedex 01, France

Disclosure Block: **I. Charles:** None.

Multiple Sclerosis (MS) is a complex disease with an undeniable genetic burden and an important environmental component. In the past 10 years, several MS GWAS identified more than 200 genomic regions, with the strongest signal consistently mapping to the MHC region and HLA-DRB1*15:01. Most of these genetic risk factors only have a slight effect on MS susceptibility (odds ratios (OR) around 1.1). The Multiple Sclerosis Genetic Burden (MSGB) is a polygenic risk score (PRS) developed to summarize patientâ□□s genetic risk. It is calculated on an additive log model using allelic OR as a weight for each SNP. We used GWAS data from the Welcome Trust Case Control Consortium (WTCCC, 18,859 controls and 11,376 cases) to implement a historical approach and better understand MS genetics, by calculating the MSGB using SNPs known in 2011a, 2011b, 2013, 2016 and 2019. As expected, the addition of newly discovered SNPs increased the score. We also observed:

- The 2019 score showed no significant differences between male and female, average of 20.43 and 20.36, respectively. This suggests that women higher MS risk could be explained by environmental factors rather than genetics.
- We do not observe correlation between the first principal component of the ancestry PCA (which reflects the latitude) and the score.
- The effect of the log(OR) weighting is limited by the large number of associated variants, high weighted / unweighted score correlation (r2=0.93). Similarly, the HLA SNPs effect on MSGB is also limited, high with / without HLA score correlation (r2=0.90).
- Case-control scores differences gradually increased: 6 SNP (2011a), Effect Size=0.39Â±0.01; 15 SNP (2016), ES=0.45Â±0.01; 51 SNP (2011b), ES=0.28Â±0.01; 90 SNP (2013), ES=0.34Â±0.01; 184 SNP (2019), ES=0.78Â±0.01. All p-values were below the smallest representable number -308.
- The 2019 score showed larger standard deviation between extreme individuals compared to other scores: 2011a SD=0.68, 2011b SD=0.55, 2013 SD=0.67, 2016 SD=0.75, 2019 SD=0.97.
- The MS individual with the highest 2019 score is not the same MS individual with the highest score in other years. We observe a high variation between the MSGB score of a given individual throughout the years.

PRS calculation is by definition dependent of the genetic data. Here we showed that even though MSGB is consistently higher in MS compared to controls in population, it is highly variable at the individual level. Moreover, we could not identify any genetic impact on known confounding factor in MS (sex and latitude). Overall, our results illustrate the necessity to pursue our effort in exploring PRS in MS disease to better understand genetic component of this complex pathology.

PrgmNr 2431 - Whole genome sequencing association analysis of general cognitive function in a multi-ethnic sample from the Trans-Omics for Precision Medicine (TOPMed) Program

Background: General cognitive function is an index of performance in multiple cognitive domains. GWAS of general cognitive function, conducted mostly in European ancestry (EA) populations, have identified hundreds of genetic variants. However, investigations of rare (MAFMethods: We performed whole-genome sequence (WGS) association analysis for general cognitive function in N=12,615 EA, N=4,419 African ancestry (AA), and N=1,140 Hispanic/Latino ethnicity (HIS) participants from the NHLBI TOPMed Program, after exclusion for dementia, clinical stroke, or age =10), and SKAT-O was used for rare variant aggregation tests (MAF5 alternate alleles). Using SKAT-O, we tested coding variants within genes (high-confidence LoF, predicted deleterious missense and protein-altering) and both coding and non-coding variants within genes and their regulatory elements (enhancers and promoters). Associations were evaluated within and across ancestry/ethnicity with adjustment for age, sex, study, and genetic principal components, before and after adjustment for educational attainment. **Results**: Single-variant association analysis identified three genome-wide significant loci for general cognitive function: intronic in *AMPH* (rs17500486, MAF=3.2%, P=3.4x10^{-8}) in EA, proximal to *FTLP5* and *ATCAY* (rs570203641, MAF=0.1%, P=2.7x10^{-8}) in EA, and upstream of *RN7SL300P* (rs113037723, MAF=8.0%, P=8.8x10^{-9}) in AA. After adjustment for educational attainment, an additional two loci were identified: intronic in *SYNPO2* (rs146805942, MAF=2.1%, P=3.4x10^{-8}) in AA and intronic in *BRINP3* in HIS (rs72729138, MAF=6.6%, P=3.0x10^{-8}). Rare variant aggregation tests identified two suggestive associations using coding variants (*SH3GL3* in EA (P=3.2x10^{-6}) and *P2RY11* in AA (P=9.0x10^{-6})) and one association using coding and noncoding variants (*AC113410.3* in EA, P=9.06x10^{-6}). Of the nine genes identified, all except *RN7SL300P* and *AC113410.3* had previous evidence of association with neuronal development or activity, neurological/cognitive disorders, or cognitive function. No variants or genes were associated with general cognitive function at the genome-wide threshold in the pooled analysis of all ancestry/ethnic groups. **Conclusions**: In this WGS association analysis, we identified several new variants associated with general cognitive function, many of which lie in genes that play a role in brain function. Identified loci tended to be specific to ancestry/ethnicity.

PrgmNr 2432 - An IQ-matched genetic comparison between cases with ASD and typically-developing controls

Disclosure Block: **Z. Schmilovich:** None.

Autism spectrum disorder (ASD) is a clinically and etiologically heterogeneous disorder that affects ~1% of the global population. The estimated heritability of ASD is high (0.65-0.91) and both rare and common variants contribute to ASD-risk. Rare de novo and inherited CNVs that substantially increase ASD-risk are present in 8-14% of cases with ASD. In fact, we have estimated that any CNV genome-wide encompassing genes intolerant to haploinsufficiency increase ASD-risk even after adjusting for their negative effects on cognition. Conversely, there is a strong (rG = 0.199) genetic correlation between ASD and IQ, such that common variants which increase ASD-risk also increase IQ in the general population.

The relationship between genetic risk, cognitive ability, and ASD is paradoxical and remains contentious. We aim to study how rare and common variants interact to confer ASD-risk, while carefully controlling for their effects on cognition using IQ-matched cases and controls.

Standard genotyping QC was performed on cases with ASD from the SPARK cohort (n = 1988) and typically-developing (TD) controls from the IMAGEN cohort (n = 1,503). Samples of inferred European ancestry were selected using the KING software and MDS parameters. Following a 1:1 matching based on NVIQ, 1251 cases and 1251 controls (mean NVIQ = 107) were included. PRS for intelligence using the Savage et al. (2018) GWAS summary statistics were computed using PRS-CS and the PLINK â□□scoreâ□□ parameter. ASD diagnosis was modelled as a function of intelligence PRS, including NVIQ, age, and sex as covariates in the logistic regression.

Our findings showed that cases with ASD had a significantly greater burden (p=1.66e-9; OR=1.32[1.21-1.45]) of polygenic risk for intelligence compared to their TD counterparts adjusted or even matched for IQ. We hypothesize that rare genetic variants (ie.: CNVs) interact with common variation increasing IQ to confer risk for ASD. We will further investigate the interaction or additive effects of these two categories of variants.

Evaluating the combined contribution of rare and common variants across IQ-matched case-control groups may reveal ASD-specific biomarkers - a long-standing aim in the field.

PrgmNr 2433 - Analysis of age- and sex-specific comorbidity patterns among brain disorders

Many research studies describe comorbid neurological and psychiatric disorders in individuals with a brain disorder. Shared genetic risk factors can partially explain the observed phenotypic overlap, with a higher genetic correlation between psychiatric compared to neurological disorders. However, no studies comprehensively examined the comorbidity patterns of neurological and psychiatric disorders across the common types of brain disorders. Additionally, although many studies consider age, only a few studies have examined the sex-specific comorbidity of brain disorders. To fill this knowledge gap, we assessed the co-occurrence of brain disorders across age and sex in a large healthcare system.Based on ICD-10 diagnosis codes, we identified over one million individuals diagnosed with at least one out of 20 common brain disorder types present in the aggregated health care data of eight million patients from the Cleveland Clinic healthcare system. The identified individuals were stratified into six distinct demographic groups based on age (children, adult, and elderly) and sex (male and female). For each of the 20 brain disorders and six demographic groups, we tested the enrichment of each comorbid neurological or psychiatric disorder compared to age- and sex-matched controls without brain disorders. Overall, we performed 2,280 tests and identified 327 significantly associated brain disorder pairs with an odds ratio >4. On average, each brain disorder had five significant comorbidities across all demographic groups. We replicated well-established disease-disease associations such as the co-occurrence of stroke and focal epilepsy. In line with previous evidence, we found that psychiatric disorders had, on average, a greater number of significant associations with other brain disorders compared to neurological disorders. Specifically, individuals with psychiatric disorders were enriched for other psychiatric disorders across all three age groups. We further identified distinct patterns of comorbid brain disorders for each age and sex group. For example, while generalized epilepsy was associated with autism spectrum disorder in children and adults, it was associated with Alzheimerâ□□s disease and stroke in the elderly. Finally, we observed sex-specific differential patterns of enrichment across all tested brain disorders.The goal of this research was to provide a unified resource for the age- and sex-specific clinical relationships between brain disorders. The results of our study will inform the clinical care of patients diagnosed with these conditions.

PrgmNr 2434 - Exome reanalysis of 242 Brazilian trios reveals *NPAS3* as a new possible novel autism risk locus

View session detail

Passos-Bueno[1,2]; [1]Dept. of Genetics and Evolutionary Biology, Univ. of SÃ£o Paulo, SÃ£o Paulo, Brazil, [2]Human Genome and Stem Cell Res. Ctr., Univ. of SÃ£o Paulo, SÃ£o Paulo, Brazil, [3]The Ctr. for Applied Genomics, The Hosp. for Sick Children, Toronto, ON, Canada, [4]Dept. of Molecular Genetics and the McLaughlin Ctr., Univ. of Toronto, Toronto, ON, Canada
Disclosure Block: **G. Campos:** None.
Autism spectrum disorder (ASD) is a complex and heterogeneous neurodevelopmental disorder (NDD) characterized by impairment in social and communication skills, in addition to restricted and repetitive behavior. In the present study, we present a reanalysis of exome sequencing data from 242 Brazilian trios attended at CEGH-CEL, in SÃ£o Paulo, Brazil, and sequenced by the Autism Sequencing Consortium. Our cohort has been evaluated by neurologists, psychiatrists, or neuropediatrician and diagnosed with ASD. We primarily address rare *de novo* variants in autism risk genes (compiled in SFARI Human Gene Module) and describe 20 *de novo* pathogenic variants, totaling an 8,26% (20/242) molecular diagnosis rate. Most of these variants take place in well-established genes, but we report a new variant (NM_003957:c.956dupT, in addition to c.1617A>C) in the newly associated gene *BRSK2* (#MIM 609236). *BRSK2* was linked to NDDs, including ASD, and to date, only nine patients were reported in the literature. We are also looking for new candidate genes associated with ASD. Currently, we are analyzing *NPAS3* (#MIM 609430), a gene that encodes a transcription factor involved in the regulation of other genes during neurogenesis; it was already associated with schizophrenia and cognitive disability, and mice lacking both *Npas3* and *Npas1* have behavioral and neurochemical alterations. *NPAS3* is absent in SFARI and is not associated with any condition in OMIM. Our patient had regression at age 1 and at the time she was evaluated had mild ASD features and motor difficulty. She harbors a *de novo* stop-gain variant (NM_001164749:c.400C>T; p.Arg134Ter) that is absent in the control population, predicted to be deleterious (CADD score >42) and results in loss of the two PAS protein domains. *NPAS3* is intolerant to null variation (pLI=1; o/e= 0.2); there is only one equivalent loss of function variant in the gnomAD database, specifically in the neuro subset. We also identified an ASD patient in the MSSNG database with a predicted splicing disruptive *de novo* variant. Therefore, we elevate *NPAS3* as a possible novel autism risk gene candidate. Identification of additional cases will be of utmost importance to confirm this hypothesis. Altogether, this work contributes to the estimation of a molecular diagnostic rate in a diverse cohort of ASD and description of new variants, since 11/20 variants were not reported before, adds clinical and molecular information to the delineation of *BRSK2* associated Mendelian condition and suggests a novel ASD candidate. Financial support: FAPESP/CEPID 2013/08028-1.

Severe mental health disorders are the leading cause of disability in the United States. The impact of these diseases underscores the importance of elucidating genetic markers that predispose an individual to developing a psychiatric disorder. Our work extends beyond prior research that has detected associations via GWAS or linkage analyses. We use whole genome sequencing (WGS) of family trios to identify rare variants that may underlie psychiatric disorders, including bipolar disorder, early-onset psychosis, autism, and depression/suicide. For this pilot study, we anticipate enrollment of at least 80 individuals from 20 families, half of which have already been sequenced. Eligible families are referred by physicians and behavioral health providers at Nationwide Childrenâ□□s Hospital, frequently following psychiatric inpatient admissions. Participating family members are administered structured diagnostic interviews as a measure of their own psychological well-being, as well as a comprehensive Family History Screen (FHS) to assess for psychiatric illness in the extended family. In a 17-year-old male who presented with severe early-onset bipolar 1 disorder with psychotic features, WGS revealed a de novo missense mutation (c.3501T>A) in CACNA1D, an L-type calcium channel gene that has been implicated previously in bipolar disorder. In another family, a 16-year-old female with a diagnosis of Prader-Willi syndrome (PWS) presented with severe psychosis and a maternal family history of bipolar disorder. Genome sequencing uncovered a unique pattern of mixed, maternally-inherited uniparental disomy (UPD) affecting two distinct locations along chromosome 15: the PWS critical region, and a distal region (15q25-26) implicated in bipolar susceptibility. These findings illustrate the power of whole-genome sequencing to identify rare large-effect variants contributing to severe, early-onset presentations of otherwise complex psychiatric conditions.

PrgmNr 2436 - Genome-wide rare variant score associates with morphological subtypes of Autism Spectrum Disorder

Defining different genetic subtypes of Autism Spectrum Disorder (ASD) can help enable the prediction of developmental outcomes. Rare variant studies often use burden analyses to compare the frequency of rare variants, equally weighted, between cases and controls or among ASD subtypes. However, effect sizes depend on the affected gene and variant type, and these variables should be considered in rare variant analyses. Here, we used whole-genome sequencing (WGS) data and detailed clinical morphology data from two independent cohorts to: 1) develop a genome-wide rare variant score (GRVS) to measure the relationship between rare variants and dysmorphology, and 2) examine the contribution of rare and common variants in morphological ASD subtypes. Based on minor physical and major congenital anomalies, we categorized 325 Canadian children into dysmorphic (n=138) and non-dysmorphic (n=181) ASD. We identified clinically significant single nucleotide variants, short insertions/deletions and copy number variants in 14.2% (46/325) of ASD cases. The yield of clinically significant variants (CSVs) was significantly higher in dysmorphic (25.9%; 35/135) compared to non-dysmorphic (5.8%, 11/190, p=8.7Ã□10^{-5}) ASD. We developed a method to calculate a GRVS from WGS in each individual. GRVS is a weighted sum of the number of variants in morphology-associated coding and non-coding regions, weighted by their effect sizes. Probands with dysmorphic ASD had a significantly higher GRVS compared to those with non-dysmorphic ASD (*P*= 0.027). Using the GRVS formula, we calculated a score for CSVs that overlapped a morphology-associated region. In 47% of probands with CSVs, CSVs contributed to the majority (>50%) of GRVS. When we excluded the 46 probands with CSVs, those with dysmorphic ASD still had significantly higher average GRVSs than those with non-dysmorphic ASD (*P*= 0.048). Using the polygenic transmission disequilibrium test, we observed an over-transmission of ASD-related common variants in non-dysmorphic ASD probands (*P*= 2.9Ã□10^{-3}). We replicated our findings using WGS data from 442 ASD probands that had accompanying morphology data from the Simons Simplex Collection. Our findings provide support for an alternative genomic classification of ASD subgroups using morphology data, which may inform intervention protocols. The GRVS method can also be applied to future studies to better measure the full impact of rare variants on susceptibility to ASD and other complex disorders.

Cigarette smoking is associated with persistent neurochemical and pathological changes in brain. Recently UK Biobank retrieved MRI data from healthy individuals which allows for the opportunity to identify pre-symptomatic markers for neuropathological conditions associated with smoking behaviors.
Using the currently available subset of UK Biobank data of 19,301 individuals, we first studied the association between cigarette smoking and brain imaging-derived phenotypes (IDPs). We used total of 359 IDPs (305 structural MRI-derived phenotypes and 54 diffusion MRI-derived phenotypes). Smokers were divided into 1) Current daily smokers (n=799), former daily smokers (n=4,324), former occasional smokers (n=2,385), non-smokers who smoked less than 100 cigarettes (n=3,290) and never smokers (n=8,247). We performed regression analyses to measure the association between 359 IDPs and 1) smoking status and 2) pack years. Then we created smoking-related polygenic risk scores (PRSs) using summary statistics from GWAS & Sequencing Consortium of Alcohol and Nicotine use. After assessing its predictive ability for UK Biobank smoking phenotypes, we performed regression analyses to observe the association between PRSs and IDPs.
Current daily smokers (compared to never smokers) had strong association after correcting for multiple testing with 48 of 359 IDPs, former daily smokers had 72 associations, former occasional smokers had 1 association, and non-smokers had none. The brain regions most significantly associated were caudate, putamen, amygdala, pallidum and thalamus for both current and former daily smokers. Tract posterior thalamic radiation was most significant for the two groups. The statistical significance for these regions and the tract decreased for former occasional smokers. The dose-effect of smoking (pack years) generally showed that higher dose of cigarettes was associated with decreased brain volume and white matter integrity. For PRSs and IDPs, smoking cessation PRS was significantly associated with volumes in putamen, pallidum and accumbens while cigarettes per day PRS was associated with volume in putamen and smoking initiation PRS with volume in pallidum. This study aims to establish a link between genetics, brain, and smoking behavior. By dividing the smokers into different groups and observing the dose-effect of cigarettes, we concluded that depending on the smoking dosage, the brain can either be recovered or permanently affected following smoking cessation. Also, PRS showed how genetic predisposition to different stages of smoking behavior can affect different regions of the brain.

PrgmNr 2438 - Interactions between variants in detoxification and permeability barrier genes and xenobiotics in Autism Spectrum Disorder

View session detail

Author Block: **J. Xavier Santos**[1,2], A. Marques[1,2], C. Rasga[1,2], H. Martiniano[1,2], J. Vilela[1,2], A. M. Vicente[1,2]; [1]NIH Doutor Ricardo Jorge, Lisbon, Portugal, [2]Faculdade de CiÃªncias, BioISI - Biosystems & Integrative Sci. Inst., Univ.e de Lisboa, Lisbon, Portugal
Disclosure Block: **J. Xavier Santos:** None.
Introduction: While heritability estimates of 50-80% suggest that gene-environment interactions may contribute to the etiology of Autism Spectrum Disorder (ASD), there are insufficient studies simultaneously addressing both components. Thus, we implemented the GEnvIA project, aiming at the integration of genetic variants and early-life exposure data collected from ASD-subjects. The objectives of the current work were: 1) to identify Single Nucleotide Variants (SNVs) in a panel of 18 genes (the XenoReg gene panel), that regulate detoxification and permeability barriers (placenta and blood-brain barrier - BBB) processes, in ASD subjects; 2) to search for interactions between these genes and xenobiotics implicated in ASD. **Methods:** Samples from 218 ASD subjects were sequenced using Illumina platforms. GATK best practices were applied for read alignment and variant calling. Variant functional annotation was done with Variant Effect Predictor tool. Only rare (gnomAD MAF in silico were considered. The Comparative Toxicogenomics Database (CTD) was interrogated for gene-environment interactions. **Results:** In 60/218 (27.5%) subjects, we identified 55 unique variants (4 LoF and 51 missense) in 16 out of the 18 XenoReg genes. These included *CYP2A13*, *CYP4X1*, *NQO1*, *STS*, *UGT2B10* and *UGT2B15,* which encode enzymes responsible for the metabolism of xenobiotics; *ABCA8, ABCB1, SLC3A2* and *SLC22A5,* which encode transporters controlling the flux of toxins across the BBB and placenta; *CLDN3* and *TJP3* that encode components of BBB tight junctions; and *KIF17* a kinesin likely involved in the formation of the placenta. Based on CTD query we constructed a novel gene-environment interactions network putatively relevant for ASD, revealing that all 16 genes interact with xenobiotics implicated in ASD, including benzo(a)pyrene, bisphenol A, particulate matter, phthalates, pesticides and valproic acid. These are ubiquitous neurotoxins, present in everyday products, to which exposure can, at some extent, be mitigated. **Discussion:** Given the extreme vulnerability of the developing brain to toxins, subjects with variants in XenoReg genes might be at higher risk of ASD onset due to early-life exposure to ubiquitous xenobiotics even at permitted concentrations. The dysregulation of detoxification and barrier permeability processes may lead to the buildup of toxins in the immature brain, culminating in neuropathological processes (eg. epigenetics, oxidative stress, neuroinflammation and endocrine disruption) that impair neuronal, synaptic and chromatin remodeling functions associated with ASD.

PrgmNr 2439 - Polygenic scores for cortical and subcortical brain structures are associated with cognition

View session detail

Author Block: **T. Silzer**[1], C. Burton[1], M. Lemire[1], P. Arnold[2], R. Schachar[1], J. Crosbie[1]; [1]Hosp. for Sick Children, Toronto, ON, Canada, [2]Univ. of Calgary, Calgary, AB, Canada
Disclosure Block: **T. Silzer:** None.
Background. Variation in brain structures has been linked to neuropsychiatric disorders including schizophrenia, attention deficit-hyperactivity disorder (ADHD) and autism spectrum disorder. Across these disorders, cognitive deficits are common. Genetics plays an important role in determining both brai structure and cognition; however, a gap exists in our understanding of the potential shared genetic variation between brain structure and cognitive function. The purpose of the study was to test if polygenic scores (PGS) derived from GWAS of global and regional brain structures (e.g. surface area and thickness) were associated with aspects of cognition (e.g. response variability). **Methods.** PGS were computed in the population-based Spit for Science sample of children and youth (N=~5200) from summary statistics of genome-wide meta-analyses of global and regional cortical and sub-cortical surface area and thickness (N=~30,000) published by the Enhancing Neuro Imaging Genetics Through Meta-Analysis (ENIGMA) consortium. PGS were generated using PRSice v1.25. PGS were tested for association with aspects of cognition (e.g. response variability), as measured by the Stop Signal Task in Spit for Science. **Results and Conclusion.** Preliminary results indicate a lack of global brain structure correlates but a presence of regional associations with cognition. However, significant brain region associations suggest that genetic variation underlying specific cortical and sub-cortical structures may be linked to key features of neuropsychiatric disorders. Study findings will have direct implications for understanding the potential shared biology of brain structure and cognition, and the genetic etiology of neuropsychiatric disorders that feature deficits in cognition. Future works will also investigate the genetic overlap between regional brain volume and cognition.

MÃ©niÃ¨re disease (MD) has been a biological conundrum since its recognition in 1861. MD is a moderately common, complex disorder characterised by episodes of vertigo/nausea and fluctuating but progressive hearing impairment, often accompanied by tinnitus. It affects approx. 1/2,000 people of European origin (females > males) and is associated pathologically with endolymphatic hydrops. MD is often associated with considerably reduced quality of life and there are few effective non-surgical therapies. It is often confused with other vestibular and migraine-related disorders, and is comorbid with a variety of neurological and psychiatric conditions, including depression. The aetiology of MD is largely unclear. Previous HLA association reports are thus far uncorroborated in large cohorts. About 95% of cases are sporadic, with 5% familial. There are a few, thus far unreplicated, reports of rare, high-penetrance variants/loci associated with MD status within families or in sporadic cases. There are no reliable estimates of heritability. We hypothesized a polygenic component to MD in sporadic cases and carried out a case/control GWAS in UK Biobank to elucidate causal loci and aspects of the genetic epidemiology of MD.

Our analysis used 2,594 likely MD cases ascertained via either self-report, hospital inpatient records or primary care records, and approx. 441K controls excluding individuals with a history of vestibular problems. GWAS analysis using SAIGE (adjusting for age, sex, genotyping chip and evaluation centre) revealed one genome-wide significant locus in Chr. 2q14.1 (lead SNP: rs3977027; MAF = 0.15; $p = 2.9 \times 10^{-8}$), within an intron of *CBWD2*. Ancillary and downstream analyses are ongoing, but there is evidence for a small polygenic contribution, though SNP heritability estimates are low (g values 0.25 - 0.41; FDR-adj. $p = 0.020$ - 0.034), negatively genetically correlated with educational attainment (r_g -0.34; FDR-adj. $p = 0.034$) and nominally correlated with coeliac disease. These findings support a biological basis for MD, but with a modest genetic component, and establish a biological connection, based on pleiotropy or mediated effects, between MD and mood/anxiety-related brain functionality. Further understanding of the biology of MD will inform the development of more effective preventative and therapeutic approaches aimed at improving quality of life for sufferers.

PrgmNr 2443 - A phenotype-driven machine-learning model to assess the pathogenicity of digenic variant combinations: a case study on ciliopathies

View session detail

Author Block: **F. De Paoli**[1,2], I. Limongelli[1], S. Zucca[1], F. Baccalini[2], V. Serpieri[3,4], F. D'Abrusco[4], E. M. Valente[3], P. Disclosure Block: **F. De Paoli:** None.
Background:
For decades, the inheritance mechanism of genetic disorders was explained through the '*one-gene, one-disease*' paradigm according to which mutations affecting a single gene could be causative of several rare Mendelian disorders. Recently, more complex genetic models have been proposed to explain a series of genetic disorders which could not be solved through a single causative mutation, such as digenic or oligogenic inheritance. In the digenic model, two different mutated genes concur to cause the patient's phenotype. Here, we propose a method (DIVAs) to assess the pathogenicity of digenic variant combinations.
Methods:
DIVAs is a sophisticated machine learning model developed to classify combinations of variants on two different genes according to patient's phenotypes. The input to this model is the list of variants identified in the patient and a set of Human Phenotype Ontology terms describing his medical condition. Model features capture all the characteristics of a variant combination and its association with patient's phenotypes at variant, gene and gene-pair level. The output reports the list of all possible combinations, ranked according to their probability of causation. The algorithm was trained and tested on a dataset of validated pathogenic (http://dida.ibsquare.be, internal database and public literature review) and benign (https://www.internationalgenome.org/) variant combinations.
Results:
DIVAs was preliminary validated on an independent dataset of 78 cases published in the scientific literature (sensitivity 82%). The algorithm was then tested on 4 solved digenic clinical cases for which WES data were available. All the cases were related to the wide and genetically heterogeneous disease spectrum of ciliopathies whose genetic diagnosis could be driven by an oligogenic inheritance pattern. First, two male siblings with complex traits such as microcephaly, intellectual disability and seizures have been analyzed through our algorithm: DIVAs correctly classified the pathogenic variant combination involving *FRMPD4* and *PAK3* genes and ranked it in the first position. Second, DIVAs correctly prioritized the *TMEM67-MKS1* digenic combination which explains the complex traits of two fetuses affected by Meckel-Gruber syndrome, a lethal form of ciliopathy. DIVAs was also tested on unsolved cases of patients with suspected ciliopathy and results interpretation is ongoing.In conclusion, our method proved to be reliable to identify causative digenic variant combinations, contributing to uncover the missing heritability of rare genetic disorders.

PrgmNr 2444 - Associated anomalies in cases with oral clefts

View session detail

Author Block: **C. Stoll**; Laboratoire de Genetique Med.e, Strasbourg, France
Disclosure Block: **C. Stoll:** None.
Cases with oral clefts (OCs) often have other associated congenital anomalies. The reported prevalence and the types of associated anomalies vary between different studies. The purpose of this investigation was to assess the prevalence and the types of associated anomalies in a geographically well defined population. The prevalence and the types of associated anomalies in cases with OCs were collected in all live births, stillbirths and terminations of pregnancy between 1979 and 2007 in 387,067 consecutive births in the area covered by our population-based registry of congenital anomalies. Of the 789 OCs cases ascertained during this period (prevalence of 20.4 per 10,000 births), 39.5% had associated non-OCs anomalies. Associated anomalies were more frequent in cases with cleft palate (52.4%) than in cases with cleft lip and palate (37.3%) and in cases with cleft lip only (16.8%). There were 94 (11.9%) cases with chromosomal abnormalities, including 27 trisomies 13, 15 trisomies 18, 12 22 q11.2 deletion, and 40 other chromosomal abnormalities, 38 (4.8%) cases with non-chromosomal recognizable conditions including syndromes, associations, spectrums and sequence and 180 cases (22.8%) with multiple congenital anomalies (MCA). Anomalies in the musculoskeletal system (16.7%), the central nervous system (15.0%), the urogenital system (13.7%), the cardiovascular system (8.6%), and the digestive system (6.6%) were the most common MCA. The overall prevalence of associated anomalies emphasizes the need for a thorough investigation of cases with OCs. A routine screening for other congenital anomalies need to be considered in infants and in fetuses with OCs.

PrgmNr 2445 - Characteristics of keratoconus corneal epithelium in multi-omic approach

Disclosure Block: **K. Jaskiewicz:** None.
Introduction: Keratoconus (KTCN) is a corneal disease, characterized by multifaceted etiology with genetic heterogeneity. KTCN affects 1:2000 individuals worldwide and causes substantial vision impairment on account of increased thinning. Due to pathological cone formation, the corneal epithelium (CE) in KTCN patients demonstrates a specific doughnut pattern, therefore we aimed to implement a multi-omic approach to assess in detail three distinct CE regions.
Materials and Methods: The CE samples collected during the cross-linking procedure in X KTCN patients and refractive error correction in Y myopia individuals as non-KTCN controls were separated into central, middle, and periphery regions regarding cone location. All individuals underwent detailed ophthalmological examination. The RNA/DNA/protein samples were extracted simultaneously (RNA/DNA/Protein Purification Plus MicroKit, Norgen Biotek) towards WGS (30x coverage), RNAseq (TruSeq Stranded Total RNA LibraryPrep Gold, 100mln reads/sample), and MALDI-TOF MS analyses. The obtained data were integrated.
Results: The average CE thickness values of the three analyzed regions were found to be statistically different in KTCN patients showing a characteristic doughnut pattern. The GO analysis of the 3 youngest patientsâ gene variants points to changes in pathways of immune responses and extracellular matrix composition. The effect of sex on transcriptomic and proteomic profiles was revealed. Still, we identified differentially expressed pathways involved in an extracellular matrix organization, collagen-containing extracellular matrix, and apoptosis. Characteristics of the KTCN proteomic profile were obtained.
Conclusions: The results allowed to characterize the KTCN cone corneal regions, and further pointed to the KTCN genetic heterogeneity. The differences found between the three CE regions reflect the thickness abnormalities in the KTCN cone.
Support: The National Science Centre grant no.2018/31/B/NZ5/03280.

PrgmNr 2447 - Extreme Expression Genotypes revealed regulatory effects on gene expression linked to traits and footprints of positive selection

View session detail

Author Block: **A. Sartori**[1], T. Dupuis[2], A. Brown[3], E. T. Dermitzakis[4]; [1]Genetic Med. and Dev., Univ. of Geneva, Geneva, Switzerland, [2]Population Hlth.and Genomics, Univ. of Dundee, Sch. of Med., Dundee, United Kingdom, [3]Univ. of Dundee, Dundee, United Kingdom, [4]Univ. of Geneva, Geneva, Switzerland
Disclosure Block: **A. Sartori:** None.
Rare variants can have effects on gene expression with mendelian-type consequences for disease risk. Similarly, we have now observed that genes can be regulated by multiple independent common variants (independent *cis*-eQTLs), with 686 genes identified in the latest GTEx release as regulated by 4 or more *cis*-eQTLs. In this study, we hypothesize that combinations of *cis*-eQTL alleles with common direction of effect could show as extreme cumulative effects as those observed for rare variants, and with similar downstream consequences on disease risk. We refer these multiple consistent eQTL alleles as Extreme Expression Genotypes (EEG). Using eQTLs from 49 GTEx tissues, we defined EEGs for genes with 2 or more eQTLs and tested them for association with BMI on 405719 individuals in the UK Biobank cohort. BMI was chosen as a robust polygenic phenotype, with an important causal role in disease. We found 61 significant associations between predicted extreme expression and BMI, 45 extreme predicted high expression and 16 with extreme predicted low gene expression. Among the top BMI-associated genes for high EEG there were MON1A (p = 3.04E-11), GDPD3 (p = 7.92E-10) and TMEM19 (p = 1.52E-09). The top associated low EEG effect genes were RBM6 (p =5.8E-11), GBA (p = 1.16E-08) and EIF3CL (p = 2.90E-08). We are currently investigating for footprints of positive selection on these EEHs by applying Extended Haplotype Homozygosity based - statistics.

PrgmNr 2448 - From GWAS to GWANN: Genome Wide Artificial Neural Networks and the interpretability of non-coding associations

View session detail

Author Block: **R. van der Winden**[1], A. van Hilten[1], A. Lal[2], L. Slim[2], J. Israeli[2], W. J. Niessen[1,3], H. W. Clifford[2], G. V. Roshchupkin[1]; [1]Erasmus MC, Rotterdam, Netherlands, [2]NVIDIA, Santa Clara, CA, [3]Delft Univ. of Technology, Delft, Netherlands
Disclosure Block: **R. van der Winden:** None.
While we have learned that many human traits and health conditions have genetic components, our understanding of the underlying processes is still limited due to the complexity of polygenic phenotypes. Approaches like GWAS have shown success in identifying genetic variants associated with various traits, however, most of those variants are non-coding and, in some way, regulate gene expressions. Non-coding genome annotation resources can give more knowledge about disease etiology and individual differences in humans, but we are still far away from understanding the complex relationships between genetic variants and traits.
More advanced modeling methods, such as artificial neural networks, are beginning to emerge with the aim of tackling such complexity. Several of these, such as our GenNet framework and Microsoftâ□□s Biologically Annotated Neural Networks, aim to balance complexity with interpretability by using architectures that are based on biological annotations. This somewhat solves the issues of understanding the underlying biology, but these models are not yet truly genome-wide, being limited to coding regions due to computational burdens.
Here, we present an expanded GenNet framework which links non-coding variants to nearby gene models. The network uses the whole genotype array for each individual as input (~780,000 variants). Subsequently, each variant is connected to their nearest gene to construct a second network layer of 23,654 neurons, which represent genes. We have trained the network on several traits from the UK Biobank cohort, such as hair color (9,615 cases and 9,718 controls) and type 2 diabetes (12,619 cases and 12,812 controls).
Training the network on a single GPU (NVIDIA Tesla K40m) took an average of 2.8 hours. For red hair, the model reaches an area under the curve (AUC) of 0.95 and an accuracy of ~87%. For diabetes type 2, the AUC is 0.62 with an accuracy of ~59%, versus an AUC of 0.54 achieved with the exome-based network. The five most important genes for the identification of diabetes type 2 are *GRM7*, *BRCA2*, *NYAP2*, *RBFOX1* and *LDLR*. Four out of five of these genes have previously been linked to type 2 diabetes.
Here we have demonstrated a proof of concept of the extended GenNet framework, which uses all variants on a genotype array and shows greater predictive power compared to other methods.

PrgmNr 2449 - Fusion of multiplex whole-exome and low-depth whole-genome sequencing for cost-effective rare variant assessment in the genome-wide association studies

Bourque[3,4,1,5], J. Ragoussis[3,1], v. Mooser[3,2,1]; [1]McGill Univ., Montreal, QC, Canada, [2]Canada Excellence Res. Chair (CERC) Program in Genomic Med. at McGill Univ., Montreal, QC, Canada, [3]McGill Genome Ctr., Montreal, QC, Canada, [4]Canadian Ctr. for Computational Genomics (C3G), Montreal, QC, Canada, [5]Kyoto Univ., Kyoto, Japan
Disclosure Block: **D. Taliun:** None.
Rare genetic variants (minor allele frequency We sequenced an Ashkenazi Jewish trio (HG002, HG003, and HG004) using: (i) traditional WES at ~96X and ~84X in coding and UTR regions, respectively; (ii) $WEGS_{2X}$ â 4-plex WES at ~110X in coding regions and WGS at ~2X; (iii) $WEGS_{5X}$ â 4-plex WES at ~110X in coding regions and WGS at ~5X. We increased the coding region coverage in WEGS to compensate for the increase in GC bias due to multiplexing. We performed SNV and indel calling following the GATK4 best practices pipeline and evaluated precision and recall against high confidence variant calls from the Genome in a Bottle Consortium. The SNV calling precision in coding regions was concordant between WEGS (~0.996) and WES (~0.997), while recall was slightly lower in $WEGS_{2X}$ and $WEGS_{5X}$ (~0.983 and ~0.985 vs. 0.995, respectively). WES had higher rates of both precision (~0.957) and recall (~0.980) for indels in coding regions compared to $WEGS_{2X}$ (~0.918 and ~0.960, respectively) and $WEGS_{5X}$ (~0.920 and ~0.965, respectively). Although $WEGS_{5X}$ showed a slight increase in variant calling accuracy in coding regions compared to $WEGS_{2X}$, it detected more SNVs (~2,1M vs. ~1,5M) and more indels (339K vs. 215K) in non-coding regions and showed better results in downstream genotype imputation (~3,6M vs ~3,1M imputed SNVs with imputation quality r2>0.3).

In summary, we experimentally demonstrate that WEGS maintains similar precision and recall in the discovery of short coding variants compared to traditional WES, but at the same time allows for the assessment of low-frequency and common variants in non-coding part of the genome. Because WEGS pools 4 samples simultaneously and uses smaller UTR-free target sequence capture, this approach could serve as a cost-effective alternative between traditional WES and high-coverage WGS in genetic association studies.

PrgmNr 2450 - Genetically independent phenotype analysis identifies LPA and VCAM1 as drug targets for human ageing

The length and quality of life is important to us all, yet identification of promising drug targets for human ageing using genetics has had limited success. Here, we combine six large European-ancestry genome-wide association studies (GWAS) of human ageing traitsâ□□healthspan, father and mother lifespan, exceptional longevity, frailty index, and self-rated healthâ□□in a principal component framework which maximises their shared genetic architecture. The first principal component (GIP1) is more heritable than the original studies and shows strong genetic correlations with length of life as well as multiple indices of mental and physical wellbeing. We identify 27 genomic regions associated with GIP1, and provide additional, independent evidence for an effect on human ageing for loci near *HTT* and *MAML3* using a study of Finnish and Japanese subject survival. Across the genome, GIP1 associations are enriched in genes involved in haem metabolism and pathways related to transcription, neurogenesis, homeostasis, proteolysis, intracellular signalling, immunity, and the muscle system. Finally, using proteome-wide two-sample Mendelian randomisation and colocalisation, we provide robust evidence for a detrimental effect of blood levels of apolipoprotein(a) (LPA) and vascular cell adhesion molecule 1 (VCAM1) on GIP1. Together, our results demonstrate that combining multiple ageing traits using genetic principal components enhances power to detect biological targets for human ageing.

PrgmNr 2451 - Genome-wide investigation of the interplay between age-related hearing loss, tobacco smoking, and noise

In the US, approximately 33% of the population aged 65 to 74 suffers from hearing loss. Although age-related hearing loss has been linked to several adverse physical and mental health outcomes, information on genetic susceptibility and how it moderates the effect of known environmental risk factors is limited. We conducted a large-scale genome-wide association study of self-reported hearing difficulties among >400,000 unrelated participants of European descent in the UK Biobank (ages 37-73). Eighty-three independent genome-wide significant (GWS) loci (PKLHDC7B rs36062310 (P=2.63E-32). Many of GWS variants mapped to genes regulating the development and function of the inner ear. Some of the loci identified have also been previously associated with personality disorders and psychological traits (e.g., rs483143 with anxiety, neuroticism, and unipolar depression; rs12938775 neuroticism and depressed affect). The gene ontology for the loci associated with self-reported hearing difficulty were enriched in processes involved in sensory perception (GO:0050954, P=1.14E-05), nervous system synaptic processes (GO:1905244, P=7.26E-06), and cytoskeletal morphology (GO:0014731, P=2.81E-05). To further investigate hearing loss biology, we conducted a multivariate gene-by-environment analysis, testing simultaneously the interactive effects of traits related to noise and tobacco smoking. Among the GWS loci, several variants showed interactive effects with the noise-smoking covariance matrix (e.g., rs2173109, rs55938136, and rs1170465). In summary, our findings provide the first genome-wide evidence of the complex interplay linking genetic variation and environmental risk factors in the context of age-related hearing loss.

PrgmNr 2452 - Global Biobank Meta-Analysis Initiative: A genome-wide association meta-analysis identifies novel primary open-angle glaucoma loci and shared biology with vascular mechanisms

View session detail

Disclosure Block: **V. Lo Faro:** None.

Primary open-angle glaucoma (POAG) is a complex eye disease characterized by progressive loss of optic nerve function that if untreated ultimately leads to irreversible blindness. To date, the biological mechanisms causing POAG are still unclear. A vascular hypothesis of unstable ocular perfusion has been suggested to explain the process of optic nerve damage. However, no study has previously provided a detailed exploration of the biology underlying the potential vascular connection with POAG. The Global Biobank Meta-Initiative (GBMI), a collaboration of 20 global biobanks, provides an exceptional resource to examine potential shared vascular POAG biology. A large-scale Genome-wide association studies meta-analysis was conducted in subjects sourced from 15 global biobanks and from six ancestries (n=1,487,447). A total of 59 statistically significant loci-trait associations were identified, seven of which were novel. Four loci encompassing the genes *ZFP91-CNTF, GLYAT, KALRN, CCDC13, MIR2054* and *INTU* were tested and replicated in an independent POAG cohort (n=383,500). To add biological context to these variant-trait associations, we performed TWAS using JTI cis models in 24 GTEx tissues potentially relevant to ocular conditions. We then performed fine-mapping identifying 29 gene-trait associations, five of which have been implicated or have vascular related functions: *CDKN2B, SLC35E2A, ITGB5* and *MYL4*. Further, we performed a gene enrichment analysis in which morphology and development of blood vessels, and angiogenesis pathways were significantly enriched. A gene prioritization analysis found 60 co-regulated genes of which 39 were novel. In total, 15 of the 39 novel POAG genes identified were associated with blood regulation, cardiac disease and arterial stiffness measurement. We did extensive statistical validation analysis of genes in *SIX6* and *CDKN2B-AS1* loci, previously implicated in POAG, cardiovascular diseases and cancers across multiple ancestries. Results from this analysis confirmed that the TWAS association signals in these loci are attributed to the sentinel rs33912345 missense variant in the SIX6 gene and variants linked to the *CDKN2B-AS1* gene. We also found evidence of significant interaction between the rs33912345 and causal variants in chr9p21.3, with concomitant effect on expression of the genes *CDKN2A* and *CDKN2B*. We confirmed shared biology between cardiovascular diseases and POAG by performing meta-analysis cis model TWAS-PheWAS across the whole phenome in BioVU and UKbiobank data (n=456,423). Taken together, these findings enforce the contribution of genes involved in vascular mechanisms to POAG pathogenesis.

PrgmNr 2453 - GWAS and ExWAS of blood Mitochondrial DNA copy number identifies 71 loci and highlights a potential causal role in dementia

View session detail

Disclosure Block: **M. Chong:** Consultant/Consulting Fees/Other Remuneration; Bayer.

Background: Mitochondrial DNA copy number (mtDNA-CN) is an accessible blood-based measurement believed to capture underlying mitochondrial function. The specific biological processes underpinning its regulation, and whether those processes are causative for disease, is an area of active investigation.

Methods: We developed a novel method for array-based mtDNA-CN estimation suitable for biobank-scale studies, called â□□AutoMitoCâ□□. We applied AutoMitoC to 395,781 UKBiobank study participants and performed genome and exome-wide association studies, identifying novel common and rare genetic determinants. Finally, we performed two-sample Mendelian Randomization to assess whether genetically low mtDNA-CN influenced select mitochondrial phenotypes.

Results: Overall, genetic analyses identified 71 loci for mtDNA-CN, which implicated several genes involved in rare mtDNA depletion disorders, dNTP metabolism, and the mitochondrial central dogma. Rare variant analysis identified SAMHD1 mutation carriers as having higher mtDNA-CN (beta=0.23 SDs; 95% CI, 0.18- 0.29; P=2.6x10-19), a potential therapeutic target for patients with mtDNA depletion disorders, but at increased risk of breast cancer (OR=1.91; 95% CI, 1.52-2.40; P=2.7x10- 8). Finally, Mendelian randomization analyses suggest a causal effect of low mtDNA-CN on dementia risk (OR=1.94 per 1 SD decrease in mtDNA-CN; 95% CI, 1.55-2.32; P=7.5x10-4).

Conclusions: Altogether, our genetic findings indicate that mtDNA-CN is a complex biomarker reflecting specific mitochondrial processes related to mtDNA regulation, and that these processes are causally related to human diseases.

There is extensive evidence linking higher body mass index (BMI) to higher risk of depression in adult European ancestry populations. However, our understanding of the relationship across different settings and ethnicities is limited. A recent East Asian (EAS) genome-wide association study (GWAS) of major depression showed an inverse genetic correlation of major depression with BMI (r_g=-0.212, SE=0.084). Here, we investigate the relationship between BMI and depression in EAS using a) summary statistics from the recent EAS major depression GWAS and b) individual level data in the China Kadoorie Biobank (CKB). Mendelian randomisation (MR) methods were used to test the relationships of BMI with depression. Firstly, two-sample MR was performed using major depression summary statistics from up to 15,771 cases and 178,777 controls of EAS ancestry. We repeated these analyses using a clinical measure of depression and stratifying by home location status: East Asia versus UK or USA. Secondly, one-sample MR approaches were used within CKB to investigate the relationship between higher BMI and depression in up to 100,377 individuals. Here, we tested the effects in men and women separately and compared estimates in urban versus rural dwellers.2-sample MR implied that higher BMI was associated with lower risk of depression in East Asians. For example, using a clinical depression definition and the IVW method, one-SD higher genetically-instrumented BMI was associated with lower odds of depression [OR: 0.96, 95% CI:0.93, 0.98]. Stratifying by location, there was little evidence for an inverse association for samples with East Asian ancestry living in the UK or USA, but there was for those living in East Asian countries. Consistent with this, one-sample MR in CKB also found an inverse relationship between BMI and depression [OR: 0.77, 95%CI:0.63, 0.95]. Higher BMI was consistently associated with lower odds of depression in rural dwellers in the CKB but, among urban participants, the inverse relationship was only seen for men.This study is the first formal MR analysis performed in an EAS cohort and suggests an inverse relationship between BMI and depression in this population. This is in contrast to European populations, in which genetically determined higher BMI associates with higher odds of depression. This suggests potential setting-specific causality, which is further evidenced by the lack of association between BMI genetics and depression in East Asians living in the USA or UK. Further this study highlights the importance of using ethnically diverse data, especially when the relationship under study is not purely biological and may involve socio-cultural factors.

PrgmNr 2455 - Identification of known and novel long non-coding RNAs potentially responsible for the effects of BMD GWAS loci

Osteoporosis, characterized by low bone mineral density (BMD), is the most common complex disease affecting bone and constitutes a major societal health problem. Genome wide association studies (GWAS) have identified over 1100 associations influencing BMD. It has been shown that perturbations to long non-coding RNAs (lncRNAs) influence BMD and the activities of bone cells; however, the potential role of lncRNAs in explaining the genetics of BMD is unknown. Here, we applied allele-specific expression analysis, a Transcriptome Wide Association Study (TWAS), and Bayesian colocalization to RNA-seq data from human acetabular bone fragments (N=17; 5 males and 12 females; ages 43 to 80) and the Genotype-Tissue Expression (GTEx) project to identify lncRNAs potentially responsible for GWAS associations. We identified eight lncRNAs in bone RNA-seq data that are located in proximity to a BMD GWAS association and are under allele-specific expression. Using GTEx data we identified an additional 31 lncRNAs whose expression was associated (FDR0.1). The 39 lncRNAs are located in 43 BMD associations. To further support a causal role for the lncRNAs, we show that 23 of the 39 lncRNAs are differentially expressed as a function of osteoblast differentiation. Our approach identifies lncRNAs that are potentially responsible for BMD GWAS associations and suggest that lncRNAs play a role in the genetics of osteoporosis.

PrgmNr 2456 - Identifying the mediator metabolites between obesity and osteoporosis through high-dimensional mediation analysis

Disclosure Block: **G. Zhang:** None.

Osteoporosis, mainly characterized by low bone mineral density (BMD), is a common metabolic bone disorder. Obesity has been shown positively associated with osteoporosis, and weight loss leads to bone loss. However, the molecular links between obesity and osteoporosis are still largely unknown. Investigating the biological mechanisms underlying the impact of obesity on BMD may contribute to a better understanding of bone regulation, reducing potential bone loss during weight loss in obese patients. This study aimed to identify metabolic mediators and pathways between obesity and BMD using a metabolomics and lipidomics approach. Considering the inherent correlations among the high-dimensional metabolites/lipidomics data, we built a framework with a high-dimensional multivariate mediation analysis (HDMMA) to identify the potential intermediate groups of metabolites/lipids potentially causally mediating variation from body mass index (BMI) to BMD. Using liquid chromatography-mass spectrometry-based metabolomics and lipidomics profiling, a total of 279 serum metabolites/lipids from 136 Caucasian women aged 20 to 40 in the Louisiana Osteoporosis Study (LOS) were evaluated. We performed the HDMMA for the potential metabolites group identification, and applied the causal inference using Non-combinatorial Optimization via Trace Exponential and Augmented lagRangian for Structure learning (NOTEARS) algorithm to pinpoint the critical metabolites. Finally, enrichment analysis (MetaboAnalyst 4.0) was employed to identify the metabolomic pathways associated with BMI and BMD. Five metabolitesâ□□ groups were identified as significant mediating components in which we rank the top metabolites including 3-methyl-2-oxovaleric, anthranilate, 1-aminocyclopropane-1-carboxylate, succinic acid, taurine, DHA, and 4-oxoproline. The enrichment analysis confirmed four significant pathways including tryptophan metabolism, branched-chain amino acids degradation, bile acid biosynthesis, and carnitine synthesis. Overall, our computational findings contribute considerably to understanding the novel metabolite interplay underlying the relationship between obesity and osteoporosis. Specifically, we identified several mediation pathways between BMI and BMD, which may generate metabolomic-guided hypotheses for further functional experiment studies.

PrgmNr 2457 - Incorporating the gene-gene regulatory network into the estimation of effect size

Over the last few years, genome-wide association studies (GWAS) have been a successful tool to unveil genetic risk variants to a variety of complex diseases. However, additional analyses are required to identify disease susceptibility variants underlying GWAS findings and estimate their true effect sizes. For this purpose, we can leverage sources of biological information beyond analyzing the patterns of linkage disequilibrium. As most GWAS hits modify gene transcription, transcriptional data provides such biological information. However, including transcription requires modeling the interaction of gene expression in the underlying pathways of networks. In this project, we aim to incorporate gene-gene interaction network information into the posterior estimation of causal variants.
To be more specific, we aim to construct the gene expression network through gene-gene interaction data. The set of closely interacting genes in the regulatory network can be identified by existing community detection methods, such as the modularity-based or the profile likelihood-based algorithms. This will give us the transcriptional level annotation for each SNP. That is a binary matrix indicating whether the variants belong to one of the gene regulatory modules. We treat the annotation information as the prior and integrate it with the GWAS summary statistics. The posterior of the effect sizes can be achieved through the EM algorithm.
With a better understanding of the biological networks, we expect the identification of the causal variants, and the estimation of the effect sizes will be more precise. The results of our work can shed light on the biological interpretation of the direct GWAS results, as well as contribute to broad fields, such as the construction of the polygenic risk score.

PrgmNr 2458 - Mapping the proteo-genomic convergence of human diseases

Characterization of the genetic regulation of protein abundance and function is essential for understanding disease aetiology and identifying new therapies. Here we identify 10,674 genetic associations for 3,892 plasma proteins to create the first *cis*-anchored gene-protein-disease map of 1,859 connections that highlights strong cross-disease biological convergence. For example, the genetic signal at *EFEMP1* for FBLN3 was shared across diverse connective tissue disorders consistent with abnormal elastic fibre morphology *in the Efemp1* knock-out mice. Integration of diverse â□□omicâ□□ layers identifies a supersaturated bile to promote cholesterol crystallization and gallstone formation as mode of action of *SULT2A1*. We demonstrate the specific value of *cis*-protein quantitative trait loci (pQTLs) for causal annotation of disease genes at established GWAS loci, such as *PRSS8* underlying the Alzheimerâ□□s signal currently assigned to *KAT8.* We develop a new data-driven methodology that identifies 39% of 2,303 distant protein-associated *trans*-pQTLs as protein- or pathway-specific through their protein-network profile, including known disease variants such as for *PNPLA3* and a community of metabolic and detoxification enzymes. Our results establish proteo-genomic connections with and among diseases even of seemingly unrelated aetiology and help to address one of the major barriers for experimental validation and clinical translation of GWAS discoveries. We make results accessible via an interactive web resource upon publication (https://www.omicscience.org/).

PrgmNr 2459 - Mitochondrial and sex chromosome genetically regulated gene expression implicates new genes in complex traits across multiple human populations

View session detail

Chicago, Chicago, IL, [2]Univ Virginia, Charlottesville, VA, [3]Lundquist Inst., Harbor-UCLA Med Ctr, Torrance, CA, [4]The Univ. of Chicago, Chicago, IL, [5]Loyola Univ Chicago, Chicago, IL

Disclosure Block: **D. AraÃºjo:** None.

The majority of GWAS are conducted in European ancestry populations and are limited to autosomal chromosomes, ignoring the genetic content of the mitochondria and sex chromosomes. Alongside GWAS, transcriptome-wide association studies (TWAS) can provide useful information about the direction of gene regulation underlying complex traits. Given the genetic diversity among individuals, we sought to build mitochondrial and sex chromosome transcriptome prediction models for use in TWAS in diverse populations, including those underrepresented in GWAS and TWAS.

We used transcriptome data from the Multi-Ethnic Study of Atherosclerosis (MESA) comprised of up to 1004 individuals of African, Chinese, European and Hispanic/Latino ancestries. For each of 3 blood cell types, peripheral blood mononuclear cells (PBMC), CD16+ monocytes, and CD4+ T cells, we built models in each population and also a model including all individuals. We used cross-validated elastic net to estimate gene expression from local SNPs within 1Mb of each gene through an additive linear model. Depending on population, our modeling resulted in 24-57 genes with Spearman correlation Ï>0.1. Smaller sample sizes were available for monocytes and T cells, resulting in 3-16 and 4-13 genes with Ï>0.1, respectively. Most predicted genes were on the X chromosome, while few Y chromosome and mitochondrial genes had Ï>0.1.

With these prediction models, we applied S-PrediXcan to X chromosome GWAS summary statistics from two different multi-ancestry studies, the Population Architecture using Genomics and Epidemiology (PAGE) study (n=49,839) and Pan UK Biobank (PanUKB, n=488,377). We identified 5 gene-trait pairs that were significant in both studies (PGRIPAP1 associated with diastolic blood pressure, *STARD8* with platelet count, *PLXNA3* with triglyceride levels, and both *TSC22D3* and *SPIN2B* with height. Of these 5 gene-trait pairs, only *STARD8* - platelet count association had been reported previously; thus, the remaining 4 correlations may be novel. For the mitochondrial genes, GWAS summary statistics were only available from the UK Biobank. We identified statistically significant correlations between *MT-ND3* and mean corpuscular hemoglobin, mean corpuscular volume, mean platelet volume, plateletcrit, red blood cell count and red blood cell width distribution (P-7). We expect that conducting more integrative omics studies that include mitochondria and sex chromosomes in multi-ethnic cohorts will identify new gene-trait associations and promote diversity in biomedical research.

PrgmNr 2460 - Parent-of-origin inference in the UK biobank reveals new imprinted variants

Sex-specific genetic effects have been reported in many diseases and phenotypes through Genome-Wide Association Studies (GWAS) conducted separately on men and women. Recently, GWAS have pinpointed more complex sex-specific effects in which identical genetic variations have different phenotypic effects depending on their parent-of-origin (PO). Yet, such studies were largely limited in terms of sample size: researchers usually rely on the parental genomes or known genealogies to characterize the PO. However, these requirements are rarely available in biobanks, preventing the study of PO effects on a large number of phenotypes and samples.
Here, we present a novel probabilistic approach to determine the PO of an individualâ□□s haplotypes that does not require prior knowledge of genealogy. Our model (i) identifies surrogate parents using identity-by-descent (IBD) sharing between individuals, (ii) uses a Hidden Markov Model to represent a specific haplotype as a mosaic of haplotypes of its close relatives, (iii) assigns paternal or maternal origin to these shared haplotype segments, and (iv) extends this assignment to entire chromosomes. Using the UK Biobank dataset, we were able to infer the PO for ~25,000 samples. This represents a five-times increase of sample size compared to classical approaches. We assessed the accuracy of our inference using a total of 1,397 UK biobank duos and trios, resulting in a call rate of ~75% (% of sites with PO assignment) and an error rate of ~0.5% (% heterozygous sites with incorrect PO assignment). We then performed association scans for PO effects across hundreds of phenotypes, ranging from physiological traits to complex diseases, allowing us to replicate known and discover new imprinted variants at a scale never reached before. We also showed that many of these variants could reach genome-wide significance only thanks to the larger sample size offered by our approach. As an example, we discovered four loci associated with platelet crit exhibiting strong PO effects. One of these loci corresponds to an expression Quantitative Trait Loci of the well-known imprinted gene MEG3 (Maternally Expressed Gene 3), previously shown to be involved in the platelet phagocytosis. Our approach, designed to leverage the relatedness of individuals in large biobanks, greatly increases the effective sample size for PO studies and therefore offers the means necessary to further characterize the genetic architecture of sex-specific effects in complex traits and diseases.

PrgmNr 2461 - Phenome-wide association study of clonal haematopoiesis somatic mutations in 391,756 UK Biobank participants

View session detail

Author Block: **J. Mitchell**, K. J. Carss, Q. Wang, A. R. Harper, S. Petrovski; Ctr. for Genomics Res., Discovery Sci., R&D, AstraZeneca, Cambridge, United Kingdom
Disclosure Block: **J. Mitchell:** Salary/Employment; AstraZeneca.
Clonal haematopoiesis (CH) is a common, age-related process that describes the clonal expansion of blood cells with somatic mutations (i.e. variant allele frequency (VAF) >2%), predominantly in three genes (*DNMT3A*, *T*ET2, *ASXL1*). In addition to being a well-established risk factor for haematological malignancy, CH has demonstrated strong associations with cardiovascular disease and all-cause mortality. To further appreciate gene-phenotype associations attributable to CH we analysed exome sequencing data from 391,756 UK Biobank participants. Our approach repurposed a germline-optimised calling pipeline to enable the detection of somatic variants with high VAF. Adoption of this approach identified protein truncating (putatively somatic) variants across *DNMT3A*, *TET2* and *ASXL1* in 2,888 individuals with a mean VAF of 0.276 Â± 0.093. This is higher than a recent Trans-Omics for Precision Medicine program study which, utilising a somatic variant calling pipeline, reported a CH variant mean VAF of 0.190 Â± 0.102 and largely accounts for the approximately four times lower detectable CH rate observed in the study presented here. As expected, and comparable with other large sequencing based efforts characterising CH, prevalence was correlated with age ($\tilde{A}$ = 0.096, $P = 1.91x10^{-190}$). To discover novel trait associations, and further investigate known associations, we performed a gene-level collapsing analysis-based phenome-wide association study (PheWAS) of the detectable somatic mutations with 16,259 binary and 1,568 quantitative phenotypes. We found 251 statistically significant (*P* -8) binary trait associations, of which 81 (32%) were not cancer-related, and 33 associations with quantitative traits. Of the three studied genes, most associations were with *ASXL1* (n=142) with slightly fewer for *TET2* (n=135) and far fewer for *DNMT3A* (n=7). We have analysed sequencing data for CH mutations in the largest cohort to date and validated and expanded upon their known trait associations. We will repeat these analyses adopting the calls from a somatic-optimised bioinformatics pipeline to increase our sensitivity for CH detection in these three genes.

PrgmNr 2463 - Shared genetic effects for type 2 diabetes and four cancers uncovered through multi-phenotype genome-wide association study

Disclosure Block: **A. Demirkan:** None.
Introduction: There are established relationships between type 2 diabetes (T2D) and cancer, including cancer being the most common cause of death in T2D. We aimed to gain insights into the pathophysiological processes shared between T2D and four cancers through multi-phenotype (MP) genome-wide association study (GWAS). Methods: We combined GWAS on 36,173 individuals from the pan-European EPIC study, including 10,855 T2D cases, 4,126 postmenopausal breast, 2,111 colorectal, 473 pancreatic and 419 prostate cancer cases. The combined GWAS dataset was quality controlled and imputed against the HRC reference panel providing 39.3M DNA variants for analysis. We performed MP-GWAS reverse regression for five outcomes using SCOPA software. We evaluated single and multi-phenotypes effects at associated (P10 as important model fit improvement. Results: Within MP-GWAS, we identified 174 independent loci for the full five-phenotype model. Among them, 31 overlapped established T2D/cancer variants, specifically we replicated 12 loci associated with breast cancer, 10 with prostate, one with colorectal cancer, and 15 with T2D. Seven of the previously established loci were reported for multiple cancer/T2D outcomes before. These were rs67798996 (ASCL2), rs57096576 (SMIM38), rs12524664 (TNXB), rs2019689 (MBNL1) rs7756992 (CDKAL1), rs35011184 (TCF7L2) and rs62033406 (FTO), each previously reported for two out of five outcomes we studied. Six of these (ASCL2, SMIM38, MBNL1, TNXB, CDKAL1, TCF7L2 and FTO), except TNXB yielded better model fit for single phenotype tests as defined by deltaBIC. The 143 novel signals included 112 performing better in single-phenotype association, 10 loci with the five-phenotype model suggesting T2D-cancers shared effects. Conclusions: The large data and power, improved through implementation of multi-variate GWAS analysis enabled identification of 10% of loci with shared T2D-cancer effects that contribute to these diseasesâ comorbidity through shared genetic effects. Funding: WCRF-2017/1641, LonglTools H2020-SC1-2019-874739, PreciDIAB, ANR-18-IBHU-0001

PrgmNr 2464 - The chromatin accessibility signature of selection for exercise capacity in skeletal muscle

View session detail

Author Block: **P. Orchard**[1], N. Manickam[1], M. K. Treutelaar[1], Y. Zhang[1,2], C. R. Evans[1], J. Z. Li[1], C. F. Burant[1], S. C. J. Parker[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Soochow Univ., Suzhou, China
Disclosure Block: **P. Orchard:** None.
Aerobic exercise capacity is negatively associated with mortality and complex disease susceptibility. Understanding the genetics and epigenomics of aerobic exercise capacity may clarify the molecular mechanisms behind this relationship. Artificial selection on untrained running capacity was previously used to generate two rat lines, one with high capacity runners (HCRs) and one with low capacity runners (LCRs). The lines show >9-fold difference in running capacity, and heritability estimates of running capacity within each line are >0.4; however, a genome wide association study on running capacity in a HCR-LCR F2 population identified no genome-wide significant associations, suggesting the trait is highly polygenic. To understand the noncoding landscape driving differences in exercise capacity and the response to exercise, we profiled chromatin accessibility (ATAC-seq) on 253 rat skeletal muscle samples, representing HCRs and LCRs before, during, and 1 hour after exercise, and from a HCR-LCR F2 cross.

We identified 4,932 HCR-LCR differential open chromatin regions (5% FDR). Consistent with the hypothesis that the cross-line chromatin accessibility differences are driven by genetics and are selected for, we find cross-line genetic differences (measured by F_{ST}) are significantly enriched ($p = 9.1x10^{-16}$) in HCR-LCR differential peaks but not differential peaks from other comparisons. Peaks with greater accessibility in HCR rats (HCR-up peaks) are enriched ($p = 1.2x10^{-8}$) for nuclear receptor family transcription factor (TF) motifs, nominating their role in determining exercise capacity. HCR-up peaks showed inflated p-values for positive correlation with running capacity in the F2 rats, suggesting that the differential peaks contribute to the cross-line difference in running capacity. We performed a chromatin accessibility quantitative trait locus (caQTL) scan using the F2 rats and identified 7,775 significant peaks (5% FDR). HCR-LCR differential peaks were more likely than non-differential peaks to associate with a caQTL (p -300), indicating SNPs in the F2 population that may drive the line-differential peaks.

We identified 22,731 differential peaks between rats at rest vs. during exercise, and 32,095 differential peaks between rats at rest vs. 1 hour post exercise (5% FDR). We find MEF2 and ATF3 TF motifs are enriched in exercise-responsive peaks, and a motif for NRF2, a regulator of the antioxidant response, is enriched in peaks with greater accessibility post exercise.

These results highlight the widespread epigenomic response to exercise and nominate transcription factors that underlie exercise capacity and response to exercise.

PrgmNr 2465 - The effect of mitochondrial population genome variation on nuclear gene expression and its link to disease

View session detail

Author Block: **J. Lascano Maillard**[1,2], H. Ongen[3,2], E. T. Dermitzakis[4,2]; [1]Genetic Med. and Dev., Univ. of Geneva, Geneva, Switzerland., Geneva, Switzerland, [2]Swiss Inst. of Bioinformatics, Geneva, Switzerland, [3]Genetic Med. and Dev., Univ. of Geneva, Geneva, Switzerland, Geneva, Geneva, Switzerland, [4]Univ. of Geneva, Geneva, Switzerland
Disclosure Block: **J. Lascano Maillard:** None.
Mitochondria are involved in different key aspects of cell homeostasis. Somatic mutations in the mitochondrial genome are linked to varying patterns of nuclear DNA methylation and acetylation, contributing to differential gene expression and to the development of particular diseases such as diabetes, encephalomyelitis and cardiomyopathies. Although mitochondrial sequence alteration was investigated in the pathological context, little is known about the effect of its population variation on phenotypic traits. Two previous studies on whole blood containing a mix of cell types examined the impact of variation among northern European and the Finnish population, respectively, finding only a few mito-nuclear expression quantitative trait-loci (eQTLs). Here, we extended the analysis using 358 samples of four European regions from the *1000 Genomes* consortium and matched lymphoblastoid cell lines (LCLs) RNA-seq data from the *GEUVADIS* project giving us the potential to unravel more mitochondrial genetic associations with nuclear gene expression. First, to assess the extent of genetic control of the mitochondrial genome on nuclear genes, we performed an eQTL analysis using mitochondrial genotypes and nuclear gene expression data. We further explored potential gene pathways involving mito-nuclear eQTL genes using Bayesian Networks. We find a total of 66 mito-nuclear eQTLs involving 21 different mitochondrial variants and 65 unique nuclear genes. Mitochondrial eQTL variants were grouped into high LD genotypic blocks ($r2 > 0.7$) and the corresponding eQTL genes were enriched for ontology terms related to mitochondrial genetic diseases, such as encephalomyelitis and muscular dystrophy. Each genotypic block defining specific mitochondrial haplogroups were associated with eQTL genes enriched in the corresponding disease terms from known specific haplogroup-enriched diseases, such as osteoarthritis and auditory-loss. Within genotypic blocks, eQTL genes were connected within pathways and included the known *FOXP2-TDO2* axis. In conclusion, we show that the mitochondrion carries genetic determinants for nuclear gene expression that might explain predisposition to specific diseases. Our findings point towards an expanded role of the mitochondrial genome on human phenotypic variation and pave the way for future studies which would include mitochondrial SNPs in polygenic risk scores calculation.

PrgmNr 2466 - The Netherlands Neurogenomics Database - Genetic susceptibility for brain disorders, clinical disease trajectories and end-stage neuropathology

View session detail

Author Block: **I. Holtman**[1], E. Boddeke[1], B. Eggen[1], J. Hamann[2], M. Swertz[1], A. Rozemuller[2], S. Wehrens[3], M. Groot[3], I. Huitinga[3]; [1]Univ. Med. Ctr. Groningen, Groningen, Netherlands, [2]Amsterdam Med. Ctr., Amsterdam, Netherlands, [3]Netherlands Inst. for NeuroSci., Amsterdam, Netherlands
Disclosure Block: **I. Holtman:** None.
The brain is a highly complex organ that consists of many intricately linked substructures and cell types and is susceptible to a wide range of psychiatric and neurodegenerative diseases. The Netherlands Brain Bank (NBB) has performed more than 4.500 human brain autopsies from donors with a wide range of psychiatric and neurodegenerative conditions as well as matched controls. From each brain, brain regions were dissected according to disease-specific protocols, and a range of clinical and pathological data were collected in extensive clinical-pathological summaries. We recently initiated the Netherlands Neurogenomics Database, which aims to integrate the extensive clinical and neuropathological data, with a multi-omics map from a large number of donors in order to study the effects of genetic variation on brain disease. Using text mining approaches, we aimed to convert the vast amount of qualitative clinical neuropathological summaries into standardized clinical and neuropathological trait assessments. We identified a set of 80 key clinical and neurological parameters and manually labeled almost 20.000 sentences. This data was used to train and compare different Google Bidirectional Encoder Representations from Transformers (BERT) multilabel classification models. The trained model was highly reliably able to score these predefined parameters. As these clinical parameters have a temporal aspect, we are currently implementing graph-based approaches to convert these data types into clinical disease trajectories. Neuropathological examination reports are converted into standardized neuropathological trait assessments using a combination of BERT based multilabel classification and regression approaches. Additionally, we are processing Illumina GSA SNP chips for around 3000 donors and aim to calculate polygenic risk scores (PRS) for a wide range of Central Nervous System (CNS) disorders and neurobehavioral traits. These PRS will be used to determine the relationship between genetic susceptibility and clinical disease trajectories and end-stage neuropathology. This unique resource will be open-access and made readily available to the large scientific community. It will facilitate many existing lines of research into the understanding of CNS disease susceptibility.

Background: In most laboratories multigene NGS panels are used to diagnose specific phenotypes. However, in infants and young children some conditions may be missed using focused gene analysis. Trio clinical exome can accelerate the discovery of additional genetic variants not related to the referring phenotype of the patient but can still have clinical implications. Here, we present the case of a child with congenital deafness.
Patients concerns: The family came to our observation for genetic counselling about the familiar congenital deafness of a 19-month-old baby. While the NGS analysis was in progress, the patient was found with elevated serum creatine kinase levels and mild development delay.
Results: We detected two compound heterozygous missense variants in the TBC1D24 gene causing deafness. Strikingly, we found an additional maternally inherited variant in the intron 55 of DMD gene c.8217+1G>T. This allele is new but predicted to cause Duchenne Muscular Dystrophy through an out-of-frame skipping of exon 55. The genetic diagnosis was done prior of any clinical sign of muscular dystrophy.
Conclusions: Here we report an example of the urgency of trio clinical exome analysis in paediatric contest instead of panels. In this case, early diagnosis was crucial in DMD to organize the best long-term care and to provide genetic counselling for the whole family.

PrgmNr 2468 - Validation of cross-ancestry and cross-trait polygenic risk scores in the Genomics England cohort

View session detail

Author Block: **S. Selzam**, F. Riveros-Mckay, D. Thompson, R. Moore, D. Wells, D. Palmer, J. Harrison, Genomics England Research Consortium, V. Plagnol, G. McVean, P. Donnelly, M. E. Weale; Genomics plc, Oxford, United Kingdom

PRS models are often trained and evaluated within the same cohort by artificially splitting into training and testing samples. External validation is considered a more robust test of true performance. We developed PRS models for ten common diseases: four cancers (ovarian, prostate, bowel, breast), type 2 diabetes, atrial fibrillation, ischemic stroke, hypertension, coronary artery disease, and cardiovascular disease. We included a subset of the UK Biobank (UKB) data for training (N=~340,000) and investigated their predictive performance in both the held-out UKB samples and a separate UK cohort, the 100,000 Genomes Project (Genomics England; n=40,001). We boosted cross-ancestry performance and trait prediction by incorporating ancestry-specific effect sizes and linkage disequilibrium, and by leveraging cross-trait correlations. Validation of PRS performance in UKB and the 100,000 Genomes Project showed high and consistent performance, with 90% of the prediction estimates showing overlapping 95% AUC confidence intervals between the two cohorts across the different traits and ancestries. The prostate cancer PRS was our most predictive PRS model, with an AUC of 0.72 and 0.71 in UKB and the 100,000 Genomes Project, respectively. For type 2 diabetes, the cross-ancestry method improved prediction (relative AUC increase) in all ancestry groups, ranging from a 9.7% improvement in East Asian ancestries (AUC=0.68 vs. 0.62) to a 1.4% improvement in African ancestries (AUC=0.61 vs. 0.60). Our cross-trait methodology increased ischemic stroke prediction by 4.4% (AUC=0.60 vs 0.58). Our PRS models outperformed best-in-class published PRS across all traits and across a range of ancestries (mean Î AUC=0.04; mean Î improvement=7.2%), with the largest gains observed for type 2 diabetes in East Asian populations (Î AUC=0.12; prediction improvement=20.7%). Using the UK Biobank sample to train the PRS for evaluation in the 100,000 Genomes Project generally increased performance, although in some cases only by moderate amounts. The increase in prediction was largest for hypertension in South Asian ancestries, with an improvement of 6.7% (Î AUC=0.04). Our results show that our PRS models perform well in an external cohort with different study characteristics to the UKB training cohort. The calculated PRS values in individuals from UK Biobank and the 100,000 Genomes Project will be made available as an additional resource to the scientific community.This research was made possible through access to the data and findings generated by the 100,000 Genomes Project; http://www.genomicsengland.co.uk, and the UK Biobank Project, https://www.ukbiobank.ac.uk/.

PrgmNr 2469 - Whole genome sequencing association study among 24,870 individuals from multiple ancestry-ethnicity groups identifies common and rare variants associated with serum urate

View session detail

Author Block: **A. Tin**[1,2], P. Sekula[3], J. A. Brody[4], D. Jain[5], A. Hoppmann[3], L. M. Raffield[6], S-J. Hwang[7], R. Irvin[8], W. Zhao[9], I. Chen[10], J. Blangero[11], J. S. Floyd[5], R. Disclosure Block: **A. Tin:** None.
Background Elevation of serum urate levels can cause gout, a common and painful form of inflammatory arthritis. Previous genome-wide association studies (GWAS) of serum urate based on genotyped and imputed variants have identified nearly 200 genetic loci. The index variants at most loci are common and map outside of coding regions. Whole genome sequencing (WGS) provides more comprehensive coverage of the genome and provides the opportunity to identify rare variant associations in both coding and non-coding regions. **Methods** We performed a transethnic WGS association study of serum urate among participants of the Trans-omics for Precision Medicine (TOPMed) program using the Analysis Commons platform. After data cleaning, serum urate levels were transformed to be normally distributed. A kinship matrix was used to account for relatedness. The analysis controlled for age, sex, body mass index, cohort-ancestry-ethnicity strata, and genetic principal components. Single variant analysis (SVA) was conducted using the GENESIS (GENetic EStimation and Inference in Structured samples) software and included variants with minor allele count â¥10. Gene-centric aggregated variant analysis was conducted using STAAR (variant-Set Test for Association using Annotation information). Aggregation analysis of variants with minor allele frequency (MAF) Results We included 24,870 participants from multiple ancestry-ethnicity groups from 10 cohorts. The genomic control factor of SVA of serum urate indicated little inflation (1.03). After successively conditioning on the most significant variant(s) in each chromosome, we identified 12 independent single variant associations (4 with MAF SLC2A9 and *SLC22A12* encoding urate transporter genes contained 3 and 4 independent variants, respectively. Aggregation analysis identified significant rare variant associations with lower urate levels at *SLC22A12* (median effect size: -1.4 SD), driven by disruptive missense and loss-of-function (LoF) variants as well as variants in promoter and upstream regulatory regions. Rare variant signals at *SLC2A9* was driven by disruptive missense and LoF variants associated with urate in both directions. **Conclusion** This large-scale WGS study of serum urate identified potentially novel rare variants associated with serum urate levels.

PrgmNr 2470 - Whole-exome association analyses of polygenic deviators for height in 183,948 individuals from the UK Biobank

View session detail

Author Block: **G. Hawkes**[1], L. Yengo[2], S. Vedantam[3], E. Marouli[4], G. Lettre[5], Y. Okada[6], J. N. Hirschhorn[7], T. Frayling[1], A. R. Wood[1], GIANT Consortium; [1]Genetics of Complex Traits, Coll. of Med. and Hlth., Univ. of Exeter, Exeter, Devon, United Kingdom, [2]Inst. for Molecular BioSci., The Univ. of Queensland, Brisbane, Australia, [3]Endocrinology, Boston Children's Hosp, Sharon, MA, [4]William Harvey Res. Disclosure Block: **G. Hawkes:** None.

Genome-wide association studies have explained ~25% of normal variation in height through thousands of common genetic variants. Individuals with short stature may carry a large number of height-lowering alleles. Alternatively, they may deviate from this model because of a rare and highly deleterious variant, monogenic cause, or environmental factors. Using 183,948 individuals from the UK Biobank of European ancestry with imputed and whole-exome sequence (WES) data, we aimed to 1) define individuals as polygenic â□□deviatorsâ□□ based on height and polygenic risk scores (PRS), and 2) perform single-variant and burden association testing of rare variants to identify putative novel loci for â□□deviatorâ□□ case status.

A polygenic risk score (PRS) was generated in UK Biobank using effect estimates of 3,198 independent SNPs associated with height (P-8) available from an interim GIANT meta-analysis of 1,400,860 individuals of European ancestry that excluded UK Biobank. The correlation between height (adjusted for age, sex, and centre) and PRS was assessed relative to a simulated population with an additive genetic architecture to identify â□□shortâ□□ deviators. Deviators were defined using both Mahalanobis distances (MD) (*P*The PRS explained 32% of the variance in height within the UK Biobank samples. We identified 813 and 4,249 â□□shortâ□□ deviators based on MD and RO, respectively. Single variant association analysis identified a total of 6 missense variant associations and 1 LoF association at exome-wide significance (P-7). Putative novel associations included a missense-variant association in *NBPF4* (P=1x10^{-10}) and the LoF variant association was located in *MSH4* (P=9x10^{-9}). Burden testing identified 5 genes associated with short deviator status, all previously associated with single gene growth disorders.

In conclusion, we have identified putative novel genes by identifying individuals with phenotypes deviating from polygenic expectation.

PrgmNr 2471 - *PAX6*-associated microphthalmia: Transcriptome-wide investigation of patient-derived optic vesicle iPSC models reveals molecular disruption during early eye development associated with missense *PAX6* variant

View session detail

Author Block: **P. Harding**[1], D. Lima Cunha[1], N. Owen[1], J. Eintracht[1], M. Moosajee[1,2,3,4]; [1]UCL Inst. of Ophthalmology, London, United Kingdom, [2]The Francis Crick Inst., London, United Kingdom, [3]Moorfields Eye Hosp. NHS Fndn. Trust, London, United Kingdom, [4]Great Ormond Street Hosp. for Children NHS Trust, London, United Kingdom
Disclosure Block: **P. Harding:** None.
PAX6 is an essential transcription factor for eye development, regulating diverse genetic pathways. Heterozygous pathogenic *PAX6* variants cause a wide range of ocular disorders, including aniridia, cataracts and Peterâ□□s anomaly. Missense variants are typically associated with milder phenotypes, however, substitutions in the highly conserved DNA-binding paired domain can give rise to more severe ocular features including microphthalmia, a congenital, structural disorder resulting in a small, underdeveloped eye. Microphthalmia is reported in 11% of blind children, yet currently no treatments are available to improve visual function. The disease-causing downstream pathways affected in these patients remain unclear. We aim to clarify direct and indirect targets of *PAX6* in eye development that are perturbed in *PAX6*-associated microphthalmia.
3D optic vesicles were differentiated from iPSCs of a patient exhibiting severe microphthalmia, aniridia and cataracts diagnosed with heterozygous *PAX6* variant c.372C>A, p.Asn124Lys. Molecular characterisation was performed at 20- and 35-days differentiation through qRT-PCR and immunostaining to confirm an early-stage disease phenotype. Total RNAseq transcriptome-wide profiling was utilised to characterise global gene expression changes associated with the missense variant compared to unaffected wildtype (WT) controls and vesicles from a non-microphthalmic aniridia patient with nonsense *PAX6* variant c.781C>T, p.Arg261*.
PAX6 microphthalmic vesicles showed significantly reduced mRNA expression of early eye transcription factors *PAX6, RAX, OTX2* and *SOX2* relative to WT controls, alongside absence of neural retina marker VSX2 protein, which was present in aniridia and WT vesicles at day 35. Principal component analysis of RNAseq data displayed robust clustering of samples by disease state, with differential gene expression analysis revealing significant molecular changes, including pathways relating to cellular metabolism and growth.
We present a cellular model of *PAX6*-related microphthalmia which mimics the severe phenotype observed in patients, with early optic vesicles failing to induce eyefield transcription factors and subsequently form presumptive neural retina. Variant-specific molecular disruption identified by RNAseq provides insights into genotype-phenotype correlations observed in *PAX6* patient cohorts. This work creates a valuable resource for exploring the roles of *PAX6* in human eye development, and further investigation will enhance understanding of microphthalmia pathogenesis, which could lead to development of novel therapies.

PrgmNr 2472 - A Novel Method of Cell-type-level EWAS of HIV Infection Following Deconvoluting DNA Methylation in Blood

View session detail

Author Block: **X. Zhang**[1], A. Justice[1], B. E. Aouizerat[2], X. Ke[1]; [1]Yale Sch. of Med., New Haven, CT, [2]Univ California San Francisco, San Francisco, CA
Disclosure Block: **X. Zhang:** None.
Background. Epigenome-wide association studies (EWAS) have previously linked DNA methylation in blood to HIV infection. However, the interpretation of epigenome data from blood samples is complicated by current approaches to addressing cell composition heterogeneity. Clarifying the precise DNA methylation mechanism of HIV infection in each cell type would require the dissection of HIV infection-associated methylation signals. Here, we developed a new method to carry out cell type level EWAS for HIV infection following computational deconvolution of the methylome in each cell type.**Methods**. DNA methylation for 718 whole blood DNA samples from Veterans Aging Cohort Study (VACS) cohort was profiled by using Illumina HumanMethylation 450K Beadchip (HIV-positive=614; HIV-negative=104). Cell type proportions for each sample were estimated. We applied a Tensor Composition Analysis (TCA) approach to deconvolute cell-type-specific DNA methylation signals in 6 major cell types (CD4+ T cell, CD8+ T cell, monocyte, B cell, Nature Killer, granulocytes). We followed a two-step general linear regression model to adjust systematic bias, known biological confounders and unknown global confounders. CpGs associated with HIV infection in each cell type were declared significant at a Bonferroni adjusted p Results. We identified significant CpG sites for HIV infection in each cell type: CD4+ (107 CpGs), CD8+ (12 CpGs), B cells (2 CpGs), Nature Killer (12 CpGs), monocytes (6 CpGs), and granulocytes (8 CpGs). We replicated our previously reported HIV-associated CpG sites from bulk methylome EWAS, *NLRC5* and *LPCAT1*, which were less methylated in HIV-positive samples. Importantly, we dissected these significant signals from bulk methylome to specific cell types. Two previously identified *NLRC5* promoter region CpG sites (cg07839457, cg16411857) were hypomethylated in CD4+ T cells (t=-6.24, p_{adj}=3.34E-04; t=-6.63, p_{adj} =3.01E-05) and granulocytes (t=-7.08, p_{adj}=1.56E-06; t=-6.04; p_{adj}=1.07E-03). A third *NLRC5* CpG, cg05757530, was only significant in CD4+ T cells (t=-6.70, p_{adj}=1.35E-06). One *LPCAT1* CpG, cg16272981, was hypomethylated in CD4+ T cells, B cells, monocytes, and granulocytes (t=-7.84~-5.97, p_{adj}=1E-04~8.49E-09). Additionally, we identified a few novel CpG sites for HIV infection in different cell types. For example, we found two differentially methylated *SHANK2* CpG sites in CD4 T cells. **Conclusions**: Computationally deconvoluted DNA methylation is a robust and effective approach to dissect cell type-specific DNA methylation signals for HIV infection. Our results further reveal cellular epigenetic mechanisms involving HIV pathology.

PrgmNr 2473 - Association of peripheral blood microRNAs with cardiovascular endophenotypes in a population-based study

View session detail

Author Block: **V. Talevi**[1], G. Pehlivan[1], T. Pena Centeno[2], S. Burkhardt[2], A. Fischer[2,3], M. M.B. Breteler[1,4]; [1]Population Hlth.Sci., German Ctr. for Neurodegenerative Diseases (DZNE), Bonn, Germany, [2]Dept. of Systems Med. and Epigenetics, German Ctr. for Neurodegenerative Diseases (DZNE), Bonn, Germany, [3]Dept. of Psychiatry and Psychotherapy, Univ. Med. Ctr., Goettingen, Germany, [4]Inst. for Med. Biometry, Informatics and Epidemiology (IMBIE), Faculty of Med., Univ. of Bonn, Bonn, Germany
Disclosure Block: **V. Talevi:** None.
Aging is characterized by a progressive decline of molecular processes which can lead to the development of cardiovascular disease (CVD). MicroRNAs are regulators of gene expression via base-pairing to the target mRNA and they are involved in numerous complex biological processes, including those linked to CVD.
We investigated the association of peripheral blood microRNAs with the main cardiovascular (CV) endophenotypes in a population-based study. In addition, to reveal the biological role of CV-associated microRNAs, we investigated their corresponding targeted genes by microRNA target prediction.
Peripheral blood microRNA expression was acquired through RNA-Seq for 2196 participants from the Rhineland Study, an ongoing population-based cohort study in Bonn, Germany. MicroRNAs expressed in more than 5% of the participants with an average count greater than five were included in the analysis. Blood pressure (BP) and arterial stiffness (total arterial compliance index (TACI) and pulse wave velocity (PWV)) were assessed in all participants. Associations of microRNA expression with CV endophenotypes were determined through linear regression, adjusted for age, sex, batch and traditional cardiovascular risk factors (including BMI, smoking status, diabetes and total cholesterol). False discovery rate (FDR)-adjusted p-values were applied to account for multiple comparisons. We further investigate the microRNA-targeted genes by querying microT-CDS, TargetScan and miRDB databases.
A total of 2174 participants (mean age = 55 years, range 30.0 - 95.0), 56.0% women) were included in the analysis. Out of 666 microRNAs, we found miR-382-5p, miR-654-5p and miR-424-3p significantly (pFDRIn summary, our results suggest that miR-382-5p, miR-654-5p, miR-424-3p are candidate biomarkers for BP, and miR-1292-5p for arterial stiffness trait. Based on microRNA target prediction, we identified a possible role of these microRNAs in CV-related pathways, which must be verified by further microRNA-mRNA coexpression analyses.

PrgmNr 2474 - Characterization of caffeine response regulatory variants in vascular endothelial cells

View session detail

Author Block: **C. Boye**[1], C. Kalita[2], A. S. Findley[1], A. Alazizi[1], R. Pique-Regi[3], F. Luca[3]; [1]Wayne State Univ., Detroit, MI, [2]Dana-Farber Cancer Inst., Boston, MA, [3]Wayne State Univ, Detroit, MI
Disclosure Block: **C. Boye:** None.
The human genome consists mostly of non-coding regions containing regulatory sequences that are important determinants of gene expression. Variants within these regions can contribute to phenotypes by modulating gene expression. These regulatory regions are also key mediators of the response to environmental stimuli. Gene-environment (GxE) interactions may contribute to conditions such as cardiovascular disease (CVD). Caffeine in particular is the most widely consumed stimulant and is known to produce a vascular response. Though results on the role of caffeine in cardiovascular health have been conflicting, previous studies of GxE in gene expression have confirmed the importance of caffeine in coronary artery disease (CAD) risk. In particular eQTLs for artery tissue that colocalize with CAD risk variants are enriched in binding sites for caffeine response factors. To further investigate GxE interactions for caffeine, we treated vascular endothelial cells with caffeine to measure allele-specific effects (ASE) of these regulatory variants using the massively parallel reporter assay Biallelic Targeted STARR-Seq (BiT-STARR-Seq). This approach has the advantage of avoiding confounding trans effects and is not limited by the allele frequency of the variants to be tested. We performed 6 BiT-STARR-seq experimental replicates and investigated 34,420 SNPs computationally predicted to be regulatory variants. In total we found 4,669 variants with significant ASE (FDR

PrgmNr 2475 - Converging evidence for differential regulatory control of *APOEÎµ4* on African versus European haplotypes

View session detail

Author Block: **K. Nuytemans**[1,2], M. Lipkin[1], L. Wang[1,2], D. Van Booven[1], A. J. Griswold[1,2], F. Rajabli[1], K. Celis[1], O. Oron[1], S. Zhang[3], F. Jin[3], M. Argenziano[4], S. F. Grant[5], A. Chesi[6], C. Brown[7], J. Young[1,2], D. M. Dykxhoorn[1,2], M. A. Pericak-Vance[1,2], J. M. Vance[1,2]; [1]John P. Hussman Inst. for Human Genomics, Miami, FL, [2]Dr. John T. Disclosure Block: **K. Nuytemans:** None.

Background: The difference in *APOEÎµ4* risk for Alzheimer disease (AD) between different populations is associated with *APOEÎµ4* local ancestry (LA), with protective effects seen on African versus European or Japanese LA background. Recently, we have shown that *APOEÎµ4* expression in the frontal cortex from European LA AD patients who are homozygous for *APOEÎµ4* is significantly increased relative to AD homozygous *APOEÎµ4* carriers with African LA. Thus, regulatory differences in LA are most likely involved in the protective factor(s) lowering the risk for African carriers of *APOEÎµ4.* We examined LA SNPs with significant frequency differences between African and European/Japanese *APOEÎµ4* haplotypes for areas of differential regulation. Methods: To assess the regulatory potential of enhancer activity in microglial, neuronal and astrocytic cell lines, we performed two different Massively Parallel Reporter Assay (MPRA) approaches assessing haplotype or single variant effects, supplemented with single fragment reporter assays. Additionally, we utilized Capture C analyses in the same cell types to support chromatin interactions with the *APOE* promoter and performed in-silico annotation for the LA region surrounding *APOE*. Results: A region in *TOMM40* spanning introns 2 and 3 was identified to have increased regulatory activity in the European/Japanese LA haplotypes versus the African LA in both astrocytes and microglia. This region overlaps with *APOE* promoter interactions in Capture C in the same cell types. Single variant analyses pinpoints rs2075650, rs157581 and rs59007384 as functionally different between African and European/Japanese *APOE* LA. Conclusion: Both differential regulatory function and Capture C data support an intronic region in *TOMM40* as contributing to the differential *APOE* expression between African and European/Japanese LA, with European/Japanese LA driving higher expression levels. Follow-up functional analyses of the enhancer region is currently ongoing.

PrgmNr 2476 - Genetic Variation in Cis Regulatory Domains and Trans Regulatory Hubs of Immunity

View session detail

Author Block: **D. Avalos**[1], G. Rey[2], A. Ramisch[3], O. Delaneau[4], E. T. Dermitzakis[2]; [1]Dept. of Computational Biology, Univ. of Lausanne, Lausanne, Switzerland, [2]Univ. of Geneva, Geneva, Switzerland, [3]Geneva, Switzerland, [4]Univ. of Lausanne, Lausanne, Switzerland
Disclosure Block: **D. Avalos:** None.
Studying the interplay between genetic variation and regulation of gene expression in immune cells is important to understand how cellular states are modified in various conditions, including immune diseases. Here we built cis and trans maps of regulatory regions with coordinated activity, also named as Cis Regulatory Domains (CRDs) using data from the BLUEPRINT consortium. This dataset includes whole genome sequencing, histone ChIP-Seq, RNA-Seq and DNA methylomics for up to 200 individuals. We were able to discover 7666, 9287, 4947 histone CRDs and 6112, 6053, 5701 methyl CRDs respectively in neutrophils, monocytes and T cells. Only ~35% of CRDs are shared between cell types, indicating that CRDs show a high level of cell-type specificity. Moreover, most CRDs are under strong genetic control: we found 9980 CRD-QTLs in monocytes. CRD-QTL sharing among cell-types varied between 39% and 86%. We discovered 15294 histone and 6185 methyl CRD-gene associations, with only 33% of sharing between cells, which reveals important cell-type specific regulation of gene expression by CRDs. We defined triplets (genetic variant, CRD, and gene) and subsequently found expression-CRD-QTLs: 21528, 17877 and 5457 histone eCRD-QTLs respectively in neutrophils, monocytes and T-cells. We also integrated CRD maps and associations with Promoter Capture Hi-C (PCHi-C) data available for the same cell types to investigate how functional interactions were related to physical 3D proximity. Analyses in trans revealed extensive inter-chromosomal interactions in primary immune cells, with up to 159422 histone CRD associations in neutrophils and 308 histone trans regulatory hubs (TRHs) in monocytes. 2 of these TRHs (in neutrophils and T-cells) were significantly linked to GO terms associated with immune response (64 terms at 5% FDR). We explored the patterns of histone trans CRD association sharing among cell types and found 25% to 58% of sharing.Finally, we integrated the trans networks with QTL data to discover hundreds of trans-eQTLs across cell types. Overlapping our hits with the trans-eQTLs from a meta-analysis in whole blood (eQTLGen Consortium) revealed that from 121 unique trans-eQTLs found in neutrophils, 40 were trans-eQTLs in eQTLGen involving a gene and a variant in LD with our variant. These results support that our data integration strategy is able to discover trans-eQTLs with a good overlap with existing datasets. Together, we show that mapping functional regulatory units using population genomics data allows discovering important mechanisms in the regulation of gene expression in immune cells.

PrgmNr 2477 - Insulin Resistance is associated with *PPARGC1A* promoter DNA-methylation in Ecuadorian women with Turner syndrome

View session detail

Author Block: **F. Alvarez-Nava**, M. Salinas, D. Bastidas, Y. VicuÃ±a, M. Racines-Orbe; Central Univ. of Ecuador, Quito, Ecuador
Disclosure Block: **F. Alvarez-Nava:** None.
We explored peroxisome proliferator-activated receptor-Î³ co-activator 1Î± gene (*PPARGC1A*) promoter DNA methylation status and mitochondrial content in lymphocytes in relation with glucose metabolism in Ecuadorian Women with Turner Syndrome (TS). In a cross-sectional study, a cohort of 34 Ecuadorian patients with TS along with a sex-, age- and body mass index (BMI)-matched reference group was studied. Insulin resistance and secretion indices were calculated. After bisulphite treatment of peripheral blood lymphocyte genomic DNA, a real-time methylation-specific PCR was used to determine the *PPARGC1A* methylated DNA/unmethylated DNA ratio in selected CpGs. Remarkably, *PPARGC1A* methylated DNA/unmethylated DNA ratios in the study group were significantly higher, compared to the reference group (1.036 vs 0.6097; 95% CI: 0.14 to 0.69; *P*=0.001). This ratio was directly correlated with overweight/obesity and inversely correlated with the biochemical features of insulin resistance (HOMA-IR and Matsuda indices). The mean mtDNA copy numbers of the study and reference groups were estimated as 27.15 Â± 3.21 and 49.93 Â± 6.699, respectively, and was indirectly correlated with methylated DNA/unmethylated DNA ratio of the *PPARGC1A* promoter (r= -0.78; 95 CI -0.9 to -0.55; *P*=PPARGC1A, independently of age or BMI, and contributed to 20% of the total variability in HOMA-IR index in TS subjects. Our findings suggest that PPARGC1A promoter DNA methylation status and lower mitochondrial number affect the metabolic phenotype in TS subjects.

PrgmNr 2478 - Investigating the role of a cardiac enhancer in the development of heart failure

View session detail

Author Block: **M. Htet**, M. Arvanitis, B. Lin, H. Gangrade, E. Tampakakis; Johns Hopkins Univ. Sch. of Med., Baltimore, MD
Disclosure Block: **M. Htet:** None.
Introduction: Alpha actinin-2 (ACTN2) is a major cytoskeletal protein that plays a critical role in maintaining the structural and functional integrity of the sarcomere. *ACTN2* mutations, although rare, have been shown to be associated with various types of cardiomyopathy. Using genome-wide association and multi-omic approaches, we recently identified non-coding variants that showed a strong association with heart failure (HF). Two of the variants are within an evolutionary conserved transcriptional enhancer region that regulates the *ACTN2* gene in human stem cell derived cardiomyocytes (hPSC-CMs). However, the role of cardiac enhancers in the development of HF remains unknown, therefore we used engineered heart tissues (EHT) from hPSC-CMs to investigate the effects of the ACTN2 enhancer. **Methods:** We used hPSC-CMs and performed morphologic and functional analyses by immunostaining, calcium transient measurements and quantitative assays such as western blotting, proteomics, qPCR and single cell transcriptomics. Next, we utilized CRISPR interference (CRISPRi) and chromatin immunoprecipitation (ChIP) to analyze the transcriptional regulation of the *ACTN2* enhancer. Finally, we measured force generation using EHTs. **Results:** We first engineered hPSC-CMs carrying an *ACTN2* enhancer deletion. This resulted in decreased *ACTN2* gene and protein expression, and cardiomyocytes developed myofibrillar disarray, hypertrophy, lower beating rates and suppressed calcium transients. Moreover, EHTs demonstrated reduced mechanical force. Using CRISPRi and ChIP we found that the transcription factor MEF2c binds a short DNA sequence containing an enhancer variant to regulate *ACTN2* expression. Single cell RNA-Seq analysis of hPSC-CMs treated with isoproterenol to model the hyperadrenergic state observed in HF, revealed the induction of pathways involved in protein quality control, actin fragmentation and apoptosis. We have also recently developed a mouse model to address the effect of the enhancer *in vivo*. **Conclusions:** Our study confirms that a conserved and clinically relevant enhancer region can effectively regulate *ACTN2*, and variants within that region can have detrimental consequences on CMs which can contribute to HF.

PrgmNr 2479 - Linking GWAS signals to target genes in skeletal muscle using single-nuclei multi-omic analyses

View session detail

Author Block: **C. Ventresca**[1], P. Orchard[2], N. Manickam[3], K. Gallagher[4,5], S. Parker[2]; [1]Dept. of Human Genetics, Univ. of Michigan, Ann Arbor, MI, [2]Univ. of Michigan, Ann Arbor, MI, [3]Dept. of Computational Med. and Bioinformatics, Univ. of Michigan, Ann Arbor, MI, [4]Dept. of Surgery, Univ. of Michigan, Ann Arbor, MI, [5]Dept. of Microbiol. and Immunology, Univ. of Michigan, Ann Arbor, MI

Type 2 diabetes (T2D) is a complex disease that arises from a combination of genes and environmental factors. Previous genome wide association studies (GWAS) of T2D have identified >600 independent genetic signals, but most fall within non-coding regions of the genome, which makes identifying underlying mechanisms difficult. These signals can be cell-type specific, which adds another layer of complexity to nominating mechanisms. Previous studies have established that chromatin architecture can pre-determine transcriptional responses and is therefore a critical molecular property of cell state potential. With this in mind, to investigate gene expression and chromatin accessibility in a more integrated manner, we generated single-nucleus multi-omic (joint RNA and ATAC profiling on the same nucleus) profiles in skeletal muscle. From this experiment we generated 7,613 high-quality pass-QC nuclei with a mean of >2k RNA UMIs and >48k ATAC reads per nucleus. From this sample we have identified nine different cell types ranging in abundance from 46% (type 1 muscle fibers) to 0.08% (smooth muscle) of all nuclei. This data is being used to link chromatin peaks to target genes with higher precision, since both RNA and ATAC datasets originate from the same nucleus. By performing peak-gene and peak-peak association analyses, we are linking GWAS signals to effector transcripts. We aim to use this multi-omics approach to compare the genetic control of gene expression and chromatin accessibility with the goal of nominating cell-specific skeletal muscle mechanisms at T2D and related trait GWAS signals.

PrgmNr 2480 - New epigenomic panel to detect mendelian disorders in Brazilian health system

Methylation is a main epigenomic tool for gene expression control in mammals. Through this mechanism, the genome presents a variable expression pattern between tissues, cells and alleles from different parental origin. Thus, structural variations in DNA, such as CNVs and point mutations, are not the only or definitive causes for clinical phenotypes. Several imprinting disorders, as well as recurrent changes in the methylation pattern in multifactorial diseases, are reported in the literature. However, diagnosis by epigenetic investigation tools still does not have a broad and consolidated pipeline, consequently making it difficult to use this in diagnostic routine. In this study, we sought to identify and validate, through a meta-analysis, the existence of epi-signatures for 16 different Mendelian diseases related to genomic imprinting or epigenomic changes in methylation. The data were obtained by searching public databases, such as Gene Expression Omnibus (GEO), and in several published studies. It was possible to identify the existence of epi-signatures for 11 Mendelian disorders. All diseases related to genomic imprinting (Angelman, Prader-Willi, Beckwith-Wiedemann, Silver-Russel, Kagami-Ogata and Temple syndromes) has significant data for correlation with characteristic DMRs. Kabuki, CHARGE, Claes-Jensen, Fragile X and Williams-Beuren syndromes do not have an etiology related to genomic imprinting, although present DMRs in recurrent regions. With these results, it was possible to develop an epigenomic array panel for screening epigenomics changes related to these diseases. Even among multifactorial diseases, there is an epigenetic profile. Thus, the use of epigenomic array screening platforms, can be considered promising for a new level of diagnostic analysis, providing a multidimensional characterization of the genomic structure. Furthermore, the consolidation of epigenomic diagnostic methodologies into a single tool, such as the one proposed in this study, provides economic, laboratory and diagnostic advantages.

PrgmNr 2481 - Promoter methylation analysis in candidate genes of severe preterm birth

Preterm birth (PTB), defined as the delivery of an infant before 37 weeks of gestation, results from the interaction of genetic and environmental components and constitutes a complex multifactorial syndrome. The etiology of PTB is not completely understood because of the complex interplay of genetic, environmental, and host factors. Therefore, it is key to develop approaches that integrate genetic, expression, epigenetic and epidemiological data, to identify biomarkers that allow progress in translational medicine.To this end, we developed an analysis pipeline to study the methylation status of gene promoters. In this work, we tested this workflow in candidate genes for severe premature labor, selected because they were previously found differentially expressed in chorioamniotic tissue in preterm birth in an Uruguayan population. To test the methylation levels in preterm birth gene promoters, we analyzed chorioamniotic tissue from 6 severe preterm birth and 4 controls delivered at term. Genomic DNA was treated with sodium bisulfite and 13 gene promoters of preterm birth candidate genes were amplified: *ANKRD2*, *ACCS*, *BIRC3*, *WNT1*, *CXCL2*, *NRN1*, *STEAP1*, *EGR3*, *MAMDC2*, *CNTNAP3B*, *GK*, *PIK3AP1* and *MIR155HG*. Amplicons, with an average length of 1000bp, were sequenced using the MinION platform (Oxford Nanopore). We pooled amplicons of each individual, prepared libraries using PCR Barcoding kit and sequenced them in Spot-ON 106D R9 flow cell. Basecalling and debarcoing were carried out in MinKnow, reads were filtered by quality with Nanofilt. We used Bismark with custom score parameters to align bisulfite treated sequenced reads to a human reference genome (hg38) and to extract methylation status. CpGs were filtered by coverage (30x) and analyzed in R software. We detected hypomethylated regions in severe preterm birth as compared to controls. We found differential methylation in promoters between patients and controls in genes *NRN1* and *MAMDC2* (Wilcoxon test, p

PrgmNr 2482 - Using cellular deconvolution to investigate cell subtype proportions in cortical gene expression data in schizophrenia

Schizophrenia is a psychiatric disorder that affects 1% of adults and is a major global health problem in that only 13.5% of affected individuals achieve full recovery criteria. Altered gene expression in the brain has previously been associated with neuropsychiatric disorders but this research has primarily focused on bulk tissue. Further analysis of data from bulk tissue to isolate and study predicted cell types based on gene expression profiles could uncover further insights into the altered expression of genes and pathways that contribute to schizophrenia etiology. Cell subtype deconvolution is used to estimate the proportion of cell subtypes present in bulk expression data. Here, we reanalyzed gene expression data from the PsychENCODE consortium (n= 558 schizophrenia cases and 1039 controls; cortical samples) by using new single cell sequencing data that allowed for an improved cell subtype deconvolution analysis.
New single cell data for ~30,000 cells was added to the original dataset to give an increased sample of ~62,000 cells. In comparison to the original analysis, we observed alterations in astrocyte proportions between cases and controls, particularly for two distinct astrocyte populations, only one of which had significantly different proportions between cases and controls (p=

PrgmNr 2483 - Cas9 targeted enrichment of mobile elements using nanopore sequencing

View session detail

Author Block: **W. Zhou**[1], T. McDonald[1], C. Castro[1], C. Mumm[1], J. Switzenberg[1], R. Mills[2], A. P. Boyle[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Univ Michigan Med Sch, Ann Arbor, MI
Disclosure Block: **W. Zhou:** None.
Mobile element insertions (MEIs) are repetitive genomic sequences that contribute to genetic variation as well as various genetic disorders. Targeted and whole-genome approaches using short-read sequencing have been developed to identify reference and non-reference MEIs; however, the read length hampers the detection of these elements in complex genomic regions. Here, we pair Cas9-targeted nanopore sequencing with customized computational methodology (Nano-Pal) to capture active MEIs in human genomes. We design the guide RNAs for repetitive MEIs using unique subfamily-specific sequences. We demonstrate parallel enrichment for distinct classes of MEIs, averaging 44% of reads on-targeted signals (64% L1Hs, 52% *Alu*Yb, 64% *Alu*Ya, 10% SVA_F, 3% SVA_E, and 56% pooled) and exhibiting a 13.4-54x enrichment over whole-genome approaches. We show an individual MinION flow cell can recover most MEIs (97% L1Hs, 93% *Alu*Yb, 51% *Alu*Ya, 99% SVA_F, and 65% SVA_E). In a well-characterized benchmark genome, NA12878, we identify seventeen non-reference MEIs with retrotransposition hallmarks overlooked by modern, long-read analysis pipelines, primarily in repetitive genomic regions. We further provide the CpG methylation profiles of reference and non-reference MEIs derived from individual nanopore reads. This work introduces the utility of nanopore sequencing for MEI enrichment and lays the foundation for rapid discovery and potential functional analysis of elusive, repetitive genetic elements.

PrgmNr 2484 - Comparative transcriptomics of the human lung and epididymis epithelia

The different cell lineages within epithelial tissues have distinct gene expression profiles. These unique transcriptomes confer the identity and region-specific diversity in epithelial function, for example in human airway/bronchial and male genital duct/epididymal epithelium (HBE and HEE). Here, we perform comparative analysis of whole epithelium RNA-seq and of single cell (sc)RNA-seq to identify patterns of gene expression shared and contrasted between these two similar tissues. Gene ontology and gene set enrichment analysis of whole epithelium datasets identified genes and molecular processes specific for the lung or epididymis, which may help explain mechanisms behind their unique biological functions. We next performed the same analysis between clusters in HBE and HEE single cell data to generate similarity matrices for gene expression. Varying degrees of correspondence in the inter-cell comparison offers insights into the differentiation of known cell types between the lung and epididymis. Integration of the datasets further reveals the concordance and discordance of gene expression profiles between stratified clusters. Finally, we annotated and performed DNA footprinting of HBE and HEE open chromatin data to elucidate similarities at the transcription factor binding level.

PrgmNr 2485 - Detecting differentially methylated regions in individual methylomes

View session detail

Author Block: **C. Hansen**, M. Janecka; Mount Sinai, New York, NY
Disclosure Block: **C. Hansen:** None.
Recent exome sequencing studies have demonstrated a number of highly penetrant rare and *de novo* variants and copy number variations underlining rare monogenic forms of autism spectrum disorder (ASD) - suggesting a multiple rare variants etiology. Rare and extreme deviations in individual methylomes, called epivariations, have also been linked with the risk of neurodevelopmental disorders, including ASD. Epivariations may be a consequence of rare or *de novo* genetic events, but also of environmental/stochastic effects in cases with no discernable genetic cause - explaining an otherwise unknown etiology. An epivariation is defined as an extreme methylomic deviation across a genomic region, compared to a set of reference methylomes. In this study we devised a novel approach to detect and quantify epivariations from differentially methylated regions (DMRs) in individual methylomes assessed by DNA methylation array. Our method uses individual genome-wide M-values, which we z-score transform by the cohort median and median absolute deviation. This ensures similar variance across all CpG sites, and is robust towards outliers. We combine all possible sequential combinations of z-scores in a genomic region with the Stouffer-Liptak method, with the Kechris adjustment for spatial auto-correlation between neighbouring CpG sites. The sequences of non-overlapping CpG sites resulting in the highest absolute combined z-scores indicate the optimal boundaries of each DMR. Within these boundaries we assess methylation deviation across the DMR by taking the mean of all z-scores. This method robustly detects DMRs across samples and quantifies their deviance unbiased by the number of CpG sites included in the DMR - which may vary between array designs and genomic regions. We use this information to bin DMRs by their deviance and evaluate their frequency and functional properties in relation to neurodevelopmental phenotypes. Individual DMR pathogenicity is evaluated from a list of genes previously linked with psychiatric disorders, methylomic developmental sites as well as loss of function intolerance scores. We find that epivariations underlie phenotypical heterogeneity in ASD, mark monozygotic twins discordant for disease, and that moderate DMRs bridge the gap between the small but common methylomic deviations observed in epigenome-wide association studies and the rare high impact epivariations observed in previous studies.

PrgmNr 2486 - Direct assessment of impact of transcription factors on enhancer activity

Identification and quantification of cis-regulatory elements have provided new insights into their roles in complex disease. There has been significant progress in the ability to assess enhancer function, enhancer-gene interactions, and effects of enhancer variants on phenotypes using both experimental and computational approaches. However, direct functional evidence of enhancer activity in response to transcription factor binding is limited. Traditionally, enhancers have been identified using ChIP-seq of enhancer-binding transcription factors or histone marks as well as profiling open-chromatin regions using DNase-seq and ATAC-seq. Further, massively-parallel reporter assays including STARR-seq have been used to directly quantify enhancers by transfecting candidate enhancer libraries into a host cell and sequencing self-transcribed enhancer fragments. Here, using a series of STARR-seq assays on HEK293T cell lines deleted for a suite of six transcription factors compared to control lines, we provide direct evidence of association of transcription factors towards enhancer activity. We hypothesized that deletion of each transcription factor will alter activity of specific enhancers and will help categorize enhancers that are unique to or shared across multiple transcription factors. We generated a comprehensive library of 46,000 enhancer fragments curated from both cell-type specific DNase-seq and ChIP-seq sites as well as global enhancer marks for the six transcription factors. Using CRISPR-Cas9, we then performed genomic deletions to obtain significant (>75%) depletion of the transcription factor proteins, as assessed using western blots. We will use STARR-seq to assess and quantify enhancer activity for each deletion line, grouped by their roles in gene regulation. For instance, we will test enhancer activity changes in deletion lines for canonical transcription factors such as ATF2, FOXA1 and CTCF. Similarly, we will assess enhancer activity for lines individually deleted for Wnt signaling genes LEF1 and TCF7L2. We will finally assess enhancer activity after deleting neurodevelopmental disease associated SCRT1 (a neurodevelopmental gene) and the 16p12.1 deletion. We will use enhancer activity change in combination with differential gene expression data to uncover the genetic etiology of complex neurodevelopmental disease. Comparison of the activity patterns across groups will provide a framework for understanding enhancer activity signatures demonstrated by distinct gene regulatory groups. Our strategy will help formulate and refine enhancer-based gene regulatory networks responsible for disease complexity.

PrgmNr 2488 - Escape from X-inactivation in twins exhibits intra- and inter-individual variability across tissues

X-chromosome inactivation (XCI) silences one X in females to balance the unequal X-linked transcriptional dosage between the sexes. However, over 15% of X-genes escape XCI and is biallelically expressed. Our knowledge of XCI escape in humans largely rely on sex-differences, hybrid cell lines, and epigenetic marks, which are all indirect proxies of escape. Differently, tissue samples with skewed XCI enable the detection and measurement of escape directly in females. At present, the incidence and variability of escape across cells, tissues and individuals are not well known. The extent to which genetics and environment influence escape is also largely unknown. Using RNAseq and DNAseq data in a multi-tissue dataset sampled from 248 skewed female twins, we investigated escape prevalence and variability across fat and skin tissues, lymphoblastoid cell lines (LCLs), and purified immune cells (monocytes, B, T-CD4$^+$, T-CD8$^+$, NK), and individuals.

Solid tissues exhibit up to 13% higher incidence of escape than LCLs. 159 genes escaped XCI in least one tissue. This set includes 54 novel candidate escapees, of which 35% are long-non-coding RNAs. 24 genes constitutively escaped XCI across tissues, while a separate set of 51 genes exhibited tissue-restricted escape. Within an individual, there are both genes escaping XCI in all tissues, and genes showing tissue-restricted escape. Analysis of inter-individual variability revealed 40 genes (e.g. *BTK*, *CD99L2*) exhibiting consistent escape levels across females in at least one tissue, and 62 genes (e.g. *DDX3X*, *KDM6A*, *UBA1*) exhibiting inter-female variability in multiple tissues. Escape is heterogeneous across immune cell types, with higher incidence in lymphocytes than monocytes. There are both genes escaping XCI in multiple immune cell types, and immune cell type-specific escapees. Protein-protein network analysis highlighted that escapees interact with other proteins on a genome-wide scale, and are involved in varied processes and pathways such as epigenetic control of gene activity. Monozygotic (MZ) co-twins share significantly more similar escape levels than dizygotic (DZ) co-twins (corr.MZ=0.6; corr.DZ=0.46; P

PrgmNr 2489 - Genetic variants regulating microRNA expression in the developing human neocortex

Genome-wide association studies (GWAS) have revealed a number of genomic loci associated with risk for neuropsychiatric disorders and brain-related traits, but for many of these loci, the causal mechanisms are unknown. Using expression quantitative trait loci (eQTL) data, many of the risk loci can be linked to protein-coding genes or lincRNAs. However, the mechanism underlying a significant proportion of loci remain unexplained. MicroRNAs (miRNAs) are poorly measured in standard eQTL studies yet have important influences on neurogenesis and have been found to be differentially expressed in brain tissue from patients with neuropsychiatric disorders. By linking these miRNA-eQTLs to previously defined mRNA-eQTLs and genome-wide significant loci for brain traits, we aim to reveal causal mechanisms by which common genetic variation influences gene regulation and risk for brain-related traits.

Here, in 212 donors, we identified 85 miRNA-eQTLs associated with expression of 70 miRNAs (emiRs) in human cortical tissue during mid-gestation. Moreover, 13 miRNA-eQTLs were associated with expression of previously unannotated miRNAs which we discovered here in developing cortical tissue. We found enrichment of miRNA-eQTL signal within active transcription start sights and among chromatin associated with transcription. Co-localization with mRNA-eQTLs within the same population of tissue samples yielded 23 miRNA-eQTLs that co-localize with 33 mRNA-eQTLs. Of the 23 miRNA-eQTL co-localizations, 18 of the emiRs are within the expressed host-gene of the mRNA-eQTL, indicating a co-transcriptional mechanism by which a mRNA-eQTL also influences miRNA expression. Co-localization of miRNA-eQTLs with GWAS summary statistics yielded one robust co-localization of miR-4707-3p expression to educational attainment and head size phenotypes. MiR-4707-3p also co-localizes with a mRNA-eQTL of HAUS4, which is the host-gene of miR-4707 (located within exon 1 of HAUS4). Expression of HAUS4, a protein-coding gene known to play a role in cell-cycle regulation and proliferation, is anti-correlated with miR-4707-3p expression, consistent with miRNA biogenesis from an exon of the host-gene.

Ongoing work will identify miR-4707-3p targets and the effect of miR-4707-3p and HAUS4 overexpression on proliferation in human neural progenitor cell lines. Using local-miRNA-eQTLs, we propose novel mechanisms by which genetic variation influences brain related traits.

PrgmNr 2490 - Mapping chromatin interactions within the *CYP3A* gene locus

View session detail

Author Block: **J. M. Collins**[1], D. Wang[2]; [1]Pharmacotherapy and translational research, Univeristy of Florida, Gainesville, FL, [2]Univ. of Florida, Gainesville, FL
Disclosure Block: **J.M. Collins:** None.
The cytochrome P450 CYP3A4 is the most abundant drug-metabolizing enzyme in the liver, metabolizing nearly half of the commonly prescribed medications. CYP3A4 expression is highly heritable and shows significant variation between individuals, but to date, functionally classified SNPs do not explain most of the variation, and cis-acting regulatory elements controlling CYP3A4 transcription remain uncertain. CYP3A4 is located within a cluster of four CYP3A genes (CYP3A4, 3A5, 3A7 and 3A43) that have different tissue and developmental expression profiles. Previously, using chromatin conformation capture (4C) assays and CRISPR-mediated deletion, we identified and characterized several cis-acting regulatory elements controlling CYP3A4 expression in the human liver. To further elucidate potential distal enhancers/regulatory elements and their interactions that regulate expression of the four CYP3A genes, we conducted 4C experiments targeting all four CYP3A promoters as viewpoints. We prepared 4C templates from several cell types that show different CYP3A expression patterns: LS174T (intestinal epithelial carcinoma), Huh7 (hepatoma), and human primary hepatocytes from both black and white donors. Moreover, we performed ATAC-Seq on the same hepatocytes from black and white donors to explore accessible chromatin indicative of regulatory regions. By leveraging 4C, ATACseq, and publicly-available ChIP-Seq datasets for enhancer marks: the histone modifications H3K4me1 and H3K27ac and the p300 histone acetyltransferase protein, we have identified several putative regulatory regions across the CYP3A locus. We are in the process of validating these peaks and expect to draw a chromatin interaction map for the CYP3A locus. The identification of cis-acting regulatory elements controlling CYP3A gene expression is a critical step toward understanding genetic and epigenetic factors contributing to large inter-person variabilities in CYP3A gene expression, with the promise of identifying biomarkers for personalized drug therapy

Skeletal muscle is quantitatively the largest organ to regulate metabolism. Our goal is to understand the interplay of skeletal muscle tissue cell type composition and cell state with sex, physical activity and T2D-related physiological traits. We profiled single nucleus resolution chromatin accessibility (snATAC-seq) and gene expression (snRNA-seq) across 287 Finnish individuals with frozen human vastus lateralis skeletal muscle biopsies. We clustered 224,690 snATAC-seq and 190,291 snRNA-seq nuclei using LIGER and identified three main muscle cell clusters corresponding to Type 1 (slow twitch oxidative), Type 2A (fast twitch oxidative), and Type 2X (fast twitch glycolytic) muscle fibers, as well as 10 additional cell types. In each cell type, we used a negative binomial regression model to test for association of the number of nuclei (RNA and ATAC-seq) with sex, age, physical activity levels and T2D-related traits (accounting for total nuclei number). Using linear regression, we tested separately for association of snATAC-seq peaks levels and gene expression with the same set of traits. We used FDR -7), higher energy expended was associated with higher proportion of smooth muscle cells (p= 7.6×10^{-6}), and higher 24 hr physical activity was associated with higher proportion of endothelial cell (p= 8.0×10^{-4}). For the most abundant cell types (in order of overall abundance Type 1, Type 2A and Type 2X), being male (p= 8.7×10^{-13}) and having a higher fasting insulin concentration (p= 3.2×10^{-8}), were associated with higher proportion of Type 2X muscle fiber nuclei, whereas female sex (p=.00022) and lower fasting insulin (p=7.6×10^{-4}) were associated with higher proportion of Type 1 muscle fiber nuclei. No physiological traits were associated with Type 2A fiber nuclei proportions. We tested for association of chromatin accessibility and gene expression with physiological traits in each cell type. Type 2A muscle fiber nuclei had between 1.2->10 fold more ATAC-Seq peaks and genes were associated with sex and fasting insulin than Type 1 and 2X muscle fiber nuclei. This suggests that cell types with relatively low variability in proportion of nuclei by phenotypic trait, such as Type 2A muscle fibers, can have relatively high variability in gene expression and chromatin accessibility for the same traits. Deeper understanding of the interplay between physiological traits, cell type composition and cell states will provide clues to metabolic disease progression.

Disclosure Block: **T. Dupuis:** None.

RNA-seq experiments can be used to identify the genes which mediate GWAS genetic effects on disease risk. However, it will not explain those variants that act on regulatory processes downstream of transcription. Studies have found low correlations between expression and protein levels, but these could be due to environmental and technical factors. Here, we evaluate the effect of eQTLs on translation by quantifying shared genetics regulation of expression and protein levels. We estimated the heritability and genetic correlations (rho_G) of whole-blood gene expression (RNA-seq) and plasma proteins (Olink) in a pedigree from the GAIT2 project (N=67, 90 proteins, expression of 16748 genes). We identified 42 expression-protein pairs with high reliable estimates of rho_G. We observed a low phenotypic correlation (median $|rho_P|$ of 0.11) but high absolute genetic correlations median $|rho_G|$=0.25, Wilcoxon test $|rho_G| > |rho_P|$, p=2.5e-6). This implies that for many genes there is a common set of variants regulating both expression and protein levels. One example is *RETN*, with rho_G=0.78 and rho_P=0.49. The gene has been previously associated with LDL cholesterol levels, and it is known to have a variant (rs62109837) associated with both expression and protein levels. Overall, for a considerable proportion of genes (18/42) the genetic correlation between expression and protein levels is negative, implying genetic effects of opposite directions. Of known genetic effects on expression and protein levels, a far smaller proportion have opposite signs. For instance, studies in DIRECT[1] have identified 48 variants with effects on both the expression and protein levels, among which only 4 had opposite directions of effect, meaning more work is needed to understand the mechanism behind this finding. Our results indicate that the low phenotypic correlation between expression and protein levels is mainly driven by environmental and technical factors, and that there is a substantial sharing of genetic effects between expression and proteins abundance.

PrgmNr 2493 - Sex-specific and Generational Effects of Alcohol Use and Tobacco Smoking on Epigenetic Age Acceleration in the Michigan Longitudinal Study

View session detail

Author Block: **W. Zhao**[1], A. Carter[1], C. Bares[2], L. Lin[1], B. G. Reed[2,3], M. Bowden[2,4], R. A. Zucker[5,6], J. A. Smith[1,7], J. B. Becker[5,8]; [1]Dept. of Epidemiology, Sch. of Publ. Hlth., Univ. of Michigan, Ann Arbor, MI, [2]Sch. of Social Work, Univ. of Michigan, Ann Arbor, MI, [3]Dept. of Women's and Gender Studies, Univ. of Michigan, Ann Arbor, MI, [4]Michigan Med., Univ. of Michigan, Ann Arbor, MI, [5]Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI, [6]Dept. Psychiatry and Addiction Ctr., Univ. of Michigan, Ann Arbor, MI, [7]Survey Res. Ctr., Inst. for Social Res., Univ. of Michigan, Ann Arbor, MI, [8]Michigan NeuroSci. Inst., Univ. of Michigan, Ann Arbor, MI

Disclosure Block: **W. Zhao:** None.

Background: Excessive alcohol use and tobacco smoking are risk factors for poor health in both men and women, but use patterns and relationships with diseases and mortality differ between sexes. The impact of these lifestyle factors on biological markers, such as DNA methylation, may also be different by sex. Whether parental alcohol or tobacco intake has effects on the epigenetic profiles of children that persist into adulthood is not well studied. The epigenetic age (DNAmAge), an aggregated measure over many aging-related methylation sites across the genome, is an emerging biomarker of aging. The difference between DNAmAge and chronological age, herein referred to as epigenetic age acceleration (DNAmAA), correlates with a variety of health outcomes. In this study, we assessed the sex-specific effects of alcohol and tobacco use, as well as parental alcohol/tobacco use, on four measures of DNAmAA in a longitudinal cohort with multiple generations.

Methods: In 42 parents and 45 offspring from the Michigan Longitudinal Study (MLS), four measures of DNAmAA (HannumAA, HorvathAA, PhenoAA and GrimAA) were estimated from saliva samples. Linear mixed models were used to assess the associations between alcohol use or tobacco smoking and DNAmAA in males and females separately. Alcohol use/tobacco smoking by sex interaction models were used to assess whether the effects differ by sex. In the offspring only, the association between parental alcohol use and tobacco smoking (when the offspring was 12 years old or younger) with adult DNAmAA was also examined.

Results: In females, but not males, each additional alcoholic drink per month was associated with a 0.047-year increase in GrimAA (p = 0.046). Males who were current tobacco smokers had an increased HannumAA of 2.19 years (p = 0.043); this was not found in females. Heavy paternal alcohol use was associated with a 3.75-year increase in GrimAA (p = 0.046) among offspring. Parental tobacco smoking was not associated with any DNAmAA measure.

Conclusions: This study found sex-specific effects of alcohol use and tobacco smoking on epigenetic age acceleration. Heavy paternal alcohol use when the offspring were 12 years old or younger was associated with increased offspring age acceleration in adulthood. These findings suggest that paternal alcohol use influences adult DNAmAA among offspring, and that sex-specific differences in the effects of alcohol use and tobacco smoking on DNAmAA should be further examined.

PrgmNr 2494 - Stressing out epigenetics: How chronic stress alters the epigenetic landscape during neurodevelopment

View session detail

Author Block: **J. N. Kuehner**; Emory Universtiy, Atlanta, GA
Disclosure Block: **J.N. Kuehner:** None.
Stress is the multi-level response an organism has to an environmental stimulus, and when experienced chronically, has negative consequences such as the development of anxiety or depressive behaviors. It is well documented that epigenetics has critical roles in brain development and function; however, a major gap in our knowledge about chronic stress and depression are what rolls stress-induced epigenetic alterations could be contributing to. Whether DNA modifications and their machinery are involved in stress response has yet to be elucidated. 5-methylcytosine (5mC) and 5-hydroxymethylcytosine (5hmC) are two of the most abundant DNA modifications in the mammalian genome and have been implicated in stress response. However, a genome-wide analysis of the 5mC or the 5hmC landscape in response to chronic stress have yet to be rigorously investigated. To determine how chronic stress can alter the epigenetic profile in various brain regions during mouse brain maturation, we employed the chronic social defeat stress (CSDS) paradigm. CSDS is an ethologically relevant paradigm that robustly and reproducibly induce depressive-like phenotypes and anxiety symptoms in rodents. We therefor performed CSDS on several cohorts of 3- and 6-month-old male mice and observed depressive-like behaviors using established measurements such as: nest building, food consumption, weight, sucrose preference testing and social interaction. From our behavior data, we found that both age groups demonstrated an acute stress response, social avoidance and significantly higher blood corticosterone levels. However, we found that anhedonic-like behavior was only observed in the 6-month animals, suggesting an age-dependent response to stress. A unique characteristic of the CSDS paradigm is that defeated animals are bimodally distributed into either â□□susceptibleâ□□ or â□□resilientâ□□ categories based on the social interaction test. Dot blot analysis revealed that in the cortex of susceptible animals, global levels of both 5mC and 5hmC were elevated compared to resilient animals. Using 5hmC-capture coupled with high-throughput sequencing, we analyzed the cortical 5hmC landscape in our 3-month CSDS resilient and susceptible animals. Differentially hydroxymethylated regions associated with either stress resilience or susceptibility were obtained and distinctive biological networks were identified. Cumulatively, our data demonstrates that the CSDS paradigm induces both physiological and biological symptoms of depression and that DNA modifications could play key roles in responding to stress that could ultimately contribute to mental illness.

PrgmNr 2495 - Transcriptome profiling using long-read sequencing to dissect the interplay between genetic variant and transcript variations in a population-based study

View session detail

Author Block: **A. Real**[1], C. Borel[2], N. Lykoskoufis[3], J. Seebach[1], A. Ramisch[4], E. T. Dermitzakis[3]; [1]Univ. Geneva, 1205, Switzerland, [2]Univ. of Geneva, Geneva 4, Switzerland, [3]Univ. of Geneva, Geneva, Switzerland, [4]Geneva, Switzerland

Disclosure Block: **A. Real:** None.

Over the last decade, RNA-seq technologies have vastly increased our knowledge of gene expression and transcript isoform signatures. However, current short-read RNA-seq methods show limitations in identifying complex transcript isoforms as full-length transcripts and RNA modifications are not retained. In this study, we address these limitations exploiting the advantages of long-read native poly(A) RNA-seq using the Oxford Nanopore Technologies (ONT) gridION platform. We direct RNA sequenced 60 genotyped lymphoblastoid cell lines from European ancestry obtaining a median of 3.2 million reads per sample with a median read length of 0.9M bps. We aim to understand the effect of genetic variation on transcription, alternative splicing and mRNA modification within a population.We identified 12,045 protein coding genes transcribed in at least 90% of the samples. In comparison, for the short-read RNA-seq (Illumina), the number of detected transcripts are similar (85%) with a variable transcripts abundance correlation among the samples (spearman r^2 0.49-0.68).We performed a preliminary isoform analysis on 42 samples using the FLAIR pipeline (Tang et al. Nature Communication, 2020), and detected a total of 234,513 transcript isoforms from which one third are expressed in at least 50% of the samples. It includes 40,449 isoforms accounting for 13,362 genes, 23080 are not annotated (GENCODE v27).Moreover, we observe variation of isoform usage across the population which is encouraging for our future analysis to understand the underlying mechanisms of these variations.Our next steps will be to perform allele-specific expression analysis to understand the effect of common and rare genetic variants on specific transcript alterations with the advantage of high resolution given by long-read sequence technology. Furthermore, the identification of RNA modifications combine with ChIP-seq data from our previous work will be of interest to dissect the contribution of RNA and histone modifications to gene regulation.

PrgmNr 2496 - Transcriptomic mapping of bursting kinetics in human cells

View session detail

Author Block: **B. Jin**, W. S. Bush; Case Western Reserve Univ., Cleveland, OH
Disclosure Block: **B. Jin:** None.

Most studies consider gene expression in terms of global transcript levels; however, growing evidence illustrates that promoters in eukaryotic cells tend to exhibit bursting patterns by repeatedly alternating between an activated and inactivated state. This promoter bursting can introduce significant cell-cell heterogeneity even in clonal cells. However, the molecular mechanism for bursting kinetics is not clear. Meanwhile, studying bursting kinetics has been limited to a small number of genes and model organisms due to difficulties in measuring transcript levels over time. Single-cell RNA-seq can measure individual cell expression profile, where each cell can be assumed as a temporal snapshot of an individual promoterâ□□s activity. Hence, we use single-cell RNA-seq data to at first time construct a transcriptomic kinetics map of two human cell lines: GM12878 and K562. Then, we further investigate how regulatory factors and histone markers are related to bursting kinetics within them. We found that the estimated bursting kinetics show two features: 1. Genes classified as bursting genes (14% genes for GM12878) exhibit a higher mean expression level. Furthermore, within a 2000bp window around the TSS, 4 out of 10 ranked regulators that discriminate bursting genes from non-bursting genes are shared between GM12878 and K562 (H3K36me3, POLR2Aphosphos2, CBFB, ZBED1) 2. The bursting frequency of genes in both GM12878 and K562 increase with the existence of putatively positive markers(e.g., H3K9ac, H3K27ac) and decrease trend with the existence of putatively negative markers(e.g., H3K9me3 and H3K36me3).By further examining experimental data perturbing enhancer regions within the K562 cell line, we validate the changes in promoter bursting kinetics. Overall, ~300 genes show a significant difference in the distribution of transcripts across perturbated cells compared to controlled cells. While some of these genes exhibit a similar increase or decrease in mean expression level, the changes in promoter kinetics are modulated differently. Our results show that bursting kinetics is independent information from the mean expression level and provides additional information on gene-specific regulatory mechanisms. Furthermore, as cell-cell heterogeneity has been associated with various cellular phenotypes(e.g., cell differentiation, aging, etc.), analyzing the bursting kinetics could add to our understanding of how regulatory variation influences disease risk.

PrgmNr 2497 - Chromolooper:Building genetic neighborhoods using a physically informed graph algorithm

View session detail

Author Block: **D. Borges-Rivera**, T. T. Tibbitts; Dogodan Therapeutics, Inc., Westford, MA
Disclosure Block: **D. Borges-Rivera:** None.
How a eukaryotic cell controls the many-to-many interactions between cis-regulatory elements and their cognate genes must be robust and simple, since it is a process that shows remarkable stability and fortitude to mutations while being rebuilt every cell division. Here we use a physically informed graph partitioning algorithm to calculate eukaryotic genetic neighborhoods, defining the genomic area by which each gene is likely to be regulated. We use as input chromatin loops, CTCF binding peaks, and RNA expression sourced from various large scale projects, such as ENCODE, to parametrize a modified louvain graph partitioning algorithm. We are able to recover previously described human genetic neighborhoods, such as the one encompassing IRX3 and IRX5, while predicting tens of thousands more per genome. These eukaryotic genetic neighborhoods, which reflect the local state-sensitive genetic regulatory architecture, are key for assessing the impact of disease-associated sequence variation not falling within protein coding regions. We connect our mendelian knowledge of genes to the non-coding using chromatin loops. We provide this algorithm as a python package, Chromolooper, to promote use in the wider community.

PrgmNr 2498 - Differential network analysis of time-series RNA-sequencing in response to perturbation

View session detail

Author Block: **S. Xue**[1,2], C. Piermarocchi[1], G. Mias[3]; [1]Dept. of Physics and Astronomy, Michigan State Univ., East Lansing, MI, [2]IQ Ctr., Michigan State Univ., East Lansing, MI, [3]Michigan State Univ., East Lansing, MI

Disclosure Block: **S. Xue:** None.

Differential Network (DN) analysis is a method that has long been used to interpret static gene expression data. The method identifies the rewiring of co-expression gene networks in response to external perturbations. Our study extends the DN method to time-series RNA sequencing (RNA-seq) data. We used DNs to analyze two sets of RNA-seq time series. The first dataset was obtained from an experiment profiling saliva expression in a human subject before and after vaccination with a 23-valent pneumococcal polysaccharide vaccine (PPSV23). Expression data covered 24 timepoints of hourly sampling over each of two periods, before and after vaccination respectively. The second dataset was from an ex-vivo experiment of primary B cell expression before and after treatment with Rituximab, covering six timepoints collected over 15 hours. We first preprocessed the experimental data to eliminate duplicate and sparsely sampled genes. We then calculated the fold-change between the treated and untreated data sets, selecting those genes which showed the biggest change in expression. With these target genes, we constructed a co-expression network for both the treated and untreated data sets. Subtracting the untreated network from the treated network produced a differential network. Finally, we detected gene communities and carried out Reactome pathway enrichment analyses to ascertain the biological significance of the DN results. Plotting the data from the DN into heatmaps enabled us to visualize the dynamic changes in individual communities. The DN method enabled us to identify biological pathways consistent with the mechanisms of action of the PPSV23 vaccine, and target pathways of Rituximab. The community detection algorithm on the DN revealed clusters of genes characterized by a collective behavior. Some DN communities, especially in the case of saliva, showed characteristic time signatures, outlining a chronological order in pathway activation in response to the perturbation. Our DN method confirmed the existence of temporal features in the changes of gene expression patterns. Moreover, we identified early and delayed responses within network modules in the saliva dataset, and three temporal trend patterns in the B cell data. Our DN method is simpler to implement and computationally more efficient than other network-based analysis for time-series RNA-seq data, such as Bayesian networks. Therefore, the DN method may be useful in drug development by providing a description of changes in gene expression in response to a drug.

PrgmNr 2499 - Effective gene expression prediction from sequence by integrating long-range interactions

The next phase of genome biology research requires understanding how DNA sequence encodes phenotypes, from the molecular to organismal levels. How noncoding DNA determines gene expression in different cell types is a major unsolved problem, and critical downstream applications in human genetics depend on improved solutions. Here, we report substantially improved gene expression prediction accuracy from DNA sequence through the use of a new deep learning architecture called Enformer that is able to integrate long-range interactions (up to 100 kb away) in the genome. This improvement yielded more accurate variant effect predictions on gene expression for both natural genetic variants and saturation mutagenesis measured by massively parallel reporter assays. Notably, Enformer outperformed the best team on the critical assessment of genome interpretation (CAGI5) challenge for noncoding variant interpretation with no additional training. Furthermore, Enformer learned to predict enhancer-promoter interactions directly from DNA sequence competitively with methods that take direct experimental data as input. We expect that these advances will enable more effective fine-mapping of growing human disease associations to cell-type-specific gene regulatory mechanisms and provide a framework to interpret cis-regulatory evolution. To foster these downstream applications, we have made the pre-trained Enformer model openly available, and provide pre-computed effect predictions for all common variants in the 1000 Genomes dataset.

Network approaches can provide unique pathobiological insights when applied to transcriptomics data. Particularly, gene expression correlation networks contain information about the regulatory relationships between genes and their co-functionality. A shortcoming is that interactions between genes may be individual-specific and can be underestimated in global network analysis approaches. To address this issue, Individual-specific networks (ISNs) have been proposed, thus allowing network analysis to capture inter-individual heterogeneity. ISNs can be constructed in multiple ways, and, in the literature, the same term identifies networks with very different rationales and construction methods. While ISNs may be powerful, their full potential has not yet been exploited: incorporating ISNs to construct complex predictors or explanatory variables in modelling or identifying latent classes of â□□similarâ□□ ISNs. Here, we focus on the method proposed in Kuijier et al. (2019), where the impact of removing an observation is captured by edge-specific weights.

We propose a novel algorithm (named HotZone) to find the network regions (â□□zonesâ□□) in ISNs that vary significantly across individuals and thus form interesting subgraphs for subsequent analyses and interpretation. Our algorithm consists of two steps: [i] find the gene communities in the global network, and [ii] test whether the individuals form sub-populations based on the variation of each gene module. The first step is performed using hierarchical clustering with a custom-defined resolution. Next, for each gene module, a graph-based individual similarity metric is constructed, which enables a statistical test to define the optimal number of clusters (related to the gene-module). Finally, after performing and correcting for multiple testing, the gene modules linked to sub-populations of individuals are recognized as network-hot-zones. We evaluate the performance of this algorithm on a reduced set of blood transcriptomics data from 2604 individuals in the COPDGene study, where the individuals have various levels of chronic lung disease.

Our results confirm the existence of biologically meaningful hot zones that foster simplified analyses with ISNs, and help improve our understanding mechanisms underlying patient-heterogeneity. Our analysis pipeline also introduces and highlights, in the field of ISN analysis, the concept of biclustering, for both gene expression and individuals. The code to perform the analysis will be freely available on GitHub.

PrgmNr 2501 - Local gene co-expression: prevalence and molecular features across human tissues and single-cells

View session detail

Author Block: **D. Ribeiro**[1,2], C. Ziyani[1], S. Rubinacci[1,2], R. Hofmeister[1,2], O. Delaneau[1,2]; [1]Univ. of Lausanne, Lausanne, Switzerland, [2]Swiss Inst. of Bioinformatics, Lausanne, Switzerland
Disclosure Block: **D. Ribeiro:** None.
Nearby genes are often expressed as a group. This local gene co-expression is more pronounced in the immediate vicinity of a gene (e.g. By leveraging gene expression measurements from the GTEx project across 49 human tissues and hundreds of individuals, we found local gene co-expression to be highly prevalent, occurring in 13% to 53% of genes per tissue. Indeed, we found that >64.000 gene pairs within 1Mb of each other are co-expressed in at least one tissue and that several features are associated with local gene co-expression, such as lower insulating CTCF sites between co-expressed gene pairs.
To understand how the observed local gene co-expression and its regulation manifests at the single-cell level, we analysed a public dataset of single-cell RNA-seq across 87 genotyped individuals in a specific cell type (iPSC, Cuomo et al. 2020 Nat. Comm.). By taking advantage of co-expression measurements across cells per individual, we identified hundreds of locally co-expressed gene pairs per individual. We found that these often participate in the same biological pathway and protein complex, indicating a strong functional link. Importantly, we show that local co-expression between two genes involves (i) concomitant co-transcription (GRO-seq data), (ii) co-regulation by shared enhancers (scATAC-seq data) and (iii) ultimately results in correlated protein levels (mass spectrometry data).
Finally, to understand whether genetic variation controls local gene co-expression, we identified expression quantitative trait loci (eQTLs) associating with co-expressed gene pairs. Interestingly, we found that these eQTLs are enriched in enhancer regions and are more often associated with multiple human traits than eQTLs associated with only one gene.
Our dissection of the genetic architecture of local gene co-expression through multiple technologies (RNA-seq, GRO-seq, ATAC-seq, proteomics) allows us to propose a model in which (i) the co-expression of nearby genes is prevalent and largely due to the sharing of enhancers, (ii) genetic variation perturbing the activity of shared enhancers may affect multiple genes and (iii) such variants have the potential to disrupt multiple traits and thus may contribute to the co-occurrence of diseases in the same individual.

PrgmNr 2502 - Modeling gene expression on the X chromosome for transcriptome-wide association studies

View session detail

Author Block: **X. Zhang**[1], W. S. Bush[2]; [1]Case Western Reserve Univ., Cleveland, OH, [2]Case Western Reserve Univ, Cleveland, OH
Disclosure Block: **X. Zhang:** None.
The X chromosome is usually neglected in the analyses of genomic data. However, as we gain more knowledge of the disease associations and tissue-specific regulatory effects of autosomal loci, there is a growing interest in building prediction models of gene expression to understand the functions of non-coding variants on the X chromosome. A key challenge of X chromosome analysis is how to model copy number differences between males and females; genetic variants on the X chromosome are hemizygous for males, while females are heterozygous or homozygous diploid. Modeling is complicated by X inactivation when one of the two X chromosome copies of a female is permanently inactivated in nearly all somatic cells. Another challenge is two pseudoautosomal regions (PARs) on the X chromosome, on the tip of the short arm (Xp1) and the long arm (Xq28), respectively. Genes located in the PAR are inherited like autosomal genes in both genders, as there is a homologous region on the Y chromosome in males.
We explore modeling approaches using WGS and RNA-seq data in 13 different Brain tissues retrieved from the GTEx project, currently restricting analyses to males only. We used elastic-net regression, which combines LASSO and ridge penalty terms with a balanced LASSO-ridge penalty (mixing parameter alpha=0.5), as recommended by Wheeler et al. 2016. For each gene in each tissue, we tuned the penalization parameter *lambda* and assessed the model performance using a nested cross-validation strategy. There are 247 genes on chromosome band Xq28, with only approximately 100 genes expressed in each GTEx brain tissue. SNPs (MAF>0.05) within the 50k bp flanking windows of the gene were included in the model. We used mean squared error to determine the penalty parameter and select the best models. For example, we included 83 males to fit the prediction model of GAB3 Gene (ENSG00000160219, X: 153903529-153979858) in Frontal Cortex BA9. 2 out of 56 *cis*-SNPs were kept in the final model (*lambda*=0.36). The model R^2 is 0.0828, explaining 8.28% of the expression variance in males. These models estimate the genetically regulated gene expression on the X chromosome in males and can be readily used in Transcriptome-wide Association Studies.

PrgmNr 2503 - A signature of Neanderthal introgression on molecular mechanisms of environmental responses

View session detail

Author Block: **A. S. Findley**[1], X. Zhang[2], C. Boye[1], Y-L. Lin[3], C. Kalita[1], L. Barreiro[3], K. E. Lohmueller[2], R. Pique-Regi[4], F. Luca[4]; [1]Wayne State Univ., Detroit, MI, [2]Univ. of California, Los Angeles, Los Angeles, CA, [3]Univ. of Chicago, Chicago, IL, [4]Wayne State Univ, Detroit, MI
Disclosure Block: **A.S. Findley:** None.
Recent studies have suggested that introgression of archaic alleles in the genome of modern humans may have contributed to adaptation to environmental pressures such as pathogen exposure. Functional genomic studies have demonstrated that variation in gene expression across individuals and in response to environmental perturbations is a main mechanism underlying complex trait variation. We considered gene expression response to in vitro treatments as a molecular phenotype to identify genes and regulatory variants that may have played an important role in adaptations to local environments. We investigated if Neanderthal introgression in the human genome may contribute to the transcriptional response to environmental perturbations. We identified 27,349 introgressed Neanderthal alleles (N-SNPs) within the binding sites for 1,255 transcription factor (TF) motifs and computationally predicted that 73% alter TF binding. TFs enriched for N-SNPs which disrupt binding (e.g. *SWI5*, *MAFA*, and *ARNT*) are important for environmental responses, including ionizing radiation and hypoxia, and for glucose metabolism. Indeed, N-SNPs are enriched among SNPs that significantly affect TF binding in a SNP-SELEX dataset of type-2 diabetes associated loci. In particular, N-SNPs alter binding for 12 glucose metabolism-associated TFs (KS test p=0.036), including *IRF5*, *HOXA6*, *POU2F3*, and *PAX2*. We then considered eQTLs for genes differentially expressed in a panel of 52 cellular environments, resulting from 5 cell types and 26 treatments. We identify an enrichment for N-SNPs among eQTLs for genes differentially expressed in response to 8 treatments, including glucocorticoids, caffeine, and vitamin D. 132 genes which respond to a treatment were regulated by N-SNPs which show evidence of adaptive introgression. Finally, using massively parallel reporter assay data, we validated the regulatory function of 21 introgressed N-SNPs in the human genome, corresponding to 8 eQTLs regulating 15 genes that respond to environmental perturbations. These findings expand the set of environments where archaic introgression may have contributed to adaptations to local environments in modern humans and provide experimental validation for the regulatory function of introgressed variants.

PrgmNr 2504 - Allelic frequency comparison to improve epidemiological decisions on hereditary diseases in a Latino population

The allelic frequency of sequence variants with clinical value for the diagnosis of hereditary diseases is a valuable indicator when making decisions for the epidemiological surveillance of these diseases in populations at risk. However, most of the values â□□â□□recorded in the available databases, for populations other than Caucasians and Afro-descendants, may present sampling biases in the values â□□â□□of this indicator. For this reason, our working group on Hunter's disease (MPS II) carried out a sampling in a disease-free population originating from the southwestern part of Colombia, in order to calculate the allelic frequencies of the main circulating sequence variants associated with the gene IDS and compare these values â□□â□□with those registered in the Gnomad database for those same variants in the Latino/admixture American subgroup. Our findings show a statistically significant difference between the values â□□â□□recorded in Gnomad and those observed in the study population. This difference shows an underestimation of the allele frequencies studied at the Gnomad base. When extrapolating the allelic frequency values â□□â□□with the incidence of MPS II in the geographical region of the study, a greater concordance of the epidemiological data with the population data is seen. Based on the values â□□â□□observed in the study population, it is suggested to maintain an active search process for undiagnosed patients to avoid clinical under-registration and thus improve the possibilities of timely care with therapeutic treatments available on the market.

The Human Leukocyte Antigen (HLA) gene complex encodes proteins that control antigen-specific immune responses. Variants in the HLA gene region are associated with many diseases associated with inflammation, such as Type 1 Diabetes and Multiple Sclerosis. Africans are underrepresented in genetic studies; therefore, it is imperative to characterize genetic variation of the HLA gene region in African ancestry genomes. We sampled ethnically and genetically diverse populations with varying subsistence patterns and infectious disease exposures from four African countries. Targeted sequencing of the HLA genes in 489 individuals generated 4,506 consensus sequences, and among those sequences there were 754 unique alleles. Among these alleles there were 348 sequences that were either novel or that completed the genomic sequences of incompletely published alleles. For a subset of 180 individuals, we generated high coverage whole genome sequence data that enables us to compare genetic variation in the HLA region with the rest of the genome. Heterozygosity is greatly increased within the HLA region compared to genome wide levels, and we estimate that variants in the classical HLA genes are some of the oldest in the human genome. Constructing a phylogeny from genome-wide patterns of genetic variation demonstrates genetic differentiation that correlates with language and geography. By contrast, we do not observe the same pattern in the phylogeny constructed from genetic variation in HLA genes, where individuals do nut cluster by geographic location or language group. This observation, combined with the increased heterozygosity and prevalence of old variants, is consistent with balancing selection at this region. To identify signatures of balancing selection and local adaptation we scanned the HLA region using the Di statistic, which identifies variants that are strongly differentiated in focal populations, and the Tajimaâ□□s D statistic which is based on the allele frequency distribution. Tajimaâ□□s D statistic identifies a strong signal of balancing selection across the HLA region. We also identify multiple candidates of local adaptation in hunter-gatherer populations, possibly due to differential pathogen exposure. The top selection signals are in the *HLA-B* and *TAP1* genes, the latter of which facilitates the transporting and loading of peptides to the HLA. Future functional genomics data will demonstrate how these positively selected

variants impact immune response and their role in human diseases. Supported by NIH grants R35GM134957-01, 5T32DK007314-39, ADA grant 1-19-VSN-02 and funding from the Chan Zuckerberg Institute.

PrgmNr 2508 - Deep variational autoencoders for population genetics: applications in classification, imputation, dimensionality reduction, and novel lossless data compression

View session detail

Author Block: **M. Geleta**[1,2], D. Mas Montserrat[3], C. D. Bustamante[3], X. GirÃ³-i-Nieto[2], A. Ioannidis[3,4]; [1]Univ. of California Irvine, Irvine, CA, [2]Univ.t PolitÃ¨cnica de Catalunya, Barcelona, Spain, [3]Dept. of BioMed. Data Sci., Stanford Univ. Sch. of Med., Palo Alto, CA, [4]Inst. for Computational & Mathematical Engineering, Stanford Univ. Sch. of Engineering, Palo Alto, CA
Disclosure Block: **M. Geleta:** None.
In this study we show the power of variational autoencoders (VAEs) for a variety of tasks relating to the interpretation and compression of genomic data. The unsupervised setting allows for detecting and learning of granular population structure and inferring of new informative latent factors, opening up an avenue for applications in dimensionality reduction, data simulation, population classification, imputation, and lossless genomic data compression. The latent spaces of VAEs are able to capture and represent clearly differentiated Gaussian-like clusters of similar genetic composition on a fine-scale with a relatively small number of SNPs as input. Furthermore, sequences can be decomposed into latent representations and reconstruction errors (residuals) providing a sparse representation that provides a means for efficient lossless compression.

Identifying genetic clusters can be important when performing genome-wide association studies and provides an alternative to self-reported ethnic labels, which are culturally constructed and vary according to the location and individual. A variety of unsupervised dimensionality reduction methods have been explored in the past for such applications, including PCA, MDS, t-SNE, and UMAP. Our proposed VAE can represent the population structure as a Gaussian-distributed continuous multi-dimensional representation and as classification probabilities providing flexible and interpretable population descriptors.

We train our VAE method with several worldwide whole genome datasets from both humans and canids and evaluate the performance of the different proposed applications with networks with and without ancestry conditioning. Our experiments show that different population groups have significantly differentiated compression ratios and classification accuracies. Additionally, we analyze the entropy of the SNP data, noting its effect on compression across populations and connect these patterns to historical migrations and ancestral relationships.

PrgmNr 2509 - Estimating ancestry-specific allele frequencies in admixed samples from large-scale sequencing data

View session detail

Author Block: **J. Wang**, A. V. Smith, The Trans-Omics for Precision Medicine (TOPMed) Consortium, G. Abecasis, S. ZÃ¶llner; Univ. of Michigan, Ann Arbor, MI
Disclosure Block: **J. Wang:** None.
Estimates of allele frequency distributions across different populations provide important insights into the transferability of GWAS results, population specific drivers of disease etiologies, and population genetic estimates such as natural selection. Allele frequencies from recently admixed groups are often more difficult to interpret in this context and it is of great interest to estimate the allele frequencies of the underlying ancestral groups. We leverage local ancestry to estimate ancestry-specific allele frequencies. After local ancestry is inferred, the ancestry of variants with homozygous ancestry background can be directly observed. To accommodate variants with heterozygous ancestry background, we developed two algorithms: (1) We derive an Expectation-Maximization approach that treats the phase information in individuals with heterozygous ancestry background as augmented data to incorporate additional information like sample-wide ancestry distributions to inform ancestral composition at the variants with heterozygous background. (2) We leverage statistical phasing of samples by duplicating each haplotype and pairing the two copies into one pseudo diploid that is homozygous for local ancestry everywhere. Both algorithms are capable of interpreting large-scale sequencing data and multi-way admixture patterns. Simulation results show a small bias of the EM estimates of 0.01 and effective sample size > 100. Variance of the EM estimator decreases with larger sample size and corresponding ancestry proportion. We plan to apply both algorithms to genome sequencing data from the TOPMed Consortium, and estimate allele frequencies based on samples. We have inferred local ancestry in this sample observing of ~55% European haplotypes, ~25% African haplotypes, ~5% Native American haplotypes, ~5% Central and South Asian haplotypes, ~5% East Asian haplotypes, ~4% Middle Eastern haplotypes, and 0.99 for common variants with allele frequency greater than 0.1%. We estimate differentiated allele frequency patterns among different ancestral groups, and observe how similarity in allele frequencies across all frequency bins > 0.1% are closely related with population histories.

PrgmNr 2510 - Exploring the role of local sequence context on patterns of germline mutation

View session detail

Author Block: **A. Beck**[1], S. Zollner[2], J. Li[2]; [1]Univ. of Michigan Sch. of Publ. Hlth., Ann Arbor, MI, [2]Univ Michigan, Ann Arbor, MI
Disclosure Block: **A. Beck:** None.
Mutation rates are known to vary across the genome, and while this variation has been shown to be correlated with both local sequence context and other genomic and epigenomic features, our current understanding of how these features influence mutation rates and processes in the germline is limited. Matrix factorization approaches have been utilized in cancer genomics to generate signatures of potential mutational processes, which have then been linked to well-characterized biological processes. However, these methods are limited to considering only one or two flanking bases up- and down-stream of a mutation due to the exponential growth of the number of motifs as more flanking positions are considered. In order to develop methods to study processes underlying germline mutation, an understanding of the extent to which nucleotides at positions flanking a variant site influence the rate of mutation in the germline, and to what degree interactions between bases at flanking positions influence the rate is an important first step. Here we evaluate the relationship between local sequence context and the distribution of singletons across 2,504 unrelated individuals in the 1000 Genomes high-coverage data. We find that models which control for genomic location (and thus genomic features) perform better than models which only account for genome-wide nucleotide composition. When evaluating the marginal influence of nucleotides at positions flanking a variant site, nucleotides at positions beyond the +/- 1 bp positions considered by signature decomposition approaches are shown to be correlated with mutation rate variation. We also find that interactions between nucleotides are also associated with mutation rate variation, but that their influence decreases as we consider both interactions between positions further from each other and higher-order interactions. These patterns are observed across all populations within 1000 Genomes. Taken together, our results suggest that methods for uncovering underlying signatures of mutation processes in the germline could benefit from both controlling for the influence of genomic positions and incorporating more sequence context without accounting for higher-order interactions, preventing the exponential growth of the complexity of the model as more flanking positions are considered.

Mutation in the germline is the source of all evolutionary genetic variation and a cause of genetic disease. Previous studies have shown parental age to be the primary determinant of the number of new germline mutations seen in an individualâ□□s genome.

Here we analysed the genome-wide sequences of 21,879 families with rare genetic diseases from the 100,000 Genomes Project (100kGP) and the Deciphering Developmental Disorders (DDD) Study and identified 12 hypermutated individuals with 2-7 times more de novo single nucleotide variants (dnSNVs) than expected. For 2/12 hypermutated individuals, the excess mutations appeared to have occurred post-zygotically, however for the majority (9) of these hypermutated individuals, the excess dnSNVs phased paternally implicating the father as the source of hypermutation. For 5 of these fathers, characteristic mutational signatures and clinical records of cancer treatment prior to conception strongly implicated the mutagenic influence of two different classes of chemotherapeutics: platinum-based drugs (3 families) and mustard-derived alkylating agents (2 families). We also identified likely paternal mutator variants in two hypermutated families. These were rare homozygous missense variants in known DNA repair genes: *XPC* and *MPG*. Functional and clinical data supported the mutagenic nature of these variants.

We estimated that germline hypermutation accounted for 7% of the variance in germline mutation rate in the 100kGP cohort and parental age explained ~70% which is substantially smaller than previous estimates. For the residual ~20%, we found that rare variants in known DNA repair genes are unlikely to account for a large proportion of this unexplained variance and that polygenic contributions from common variants (MAF>1%) are unlikely to make a large contribution although the polygenic contribution of intermediate frequency paternal variants (0.0011.5) fold increase in mutation rate.

Our results suggest that the germline is well protected from mutagenic effects, hypermutation is rare and relatively modest in degree. The absolute risk of germline hypermutated individuals having a rare genetic disease is low; we anticipate most will not be affected and germline hypermutation will also be observed in healthy population cohorts.

This research was made possible through access to the data and findings generated by the 100,000 Genomes Project http://www.genomicsengland.co.uk

PrgmNr 2512 - Genetic structure, kinship, and ancient pathogen diversity in a Moche tomb in Northern Peru

View session detail

Author Block: **C. Guerra Amorim**[1,2], S. Neuenschwander[2], Y. Arizmendi-CÃirdenas[2], B. Mota[2], D. I. Cruz-DÃivalos[2], C. Barbieri[3], J. Verano[4], L. Fehren-Schmitz[5], A. Malaspinas[2]; [1]California State Univ. Northridge, Los Angeles, CA, [2]Univ. of Lausanne, Lausanne, Switzerland, [3]Univ. of Zurich, zurich, Switzerland, [4]Tulane Univ., New Orleans, LA, [5]Univ. of California Santa Cruz, Santa Cruz, CA
Disclosure Block: **C. Guerra Amorim:** None.
The Moche culture flourished in the Northern Peruvian coast between the years 100 BCE and 800 CE, extending over a region of 500 km at its apogee. The Moche engineered many elaborate metal artifacts and figurative pottery, possessed a remarkably complex social structure, and presented dynamic funerary practice. *Huaca Cao Viejo* is one of the most prominent Moche archeological sites. It is located within the *El Brujo* archeological complex, in Northern Peru, and it is mostly known for the undisturbed burial of a female leader known as the Lady of Cao, discovered in 2006. Here, we analyze novel whole-genome sequences of n=7 ancient individuals, dated to ~350-600 CE, buried in a tomb adjacent to the main Lady of Cao burial. Our analysis of the genome-wide diversity of these ancient individuals shows that they are most similar to present-day Native American individuals from the same geographical region where they were buried (i.e., the Northern Peruvian coast). This suggests that no major population turnovers happened in the region from ~500 CE until the period of contact (~1,500 CE). The practice of burying additional persons (referred to in the literature as â□□retainersâ□□) alongside a principal individual is a common feature in the Moche mortuary practice. Yet, the relationship between retainers and principal individuals remains elusive, with no conclusive indications whether they were unrelated servants or biologically related family members. To shed light on this issue, we generated additional ancient DNA data for n=3 ancient individuals: the Lady of Cao and two individuals buried in her tomb. We found that the Lady of Cao was biologically related (2nd to 4th-degree relatedness) to the latter two individuals, but not to any of the â□□retainersâ□□ in the adjacent tomb. Furthermore, we screened all the sequenced genomic libraries for known human viruses and detected the presence of ancient Hepatitis B virus (HBV) DNA molecules in one individual.

PrgmNr 2513 - Population genetic analyses implicate biogenesis of translation machinery in human ageing

View session detail

Author Block: **S. Javidnia**[1], S. Cranwell[1], S. H. Mueller[1], K. B. Kuchenbaecker[2], N. Alic[1]; [1]UCL, London, United Kingdom, [2]Univ Coll. London, London, United Kingdom
Disclosure Block: **S. Javidnia:** None.
Reduced provision of protein translation machinery promotes healthy ageing in a number of animal models. In humans, however, inborn impairments in translation machinery are a known cause of a range of developmental disorders, collectively called ribosomopathies. Here, we employ population genetic approaches to investigate if adult, tissue-specific biogenesis of translation machinery drives human ageing. We assess naturally occurring variation in the expression of genes encoding subunits specific to the two RNA polymerases (Pols) that transcribe ribosomal and transfer RNAs, namely Pol I and III, and the variation in expression of ribosomal protein (RP) genes, using Mendelian Randomisation. We find each causally associated with human longevity (Ã=-0.15Â±0.047, p=9.6x10-4; Ã=-0.13Â±0.040, p=1.4x10- 3; Ã=-0.048Â±0.016, p=3.5x10-3, respectively). These associations do not appear to be mediated by altered susceptibility to a single disease. Interestingly, we find that reduced expression of Pol III, RPs or Pol I promote longevity from different organs, namely visceral adipose, liver and skeletal muscle, echoing the tissue-specificity of ribosomopathies, and we provide evidence that Pol I and RPs may act from organs where their expression is limiting. Our study demonstrates the utility of leveraging genetic variation in expression to elucidate how essential cellular processes impact human ageing. Our findings extend the evolutionary conservation of protein synthesis as a process that drives animal ageing to include humans.

PrgmNr 2514 - Revealing the recent demographic history of Europe via haplotype sharing in the UK Biobank

View session detail

Author Block: **E. H. Gilbert**[1,2], G. L. Cavalleri[1,2]; [1]Royal Coll. of Surgeons in Ireland, Dublin, Ireland, [2]FutureNeuro SFI Res. Ctr., RCSI, Dublin, Ireland
Disclosure Block: **E.H. Gilbert:** None.
Haplotype-based analyses have recently been leveraged to interrogate fine-scale structure in specific geographic regions, notably in Europe. An equivalent understanding across the whole of Europe with these tools however is lacking and would provide an updated map of the European genetic landscape. Similarly, a study of Identity-by-Descent (IBD) sharing in a large sample of pan-Europe genotypes would allow both direct comparison between different demographic histories and in parallel identify communities conducive to genetic mapping. In this context, we sought to investigate the extent of European ancestry captured in the UK Biobank (UKBB), a large genetic dataset with world-wide ancestry. We sampled 4,920 UKBB individuals with a European birthplace and investigated population structure and demographic history in Europe. With one of the largest samples of genotypes from across the geographical extent of Europe we show in parallel the variety of footprints of demographic history in different genetic regions around Europe and expand knowledge of the genetic landscape of the east and south-east of Europe. We highlight novel analysis of island populations such as Malta and the Channel Islands, demonstrating with IBD-segment sharing the extent of population isolation and size. Our work builds and expands upon previous work in Europe and specific populations, highlighting UK Biobank as a source of diverse ancestries beyond Britain. We find novel results in multiple communities in Europe that are of interest to genetic mapping.

PrgmNr 2515 - Sequencing the general population at a fine-geographic scale: the French POPGEN project

View session detail

Author Block: **A. Herzig**[1], G. Le Folgoc[1], M. Goldberg[2], M. Zins[2], E. GÃ©nin[3]; [1]Inserm, Univ Brest, EFS, UMR 1078, GGB, Brest, France, [2]Inserm-Paris Saclay Univ. UMS 011, UniversitÃ© de Paris, Villejuif, France, [3]Inserm UMR1078, Brest, France
Disclosure Block: **A. Herzig:** None.
Population-level genome-sequencing projects have been undertaken by many nations. The availability of these, often immense, datasets has accelerated methodological development and provided new avenues for genetic epidemiological investigation. France will soon join the growing list of nations where such datasets have been compiled through the POPGEN project; a pilot study of the National Genomic plan led by Inserm. Whilst the envisaged dataset may not rank highest in terms of size, it promises to break new ground with its meticulous selection criteria.
Using questionnaires completed by volunteers from the Constances cohort, we selected participants based on the birth-places of their four grand-parents. As participants are adults over 35 years of age (mean of 59, range of 36-80), the average birth year of their grandparents was 1906. Our key assumption was that an individual with all four grand-parents born within a small locality should be a reliable representative of that region. By using such a selection criterion, we will obtain insights on the genetic diversity between French regions at the start of the 20th century when population movement remained limited. We selected 15,000 individuals respecting a geographic distribution based on historical population proportions in France from the 1901 census. Hence, POPGEN will capture a complete genetic cross-section of the French population. The connection between each participant and a geographical origin will permit a high resolution for analyses of genetic fine-structure.
The selected individuals were sent saliva collection kits through the post, a design aimed to best avoid recruitment bias and maximize participation. A pilot study successfully showed the appropriateness of this DNA collection method for whole-genome sequencing (WGS) as well as the possibility for parallel sequencing of salivary microbiomes. Using a smaller but similarly selected group of 856 French individuals with WGS data, we established the potential for using POPGEN as a population specific reference panel for imputation. Finally, we present analyses of demographic patterns observable through the multi-generational birth-place data and how we predict these could manifest in the genetic dataset that will materialize in 2022.

PrgmNr 2516 - SIRPA V1/V2 haplotypes were selected by balancing selection

View session detail

Author Block: **N. Vince**, F. Haspot, S. Le Bas - Bernardet, N. Poirier, P-A. Gourraud, G. Blancho, S. Limou; UniversitÃ© de Nantes, Nantes Cedex 01, France
Disclosure Block: **N. Vince:** None.
Signal regulatory proteins (SIRPs) are a group of cell surface receptors involved in immune functions through immunoglobulin-like domains. Human SIRPs are composed of 5 different proteins (Î±, Î²1, Î²2, É£, Î´), but only SIRP was extensively studied so far. The SIRPÎ±/CD47 ligand/receptor pair is under active therapeutic research to tame the â□□donâ□□t eat meâ□□ mechanism preventing CD47+ cell phagocytosis, with applications in transplantation (signal stimulation) or oncology and infectious diseases (signal blocking). Both therapeutic strategies may be sensitive to polymorphisms, as *SIRPA* is highly polymorphic with 2 main haplotypes described in humans, V1 and V2, translating to 2 different proteins (13 amino acids differences). Indeed, monoclonal antibodies may bind these haplotypes with different affinity. Our study aimed at characterizing the evolutionary history of the *SIRPA* polymorphisms.
We investigated the potential selection signature on the *SIRPA* V1/V2 polymorphisms using the 1000 Genomes project 30X dataset. We computed the fixation index (F_{ST}; degree of differentiation between two populations), extended haplotype homozygosity (EHH; haplotype length which may detect recent selection event) and Tajimaâ□□s D (neutrality test, positivity may reflect balancing selection).
We showed that the V1/V2 *SIRPA* haplotypes are present at high frequencies across all human populations with large disparities (V1 frequencies in 3 populations: 71% in African, 63% in European and 31% in East-Asian). However, these distribution differences did not translate into high F_{ST} (below 0.04). V1 and V2 haplotypes also showed similar length across populations, reflecting the absence of recent selection event. In all 3 tested populations, the highest Tajimaâ□□s D score across the whole chromosome 20 was found within *SIRPA* (5.1 in African, 5.2 in European and 4.6 in East-Asian).
The combination of high Tajimaâ□□s D and high frequencies in all 3 populations tested suggest that *SIRPA* V1/V2 haplotypes were, and might still be, under balancing selection. This means that, during the course of evolution, 2 SIRPÎ± versions expressed in a given individual (i.e. V1/V2 heterozygous state) could have been important to prevent an inhibition of the immune response against infection. Differential distribution of *SIRPA* haplotypes V1/V2 frequencies across Human population may impact therapeutic successes (such as monoclonal antibodies) and individual *SIRPA* genotyping might be useful before selecting a treatment targeting SIRPÎ±.

PrgmNr 2517 - ï»¿The genetic landscape of South Native American populations

View session detail

Author Block: **M. Castro e Silva**[1], C. M. Couto-Silva[1], R. B. Lemes[1], K. Nunes[1], D. Comas[2], T. HÃ¼nemeier[1]; [1]Univ. of SÃ£o Paulo, SÃ£o Paulo, Brazil, [2]Univ.t Pompeu Fabra, Barcelona, Spain
Disclosure Block: **M. Castro e Silva:** None.
South America presents one of the most diverse sets of environments in the world, which has influenced human biological and cultural evolution from the very beginning of its occupation. At the same time, these environments were modified and adapted to human survival. This dynamic process generated a vast cultural diversity, contrasting with the low levels of Native American genetic diversity described hitherto. We analyzed genomic data from 383 present-day natives from more than 50 ethnolinguistic groups genotyped with the Affymetrix Human Origins array to shed light on the South America, Mesoamerica and northern Mexico genetic landscape. First, we find no evidence of a sharp genetic divide between Andeans and Amazonians. Conversely, we demonstrate that the genetic variation, as well as the homozygosity level, is correlated with longitude, which is compatible with an isolation by distance model, possibly tracing back to an initial settlement from the Pacific coast. Noteworthy, present-day Native American diversity recapitulates ancient local ancestries. Demographic inferences indicate higher population sizes and resilience of western South American groups to the population collapses caused by the European invasion and also indicate some pre-contact demic expansions. Finally, we find strong evidence of cultural exchanges that led to a language replacement in western Amazonia in pre-contact times.

PrgmNr 2518 - The GLAD Initiative: a database for supporting population genetics and association studies in the Americas

View session detail

Author Block: **V. Borda**[1], D. Loesch[2], B. Guo[3], R. Laboulaye[1], J. French-Kwawu[4], D. Veliz[1], GLAD Invertigators, TOPMed Population Genetics Working Group, E. E. Perez-Palma[5], I. Mata[6], R. D. Hernandez[7], E. M. Tarazona-Santos[8], T. D. O'Connor[1]; [1]Univ. of Maryland Sch. of Med., Baltimore, MD, [2]Univ. of Maryland Baltimore, Baltimore, MD, [3]China, [4]Univ. of Maryland Baltimore, Pikesville, MD, [5]Univ. zu KÃ¶ln, KÃ¶ln, Germany, [6]Lerner Res. Inst., Genomic Med., Cleveland Clinic, Cleveland, OH, [7]San Francisco, CA, [8]Univ Federal Minas Gerais, Belo Horizonte, Brazil

Disclosure Block: **V. Borda:** None.

Background: Latin Americans and U.S. Hispanics (LA) are an interesting model for evolutionary and medical studies as they result from recent admixture of highly differentiated sources (Native Americans, Europeans, East Asians, and Africans). However, underrepresentation of genetic studies in these heterogeneous groups does not allow for a comprehensive understanding of genetic determinants underlying complex traits. To overcome the underrepresentation issue, we built a comprehensive collection of genome-wide information of LA in the Genetics of Latin American Diversity (GLAD) database. **Structure of GLAD:**By gleaning all possible LA individuals through dbGaP and whole genome sequencing projects across Latin America, we gathered 80,542 (26,289 WG sequenced) LA individuals that are either self-described or Admixture-defined (i.e. individuals with at least 2% Native American ancestry). After data curation, imputation with the TOPMed Imputation Server, and merging, the GLAD data included 2.1M post QC SNPs with an $r^2 > 0.9$ (6.2M with an $r^2 > 0.3$) spanning at least sixteen countries in the Americas. By joining local ancestry and Identity-By Descent (IBD) analyses on GLAD data, we tracked patterns of higher IBD sharing on the Pacific and Atlantic sides of the continent related to Native American and African ancestries, respectively. These patterns reflect the dynamics of both ancestries during colonial times. **GLAD as a Resource:**It is a big challenge to obtain genetic information for a large number of control individuals for a specific phenotype and ancestry, specially for the LA. This is aggravated by the fact that most large-scale genetic studies suffer from data sharing issues due to consent or difficulty of access through public databases. To overcome this problem, we will provide support for association studies of LA by sharing summary statistics generated from the GLAD database in order to increase the power of association and admixture mapping studies without transferring individual-level data. We will identify control subject of similar genetic background to cases submitted by external users using a matching algorithm based on summary statistics of ancestry and genetic background (e.g. PCA and admixture proportions). Finally, our GLAD database contributes to the understanding of the genetic architecture of traits as well as the fine-scale patterns of Latin American genetic diversity.

Disclosure Block: **M. Clausen:** None.

Background: Increasing demand for genomic testing coupled with existing workforce shortages in clinical genetics has placed unsustainable pressure on the standard models of care. Patient-facing digital health applications can empower patients and provide sustainable and scalable clinical solutions to address this gap. **Aim:** To transform our original Genomics ADvISER decision aid into a comprehensive patient-centered digital health application that will deliver education, counseling, and return of results for patients undergoing various form of genomic testing. **Methods:** Driven by user-centred design principles, we developed and conducted usability and acceptance testing of the application using an iterative, mixed-methods process consisting of: 1) consultations with an advisory board of providers and patients; 2) analysis of qualitative interviews with prior patients who used the original Genomics ADvISER decision aid; 3) creation of a digital wireframe prototype; 4) usability testing of the prototype; and 5) acceptability testing of the final digital application. ***Results:*** **Prototype development:** We created a new digital application, called the â□□Genetics Adviserâ□□, building on our original â□□Genomics ADvISERâ□□ that incorporated feedback from our advisory board, patients, genetics experts and the general public. The Genetics Adviser is designed to be easily adaptable to the needs of different types of patients, test modalities, and results. It consists of a pre-test module that focuses on: education, values, FAQs, patient stories/vignettes and the selection of results. It also includes a post-test check-in module to support users while they wait for results and a function that allows clinicians to upload results for patients to review before or after clinical consults. **Usability testing:** We conducted 25 usability tests with patients, the general public and genetics practitioners (15/25 female; mean age 41 years; 5/25 diagnosed with cancer). Participants were enthusiastic about the application, found it easy to navigate and comprehend. Participants recommended clarifying content and outlining the purpose of tasks. **Acceptance testing:** The application is currently undergoing qualitative and quantitative acceptability testing with a sample of patients and the general public (n=20). The final application will then be evaluated in a RCT with patients undergoing genomic testing. **Conclusions:** We created and tested an interactive, patient-centered application to optimize delivery, access and quality of care for pre- and post-test genomic testing, counselling, and return of results adaptable to any testing platform and setting.

PrgmNr 2520 - Building Genomic Data Science Capacity for Health Discovery and Innovation in Africa

View session detail

Author Block: **T. B. Mersha**[1,2], S. W. Harrar[3], M. Altaye[1], T. Astatkie[4], T. Awoke[5], Z. Shkedy[6], J. Beyene[7]; [1]Cincinnati Children S Hosp. Med. Ctr., Cincinnati, OH, [2]Univ. of Cincinnati Coll. of Med., Cincinnati, OH, [3]2Dept. of Statistics, Univ. of Kentucky, Lexington, KY, [4]Faculty of Agriculture, Dalhousie Univ., Truro, NS, Canada, [5]Dept. of Epidemiology and Biostatistics, Univ. of Gondar, Gondar, Ethiopia, [6]I-BioStat, Hasselt Univ., Diepenbeek, Belgium, [7]McMaster Univ, Hamilton, ON, Canada
Disclosure Block: **T.B. Mersha:** None.
As rapid technological advances make it routine for genomics researchers worldwide to generate increasingly large, complex, and diverse datasets, the challenges of managing and leveraging to efficiently use such data also increase. Addressing these challenges require the collective cutting-edge expertise of computational, statistical, and genomic scientists along with domain knowledge researchers. Genomic data have boundless potential across Africa due to its high levels of genetic diversity (10% more DNA variation than the current reference genome) and disproportionate rate of infectious diseases (25% of the world disease burden). Although methods and applications of data science in genomics have been rapidly evolving over the past couple of decades in resource-rich countries and helped accelerate discovery of new knowledge, the situation is bleak in resource-limited settings such as most countries in Africa primarily due to lack of well-trained genomic data scientists. In this presentation, we describe a roadmap for building the capacities of the next generation of African scientists in genomic data science with the overarching goal of spurring health discovery and innovations. We propose a sustainable infrastructure for data security, privacy, access, analysis and visualization that empower and facilitate large-scale genomic studies, as well as the implementation of genomic medicine. We also outline current and past multiple international initiatives (e.g., *H3Africa,* DSI-Africa, Bridge2AI), potential challenges and future directions for genomics data science in Africa.

PrgmNr 2521 - Challenges to develop TBL modules that integrates genetics and genomics with basic and clinical disciplines in the first year of a Medical School

View session detail

Author Block: **F. T. Lima**, T. A. R. Silva, W. O. Pereira; Faculdade Israelita de CiÃªncia da SaÃºde Albert Einstein, Sao Paulo, Brazil
Disclosure Block: **F.T. Lima:** None.
BACKGROUND: Active methodologies are increasingly essential in the modern teaching process, as well as the delivery of an integrated curriculum, which presupposes approximation of various disciplines into meaningful associations to focus upon broader areas. Team Based Learning (TBL) seems to be a suitable method for such demands. Our Medical School uses TBL as an active methodology in the first 4 years. In two 20-week courses, during the first 2 semesters, Genetics and Genomics are taught in a single discipline that also covers Cell Biology, Molecular Biology, Biochemistry and Biophysics, and many challenges were faced developing TBL modules. AIM: Describe our experience in developing integrated TBL modules and they were approached. METHODS: Teaching plans, syllabus, pre- and in-class materials from 10 semesters (Feb 2016 to Nov 2020) were reviewed, and faculty was interviewed to provide understanding of challenges and how they overcame them. RESULTS: There were 2 TBL modules during first semester and 5-9, on the second, related to Genetics and Genomics. At each semester, until Mar 2020, at least 1 new TBL module per year was developed, totalizing 22 different modules. Development of objectives, content and appropriate application exercises integrating the different subjects, followed by lack of pre-class material in appropriate volume and difficult level were the main challenges. Literature search from the standpoint of disciplines in isolation to later find common ground, exploration of studentâ□□s early clinical experiences, clinical-research partnership and multidisciplinary discussion rounds provided clarification of objectives and ideas for exercises. Feedback from faculty from clinical years also ensured vertical integration between basic and clinical sciences. Creative pre-class videos and materials, using clippings and excerpts of different texts were developed. Reading guidelines are carefully prepared, often in the form of questions, to ensure that the student understands what goals to achieve when reading the material. Additional challenges were faced after Mar 2020, with Coronavirus Pandemic, when we migrated to an online format, the application exercises had to be revised, and several alternatives were tested. The biggest challenge was to ensure the simultaneous response, part of the 4S recommended by the traditional TBL method. CONCLUSION: Developing TBL modules integrating genetics and genomics education with basic and clinical sciences in the first year of a medical school brought many challenges. Careful and creative preparation and team work were essential to overcome them.

PrgmNr 2522 - Consumer-initiated genetic testing: A look at the current landscape in the United States

View session detail

Author Block: **J. Furnival**, S. Bradley, H. Andrighetti, S. D. Crawford; SoundRocket, Ann Arbor, MI
Disclosure Block: **J. Furnival:** None.

Consumer genomics companies offer an array of testing options, including tests for paternity, ancestry, nutrigenomics, carrier status, genetic health risk, and more. The tests vary in quality and completeness; while some tests are clinical grade performed in CAP/CLIA-certified labs, many are not, and laboratory methods range from SNP-based genotyping to whole genome or exome sequencing (WGS/WES). How does a consumer navigate these options to make an informed choice about genetic testing by browsing consumer genomics websites? We set out to understand the current landscape of online consumer-initiated genetic testing options in the U.S., with an emphasis on understanding the scope of health-related genetic testing in 2021.

We aimed to capture all U.S. companies offering genetic tests marketed to consumers. We included both true direct-to-consumer (DTC) genetic testing companies and those that offer products using a consumer-initiated, physician-mediated model. We have assembled a comprehensive, up-to-date list of U.S.-based companies offering consumer-facing genetic testing services. As of June 2021, we have analyzed the websites of 173 companies and wherever available, recorded which test(s) are offered, who initiates the test, who orders the test, type of DNA analysis performed, and lab accreditations or authorizations. To determine who initiates testing, we looked at the language (e.g.: use of â□□your patientâ□□ or â□□youâ□□), tone and user experience of the websites.

We will share a snapshot of the current consumer genomics market along with key findings related to genetic health tests - how many companies are offering physician-mediated genetic health testing, interpretations based on raw data analysis, products based on WES or WGS, or calculation of polygenic risk scores. We will also share the challenges of our approach, including the difficulty of using websites as our data source, and of generating a current list in this high-turnover emergent industry. Our final discussion will include the limitations of only including U.S.-based companies given the international nature of the industry and how online tests can be borderless.

As consumer genomics companies expand their health-related products, more options are emerging that can provide important medical insights. Without a governing body overseeing this industry as a whole, it is difficult to know what is available to consumers, and it is essential that those in the clinical genetics space work to understand what their patients may be accessing.

PrgmNr 2523 - Development and evaluation of digital decision aids with diverse patients: a systematic review

View session detail

Author Block: **S. Krishnapillai**[1,2], E. Adi-Wauran[1,2], Y. Bombard[1,2]; [1]Inst. of Hlth.Policy, Management & Evaluation, Univ. of Toronto, Toronto, ON, Canada, [2]Li Ka Shing Knowledge Inst., St. Michaelâ□□s Hosp., Toronto, ON, Canada
Disclosure Block: **S. Krishnapillai:** None.
Background: There is increasing priority and effort to engage underserved populations in genetics research and testing to mitigate existing health disparities. It is critical to clarify if decision aids (DAs) support diverse communities in their decisions to participate in genetics research and testing. This study will review literature related to design and evaluation of digital DAs with diverse populations. It aims to characterize developments in genetics and glean insights from other fields to collate strategies that support research for this audience and their digital needs. **Methods:** MEDLINE database was searched for quantitative, qualitative, and multi-method studies of DAs with adult populations composed of more than 50% of a diverse group as defined by Flaskerud & Winslowâ□□s conceptual framework of vulnerable populations. All articles were screened first at the title/abstract level and at full-text stage by two reviewers. Type of study, population and DA characteristics, modes of cultural tailoring, and digital considerations were abstracted from included studies. **Results:** 786 articles were identified through database search, ten met inclusion criteria and reported on eight digital DAs of which five examined cancer care, and three focused on birth choices, gender dysphoria or kidney disease. No genetic tools were captured in this search. Nine studies focused on ethnic/racial minority groups and one study on transmen. Studies reported combinations of incidence of disease, mortality, disparities in social determinants of health, and barriers/facilitators to decision-making as the rationale for selecting a population. All eight tools culturally tailored their DAs in the development stage using in-depth interviews or focus groups. To understand participantsâ□□ digital needs, two studies administered surveys to measure digital fluency or self-reported digital efficacy. The majority of participants had high mean scores in computer, e-mail, and web fluency, and self-reported their computer skills highly. **Conclusions:** Our systematic review found no genetic DAs that were designed or supportive for diverse groups, exposing a critical gap in efforts to foster broader recruitment of diverse participants in genetics research and testing. Culturally tailoring interventions with ethnic minorities should take into account language accessibility, involving family and community, and avoid overly simplistic or clinical narratives. Conceptions of diversity need to extend beyond only race/ethnicity to deliver tailored care that involves the breadth of social determinants of health that can influence health disparities including digital literacy.

PrgmNr 2524 - Divergent perceptions of meaning and utility of genetic testing results between families, clinicians, and laboratory directors

View session detail

Author Block: **C. Berrios**, E. Donis De Miranda, K. Pina, E. Hurley, J. Lantos; Childrens Mercy Kansas City, Kansas City, MO
Disclosure Block: **C. Berrios:** Grant/Contracted Research Support (External); Sanofi-Genzyme.
Background: Exome sequencing is frequently used for testing in children with complex symptoms and no obvious diagnosis. We wanted to better understand the responses of all stakeholders (parents, clinicians, and laboratory directors) in cases with varying types of results. Methods: We randomly selected exome sequencing cases from each of three groups of results: those in which the lab reported a diagnostic variant, no diagnostic variant but one or more VUS, and no variants. We recruited parents for in-depth interviews about the reason for testing, meaning and impact of results, and uncertainties or dilemmas resulting from the testing. For each parent interviewed, the ordering physician (OP), genetic counselor (GC) (if involved), and signing laboratory director (LD) were invited to complete interviews on the same topics. Interviews were transcribed, coded, and analyzed using grounded theory-based methodology. Results: Interviews have been analyzed for 3 parents whose child received a diagnostic finding, 3 parents whose child had only VUS, and 1 parent whose child had no reported variants; all ordered by a medical geneticist. OPs for all cases have been interviewed, GCs for 4 cases, and LDs for 5 cases. Parents and providers sometimes had differing views of the meaning and utility of results. Parents valued a diagnostic result that validated their concerns and directly guided clinical care. However, when diagnostic results were not instrumental in facilitating better treatment, parents could feel the result was inconclusive or did not provide helpful information, despite enthusiasm from OPs and LDs about a â□□clear cutâ□□ and useful result. In some cases with VUS, parents relayed extreme disappointment or irrelevance of results. In these cases, OPs and GCs perceived value in ruling out some genetic causes and hope in continued research on variants, though GCs often accurately relayed the parentsâ□□ views. Parents also discussed greater reassurance of a non-genetic etiology from negative results than providers. Differences between parent and provider views did not seem to reflect differences in factual understanding about the variants, but in the meaning and value of the test or result for the child and family. Interviews are ongoing and include purposeful sampling of cases with non-geneticist OPs. Conclusions: Providers should be aware of potential differences in professionalsâ□□ and parentsâ□□ assessment of the utility and limitations of genetic testing, especially when a result does not directly impact patient care. Further research should explore ways to align perceptions about the value of testing and results and assess ethical and psychosocial issues that may arise.

PrgmNr 2525 - Engagement in science: virtual interaction as a flexible tool

View session detail

Author Block: **O. M. Amaral**[1,2]; [1]Inst. Natl. de SaÃºde Ricardo Jorge (INSA), Porto, Porto, Portugal, [2]Univ. of Porto (CECA- ICETA), Porto, Portugal
Disclosure Block: **O.M. Amaral:** None.
The pandemic lockdowns forced a rapid switch to digital platforms. Lockdowns closed schools and laboratories pushing scientist and educators to online activities.
Digital platforms for communication are widely available for free use. These platforms, although different, are intuitive and user friendly, therefore facilitating this sudden imperative shift from in-person to virtual communication.
In an effort to bring services or science information to people new solutions were adopted. Although in-person activities were interrupted, alternative solutions were set up in order to engage wide participation. Such examples can be found among various types of initiatives regarding human genetic disorders which successfully switched to online versions.
After more than a year of digital communication, the outcome regarding interaction between peers; between students and educators; and even between common citizens and scientists can be assessed. With this work specific situations are revisited, indicating points of â□□virtual fatigueâ□□ as well as points of â□□virtual satisfactionâ□□.
Future perspectives on the advantages of using digital platforms will also be presented as part of a project, in the area of Human Genetics, expected to start in the coming year.
Keywords: virtual communication; digital methodologies; Human Genetics education.

PrgmNr 2526 - Free digital genomic educational resources: evaluation of their international value and uptake

View session detail

Author Block: **E. Tobias**[1,2], The University of Glasgow (UK) Medical Genetics and Genomics Education Team; [1]Univ. of Glasgow, Glasgow, United Kingdom, [2]West of Scotland Ctr. for Genomic Med., Queen Elizabeth Univ. Hosp., Glasgow, United Kingdom
Disclosure Block: **E. Tobias:** None.
BACKGROUND: The need for access to reliable digital educational resources for genetics and genomics is increasing significantly. This is partly due to the rapid growth in access to genetic and genomic testing by not only genetics health professionals but also, increasingly, by non-genetics specialists and the public. Understandably, the ASHG and other international societies are prioritising genetic and genomic education. Here, the creation of multiple free digital genetic and genomic educational resources, and the lessons learned in the process, will be discussed. **METHOD:** Members of an award-winning UK Glasgow University genetics and genomics teaching team have created a free educational range of resources, including: five smartphone apps (covering genomics and bioinformatics terminology & inheritance mechanisms), two free recently-launched massive open online part-time courses (MOOCs) and two websites. All are suitable for genetics specialists plus non-genetics professionals and students. One of the websites (www.EuroGEMS.org), for multiple audiences, was created on behalf of the European Society of Human Genetics (ESHG), as a guide to >110 free high-quality online worldwide resources (many USA-based). It was recently fully translated into Spanish by genetics professionals. **RESULTS:** The five free smartphone genomics apps (www.genomicsapps.org) have been installed by >5000 people in >70 countries and rated 4.9 stars. The new MOOC on Medical Genomics (https://www.futurelearn.com/courses/harnessing-the-power-of-genomics-in-medicine) covers variant filtering, naming, classification, sequencing methods, databases and precision medicine. It has, in 4 months, gained >1200 learners from >110 countries (particularly UK, India & USA), with a peak age range of 26-35. Learners contributed >650 comments and have awarded the course a 5-star rating, commending its clarity; explanations of complex topics, terminology and databases; and its online interactivity. The www.EuroGEMS.org website has been visited from 120 countries, 21% from outside Europe. Users from the USA make up a significant proportion of all of the resourcesâ□□ users but the data suggest that most potential users remain unaware of the resourcesâ□□ existence, possibly due to search engine algorithms. **CONCLUSIONS:** There is growing worldwide use and appreciation of these various digital resources, many of which can be helpful in supporting and supplementing in-person face-to-face teaching. Challenges include the time required for the resourcesâ□□ creation and the difficulties in making potential beneficiaries in the USA and elsewhere aware of their existence.

PrgmNr 2527 - Including children in a polygenic risk score return of results pragmatic trial: Considerations and decisions by consensus in the eMERGE Network

View session detail

Author Block: **C. Prows**[1], S. Wood[2], E. Bhoj[3], J. J. Connolly[3], S. L. Van Driest[4], N. S. Abul-Husn[5], W. K. Chung[6], E. W. Clayton[4], J. Gundelach[7], I. A. Holm[8], E. M. McNally[9], M. F. Myers[1], M. Sabatello[6], eMERGE Network; [1]Children's Hosp. Med. Ctr., Cincinnati, OH, [2]Univ. of Cincinnati Academic Hlth.Ctr., Cincinnati, OH, [3]Children's Hosp. of Philadelphia, Philadelphia, PA, [4]Vanderbilt Univ. Med. Ctr., Nashville, TN, [5]Icahn Sch. of Med. at Mount Sinai, New York, NY, [6]Columbia Univ., New York, NY, [7]Mayo Clinic, Rochester, MN, [8]Boston Children's Hosp., Boston, MA, [9]Northwestern Univ., Chicago, IL
Disclosure Block: **C. Prows:** None.
Polygenic risk scores (PRSs) to assess risk for common, complex diseases with adult onset such as breast cancer and coronary heart disease have become commercially available and are used in some clinical settings. Published PRSs for childhood onset diseases such as asthma and type 1 diabetes are comparatively more recent and not used in clinical settings. Guidance on PRS return to pediatric research participants is lacking. The electronic MEdical Records and Genomics Phase IV (eMERGE IV) Network consists of ten clinical sites, two of which are pediatric medical centers. Each site is expected to enroll 2500 children and adults into a pragmatic trial in which PRSs will be calculated for a number of conditions and incorporated along with family history and clinical factors into a Genomic Informed Risk Assessment (GIRA) and returned to participants and their electronic health records (EHRs). The Network considered over 60 different conditions for PRS implementation and used a consensus process to select 17 conditions for PRS validation and potential inclusion into a comprehensive GIRA. A pediatric sub-workgroup developed recommendations for PRS appropriate for testing and return to pediatric participants. Criteria appraised included scientific (e.g. sensitivity/specificity, existing validated PRS), ethical (e.g. actionability in childhood, risk vs. benefit of intervention), and practical (e.g. local expertise, age range for study recruitment, EHR access for children and parent(s)) considerations. Health promotion, disease prevention and early treatment interventions at age ranges 0 - 2, 3 - 12, and 13 - 17 years were assessed across potential pediatric conditions and used as a gauge for site votes on age inclusion criteria for the pragmatic trial. Thirteen conditions were removed from consideration due to the lack of clinical actionability during childhood or Network early determination that a PRS did not meet criteria for implementation. Rigorous PRS validation processes and comparisons followed for four conditions deemed actionable during childhood: asthma, obesity, and types 1 and 2 diabetes. Key decisions and rationales as well as remaining ethical issues to be studied will be shared. Our experience will inform others planning to calculate and return childrenâ□□s PRS in research and clinical settings.

PrgmNr 2528 - Integration of Genetic Counseling Services into an Immunodeficiency Clinic: Roles of the Genetic Counselor and Impact on Patient Evaluation and Care

View session detail

Author Block: **E. A. Varga**, P. Mustillo, B. T. Prince, R. S. Abraham; Nationwide Children's Hosp., Columbus, OH
Disclosure Block: **E.A. Varga:** None.
Background: Next generation sequencing is increasingly applied to diagnose inborn errors of immunity. Barriers to integration of genetic testing into clinical immunology practice may include the need to evaluate rapidly evolving genomic technologies without subspecialty training, unfamiliarity with the informed consent processes for genetic testing, difficulties in navigating insurance reimbursement and concerns related to variant interpretation, secondary findings and medicolegal responsibilities associated with patient and family follow-up. **Objective:** To evaluate uptake of genetic counseling services offered through an immunodeficiency clinic at a tertiary referral pediatric hospital over the course of one year and assess implications for patient care and outcomes.
Methods: The number or referral requests from immunologists, genetic counselor roles, genetic test results and outcomes were recorded. **Results:** Forty-six patients were referred for genetic counseling by a clinical immunologist. Three of these patients had a previous molecular diagnosis where follow-up genetic counseling was requested. Four patients had previous molecular testing where review of past test results and reinterpretation led to revised counseling or diagnosis. Six patients received a molecular diagnosis after further genetic testing. Five patients required genetic counseling related to incidental findings/carrier status. In addition, the genetic counselor contributed to the care team by helping to evaluate and discuss genetic testing options with clinicians and patients, assist with insurance prior authorization for genetic testing, obtain informed consent for genetic testing, enroll patients in genomic research protocols and identify patients appropriate for referral to a medical geneticist. Counseling-centric roles included pedigree intake and risk assessment, discussion of inheritance, recurrence risk and/or family planning options with patients and their family members. Genetic testing was coordinated in sixteen relatives, and cord-blood banking was facilitated in one case. A molecular diagnosis altered treatment in two cases by prompting hematopoietic cell transplant (HCT). **Conclusion:** Immunologists are likely to benefit from access to a genetic counselor to facilitate genetic testing, provide input on interpretation of genetic test results, and to ensure appropriate follow-up family testing, education, support and coordination of care.

PrgmNr 2529 - International education, awareness, celebration, and commemoration around the bicentennial of Gregor Mendelâ□□s birth

Disclosure Block: **J.J. Mulvihill:** None.

THE PERSON: Johann Mendel was born July 22, 1822, and died as Abbot Gregor Mendel on January 6, 1884. After 8 years of experiments and 18 months of compiling and interpreting his results, he founded the science of genetics, giving two lectures at the Natural Science Society in Brno (Czechia) and publishing two papers on inheritance in the societyâ□□s journal. His achievements hold lessons for today for his abilities to apply quantitative tools from physics and mathematics to qualitative biologic data, to anticipate the mechanisms of Darwinian evolution, and to improve horticulture and animal breeding, while being a faithful practicing priest and leader of his religious community. He can be held as an exemplar of mentoring (in both directions, giving and taking), thriving at the interdisciplinary interactions of botany, evolution, mathematics, physics, and agriculture, contributing to improved fruit trees, ornamental flowers, horticulture, meteorology, and beekeeping, and being a scientist-citizen, a community and social activist against inqualities, bank director and president, and a favorite member of his biologic and monastic families. He illustrates the parallel and compatible realms of science and religion and the pros and cons of solitary science and team science. His data, an early example of big data science, were challenged as too good to be true, a trope best handled with reliable research and perhaps some humor. **METHODS:** To mark the occasion, planning has involved virtual meetings with an international group representing diverse interests and perspectives. With the goals of Improving science literacy and awareness, education, appreciation of science, celebration, inspiration for trainees, students, and the public, international collaboration, and enjoyment, the vision is to increase global awareness among geneticists, other scientists, and the public of the current meanings of Mendelâ□□s life and work by helping to implement international programming designed to educate, celebrate, commemorate, and bring awareness and equity to diverse audiences. **RESULTS TO DATE:** Release of new monograph (G Mendel: *Versuche Ã¼ber Pflanzen-Hybriden, Experiments on Plant Hybrids: New Translation with Commentary.* S MÃ¼ller-Will, K Hall, O DostÃil, Eds., Brno, Masaryk University Press, 2020), improved exhibits at some museums, including the Smithsonian, an international competition for new statue of Mendel, restoration of Mendelâ□□s greenhouse, launching a bicentennial website https://www.mendel22.cz/, and announcement of the Mendel Festival and Genetics Conference, July 20-23, 2022. In February 2022, AAAS will have a Mendel session. Your input is welcomed!

PrgmNr 2530 - Participant Engagement and Cancer Genome Sequencing (PE-CGS) Network

View session detail

Author Block: **L. E. Mechanic**[1], J. C. Tiner[1], W-Y. Chou[2], K. K. Filipski[1], E. M. Gillanders[1]; [1]Natl. Cancer Inst./DCCPS/EGRP, Bethesda, MD, [2]Natl. Cancer Inst./DCCPS/BRP, Bethesda, MD
Disclosure Block: **L.E. Mechanic:** None.
While recent genome characterization efforts have been very successful, research gaps remain especially for minority and underserved populations. The Cancer Genome Atlas (TCGA) program has analyzed over 20,000 samples for 33 different cancer types, yet only an estimated 15% of TCGA cases are from non-Caucasian participants and only 3% of from Hispanic or Latino participants. One method of addressing these knowledge gaps and increasing diversity in genetic research is direct participant engagement. Direct participant engagement may include interacting with participants via the web, social media, or in collaborations with patient groups or organizations. As a part of the Cancer Moonshot^{SM} Initiative, the National Cancer Institute (NCI) has launched the Participant Engagement and Cancer Genome Sequencing (PE-CGS) Network which falls under the Blue Ribbon Panel (BRP) Recommendation A: Network for Direct Patient Engagement. In the recommendation, the BRP called for NCI to â□□enlist direct patient engagement through a federated network where patients will be offered comprehensive tumor profilingâ□□. The panel further noted the importance of directly engaging with patients to facilitate participation in research and ensure patients are respected and have access to the research enterprise. Moreover, the panel stated that efforts to reach minority and underserved populations should be a high priority. The PE-CGS Network includes several U2C Research Centers and one U24 Coordinating Center. The overall purpose of the PE-CGS Network is twofold: 1) To promote and support direct engagement of cancer patients and post-treatment cancer survivors as participants in cancer research; and 2) To use such approaches for rigorous cancer genome sequencing programs addressing important knowledge gaps in the genomic characterizations of tumors in areas such as, but not limited to: Rare cancers or rare cancer subsets; highly lethal cancers; cancers with an early age of onset; cancers with high disparities in incidence and/or mortality; or cancers in understudied populations. The PE-CGS Network aims to function as a collaborative network allowing PE-CGS U2C Research Centers to address common issues, share best practices and lessons learned, and utilize common methods where appropriate. Through this network, NCI aims to address research gaps in the genomic profiles of cancer, determine effectiveness of a direct participant engagement approach, generate a shared resource for the scientific community, and provide insights into the development and sustainability of a larger network for direct participant engagement.

PrgmNr 2531 - Public Health Genetics Week 2021: A Public Awareness Campaign

View session detail

Author Block: **M. Lyon**; American Coll. of Med. Genetics and Genomics, Bethesda, MD
Disclosure Block: **M. Lyon:** None.
Purpose Public health genetics plays a vital role in both genetics and public health, the field is often overlooked within the larger context of either specialty. To raise awareness, and celebrate the efforts of the system, the second annual Public Health Genetics Week was held from May 24-28,2021.
Methods The National Coordinating Center for the Regional Genetics Networks (NCC) held the second annual Public Health Genetics Week. In collaboration with federal agencies, state agencies, regional organizations, and non-profits, NCC developed materials and held events for Public Health Genetics Week. The week consisted of daily themes (â□□What is Public Health Genetics?â□□, â□□Who is Involved in Public Health Genetics?â□□, â□□What are Public Health Genetics Programs?â□□ â□□Public Health Screeningâ□□, and â□□Public Health Genetics Resourcesâ□□) and included public health genetics events (nightly screenings of *Ken Burns Presents The Gene: An Intimate History*, Reddit AMA, Public Health Genetics Student Panel, Digital Escape Room, Facebook Live, and Twitter Chats). The daily themes and events targeted stakeholders of the public health genetics system, as well as the general public, to raise awareness about public health genetics. **Results** Across Twitter, Facebook, Instagram from May 24-28, there were 299 mentions of Public Health Genetics Week, utilizing either #PublicHealthGenetics or #PHGW hashtags. On TikTok, videos were viewed more than 2800 times. Additionally, the conversation reached over 524,000 individuals across Facebook, Instagram, and Twiter. Throughout the week, individuals and families, federal agencies, organizations (for-profit and non-profit), engaged in conversations about public health genetics and shared resources that can be utilized by the system. *This project is supported by the Health Resources and Services Administration (HRSA) of the U.S. Department of Health and Human Services (HHS) under Cooperative Agreement #UH9MC30770-01-00 from 6/2017-5/2020 for $800,000 per award year. This information or content and conclusions are those of the author and should not be construed as the official position or policy of, nor should any endorsements be inferred by HRSA, HHS or the U.S. Government.*

PrgmNr 2532 - RNA-Seq and recurrence risk testing for breast cancer in the context of an undergraduate course: Implications for patient education

View session detail

Author Block: **P. Soneral**; Bethel Univ., Saint Paul, MN
Disclosure Block: **P. Soneral:** None.
Rapid advances in RNAÂseq technology and bioinformatic analysis of gene expression has normalized the use of precision diagnostics and recurrence risk testing for breast cancer patients. While these diagnostic approaches have numerous benefits, patients often lack the scientific literacy to evaluate data models - and their uncertainties - for enhancing their health decision-making. To increase access to scientific knowledge for stakeholders, we designed an educational module that evaluates the validity of RNA-seq gene expression as a tool for subtyping and determining the prognostic signature of a human breast tumor. Using a crowdsourced approach in the context of an undergraduate course, we recreated the workflow of prominent precision oncology companies - we prepared a whole transcriptome library from a single breast cancer patient, and used multiplex sequencing on twelve uniquely barcoded Illumina preparations. Datasets obtained from the sequencing were subjected to quality control analysis using the Green Line of DNA Subway (FAST QC, FAST X, Kallisto, Sleuth algorithms). LogÂ transformed gene expression ratios were used to determine the molecular subtype of the tumor. To calculate the recurrence risk, the Oncotype DX model was used, including 16 cancer genes and 5 reference genes. Results from the proof-of-concept experiment indicated significant overexpression of ER and PR genes (p25, suggesting high risk for 10 year distant recurrence (95% CI). Further exploration of the model indicated that normalization to aberrantly expressed reference genes can greatly skew the recurrence risk calculation, highlighting limits to the predictive power of this tool. Taken together, our findings illustrate the validity of RNA-seq based tumor subtyping through an educational module, and underscores the importance of equitable access to genomics education as a form of patient self-empowerment and decision-making. We discuss the future implications of this work for education and policy.

PrgmNr 2533 - The role of general practitioner in management of rare diseases

View session detail

Author Block: **P-H. Roux-Levy**[1], Y. Perrard[1], K. Mazalovic[1], C. Binquet[2], N. Meunier-Beillard[2], L. Faivre[3], C. Lejeune[2]; [1]Dept. of Gen. Practice, Dijon, France, [2]Inserm, CIC1432, Clinical Epidemiology Unit, Dijon, France, [3]Hosp d' Enfants, Dijon, France
Disclosure Block: **P. Roux-Levy:** None.
Background: The management of patients with rare diseases (RD) presents many challenges including diagnosis, care coordination and orientation in the health system. The general practitioner (GP) is the dedicated actor who provides long-term care to the patients and their families. The aim of this study was to determine the roles of the GP in management of the patient with RD.
Methods: We used a qualitative study by monographs. From March to October 2020, semi-structured interviews were conducted by telephone with families of adult patients who have RD with intellectual disability and with the health professionals who took part of their management. Patients were recruited through reference centers, support group or GP to have very different type of management. The interviews were transcribed and analysed by two independant investigators. A grounded theory-based analysis was realised.
Results: Eight monographs were conducted with 20 participants. The onset of the first symptoms and the disability will mark a break point with the idealized child and family. During the life of these patients, the parents, and more often the mother, are subjected to three challenges in face of which they will have to position themselves in various ways: the family balance, the caregiving and the care coordination. The parents' positioning regarding these issues will vary according to the availability of psychosocial, technical, organizational and administrative resources, but also according to their experience with their child's illness and disability. They will invest each of these positions in a more or less intense way and thus build their new identity. The GP will be involved in different ways depending on this construction.
Discussion: Although the GP has a vocation as well as all the resources to ensure the care coordination, he must take into consideration the identity construction process of the natural caregiver around the illness and the disability of his child. If the caregiver constructs his or her identity through the care coordination, the GP must position himself as a support by helping the parent to coordinate care and by providing psychological support. Once this process has evolved, he will be able to take over the care coordination and thus reduce the parent's burden.

PrgmNr 2534 - Transitioning to a virtual training model for building capacity in genomic analysis skills across world regions

View session detail

Author Block: **A. Matimba**[1], M. Aslett[1], I. Malta[1], S. Aron[2], D. Hughes[1]; [1]Wellcome Connecting Sci., Cambridge, United Kingdom, [2]Univ. of Witwatersrand, Johannesburg, South Africa
Disclosure Block: **A. Matimba:** None.
Background: Short courses offer an effective way for scientists to acquire specialised skills relevant to their work, contributing to addressing capacity gaps for genomics and bioinformatics skills, particularly in regions where the needs continue to escalate. Following a needs assessment survey among scientists in Africa, we identified genome-wide association studies (GWAS) as a priority topic for training. The COVID-19 pandemic then necessitated development of online learning formats leading to our first virtual course delivery. The â□□Human Genomic Epidemiology in African Populationsâ□□ course, aimed to provide genomic scientists with â□□hands-onâ□□ practical exercises on the study design, data processing, analysis and interpretation to understand the genetic architecture of complex human traits/diseases. This was complementary to genomics capacity building initiatives in Africa and facilitated exploration of design and development of virtual training across world regions.
Methods: The week-long course was developed collaboratively with 12 human genomics and epidemiology experts. Applicants were selected based on potential benefits to their work or research immediately or in the short term. In addition to online resources, software and relevant datasets were compiled onto a virtual machine, which was disseminated to participants providing all analysis tools and resources in one place. Preparation of participants emphasised a need for minimum technical specifications and internet connectivity. A combination of virtual teaching strategies included watching lectures online, live discussions and hands-on practical analysis exercises in small tutorial groups. The course used online meeting platforms, text chat resources and a web-based repository for training materials.
Results and conclusions: The course was delivered to 22 participants from 8 countries in Africa. Experiencing the delivery method for the first time, participants reacted positively to the effectiveness of the virtual platforms for delivery of a highly hands-on practical advanced genomics course. Over 90% of participants indicated that the course met their expectations, was relevant for their work and achieved desired learning outcomes. A follow-up survey will determine the impact of the course on their work, institutions and networks. Modelled in a similar way, and taking lessons learnt, this course will be tailored for virtual delivery in other regions. In conclusion, we identified strengths and opportunities for further refinement and tailoring of virtual training approaches for bioinformatics to audiences based in Africa, Asia and Latin America.

PrgmNr 2535 - User-centered design of genetic test reports leads to improvements on self-reported and objective measures

As genetic testing becomes more widely accessible and cost effective, there is an increasing need for non-specialist healthcare professionals to order, interpret and action a variety of genetic reports. Previous research indicates that patients and clinicians frequently have difficulties interpreting existing reports, particularly for *BRCA*. We have previously published general report recommendations and specific findings for cystic fibrosis carrier testing based on a user-centered design research project. Here we report the results of follow-up studies employing a total of six rounds of interviews and analysis to redesign report templates for *HFE* and *BRCA1*. These involved interviews with 25 healthcare providers and 41 members of the public, including but not exclusive to individuals having prior experience with *HFE* or *BRCA* testing. Feedback was gathered on wording, clarity of the next steps that should be taken (actionability), and other dimensions, and reports were revised accordingly. Report design was followed by preregistered evaluations comparing report templates having this novel design with corresponding report templates used within the UK national testing network in randomized factorial (design x template) between-participants designs. The sample consisted of (blinded) members of the public recruited by online access panels, n = 376 (*HFE*) and 456 (*BRCA1*). Endpoints included objective and subjective comprehension, communication efficacy, actionability, worry, and explainability (â□□I would be able to explain what the result means to people in my family who may need to knowâ□□). The modified templates scored higher on the communication efficacy scale, and were rated easier to understand, easier to explain and more actionable (each test *p* p

PrgmNr 2536 - Efficient delivery of *FMR1* across the blood brain barrier using AAVphp construct - feasibility of gene therapy for fragile X syndrome

View session detail

Author Block: **M. T. Velinov**[1], C-L. Dai[2], G. Merz[2], T. Wise[2], J. Goodman[2], H. Meeker[2], T. Adayev[2], N. Dolzhanskaya[2]; [1]Rutgers Robert Wood Johnson Med. Sch., New Brunswick, NJ, [2]NYS Inst. for Basic Res. in Dev.al Disabilities, Staten Island, NY

Disclosure Block: **M.T. Velinov:** None.

Background: Fragile X syndrome (FXS) is the most common single gene disorder associated with intellectual disability and autism. It results from the silencing of gene *FMR1.* The protein product of *FMR1,* FMRP binds multiple mRNA molecules and is a major regulator of protein translation and function. Patients with partially preserved *FMR1* activity due to methylation mosaicism show increased cognitive functioning suggesting that partial supplementation of FMRP may mitigate disease manifestations. Clinical trials using small molecule medications failed to demonstrate significant control of the disease core symptoms. Direct intraventricular administration of *FMR1* expression constructs resulted in uneven distribution of the construct in different brain regions. AAVphp vector constructs were recently shown to provide efficient gene delivery across the blood brain barrier. We therefore aimed to determine the efficiency of *FMR1* -AAVphp constructs delivery in the brain after peripheral administration. Methods and Results: We first used two AAV vectors that harbor fluorescent marker GFP and the human synapsin promoter (scAAV9-hSyn-GFP and scAAVphp.eb-hSyn-GFP, VirovekInc) to assess the efficiency of brain delivery after peripheral administration. We injected $2X10^{13}$ vg/kg in a final volume 200Âµl of sterile PBS in the mouse tail vein in control animals. We observed robust marker expression in neurons. Further, we administered constructs including the *FMR1* gene with both human and mouse synapsin promoter (AAVphp.ebâ□□hSyn-mFMR1IOS7, AAVphp.ebâ□□mSyn-mFMR1IOS7, Virovek Inc) in the amount $2X10^{13}$ vg/kg in a final volume 200Âµl of sterile PBS and a control empty AAVphp.eb vector in the peripheral tail veins in 5-month old control mice (FVB.129P2-Pde6b+tyr-ch Ant/J) and in a *FMR1* knockout mouse model (FVB.129P2-Pde6b+tyrc-ch Fmr1tmlCgr/J). Following 4-week post-injection interval, whole brain homogenates were examined for FMRP expression using quantitative FMRP (qFMRPm) method developed for mouse tissue analysis. The assay utilizes the FMRP-specific mAb5C2 to capture the rabbit polyclonal antibody R477 for detection, and an abbreviated recombinant protein, GST-mR7 as standard. In brains of knock out mouse models after construct injections we observed FMRP levels similar to the observed in control animals. No FMRP was noted in knock out models injected with control empty vector. Conclusions: We demonstrated robust *FMR1* delivery and expression in the brain of mouse *FMR1* knock out models after peripheral administration using AAV.php vectors. Our results suggest that further studies using the peripheral AAVphp.eb vector for *FMR1* delivery are warranted.

PrgmNr 2537 - Exon specific U1 snRNA therapeutic strategy to rescue retinal degeneration in familial dysautonomia

View session detail

Author Block: **A. Chekuri**[1], E. Morini[2], E. Logan[2], A. Krauson[1], M. Salani[1], E. Kirchner[1], J. Bolduc[1], G. Romano[3], F. Riccardi[4], F. Pagani[3], L. H. Vandenberghe[5], S. A. Slaugenhaupt[6]; [1]Massachusetts Gen. Hosp./Harvard Med. Sch., Boston, MA, [2]Massachusetts Gen. Hosp., Boston, MA, [3]Intl. Ctr. for Genetic Engineering and Biotechnology, Trieste, Italy, [4]Intl. Disclosure Block: **A. Chekuri:** None.
Familial dysautonomia (FD) is an autosomal recessive neurodegenerative disorder caused by a splice mutation in the gene encoding Elongator complex protein 1 (*ELP1*, also known as *IKBKAP*). A T-to-C base change in the 5â□□ splice site of *ELP1* exon 20 results in exon 20 skipping with tissue specific reduction of ELP1 protein predominantly in central and peripheral nervous system. In addition to complex neurological phenotype, FD patients also exhibit progressive retinal degeneration severely affecting their quality of life. To test novel splicing-targeted therapeutic approaches, we developed a phenotypic mouse model of FD, *TgFD9; Ikbkap*$^{\hat{I}\square 20/flox}$ which exhibits most of clinical features of the disease while displaying the same tissue specific mis-splicing observed in patients.Here, we report a thorough characterization of the retinae of our FD mouse using SD-OCT and immunohistochemical assays during disease progression. Our findings showed a significant decrease in the thickness of the retinal nerve fiber layer (RNFL) and the ganglion cell layer (GCL) starting from 3 months of age. Retinal whole-mount analysis showed reduction of RGC cell counts from 6 months of age. Histopathological analysis of the optic nerve from FD mice using neurofilament (NF) staining indicated diffuse degeneration of axonic bundles demonstrating that our mouse model correctly recapitulates the retinal degeneration observed in patients. To restore correct *ELP1* splicing defect and rescue retinal degeneration, we have designed a novel splice targeted therapy using modified version of the spliceosomal U1 snRNAs (ExSpeU1s) that permit targeted binding to intronic sequences downstream of the mutant 5' splice site enabling efficient recruitment of spliceosomal machinery. We have analyzed the efficiency of splicing correction in the retina of FD mouse through intravitreal injection of adeno associated vectors (AAV) expressing ExSpeU1.Our findings suggest that our novel FD mouse model exhibit most of the retinal degeneration pathology observed in FD patients. Our in vivo preliminary data demonstrate the valuable therapeutic potential of ExSpeU1 RNA delivery to treat retinal degeneration in FD.

PrgmNr 2538 - Nanoparticle-based non-viral CRISPR/Cas9 delivery platform for targeting thoracic aortic aneurysm associated heterozygous mutations

View session detail

Author Block: **L. Ellis-Aguilar**[1], C. A. Velandia-Piedrahita[2], J. Cifuentes[1], J. C. Cruz[1], C. MuÃ±oz-Camargo[1], R. Cabrera[1]; [1]Univ. de los Andes, BogotÃi, Colombia, [2]FundaciÃ³n Cardioinfantil - Inst. de CardiologÃa - Molecular Biology and High Complexity Tests Lab., BogotÃi, Colombia

From cell culture improvement to design of therapies for rare diseases, genome editing using CRISPR/Cas9 has become one of the most attractive tools for researchers due to its versatility, high efficiency and the possibility of reduced off-target effects. However, its clinical application has been hindered by the scarcity of safe and efficient delivery systems. Here, we developed a magnetite-based bionanoconjugate to efficiently deliver, both recombinant Cas9 and single guide RNA (sgRNA). Specifically, we synthesized Magnetite Nanoparticles (MNPs) and functionalized them by the conjugation of a polymer spacer (PEG) and the cell-penetrating peptide Buforin II (BUFII) for superior membrane translocation. Also, we co-immobilized recombinant Cas9 to form MNP-PEG-BUFII-Cas9 nanobioconjugates. We characterized them by Fourier transform infrared spectroscopy (FTIR), thermogravimetric analysis (TGA), dynamic light scattering (DLS) and transmission electron microscopy (TEM). We also carried out biocompatibility analyses including lactate dehydrogenase (LDH) cytotoxicity assays, platelet aggregation assays, hemolytic activity assays and the Ames test for mutagenicity. We evaluated cell internalization and compared it with electroporation. For the Cas9 activity proof-of-concept we first incubated our nanoconjugate with PCR products to evaluate *in-vitro* digestion. Second, we amplified genomic DNA from 4 patients with hereditary aortic aneurysms and designed gRNA for allele specific digesting targeting the genes *PKD1, TGFBR2, COL3A1* and *COL15A1*. Then, we performed Digenome-Seq for off-target effect detection. Third, we delivered the MNP-PEG-BUFII-Cas9 nanobioconjugate to Cos7 and HFF cells to introduce a DNA lesion at *COL3A1.* Finally, we evaluated cell internalization and endosomal escape of the nanobioconjugate by co-localization analysis of confocal images. Overall, we demonstrate the efficacy of MNPs as safe and promising non-viral delivery vehicles for CRISPR/Cas9 localized gene editing to treat heterozygous mutations.

With the development of next generation sequencing, additional information (incidental data or secondary data (SD)) may become available. This information, unrelated to the symptoms that justified the prescription of the test, may be of potential interest to patients/families, but may also of additional concern. Some foreign learned societies recommend that the patient be offered a systematic analysis of a pre-established list of so-called 'actionable' genes, while others do not recommend this analysis in the absence of clear arguments about the benefit-risk ratio. Research studies are encouraged. Two complementary French studies are being proposed.

FIND (330 patients, 3 centers, exome sequencing, developmental abnormalities) is analyzing the medical benefits, economic and psychological issues of reporting SD (group 1 late onset actionable diseases, group 2 genetic counselling, group 3 pharmacogenetics). Information about SD were given to participants after a dedicated consultation with a genetic counsellor. Semi-structured individual interviews have been conducted in parents of patients with one SD just after the results, and at 6 and 12 months. 80% of the parents accepted the search for SD in their child, and we showed an influence of the medical discourse on the parentsâ□□ choices. All the DS results of FIND have been given back to parents, and the follow-up interviews up to one year did not show regrets, but it was not without any psychological impacts in group 1. With time, some participants have forgotten the SD results, especially from group 2 and 3, and sometimes, there was confusion with the primary data.

The DEFIDIAG-DS (1200 patients, genome sequencing) will allow access to ACMG SD, not to index cases with ID, but to their parents. Quantitative data, change of opinion/ refusal questionnaire, semi-directive interviews in case of ACMG SD will be proposed at the time of results and at one year. The support of the study allows a deployment in 12 centres instead of 3, which will allow to deepen the impact of the medical discourses, and of the decisions of the parents when it concerns their health.

The results of both studies will increase knowledge on the perception and the impact of SD, and give avenues regarding information, announcement and management.

PrgmNr 2540 - Enhanced diagnosis mapping and exome sequencing identify novel variants for rare diseases in the UK Biobank

View session detail

Author Block: **M. Patrick**[1], R. Bardhi[1], W. Zhou[2], J. E. Gudjonsson[1], L. C. Tsoi[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Massachusetts general Hosp., Broad Inst., Boston, MA
Disclosure Block: **M. Patrick:** None.
While many people are affected by rare diseases, the ability to accurately identify their genetic causes can be limited due to the small sample sizes available. Population biobanks provide extensive genetic and phenotypic information on a large number of individuals, however, we previously showed that rare disease mapping can be suboptimal. We hypothesize that, by applying enhanced disease mapping in a large population biobank with whole exome sequencing (WES) data, we can enhance the identification of associated variants. We used WES data from 167,246 Caucasian individuals (cases and controls) for genetic association of 162 rare diseases (indicated as having a prevalence under 1 in 2,000 by Orphanet) in the UK Biobank. We mapped ICD-10 codes to Orpha numbers through a consensus process to ensure they identify specific rare diseases, then used SnpEff to annotate rare (JAK2 V617F mutation, for example $p=5.30x10^{-40}$ in primary myelofibrosis. We also confirmed previously reported mutations for *HBB* in beta-thalassemia ($p=7.34x10^{-12}$) and *F11* in congenital factor XI deficiency ($p=3.41x10^{-11}$). Novel (not reported in ClinVar) associations were identified between a loss of function variant in *CALR* and essential thrombocythemia ($p=1.59x10^{-13}$), as well as an *SRSF2* missense variant, predicted to be deleterious by SIFT, CADD and PROVEAN among others, and chronic myelomonocytic leukemia ($p=1.19x10^{-13}$). Together these findings demonstrate the utility of applying enhanced rare disease mapping to population biobanks for rare disease research and, as more exome sequenced samples become available for the UK Biobank and other resources, it will be important to harness this information to improve the diagnosis of rare diseases.

PrgmNr 2541 - Generation and quality control of the biobank-scale methylation dataset in the VAâ□□s Million Veteran Program (MVP)

Disclosure Block: **F. Dong:** None.

The Department of Veterans Affairs (VA) Million Veteran Program (MVP) is one of the worldâ□□s largest databases of genomic and clinical data. In addition to genotype data, the MVP project is developing multi-omic resources. Here we introduce the new MVP methylation dataset. We used Illuminaâ□□s Infinium Methylation EPIC Array to quantify methylation at over 850,000 genomic sites for ~50,000 human blood samples. To routinely prepare and analyze data at this scale, we developed a Dockerized, high-throughput SeSAMe-based quality control and preprocessing pipeline incorporating common preprocessing steps (Type I probe channel inference, noob background correction, and dye bias correction) and sensitive pOOBAH (P-value with out-of-band array hybridization)-based probe-level quality control. We determined optimal pOOBAH and sample call rate thresholds using an epigenome-wide association study (EWAS; see below for details) and found that pOOBAH 94% yield a suitable balance for data quality and sample rejection rate. SeSAMe also includes age, sex, and novel genotype inference methods beyond the standard 59-marker fingerprinting which we use for sample-level QC. We present the utility of genotype inference for sample identity verification in a biobank-scale cohort. We demonstrate the quality and scientific potential of this data set by performing EWAS for a model phenotype, Body Mass Index (BMI). We replicate previously published results including 201 significant associations and coefficient signs among 216 previously reported CpGs from 3 large scale BMI studies. We also provide insights on the correlation of methylation levels and BMI as a function of disease status, e.g. diabetes diagnosis and/or renal disease. In addition, we analyzed age acceleration, the difference between methylation-derived predicted age (353 marker Horvath model) and chronological age, as a function of disease diagnosis. For example, in HIV-positive patients we find an average acceleration consistent with previously reported results of 3-4 years. Our novel findings illustrate the potential of this dataset to elucidate the role of epigenetic variation in human disease, particularly when combined with MVPâ□□s large genomic and clinical datasets.

PrgmNr 2542 - GHGA - The German Human Genome-Phenome Archive - A new federated national infrastructure for sharing human genomes in a European framework

View session detail

Author Block: **C. Mertes**, N. Smith, J. Gagneur, GHGA consortium; Dept. of Informatics, Technical Univ. of Munich, Garching, Germany
Disclosure Block: **C. Mertes:** None.
Genome sequencing and other omics technologies are among the most prominent and high-volume data sources in the life sciences, with major applications in basic biology, translational research, and medicine. Clinical omics profiling of patients is expected to dominate large-scale data generation in the near future, providing unprecedented opportunities for use of these data in research. While initiatives exist to harmonize phenotypic data, in particular medical health records, there is a lack of infrastructure for FAIR omics data within Germany. While these data are already generated in large scale across Germany, legal, ethical, and technical hurdles currently preclude managed access and data reuse for research at a national and international level.
Here we present the German Human Genome-Phenome Archive (GHGA) - an initiative to overcome these hurdles and balance the needs of data usage and data protection. Integrated into the German National Research Data Infrastructure (NFDI) and the federated European Genome-Phenome archive (EGA), GHGA will integrate existing and future omics data resources and link them to phenotypic information. With its 21 participating institutes, it will enable major scientific avenues through the delivery of harmonized molecular (meta-) data from large cohorts and create an invaluable bridge between biomedical research and healthcare, opening the door for scientists in and beyond Germany to participate in key international research networks.
GHGA activities will build on and extend existing, reliable, and secure high-performance computing infrastructures established by members of the consortium. A network of data hubs directly connected to the major data generators in Germany will handle the data in a federated manner. Using cloud technologies, this distributed infrastructure will be accessible to researchers in an integrated and seamless manner based on GA4GH standards. Researchers will have controlled access to raw sequence data as well as analysis results generated using harmonized, internationally recognized analysis workflows. The initial focus will be on seed communities that drive the national efforts for research and clinical sequencing at scale - rare diseases, oncology, and epidemiology. GHGA plans to meet its goals within a five year milestone based timeline until 2025. The consortium will drive open science solutions that are fully aligned with ELIXIRâ□□s and EGAâ□□s federation strategies. To ensure quality and comparability with international standards, GHGA will maintain FAIR data standards and engage with projects such as GA4GH to foster international data exchange in current and upcoming studies.

PrgmNr 2543 - Natural-language processing and machine learning can systematically infer tissue annotations of omics samples by modeling their unstructured metadata

View session detail

Author Block: **A. Krishnan**, N. T. Hawkins, M. J. Maldaver, A. Yannakopoulos, L. A. Guare; Michigan State Univ., East Lansing, MI
Disclosure Block: **A. Krishnan:** None.
Currently, there are >1.3 million human -omics samples from >26,000 datasets that are publicly available in repositories such as EBI ArrayExpress and NCBI GEO. These samples capture cellular responses of diverse human tissues/cell-types under thousands of conditions, making these published data invaluable for other researchers to reuse to answer new questions. However, currently, they cannot easily find the samples of interest because important sample attributes such as tissue of origin are routinely described using non-standard terminologies that are, in turn, buried within free-text descriptions.
To address this major problem, we have developed a new approach, NLP-ML, that combines natural language processing (NLP) and machine learning (ML) to annotate samples to their tissue-of-origin solely based on their unstructured text descriptions. NLP-ML works by creating numerical representations of sample descriptions and using these representations as features in a supervised ML classifier that predicts tissue/cell-type term annotations.
NLP-ML is the first method that takes a sophisticated approach to annotate omics samples using sample description that lacks any structure. Our approach significantly outperforms an advanced graph-based reasoning annotation method (MetaSRA) and a baseline exact string matching method (TAGGER). The trained NLP-ML tissue models capture biologically meaningful signals in text. Models of anatomically related tissues are similar to each other and can correctly classify tissue-associated biological processes and diseases based on their text descriptions alone. NLP-ML models are nearly as accurate as models based on gene-expression profiles in predicting sample tissue annotations but have the distinct capability to classify samples from any omics experiment type just based on their text metadata.
NLP-ML is implemented in the software Txt2Onto https://github.com/krishnanlab/txt2onto that contains a Python utility for classifying any unstructured text to terms in a tissue ontology, along with pretrained models, demo scripts, and extensive documentation. We are now using this method to annotate and distribute tissue/cell-type annotations of >1 million human omics samples.

PrgmNr 2544 - NDD-CNV Portal: Facilitating genetic test interpretation, research and education for Neurodevelopmental CNVs

Copy number variants (CNVs) can cause a spectrum of neuropsychiatric and neurodevelopmental disorders (NDDs). However, variant interpretation, including phenotype driver and modifier gene identification, still represent a challenge, even for experts. Currently, clinical, genetic, and molecular data about CNVs are not connected and distributed across registries, databases, and the literature. To overcome current limitations, we are developing the NDD-CNV Portal, an interactive website that displays expert-curated CNV datasets alongside biomedical annotations, user-friendly analytics, and educational resources. In this ongoing project, we aggregated clinical, genomic, transcriptomic and proteomic data from 30 patients with pathogenic 8p (n=10), Ring14 (n=5), and Dup15 (n=15) CNVs from patient collaboratives. In addition, we collected and curated additional pathogenic and population CNVs from databases such as the UK-Biobank, gnomAD, ClinVar, and DECIPHER. To enable exploration of CNVs, we developed interfaces that visualize overlap of patient CNVs with population CNVs, genomic regulatory elements, disease-associated genes, SNVs, GWAS hits and >20 gene-level features such as (inter-and intraspecies) sequence constraint metric, dosage sensitivity, tissue, and cell-type level expression. By combining gene-level features, we rank genes in the order of most likely responsible genes and provide enrichment analyses of phenotype, functional, and pathway annotations. In addition to the search based on genomic position, the user can also perform disorder-specific and across-disorder genotype-phenotype analyses. We designed the NDD-CNV Portal for three user scenarios: i) Education of NDD-CNV-related diseases, ii) Expert-level variant interpretation using CNV guideline-based variant pathogenicity classification tools, and iii) Research using interactive tools and visualizations to explore the rich source of interconnected data and annotations. The NDD-CNV Portal infrastructure is scalable and will integrate novel data types. As such, it has the potential to transform variant interpretation, research, and education for neurodevelopmental CNV-associated disorders. We are actively looking for collaborators contributing to this project.

PrgmNr 2545 - SCN Portal for epilepsy genetics: Facilitating genetic test interpretation, research and education for sodium channel disorders

Pathogenic variants affecting the voltage-gated sodium channel (SCN) encoding genes *SCN1A*, *SCN2A*, *SCN3A*, and *SCN8A* cause a spectrum of neurodevelopmental disorders with or without epilepsy. Variant interpretation represents a challenge, even for SCN gene experts. Currently, clinical, genetic, and molecular data about SCN genes are not connected and distributed across registries, databases, and the literature. To overcome current limitations, we developed the SCN-Portal, which contains the largest expert-curated dataset of sodium channel disorders alongside user-friendly analytics and educational resources. Presently, we aggregated from 1849 patients with pathogenic variants in *SCN1A, SCN2A, SCN3A*, and *SCN8A* published and unpublished clinical and genetic data. We collected and curated electrophysiological data for 425 SCN gene variants from the literature and generated molecular read-outs for additional *SCN1A* and *SCN2A* variants. These data were connected with protein structures, and annotated with >40 protein features characterizing the location, physicochemical properties, and interactions of the variants within 3D protein structures. Several annotations, such as those for the size, location, and corresponding physiochemical properties of the pore, are novel and have been calculated using bioinformatic tools. Using our previously developed paralog framework, information from each SCN gene was transferred *in silico* to the other SCN genes. We designed the SCN-Portal for three user scenarios: i) Education: We provide a rich source of information in >10 languages for all known SCN1/2/3/8A-related diseases; ii) Access to expert-level variant interpretation: We provide novel expert-curated web applications that enable variant pathogenicity classification and disease trajectory prediction; iii) Research resource: Throughout the SCN-Portal, we provide novel research tools to explore our extensive and unique biomedical data resource. Users will be guided by tutorials with illustrative examples and will not require programming skills. The SCN-Portal infrastructure is scalable and, with increasing data, may transform variant interpretation, research and education for *SCN1A*, *SCN2A*, *SCN3A* and *SCN8A*. The SCN-Portal will be hosted at http://scn-portal.broadinstitute.org. We are actively looking for collaborators contributing to this project.

PrgmNr 2546 - Strategies to increase the availability of summary statistics in the GWAS Catalog

View session detail

Disclosure Block: **A. Buniello:** None.

The NHGRI-EBI GWAS Catalog is a central resource for the Genome Wide Association Study (GWAS) community, demonstrating the benefit of expert data curation and integration of full p-value GWAS summary statistics into a central repository for variant-trait associations. The Catalog aims to make GWAS data FAIR (Findable, Accessible, Interoperable and Re-usable), while serving as a starting point for investigations to identify causal variants, calculate disease risk, understand disease mechanisms and establish targets for novel therapies. The GWAS Catalog summary statistics repository is one of the largest, most visited and most frequently updated resources of its kind - now hosting full p-value results from at least 8,232 independent analyses (from 480 publications), which account for a total of 25,000 datasets from a wide variety of traits. Summary statistics can easily be accessed and downloaded from the GWAS Catalog FTP site or via a dedicated summary statistics API. In an aim to facilitate data sharing and interoperability, the GWAS team have recently released a web-based deposition interface to support scalable author submission of summary statistics and metadata from published and pre-published (e.g. submitted at the time of journal submission upon request from the reviewers) GWAS. The Nature Journals Group, for example, are proactively supporting an open access policy for their published GWAS data by adding the GWAS Catalog in their list of official summary statistics repositories. Currently, more than 80% of GWAS results are submitted to the Catalog pre-publication. The expansion of the GWAS Catalog summary statistics repository has required a considerable outreach effort from the Catalog data team and the main stakeholders, including funders and top journals. Concerns about data privacy and misuse, technical challenges and lack of standards are amongst the barriers to sharing the Catalog team encountered at the beginning of this journey. Following our successful 2020 workshop on GWAS summary statistics standards and sharing, we are continuing to work with the community to remove barriers to sharing. The rate of summary statistics data sharing, in fact, still noticeably differs among different genetics cohorts and therapy areas, and is particularly low in the cancer genetics community. Over the next few months, we will be focusing our community engagement efforts on the identification of strategies to maximise diversity of data shared in the Catalog, including underrepresented populations and traits. Furthermore, we will gather final recommendations on data and metadata standards to report and share GWAS results.

PrgmNr 2547 - The Brazilian Rare Genomes Project: the largest whole genome sequencing effort for rare disorders in South America

View session detail

Author Block: **J. OLIVEIRA FILHO**[1], T. Almeida[1], M. Cervato[1], M. Caraciolo[1], N. Zurro[1], G. Colichio[1], B. Mascaro[1], M. Nobrega[1], K. Chen[2], J. R. Ceroni[1], E. Perrone[1], L. Virmond[1], C. Quaio[1], C. A. Moreno[1], E. Alves[1], R. Siqueira[1], A. Coelho[1], R. Minillo[3]; [1]Hosp. Israelita Albert Einstein, Sao Paulo, Brazil, [2]SÃ£o Paulo, Brazil, [3]Hosp. Israelita Albert Einstein, SÃ£o Paulo, Brazil
Disclosure Block: **J. Oliveira filho:** None.
Rare diseases together comprise a group of 9,603 distinct entitites and have an estimated cumulative prevalence of 1.5 to 6.2% of the population. This represents, in Brazil, a total number of 3.2 to 13.2 million individuals, with a great impact on health services. Especially challenging is the definitive diagnosis of these patients, leading to true pilgrimages within the health system, with great delay and consequent increase in morbidity and mortality. The Rare Genomes Project is an initiative from the Albert Einstein Jewish Hospital in SÃ£o Paulo, in partnership with the National Health Ministry. It was initiated in 2020, with the aim of sequencing 7755 patients with rare disorders seen in the Brazilian public health system until the end of 2023. These patients are being recruited from participating centers spread across the country, from north to south. In 2020, the efforts were directed to building the sequencing, IT and bioinformatics infrastructure to support the project. So far, 1486 probands were recruited from 18 predefined disease groups, and whole genome sequencing was performed in over 1300 patients to date. Preliminary results are show in another abstract. Data collection is being done electronically, using Phenotips and Redcap. Sequencing protocols include PCR-free whole genome sequencing in Illumina Novaseq 6000 equipment , and bioinformatic processing is being performed using Dragen and in-house developed tools. Variant data will be deposited in Clinvar, and HPO terms with gene-level findings of negative cases will be shared via Matchmaker Exchange. The samples will be stored in a biobank, to accelerate future research in the field. This project will also allow the creation of the largest Brazilian genetic database of patients with RD and provide subsidies to assist in the implementation of genetic tools for future use in the public health system.

PrgmNr 2548 - Towards robust clinical genome interpretation: developing a consistent terminology to characterise disease-gene relationships for harmonised curation - an updated structural variant ontology for the NGS era

Clinical application of genomic data is reliant on robust, curated associations between locus, genotype, mechanism, and disease phenotypes. Members of the Gene Curation Coalition (GenCC; www.thegencc.org) are working to harmonise approaches to ensure gene-level curated resources are comparable and interoperable, to streamline gene curation efforts and facilitate interpretation of variants. The GenCC includes members of Clinical Genome Resource (ClinGen), DECIPHER/Gene2Phenotype/Transforming Genetic Medicine Initiative (DECIPHER/G2P/TGMI), Medline Plus Genetics (formerly Genetics Home Reference GHR), Genomics England PanelApp (PanelApp), PanelApp Australia, Online Mendelian Inheritance in Man (OMIM), HUGO Gene Nomenclature Committee (HGNC), Orphanet, and private sector partners including clinical testing laboratories.

Little consensus exists on the use of public ontologies for annotation of structural variants (SV); most expert groups use an in-house system.

Here we present an approach to standardize terminology for SV annotation.

Aim: to harmonise description of SV from NGS data (ie WGS) with regard to a single gene, enabling more accurate data aggregation and assumptions about the mechanism through which these variants can cause disease.

Intended use:

1. Manual curation of disease-associated variant class and functional consequence in disease-gene pairs
2. Manual annotation and interpretation of variants identified in patients in the clinical and research setting
3. Consistent output of automated consequence annotation pipelines eg Ensemblâ□□s Variant Effect Predictor (VEP)
4. Matching SV consequences to curated gene-disease mechanisms for variant filtering in genome annotation pipelines

Our SV working group includes individuals with experience in identification and evaluation of structural variants in both the clinical and research settings, bioinformatics and curation tool development, as well as individuals representing current nomenclature standards.We drafted a hierarchical ontology to describe the content, orientation and location of potentially clinically relevant SVs with regard to their impact on a single gene.

The ontology was piloted by manual annotation of SVs by a team of biocurators on 59 variants from 25 ClinGen dosage curations, and feedback incorporated. These clinical variants are enriched for transcript deletions. Further use testing is ongoing using SV from the GnomAD SV dataset including translocations and transcript duplications.
Working with Sequence Ontology we will integrate and update these terms such that these will be available centrally and with an associated public definition.

PrgmNr 2549 - *De novo* pathogenic variants predominate in exomes of a cohort of patients with intellectual disabilities and/or congenital anomalies. Preliminary results from a pilot program for Rare Undiagnosed Diseases in Chile

Rare Diseases (RD) affect populations worldwide. Countries with limited genomic resources face challenges to implement RD programs, such as availability of clinical genetics and genomics specialists, sequencing and bioinformatics resources, and lack of insurance coverage for genomic testing. To build local capacities to address these gaps, we developed a pilot program for clinical evaluation and exome sequencing (ES) of individuals with congenital anomalies and/or intellectual disabilities and unknown diagnoses in Chile. We used different NGS alternatives, from in-house singleton clinical exome sequencing (cES) (approximately 5000 known disease-causing genes) to outsourced research ES strategies, proband-only and trios, and bioinformatics analysis using in-house pipelines and commercially available tools. These processes were followed by multidisciplinary team variant interpretation and Sanger confirmation in the proband and parents if available. To date, 38 patients have participated in the study. cES was used in the first 15 participants, 3 of them (20%) had a heterozygous *de novo*, likely causative variant in *NFIX*, *TCF4* and *AHDC1*. ES-proband only was completed in 18 participants (11 with prior non-informative cES) and identified a causative variant in 8 (44.4%), including 5 *de novo* or likely *de novo* SNVs (*DDX3, ARID2, KAT6A, PUF60, SOX10*), 2 recessive conditions (*TECPR2, UBE3B*) and 1 *de novo* CNV (6q24q25 deletion). ES-trio was performed in another 16 families, resulting in 8 diagnoses (50%): 4 *de novo* SNVs (*MAF, TBC1D2B, SPTBN2, SMARCA4*), 2 inherited dominant variants (*NOG* and *EFTUD2*), 1 autosomal recessive condition (*TK2*), and 1 CNV (Xq13q21 duplication). Overall diagnostic yield was 50%, each participant had a different molecular finding and *de novo* variants accounted for 14/19 cases with a diagnosis (82%), providing information for genetic counseling. These results show the feasibility of developing RD programs in limited-resource settings, using combinations of local and outsourced capacities. Future challenges include scaling up, performing cost-utility analysis, understanding patient perceptions, assessing changes in clinical management after molecular diagnosis to guide clinical implementation in the Chilean health care system. Research funded in part by ANID-Chile grants FONDECYT 1171014 and 1211411, FONDEQUIP EQM150093, Redes 180047, US National Human Genome Research Institute (NIH) Baylor Hopkins Centers for Mendelian Genomics, and a donation from Child Health Foundation, Birmingham, AL

PrgmNr 2550 - *De novo* variants in *TCF4* with a suspected gain-of-function mechanism are responsible for a new malformative disease without intellectual disability

TCF4 loss-of-function variants cause Pitt-Hopkins syndrome (PTHS), associating intellectual disability (ID), wide mouth, distinctive facial features, and intermittent hyperventilation followed by apnea. Pathogenic missense variants are primarily clustered within the C-terminal HLH domain required for dimerization and DNA binding. Variants located elsewhere may be associated with mild non-syndromic ID. Using exome sequencing, we identified *de novo* missense variants in *TCF4* in three individuals who did not show typical PTHS hallmarks. The variants affect ultra-conserved amino acids within or close to the C-terminal HLH domain. These individuals showed consistent phenotypic features associating cranio-facial dysmorphism, limb anomalies and growth failure without ID. The main facial characteristics include an abnormal skull shape, wide forehead, sparse eyebrows, epicanthus, anteverted nares, short columella, micrognathia, low-set ears with external ear malformation. All individuals have lacrymal duct obstruction. Limbs malformations include camptodactyly of the fingers and toes, clinodactyly of the 5th finger, syndactyly and nail hypo/dysplasia. In two individuals, growth failure required growth hormone therapy. Neurological examination and psychometric assessment were normal. In order to study in vivo the role of the de novo *TCF4* missense variants, we are exploiting two vertebrate model systems: Xenopus laevis and Danio rerio (zebrafish). We firstly confirmed the conservation of the gene expression profile of tcf4 in Xenopus and zebrafish craniofacial development. Preliminary results in *Xenopus* embryos of the wild-type and the mutated forms of *TCF4* indicate an effect on cartilage development. Furthermore, we are also performing *in silico* modeling prediction as well as genome-wide DNA methylation, chromatin immuno-precipitation and mRNA sequencing in patient-derived samples. Overall, we report a new clinical entity associated with suspected gain-of-function variants in *TCF4*, distinct from PTHS, with

facial and limb dysmorphism, growth failure and no ID. The description of other individuals will help to further delineate the phenotypic description. The generation of *in silico, in vitro* data and *in vivo* models for *TCF4* variants will allow us to define their role during development and to generate new platform for drug screening approaches.

Background Voltage-gated calcium (CaV) channels are essential components and key functional regulators of excitable cells. Neuronal N-type (CaV2.2) and P/Q-type (CaV2.1) channels are critical for presynaptic neuro-transmitter release. CaV Î±1 subunits form the channel pore, whereas the Î² and Î±2Î´ subunits are crucial regulators of trafficking and bio-physical properties of channel complexes. The putative cache (Ca^{2+} channel and chemotaxis receptor) domain containing 1 (CACHD1) protein structurally mimics Î±2Î´ proteins and modulates CaV2 and CaV3 activity and expression.

Methods Using gene matching platforms, we assembled a cohort of six affected individuals from four unrelated families who present with a hitherto unreported neurodevelopmental syndrome. Exome sequencing (ES) was performed to identify the underlying genetic cause. We established stable *cachd1* zebrafish mutants on transgenic reporter lines relevant to clinical features in humans and performed quantitative phenotyping. Histology was performed on E18.5 *Cachd1* knockout mouse embryos to assess neurodevelopmental and gross morphological defects.

Results The affected individuals from families 1-3 display global psychomotor delay, facial dysmorphism, oculo-auricular malformations, congenital genitourinary abnormalities, and anorectal malformations. Family 4 consists of two aborted male fetuses both showing urethro-renal obstruction with hydronephrosis, periauricular skin tags, dysmorphic facial features, and esophageal atresia. ES led to the identification of biallelic loss-of-function variants in *CACHD1* (NM_020925.4) segregating with disease in all pedigrees: c.1783-1G>A and c.2387+1G>A in family 1; c.261+2T>C and c.648delC; p.(Ile217SerfsTer13) in family 2; homozygous c.274dup; p.(Ile92Asnfs*52) in family 3; and c.277C>T; p.(Arg93*) and c.460C>T; p.(Arg154*) in family 4. Homozygous *cachd1* mutant zebrafish larvae recapitulated hallmark features of affected humans, including aberrant craniofacial patterning and significant dilatation of the distal pronephric tubule and cloaca in comparison to wild type.

Conclusion These findings support biallelic *CACHD1* loss of function variants as the cause of a novel

neurodevelopmental syndrome and expand the clinical spectrum of voltage gated calcium channel effectors.

PrgmNr 2552 - NSD1 gene variations associated to Sotos syndrome in humans and diverse selection within exons

View session detail

Introduction Sotos syndrome is an overgrowth disease that affects 1/40 000 newborns worldwide and is associated with variants in *NSD1.* Here we report a novel duplication in an Ecuadorian toddler, perform a systematic literature review of the condition and localize a hot spot for variations in humans and primates.
Methods To find the causal molecular variation, we ordered a panel for overgrowth syndromes and identified a novel duplication in the NSD1 gene. We performed a systematic literature review of all cases reported and identified an exon susceptible to nucleotide variations. Therefore, we localize the NSD1 exons in primates and compare the percentage of similarity and synonymous/non-synonymous variations among species.
Results and Discussion There are 304 variants reported cases with this genetic condition. Most of the variants are associated with the well-known clinical manifestation and physical appearance of the syndrome. Deletions result in a classical Sotos syndrome, however, duplication on the gene results in an opposite phenotype (microcephaly and short stature). The genotype in our patient reported a duplication, however the phenotype resembles a classic mild Sotos Syndrome.
Conclusion In summary, our patientâ□□s variant leads to a misfolded protein that might simulate the common *NSD1* nonsense mutation which affects the length of the protein. Most of reported variants occur in exon 5 which suggests a relaxed selection with a pathological phenotype in humans.

PrgmNr 2553 - Clinical delineation, sex differences and genotype-phenotype correlation in pathogenic *KDM6A* variants causing X-linked Kabuki syndrome Type 2

Introduction: Kabuki syndrome is one of the most recognisable multi-system congenital disorder. Type-2 Kabuki syndrome (KS2) is a highly variable X-linked condition caused by *KDM6A* variants, and is thought to be responsible for ~5% of KS cases. Its mutation spectrum and the genotype-phenotype correlations are poorly understood. Methods: Genetic and clinical details of new and published individuals with pathogenic *KDM6A* variants were compiled and analysed. Results: 61 distinct pathogenic *KDM6A* variants (50 truncating, 11 missense) from 80 patients (34 males, 46 females) were identified. Missense variants clustered in the TRP #2, #3, #7 and Jmj-C domains. Truncating variants were significantly more likely to be *de novo*. Thirteen individuals had maternally inherited variants and one had a paternally inherited variant. Neonatal feeding difficulties, hypoglycaemia, post-natal growth retardation, poor weight gain, motor delay, intellectual disability (ID), microcephaly, congenital heart anomalies, palate defects, renal malformations, strabismus, hearing loss, recurrent infections, hyperinsulinism, seizures, joint hypermobility and gastroesophageal reflux were frequent

clinical findings. Facial features of >1/3rd patients were atypical for KS. Males were significantly more likely to be born prematurely, have shorter stature and severe developmental delay/ID. We also highlight the overlaps and differences between the phenotypes of KS2 and KS1. Conclusion: This largest-ever KS2 series expands the *KDM6A* mutation spectrum, delineates the KS2 phenotype and demonstrates its sex and variant-dependent variability. These results will improve diagnosis for patients with KS2, especially those with inherited missense variants. In future these results will inform the development of evidence-driven management guidelines in KS.

PrgmNr 2554 - Diverse phenotype genotype characterization and novel *SOX9* variation in Campomelic Dysplasia

View session detail

Author Block: **E. Vasquez**[1], C. Calvache[1], V. Romero[1], K. Hosomichi[2]; [1]USFQ, Quito, Ecuador, [2]Univ. de Kanazawa, Kanazawa, Japan
Disclosure Block: **E. Vasquez:** None.
BackgroundCampomelic dysplasia is a rare disorder (1/200,000 births) that involves the development of the skeletal and genital systems with a 10% survival rate. Our patient is a 4-year-old (female assigned at birth) with campomelic dysplasia, female sex reversal, type 1 Arnold Chiari malformation and bilateral conductive hearing loss.
Methods and Results To find the causal molecular variation, we performed in trio whole exome sequencing analysis and identified a novel variation in the *SOX9* gene. The *SOX9* gene plays a key role in the development of the endochondral skeleton and male sexual differentiation. The variation we found is a novel non-sense variation in exon 1 caused by a change of guanine (G) to adenine (A) at position 344bp, replacing the normal synthesis of tryptophan to a premature stop codon at amino acid position 115.
There is a diversity of phenotypes and genotypes expressions related to sex reversal, life span and prognosis associated with the *SOX9* gene variations. We performed a literary review of cases reported and identified hot spot locations in the gene associated to the different clinical presentations. The position of the variation correlates with the diversity of clinical manifestations and the similarity between patients with variants in the same position. In our patient it translates to a decreased level of pulmonary and airway involvement, being part of the small percentage that manages to survive beyond the first days of birth.
ConclusionsWe identified the casual novel variation responsible for the phenotype of our patient and recognized locations withing the *SOX9* gene associated to sex reversal, life span and prognosis. Our study suggests that the relation between phenotypes and genotypes is essential for the adequate counseling for the patient and the family.

PrgmNr 2555 - Exome sequencing identifies a missense mutation in *MMP14* in autosomal dominant hypotrichosis

Hypotrichosis simplex (HS) refers to a group of hereditary isolated alopecias which are characterized by diffuse hair loss that usually begins in early childhood. Inherited forms of hypotrichosis are genetically heterogeneous with 11 genes implicated so far, including *APCDD1, CDSN, EPS8L3, KRT74, RPL21, SNRPE* and *U2HR*, which are responsible for dominant forms of the disease. To identify the underlying genetic defect in an HS-affected multigenerational pedigree, we undertook whole-exome sequencing (WES) in 5 affected individuals and focused on shared heterozygous predicted protein altering substitutions and indels with a minor allele frequency (MAF) of less than 0.5% in public and in-house exome databases. This analysis highlighted two novel variants, of which only a missense variant (c.1655T>A; p.Val552Gly) in *MMP14* co-segregated with the disease. This variant maps to the transmembrane domain of the protein, possibly affecting membrane binding of MMP14 which in turn can affect the activity of other MMPs around hair follicles. To assess the functional impact of the c.1655T>A mutation on *MMP14* expression, we performed quantitative reverse transcriptase in real time PCR on RNA derived from whole scalp skin biopsy from an affected individual and a healthy control, which showed a significant reduction of *MMP14* expression as well as increased *MMP2* expression. To investigate further MMP14 pathology in the context of hypotrichosis, we obtained skin punch biopsies from Mmp14-deficient and wild-type mice and performed transmission electron microscopy which showed increased vesicular activity and dense collagen in the dermis in Mmp14-deficient skin consistent with disruption of extracellular matrix anchoring hair follicles. Of note, patchy hair loss has been observed in Mmp14-deficient mice. In summary, we present a multigenerational pedigree in which defective MMP14 leads to hypotrichosis and therefore expand the genetic causes of hair disorders.

RAI1 haploinsufficiency is involved in Smith-Magenis syndrome (SMS - OMIM 182290), associating fully penetrant traits such as mild to severe intellectual disability (ID), distinctive physical features, behavioral abnormalities, and sleep disturbance. We identified an individual presenting with an early obesity, a broad square-shaped face, midface retrusion, and an everted upper lip with a ''tented'' appearance, and sleep disturbance but without ID (VCI 116, FRI 106, WMI 94, PSI 111, Wechsler Intelligence Scale for Children-V Edition), whose clinical presentation was partially overlapping with SMS. This suspected clinical diagnosis led to the re-evaluation of exome sequencing and SNP array data, with the identification of an unreported deletion of 229 kb including the first two non-coding exons of RAI1 as well as part of its regulatory regions. Genome sequencing was performed to exclude any additional chromosomal rearrangements or aberrant events potentially accounting for the clinical presentation. The deletion extended into the adjacent intergenic region including part of the contiguous gene PEMT and containing a topologically associating domain (TAD) boundary, suggesting a possible fusion of the two contiguous TADs. We thus speculated that the atypical SMS could be due to a reshaped long-range interaction landscape of the locus, causing tissue-specific haploinsufficiency. To test this hypothesis we are currently performing mRNA sequencing coupled with whole genome chromosome conformation capture in primary fibroblasts and an in vitro
neural cell line to explore the epigenetic and transcriptional landscape associated with this variant. The identification of further patients carrying overlapping clinical features and molecular results will help us understanding the mechanisms implicated in the atypical presentation of our patient.

ZC4H2 (MIM# 300897) is a nuclear factor involved in various cellular processes including proliferation and differentiation of neural stem cells, ventral spinal patterning and osteogenic and myogenic processes. Pathogenic variants in *ZC4H2* have been associated with Wieacker-Wolff syndrome (MIM# 314580), an X-linked neurodevelopmental disorder characterized by infantile spasms, arthrogryposis, development delay, hypotonia, feeding difficulties, poor growth, skeletal abnormalities and dysmorphic features. Zebrafish *zc4h2* null mutant fish were viable beyond embryogenesis, recapitulated the human phenotype, showed complete loss of *vsx2* expression in brain, and exhibited abnormal swimming and balance problems. Here we report 5 new (4 males and 1 female) patients with *ZC4H2*-related disorder from 4 unrelated families. Three of the four *ZC4H2* variants are novel: 2 are missense, designated as c.142T>A (p.Tyr48Asn) and c.558G>A (p.Met186Ile), 1 is nonsense variant, c.618C>A (p.C206*). One variant is a splice-site (c.225+5G>A). Bioinformatic analysis of these variants supported their pathogenicity. Four patients were on the severe spectrum of clinical findings associated with *ZC4H2*-related disorder, one of whom died at 7 years of age. The male patient harboring hemizygous p.Met186Ile has a relatively mild phenotype. Of note, 3/5 patients had a tethered cord requiring a surgical repair. To study the effect of the missense variants, we performed microinjection of human *ZC4H2*wild-type or variant mRNAs into one-cell stage *zc4h2* null mutant zebrafish embryos. The p.Met186Ile mRNA variant was able to partially rescue *vsx2* expression while p.Tyr48Asn mRNA variant was not. However, swimming and balance problems could not be rescued by either *ZC4H2* variant. These results suggest that the p.Met186Ile is a hypomorphic allele, which can explain the associated milder phenotype. Our work expands the genotypes and phenotypes associated with *ZC4H2*-related disorder and demonstrates that the zebrafish system is a reliable method to determine the pathogenicity of ZC4H2 variants. Larger cohorts of patients are needed to study genotype-phenotype correlations, the effect of additional hypomorphic variants, and the prevalence of tethered cord.

Purpose: Post-zygotic activating *PIK3CA* variants are responsible for the several phenotypes under the *PIK3CA*-Related Overgrowth Spectrum (PROS). We describe 150 new patients referred for genetic testing, reporting data on their phenotype and underlined *PIK3CA* or *GNAQ, GNA11, RASA1*, and *TEK* variants. A detailed genotype-phenotype correlation in a literature-derived cohort of 1007 *PIK3CA*-mutated patients was also provided. **Methods:** We performed targeted NGS on DNA extracted from blood or buccal swab and tissue biopsy using a custom panel including genes involved in the PI3K/AKT/mTOR pathway and â□□vascularâ□□ genes (*RASA1, TEK, GNAQ,* and *GNA11*). Clinical and molecular data from literature were systematically reviewed and included in the search for correlations. **Results:** *PIK3CA* pathogenetic variants were identified in 93 of 150 unrelated patients. Fifty-seven had a wild type *PIK3CA* allele: pathogenetic variants in *GNA11*, *RASA1, GNAQ*, and *TEK* were found in 11 of them. Differences in the distribution of the variants across *PIK3CA* domains, in the Variant Allele Fraction (VAF) in different tissues, and in the degree of hyperactivation of the PI3K network related to the variant (variant strength) were found compared to current literature. Alone, 10 of the *PIK3CA* variants reported were responsible for more than 70% of cases, including the three most common mutational hotspots usually reported in several cancers. Combining our cases with those from literature review we draw up a detailed list of all the 81 pathogenic variants described so

far in PROS and related them to the respective phenotypes. Eight novel pathogenic variants were also reported. While some *PIK3CA* variants were exclusively associated with a specific PROS phenotype, some were scattered across all the phenotypes and others demonstrated enrichment in some specific phenotypes. Correlations between variant strength and absence of involvement of the central nervous system were also evident. VAF was not correlated with disease severity, and we report severe phenotypes with very low VAF. Patients with pathogenic variants in vascular genes clinically overlapped with PROS. **Conclusion:** Our findings combined with a review of the literature show novel genotype-phenotype correlations underlining the importance of performing a deep phenotyping, carry out a representative tissue sampling, and adopt a comprehensive molecular approach in PROS and overlapping phenotypes.

PrgmNr 2559 - Germline 3q21 Chromosome Deletion: A Rare Multi-System Condition

Disclosure Block: **J. Greenmyer:** None.
Background and aims: Germline 3q21 chromosome deletions result in a rare multi-system condition with diverse phenotype. The aim of this study was to conduct a systematic review of the clinical characteristics of 3q21 deletion in order to draw conclusions about the multiple aspects of care these patients should receive.**Methods:** We report our multidisciplinary observations of a patient with 3q21 deletion. Additionally, we conducted a systematic literature review for studies describing 3q21 deletion. Our systematic search strategy included Ovid MEDLINE, EBM Reviews, Embase, Scopus, and Web of Science. Any deletion including the germline 3q21 region was included in our analysis.**Results:** We identified 13 manuscripts that described 14 unique cases of 3q21 region deletion. The deleted interval in our patient (3q21.3-3q22.1) involves 77 known genes, some of which are recognized to result in abnormal phenotypes due to haploinsufficiency. Clinical features among patients with 3q21 deletion include cognitive and developmental disability, hearing loss, cardiac abnormalities, facial differences (dysmorphism), velopalatal insufficiency, retinal lacunae, myelodysplastic syndrome, urogenital malformations, and other birth defects. Agenesis of the corpus callosum was noted in four (28.6%, n=4/14) patients. Two patients (14.3%, n=2/14) developed myelodysplastic syndrome.**Conclusions**: Patients with 3q21 deletion have a predilection for multi-system complications including agenesis of the corpus callosum.

Disclosure Block: **L. Pires:** None.
Introduction: Cornelia de Lange syndrome (CdLS) is a rare genetic disorder caused by mutations in six different genes - *NIPBL, SMC1A, HDAC8, SMC3, BRD4 and RAD21.* characterized by intellectual disability, behavior abnormalities, distinctive facial features, hirsutism, growth retardation and limb reduction defects.**Aim:** To investigate the Neuropsychiatric and Behavioral phenotype of 24 brazilian CdLS patients.**Methods**: We evaluated the cognitive and neuropsychiatric phenotype of 24 Brazilian patients harboring CdLS clinical phenotype and pathogenic variants on genes associated with the syndrome, diagnosed by exome sequencing of the proband, father, and mother.**Results:** Our sample was composed of 24 individuals, 15 male and 9 female, age of diagnosis ranged from 1 month-old to 9 years (mean 13 months; median 4 months). The actual age of the patients ranged from 4 years to 43 years (mean 18 years; median 16 years). The major genetic etiology was *NIPBL* (21 patients), followed by *SMC1A* (3 patients); all pathogenic variants were *de novo*. Neurodevelopmental delay was a major found on the sample, present in all patients. Although 17 patients (70,8%) attempted to go to school, only two were literate, six recognized alphabet letters and seven were able to recognize numbers. Feeding difficulties in the first year of life and Inattention problems were found in 18 patients (75%). Intolerance to pain was present in 16 patients (66%). Excessive fear and hyperactivity were both present in 13 patients (54,1%). Aggressive behaviour was present in 10 patients (41,6%), besides self-violence was present in 12 (50%). Anxiety was present in 10 patients (41,6%). Autistic Spectrum Disorder was present in 6 patients (25%). **Conclusions:** Neuropsychiatric symptoms and behavioral deviations are an important group of findings in CdLS. Due to high incidence found on psychiatric disorders, we suggest that neuropsychological evaluation and directive therapies should be a primal focus during diagnosis and treatment. Another important approach in these patients involves their learning disability, assuming that they might need special support to ensure a minimum acquisition of learning skills in school.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is a complex disease, for which genetic and environmental factors play etiological roles. Sequencing and functional approaches have demonstrated the contribution of common and rare variants to NSCL/P, along with epigenetic signatures. Many NSCL/P-associated genes converge to the Wnt signaling pathways or interacting partners. In this study, we investigated the presence of rare variants in a custom panel of 27 genes directly or indirectly involved with the canonical Wnt / beta catenin and the noncanonical Wnt / Planar Cell Polarity (PCP) pathways: *ARHGAP29, CBLL1, CDH1, CELSR3, CTNNA1, CTNNB1, CTNND1, DVL3, ESRP1, ESRP2, FZD1, FZD2, FZD7, LRP6, PRICKLE1, PRICKLE2, RHOA, SMAD2, SMAD4, SNAIL, TGFB1, VANGL2, WNT4A, WNT10A, WNT11, YAP1, ZEB1* and *ZEB2*. After sequencing with the Illumina Ampliseq platform in MiSeq system, 309 patients, all from familial cases of NSCL/P, presented >90% of bases with 20x minimum coverage and proceeded to subsequent variant analysis. Rare (20 were filtered. Compared to ethnically matched controls from ABraOM database (exome sequencing data; only segments with 20x minimum coverage were compared), no aggregation of such variants in any gene was observed in patients (P >=0.07). Among all prioritized variants, criteria for variant classification from the American College of Medical Genetics support a pathogenic role for 19 variants, mostly located in NSCL/P-associated genes - *CTNND1* (6), *CDH1* (5) and *ARHGAP29* (2) -, but some of them in novel candidates: *CTNNA1* (3), *ESRP1* (1), *PRICKLE1* (1) and *ZEB1* (1). Segregation analysis, which was possible for only 5 families, revealed complete segregation of variants in *CDH1* (2), *CTNND1, CTNNA1* and *PRICKLE1* with NSCL/P, corroborating their pathogenic effect. *CDH1*, *CTNNA1* and *CTNND1* codify key proteins of the cadherin-catenin complex of adhesion junctions in epithelial cells, which dynamics is regulated by canonical Wnt pathway during embryogenesis. Interestingly, the variant segregating in *CTNNA1* is a missense one located at the subdomain VH1, responsible for the attachment to beta-catenin in the adhesion complex. Moreover, this family reports cases of gastric cancer, a phenotype that has been associated with *CDH1* and CTNNA1. In conclusion, we report novel pathogenic variants in *CDH1*, *CTNND1* and *ARHGAP29* and suggest the pathogenic effect of rare variants in novel candidate genes, such as *CTNNA1*, *ESRP1*, *PRICKLE1* and *ZEB1*. Functional analyses will be of interest to confirm the effect of the variants here reported

PrgmNr 2562 - A homozygous missense variant in amyloid-beta precursor protein *(APP)* may cause severe syndromic intellectual disability

View session detail

Author Block: **K. Riquin**[1], T. Besnard[1,2], A. Toutain[3], V. Vignard[1,2], S. Bezieau[1,2], B. CognÃ©[1,2]; [1]UniversitÃ© de Nantes, CHU Nantes, CNRS, INSERM, lâinstitut du thorax, Nantes, France, [2]Ctr. Disclosure Block: **K. Riquin:** None.

Intellectual disability is a clinically and genetically heterogeneous group of disorders. It is characterized by deficits in intellectual and adaptive functioning begining before adulthood, with a lasting effect on development. Recently, we identified by genome sequencing a homozygous missense variant NM_201414.3:c.440A>G:p.(His147Arg) in the E1 domain of Amyloid-beta precursor protein *(APP)* in one patient with severe intellectual disability, absent speech, epilepsy, cerebellar hyploplasia, and autistic behaviour. APP is an ubiquitous cell surface receptor able to homo- or hetero-dimerize. The most studied isoform of APP is the 695 amino-acids protein which is expressed at the surface of neurons. It has been observed that APP dimerization at neuron membrane participate to neurite growth, neuronal adhesion, axonogenesis and synaptogenesis. Many pathogenic missense variants have already been identified in the AÃ domain and are associated with the accumulation of amyloid Ã peptide leading to early onset alzheimer disease. To date, only one homozygous loss-of-function variant in *APP* was reported, in an individual presenting with global developmental delay, epilepsy and microcephaly (Klein et al. 2016). The missense variant we identified substitutes a cupper-binding histine that is required for APP dimerization. We are currently trying to modelize the functional effect of the variant in HEK293 and SH-SY5Y cell lines. We will present the first results of this functional study and we will discuss the implication of *APP* biallelic loss-of-function variants in syndromic intellectual disability.

PrgmNr 2563 - A nonsense *EBF3* variant in an individual with intellectual disability, without ataxia and hypotonia

View session detail

Author Block: **S. Spineli-Silva**[1], N. de Leeuw[2], N. Leijsten[2], M. H. A. Ruiterkamp-Versteeg[2], J. R. M. Prota[1], A. P. Marques-de-Faria[1], T. P. Vieira[1]; [1]Dept. of Translational Med., Sch. of Med. Sci., State Univ. of Campinas, Campinas, Brazil, [2]Dept. of Human Genetics, Radboud Univ. Med. Ctr., Nijmegen, Netherlands

Disclosure Block: **S. Spineli-Silva:** None.

Heterozygous variants in the Early B cell factor 3 (*EBF3*) and deletions at the 10q26.3 region, encompassing the entire *EBF3* gene, have been reported in individuals presenting with hypotonia, ataxia and delayed development syndrome (HADDS) (MIM#617330), first described in 2017. However, individuals with pathogenic variants in the *EBF3* show phenotypic heterogeneity. We report on a heterozygous *de novo* variant in the *EBF3* gene in an individual with neurodevelopmental delay, behavioural manifestations, and craniofacial features. The proband, an eleven years-old boy, the only child of a non-consanguineous and healthy couple, was referred for genetic evaluation due to speech delay, learning disability and behavioural problems that suggest an oppositional defiant disorder. It was also related hyperactivity, irritability, hetero-aggressiveness, visual hallucinations, insomnia and decreased pain sensitivity. At physical evaluation, it was observed macrocephaly, long face, prominent nasal bridge, everted lower lip, high palate, clinodactyly of 5th finger, hypoplasia of 4th and 5th metacarpus, and pes planus. The chromosomal microarray analysis showed a gain of 365 kb in Xp22.33 or Yp11.32 (pseudo autosome region 1) that was classified as a Variant of Uncertain Significance. Subsequent whole exome sequencing, performed with the Agilent SureSelect Target Enrichment V5 (Agilent TechnologiesÂ®) and the Illumina HiSeq platform (Illumina$^{Â©}$, Inc.), revealed a heterozygous nonsense variant c.1381C>T (p.Arg461*) in the *EBF3* gene (NM_001005463.2), classified as pathogenic. Validation of this variant and segregation analysis in the parents were performed by Sanger sequencing and confirmed this variant to be *de novo*. This truncating variant in the *EBF3* gene (c.1381C>T) has been reported in a single individual in the gnomAD Database. However, pathogenicity classification and clinical data are not available. Recently, this gene has been included in the Gene Reviews as the â□□*EBF3* Neurodevelopmental Disorderâ□□ and, to date, less than 50 cases have been described. The case herein described, without ataxia and hypotonia, supports the clinical variability of this condition.

PrgmNr 2564 - A predictive modeling strategy to explore the mechanism(s) underlying dominantly-inherited peripheral neuropathy caused by aminoacyl-tRNA synthetase variants

View session detail

Author Block: **A. Cale**, A. Antonellis; Univ. of Michigan, Ann Arbor, MI
Disclosure Block: **A. Cale:** None.
Aminoacyl-tRNA synthetases (ARSs) are ubiquitously expressed and essential enzymes that ligate amino acids to the appropriate tRNA molecules in the cytoplasm and mitochondria; ARSs function as monomers or dimers. Mutations in five ARSs cause autosomal dominant, axonal peripheral neuropathy (aka Charcot-Marie-Tooth [CMT] disease), which is characterized by distal muscle weakness and sensory loss. This presents the question: how do mutations in ARSs, which are essential in all tissues, lead to tissue-specific effects? There are three possibilities for the molecular pathology: haploinsufficiency, dominant-negative effects, and gain-of-function effects. Haploinsufficiency has been ruled out based on genetic studies in mouse and human, and on the observation that pathogenic variants are limited to missense and small in-frame deletion variants. Interestingly, the five ARSs associated with CMT all function as homodimers, which is consistent with a dominant-negative effect. If a dominant-negative effect is the disease mechanism, it would be expected that certain variants in any cytoplasmic, dimeric ARS could lead to peripheral neuropathy. To test this, I am employing a predictive modeling strategy in which I engineer mutations in threonyl-tRNA synthetase (*TARS1*), which is a cytoplasmic dimeric ARS that has not been implicated in CMT. Based on the observation that a small in-frame deletion in the glycine binding pocket of glycyl-tRNA synthetase (*GARS1*) causes a severe, early-onset neuropathy, I engineered six human *TARS1* variants that similarly impact the threonine binding pocket. I developed a humanized *TARS1* yeast complementation assay, which revealed that all six of the engineered variants cause a loss-of-function effect, similar to the majority of CMT-associated ARS variants. I also performed western blot analysis, which revealed that two of the loss-of-function variants do not reduce protein expression; this last set of variants are the most promising to assess for a dominant-negative effect. Moving forward, I will: (i) test the mutations for dominant-toxicity in a yeast assay expressing wild-type and mutant *TARS1*; (ii) develop heterozygous worms for any dominantly toxic variants and assess for motor behavior deficits; and (iii) develop heterozygous mice for any promising variants and assess for peripheral neuropathy. Here, I will present all of our unpublished data. Successful completion of this study will provide insight into the mechanism underlying ARS-associated CMT and inform clinicians to screen all genes encoding a cytoplasmic dimeric ARS for pathogenic variants in patients with peripheral neuropathy.

PrgmNr 2565 - Biallelic frameshift variant in the *TBC1D2B* gene in two siblings with progressive cognitive impairment, gingival overgrowth, limb tremor, and fribous dysplasia of face

View session detail

Author Block: **G. ROLDÃ□O CORREIA COSTA**[1], N. de Leeuw[2], R. Pfundt[2], I. Cristina Sgardioli[1], A. dos Santos[1], V. Gil-da-Silva-Lopes[1], T. Paiva Vieira[1]; [1]Sch. of Med. Sci., Univ. of Campinas, Campinas, Brazil, [2]Radboud Univ. Med. Ctr., Nijmegen, Netherlands
Disclosure Block: **G. RoldÃ£o correia costa:** None.
The *TBC1D2B* gene is a GTPase-activating protein involved in membrane trafficking that interacts with the early endosomal marker proteins RAB5. Biallelic lossâ□□ofâ□□function variants in this gene were first reported in 2020 as a cause for a neurodevelopmental disorder with seizures and gingival overgrowth in individuals from three unrelated families. Here we report two male siblings, with similar clinical characteristics, born to a first-degree cousin couple. The oldest sibling started with bilateral growing of soft tissues in the malar region at three years old, which evolved with significant maxillary hypertrophy and compression of the brainstem. At 17 years old, he presented mental deterioration, limb tremors, ataxia, gingival overgrowth, and fibrous dysplasia. At his last evaluation, at 38 years old, he was bedridden and dependent on assisted ventilation. His younger brother presented with a similar clinical evolution, starting also at three years old. His condition evolved with the same characteristics and, at 27 years old, he was also bedridden and with tracheostomy. Chromosomal Microarray Analysis for both siblings did not show pathogenic CNVs, however, it showed multiple regions of homozygosity (ROH) in the autosomal genome of both. Whole Exome Sequencing was performed using the Agilent SureSelect Human All Exon V5 capture kit (Agilent Technologies$^{Â®}$) and the Illumina HiSeqâ□¢ 2000 platform (Illumina$^{Â©}$, Inc.). Data analyses, including annotation and variant classification, were carried at the Genomic Diagnostics Division from the Department of Human Genetics at the Radboud University Medical Center in Nijmegen, Netherlands. A novel biallelic frameshift variant in the *TBC1D2B* gene (NM_144572.1) was found in both siblings - Chr15(GRCh37): g.78337330del c.595del p.(Val199Trpfs*22) - which creates a new stop codon at position 22. This gene is encompassed in one of the ROHs shared by the two brothers. The homozygous variant was confirmed by Sanger sequencing in both siblings and was found in heterozygous form in each of their parents. There are strong similarities of clinical characteristics, and its evolution, among the patients described here and the reported cases, including a cherubism-like phenotype with progressive gingival overgrow. This is the fourth family in the world in which a bi-allelic loss-of-function variant in the *TBC1D2B* gene has been found, in two patients with similar phenotypes. These results support that loss of *TBC1D2B* is the cause for this rare condition.

PrgmNr 2566 - Biallelic SEPSECS variants in two siblings with pontocerebellar hypoplasia type 2D underscore the relevance of splice-disrupting synonymous variants in disease

View session detail

Disclosure Block: **S. Ramadesikan:** None.

Noncoding and synonymous coding variants that exert their effects via alternative splicing are increasingly recognized as an important category of disease-causing variants. In this study, we describe two siblings, a 16-year-old female and 9-year-old male, who presented with hypotonia at birth, profound developmental delays, and seizures. MRI brain in the male at 5 years showed diffuse cerebral and cerebellar white matter volume loss. The siblings later developed ventilator-dependent respiratory insufficiency, scoliosis and are currently nonverbal and non-ambulatory. Extensive molecular testing including oligo array and clinical exome sequencing was non-diagnostic. Research genome sequencing under an IRB-approved study protocol revealed that both affected children were compound-heterozygous for variants in the *SEPSECS* gene. One variant was an initiator codon change (c.1A>T) that disrupted protein translation, consistent with the observation that most disease-causing variants are loss-of-function changes. The other variant, however, was a coding change (c.846G>A) that was predicted to be synonymous but had been demonstrated to disrupt mRNA splicing in a minigene assay.

SEPSECS gene encodes O-phosphoseryl-tRNA(Sec) selenium transferase which participates in the biosynthesis and transport of selenoproteins in the body. Mutations in *SEPSECS* cause autosomal recessive pontocerebellar hypoplasia type 2D (PCHT 2D; OMIM #613811), a neurodegenerative condition characterized by progressive cerebrocerebellar atrophy, microcephaly, and epileptic encephalopathy. The identification of biallelic pathogenic variants in this family - one of which was a synonymous change not reported in prior clinical testing - not only ended the diagnostic odyssey for this family, but also highlighted the contribution of occult pathogenic variants that may not be recognized by standard genetic testing methodologies. Further, studies like this highlight the importance and relevance of genome sequencing in the diagnosis of undiagnosed pediatric conditions.

PrgmNr 2567 - CAPRIN1: how a recurrent *de novo* mutation causes a progressive early onset neurodegenerative disorder in a prion-like domain-harboring protein

Disclosure Block: **A. Delle Vedove:** None.

CAPRIN1 is a ubiquitously expressed protein, abundant in the brain, where it regulates the transport and translation of mRNAs of genes involved in synaptic plasticity. Like other proteins (TDP-43, FUS or TIA1) related with neurodegenerative disorders (ND), CAPRIN1 is a component of stress granules and harbours a prion-like domain.

Here we describe two unrelated children from non-consanguineous families of Turkish and Italian ancestry, who respectively developed at 10 years and 7 years of age ataxia and cognitive decline. Trio whole exome sequencing unravelled an identical *de novo* c.1535C>T variant (p.Pro512Leu) in *CAPRIN1*. This variant is not reported in gnomAD and affects a highly conserved residue. Applying *in silico* prediction tools (PLAAC, Zyggregator, Aggrescan), we found an increased aggregation propensity of the p.Pro512Leu mutated protein, suggesting that protein or protein-RNA aggregation might be the underlying pathomechanism for this ND. Indeed, we observed that overexpression of the mutated but not wild type CAPRIN1 caused the formation of insoluble aggregates in transfected HEK293T and SH-SY5Y cells, as shown by immunostaining analysis and confirmed by biochemical studies. Strikingly, this change in solubility depends on the CAPRIN1 interaction with RNA: *in vitro* mCherry-CAPRIN1 remains soluble, while a fraction of mCherry-CAPRIN1^{P512L} aggregates. Moreover, we generated CAPRIN1^{P512L} heterozygous and homozygous hiPSC lines using the CRISPR/Cas9 system and differentiated them into cortical neurons, which show reduced axonal growth and reduced neuronal activity.

In conclusion, we identify a missense variant in *CAPRIN1* as a crucial change associated with an early onset neurodegenerative disorder, in contrast to *CAPRIN1* haploinsufficiency that is related to autism-spectrum disorders. CAPRIN1^{P512L} is linked to RNA-dependent increased aggregation propensity and morphological and electrophysiological alterations in neurons.

PrgmNr 2568 - Characterization of Phelan-McDermid brazilian cohort with small deletions and point mutations: focus on regression and behavioral changes across different ages

View session detail

Author Block: **E. Varella Branco**[1], E. Casella[2], I. Ramos[1], C. Samogy Costa[1], A. C. Girardi[1], H. Ferraz[3], M. R. Passos-Bueno[4]; [1]Inst. de BiociÃªncias, Univ.e de SÃ£o Paulo, SÃ£o Paulo, Brazil, [2]Unidade de Neuropediatria do Inst. da CrianÃ§a, Hosp. da ClÃnicas da Faculdade de Med., Univ.e de SÃ£o Paulo, SÃ£o Paulo, Brazil, SÃ£o Paulo, Brazil, [3]Programa de Engenharia QuÃmica, Univ.e Federal do Rio de Janeiro, Rio de Janeiro, Brazil, [4]Univ De Sao Paulo, Sao Paulo, Brazil
Disclosure Block: **E. Varella Branco:** None.

Phelan-McDermid Syndrome (PMS) is a rare genetic disorder mainly characterized by global developmental delay, intellectual disability (ID), autism spectrum disorder (ASD) caused by *SHANK3* loss-of-function mutations. Deletions (few kb to more than 9 Mb) at 22q13.3 are the most common mutational mechanisms, but point disruptive variants in *SHANK3* accounts for about 3% of the cases. Even though neurological phenotypes, like ASD and ID has been extensive described, changes in behavior (catatonia, schizophrenia) or regressions (loss of acquired abilities) during growth of these patients is still poorly characterized. It is still unclear if these changes are dependent on haploinsufficiency of *SHANK3* or other extrinsic factors. To address additional insights into these questions and to better understand the long-term course of the disorder, we aim to delineate the associated regression and behavior changes, in a group of PMS patients with small deletions or point mutations. We evaluated a total of 13 patients: nine patients with small deletions in 22q13.3 (49kb to 110kb), and four patients with pathogenic point mutations in *SHANK3*. Eight patients currently at 4 to 39 years old have developed speech until 4 years, however seven of them lose this ability. A history of regression, affecting primarily language ability and social ability at any age was present in 92% (12/13) of all patients. The onset of regression has been reported in different age periods: 11 months (n=1), 2-4 years old (n= 7), 6-7 years old (n= 2), and after 16 years old (n=2). Especially in cases of late regression, patients showed signs of behavioral and neurologic decompensation, with clinical presentations of catatonia, psychosis and schizophrenia. Our work corroborates the results described by others related to regression in PMS, which show most frequently episodes have an onset in early to middle-childhood, and highlighted the behavior changes in long-term course of the disorder in patients with *SHANK3* haploinsufficiency. These results may suggest that *SHANK3* is important for the maintenance of the nervous system in more advanced stages of neurodevelopment, which so far have not been elucidated. Furthermore, confirmation of similar findings in an ethnically different population, reinforce that the mechanisms underlying regression is mainly genetic dependent. Finally, the identifications of biological mechanisms leading to regressions in PMS are extremely important to improve interventions along life. This work is being perfomed in collaboration with PMS Brazilian Association (Amigos e Familiares da SÃndrome de Phelan-McDermid - AFSPM). Financial support: CEPID/ FAPESP.

PrgmNr 2569 - Characterization of the GARS1 mRNA interactome in glycyl-tRNA synthetase (*GARS1*)-related neurological disease

View session detail

Author Block: **M. Forrest**[1], O. Levi[2], Y. Arava[2], A. Antonellis[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Technion-Israel Inst. of Technology, Haifa, Israel
Disclosure Block: **M. Forrest:** None.
Aminoacyl-tRNA synthetases (ARSs) are a group of ubiquitously expressed essential genes that conjugate amino acids to cognate tRNAs in the cytoplasm and mitochondria, a critical process in protein synthesis and translation fidelity. Intriguingly, the phenotypic spectrum of ARS-associated disease ranges from early-onset, multi-system, recessive phenotypes with significant neuronal involvement to late-onset dominant peripheral neuropathies. Notably, heterozygosity for loss-of-function missense mutations in the bifunctional glycyl-tRNA synthetase (*GARS1*) gene cause either axonal Charcot-Marie-Tooth disease (CMT2) or infantile-onset spinal muscular atrophy (iSMA). However, the molecular mechanisms underlying these nervous system-specific disease phenotypes remain poorly understood.
One explanation for the predominance of neurological phenotypes associated with GARS1-related disease is that GARS1 may serve functions outside of tRNA charging in neurons. Indeed, recent studies have demonstrated non-canonical mRNA binding by various ARSs in yeast and human cells, suggesting a role for the tRNA anticodon binding domain (ABD) in mRNA target recognition and post-transcriptional gene regulation. We hypothesize that GARS1 binds and regulates a subset of mRNAs that are involved in nervous system function or maintenance, with potential relevance to *GARS1*-related neurological disease. To characterize the GARS1-mRNA interactome in human cells, we used RNA immunoprecipitation coupled to deep RNA sequencing (RIP-seq) to identify significantly enriched mRNAs bound by wild-type GARS1 in human cells. Preliminary results demonstrate significant enrichment of 35 RNA transcripts (log2-fold change over input control >2, p-value

Hereditary spastic paraplegia (HSP) is often considered a monogenic Mendelian disorder including all modes of inheritances. According to some reports, spastic paraplegia type 7 (SPG7) is the most common form of the autosomal recessive HSP, while an autosomal dominant form has also been suggested. In this study, we aimed to conduct a genetic analysis on one of the largest cohorts of HSP to find the spectrum of genetic inheritance of SPG7. In total, 585 HSP patients (372 probands) and 1175 controls (580 unrelated individuals) were analyzed using whole-exome sequencing and sequencing a targeted panel of genes. Among unrelated patients (N=291) and controls (N=580) who went through whole-exome sequencing, the number of heterozygous pathogenic and likely pathogenic variants of *SPG7* in patients was higher compared to controls (OR 2.88, 95% CI 1.24-6.66, P=0.009). The frequency of common heterozygous pathogenic *SPG7* variant, p.(Ala510Val), was 3.7% in patients vs. 0.85% in controls (OR 4.42, 95% CI 1.49-13.07, P=0.005). We found 4 patients carrying a heterozygous *SPG7* variant along with a pathogenic variant in another phenotype-associated gene (*SPAST*, *BSCL2* and *TBCE*). We further examined variants in genes that produce proteins that interact with SPG7, and found heterozygous variants in three genes (*CACNA1A*, *AFG3L2*, and *MORC2*). Of these, there is additional functional and protein structural evidence for co-occurrence of the variants of *SPG7* and *AFG3L2* genes. Our findings provide evidence for non-Mendelian inheritance in SPG7-HSP, including autosomal recessive, possibly dominant and digenic modes of inheritance.

PrgmNr 2571 - Defining the molecular mechanism of*GARS1*-related Charcot-Marie-Tooth disease

View session detail

Author Block: **S. Marte**, A. Antonellis; Univ. of Michigan, Ann Arbor, MI
Disclosure Block: **S. Marte:** None.
Aminoacyl-tRNA synthetases (ARSs) are essential enzymes required to charge tRNA molecules to cognate amino acids in the cytoplasm and mitochondria. Although ARSs are essential and ubiquitously expressed, loss-of-function (LOF) missense mutations in five dimeric ARS enzymes have been associated with dominant peripheral neuropathy (also known as Charcot-Marie-Tooth disease [CMT]). CMT is a genetically and clinically heterogeneous inherited peripheral neuropathy characterized by the progressive loss of motor and sensory function. Mutations in glycyl-tRNA synthetase (*GARS1*) have been associated with distinct clinical phenotypes where individuals can present with later-onset CMT or infantile spinal muscular atrophy. The mechanism by which mutations in *GARS1* lead to distinct clinical phenotypes is currently unclear. Since all five implicated ARSs function as dimers and since CMT-associated ARS variants all cause a loss-of-function effect, we propose the possibility of a dominant-negative mechanism. To test dominant-negative effects of pathogenic glycyl-tRNA synthetase (*GARS1*) variants, we will develop a humanized yeast model and test *GARS1* mutations for the ability to repress a wild-type copy of *GARS1*. To better understand the distinct clinical phenotypes, we will assess the dominant toxicity of a series of pathogenic *GARS1* alleles to determine if toxicity in our yeast model correlates with disease severity. Finally, we will identify pathways that, when manipulated, improve *GARS1* function by performing experimental evolution and gain-of-function studies using a hypomorphic allele and yeast growth assays. Here, we will present preliminary data on development of our humanized model and on initial assessments of the dominant toxicity of pathogenic *GARS1* alleles. These studies will provide insight into the pathogenic mechanism of ARS-related CMT and aid in the development of therapeutics.

PrgmNr 2572 - Defining the neurodevelopmental spectrum of *GABRA5*-associated disease

View session detail

The GABA-A receptors are Pentameric Ligand-Gated Ion Channels responsible for mediating inhibitory neurotransmission. The GABA-A receptor typically includes two alpha, two beta and one gamma subunit, with several genes coding for each subunit. Pathogenic variants disrupting the GABAergic system have been associated with a wide spectrum of neurodevelopmental disorders. *GABRA5*, one of a six alpha genes, has been recently associated with Developmental and Epileptic Encephalopathy (DEE) 79 (MIM #618559), with only seven variants reported in the literature. These private or rare variants occurred de novo or were inherited from unaffected parents, suggesting a partial penetrant phenotype, with functional testing reported to be loss-of-function of GABA-A receptor activity.

Here, we describe six additional patients (3-18yo) found to carry a *GABRA5* heterozygous variant. One individual inherited the variant from an affected mother. All but one of the de novo cases had a severe phenotype with early DEE and an EEG revealing rapid activity consistent with diffuse disturbance of cerebral function and largely absent sleep architecture. The remaining individual had similar EEG findings, but to date no seizures. Also, these individuals present with moderate to severe motor and cognitive delays and delayed to absent speech. The individual with the rare inherited variant is diagnosed with epilepsy and similarly, is developmentally delayed and non-verbal. Additional disease presentations were inconsistent, with three patients having dysmorphic features and one patient experiencing generalized hypotonia and joint hyperlaxity. Consistent with two previously published variants, p.(Val294Leu) and p.(Val294Phe), we identified two additional variants occurring in the pore of the channel, p.(Val291Leu) and p.(Thr301Arg), indicating that disruption of the ion selectivity filter is disease causing. Two additional variants, p.(Asn342His) and p.(Tyr225Asn), identified in our cohort, respectively occur in the M3-M4 intracellular or the extracellular domains. In silico analysis of each variant are highly suggestive of a deleterious effect on GABRA5 function (REVEL>0.7, CADD>20 and PolyPhen2>0.995).

In summary, we further delineate the phenotypic spectrum of *GABRA5*-associated disease, which will aid genetic diagnosis and counseling in these individuals and help understand the disease course. In addition, functional analysis of these and previously published variants are being pursued to establish pathogenicity and disease mechanism with the goal to better understand how GABRA5 dysregulation leads to seizure activity.

PrgmNr 2573 - Elucidating genomic and transcriptomic hexanucleotide repeat number and methylation in the X-linked dystonia-parkinsonism-relevant retrotransposon insertion by Nanopore sequencing

View session detail

Author Block: **J. LaÃ**[1], S. Schaake[1], I. Wohlers[2,3], T. LÃ¼th[1], J. Pozojevic[1], R. Tse[1], C. Reyes[1], H. Busch[2,3], A. Westenberger[1], C. Klein[1], J. Trinh[1]; [1]Inst. of Neurogenetics, LÃ¼beck, Germany, [2]LIED, LÃ¼beck, Germany, [3]Inst. for Cardiogenetics, LÃ¼beck, Germany
Disclosure Block: **J. LaÃ:** None.
Purpose: Establishment of long-read single-molecule Nanopore sequencing for the detection of i) repeat number, ii) methylation and iii) transcript expression of the SINE-VNTR-Alu (SVA) in the *TAF1* gene in X-linked dystonia-parkinsonism (XDP) patients. **Background:** XDP is an adult-onset neurodegenerative disorder characterized by rapidly progressive dystonia and parkinsonism. XDP is caused by a single founder mutation: an SVA retrotransposon insertion in the *TAF1* gene. Furthermore, the length of the polymorphic $(CCCTCT)_n$ domain within the *TAF1* SVA retrotransposon acts as a genetic modifier of disease onset and expressivity in XDP.
Methods: To first determine repeat number of the polymorphic $(CCCTCT)_n$ SVA domain, we used DNA derived from blood of patients with XDP (n=39). PCR amplicons of the *TAF1* SVA insertion were multiplexed with barcodes and sequenced using Nanoporeâ□□s LSK109. The hexanucleotide repeat number was obtained with NCRF. Fragment analysis was performed as a validation step for repeat detection. Secondly, to detect methylation, we used a Cas9-targeted enrichment approach with custom-designed gRNAs on DNA from blood, iPSC and brain of one patient and one control. CpG methylation detection spanning the *TAF1* SVA was performed with Nanopolish. Lastly, we used targeted IDT xGen Lockdown Probes SMARTer PCR cDNA Synthesis to obtain transcripts within the SVA on cDNA from iPSC and brain of one patient and one control. All libraries were sequenced on a R9 MinION flow cell.
Results: High concordance was observed for median repeat numbers of the $(CCCTCT)_n$ SVA domain using Nanopore sequencing and fragment analysis in blood-derived DNA (n=38 patients). The median CpG methylation frequency (MF) across blood, iPSC and brain tissue-derived DNA in the SVA is 0.912 (SD: 0.109). Likewise, the median MF up- and downstream of the SVA is 0.938 (SD: 0.124). CpG methylation in downstream enhancers flanking the SVA has a similar MF in patient with XDP compared to the control. 72 reads with the repeat polymorphism were detected in the cDNA transcripts. The average repeat number in cDNA transcripts is similar to the genomic DNA.
Conclusion: Repeat numbers and epigenetic modifications can be reliably detected using Nanopore sequencing. The insertion of the SVA retrotransposon in the *TAF1* gene does not lead to patient-specific differences of CpG MF and is linked to expression of novel transcripts containing an average of 44 hexanucleotide repeats.

PrgmNr 2574 - Exome sequencing in 200 intellectual disability/autistic patients: new candidates and atypical presentations

Disclosure Block: **L. Bruno:** None.

Intellectual disability (ID) and autism spectrum disorder (ASD) belong to neurodevelopmental disorders and occur in ~1% of the general population. Due to disease heterogeneity identifying the etiology of ID and ASD remains challenging. Exome Sequencing (ES) offers the opportunity to rapidly identify variants associated with these two entities that often co-exist. Here, we performed ES in a cohort of 200 patients: 84 with isolated ID and 116 with ID and ASD. We identified 41 pathogenic variants with a detection rate of 22% (43/200): 39% in ID patients (33/84) and 9% in ID/ASD patients (10/116). Most of the causative genes are genes responsible for well-established genetic syndromes that have not been recognized for atypical phenotypic presentations. Six genes emerged as new candidates: BOD1, CACNA2D1, COBL, GPR14, KCNJ16, and NEURL4. In conclusion, this study reinforces the importance of ES in the diagnosis of ID/ASD and underlines that â□□reverse phenotypingâ□□ is fundamental to enlarge the phenotypic spectra associated with specific genes.

PrgmNr 2575 - Exploring the phenotypic spectrum of ARID1B-related disorders: Further two case reports

View session detail

Author Block: **S. Lemos Ferreira**[1], M. Santos Melo[1], J. Catanho da Silva[1], R. Pina[2], F. Tapadinhas[3], N. Silva[3], M. Amorim[1]; [1]ServiÃ§o de GenÃ©tica MÃ©dica, Hosp. Disclosure Block: **S. Lemos Ferreira:** None.
Introduction: Haploinsufficiency of *ARID1B* gene disrupts the BAF complex, affects neural development, and it is one of the main causes of intellectual disability. Clinical evidence suggests that the spectrum of ARID1B-Ârelated disorders (ARID1B-ÂRD) is highly variable and range from non-syndromic intellectual disability (ARID1BÂ-ID) to CoffinÂ-Siris syndrome (ARID1BÂ-CSS, OMIM #135900). Typically, patients with ARID1B-CSS display hypertrichosis, sparse scalp hair, thick eyebrows, long eyelashes, thick alae nasi, long and broad philtrum, and aplasia or hypoplasia of the distal phalanx or nail of the fifth finger/toe. Other features present in ARID1BÂ-RD include structural malformations (cardiac, central nervous system, musculoskeletal, gastrointestinal and genitourinary), laryngomalacia, feeding difficulties, growth problems, behavioural issues, and sensory impairment. Here, we present two cases that contribute to an increasing understanding of the clinical spectrum of ARID1B-ÂRD. **Case reports:** One patient, a 8-year-old male, presented with intellectual disability, attention deficit hyperactivity disorder, facial dysmorphisms (posterior low hairline, low-set and posterior rotated ears, long eyelashes, thick eyebrows, abnormal nasal bridge, short nose), short stature, delayed bone age, laryngomalacia, *pectus carinatum*, *pes planus*, strabismus, and nystagmus. Exome sequencing identified a likely pathogenic variant in *ARID1B* (NM_001374820.1):c.1293_1320del p.(Ala432Metfs*11). Parent testing is ongoing. A second patient, a 3-year-old male, was referred for development delay, hypotonia, minor dysmorphisms (long eyelashes and full lips), deafness, laryngomalacia, food aversion, pyloric stenosis, umbilical hernia, recurrent infections, autistic traits, sleep disturbance and brain anomalies (midbrain and corpus callosum dysmorphisms). Exome sequencing identified a *de novo* pathogenic variant in *ARID1B* (NM_020732.3):c.5890G>T p.(Glu1964*). **Discussion:** Both patients do not have a fully recognizable phenotype associated with ARID1B-ÂCSS. Also, the overall phenotypes reflect the wide variability of ARID1B-ÂRD, and are consistent with the reported cases. To date, there is no established genotypeÂ-phenotype correlation within the spectrum of ARID1BÂ-RD and the severity of the phenotype. **Conclusions:** With this work, we stress that ARID1BÂ-RD spectrum is extremely wide and ARID1B-CSS is only the tip of the iceberg, as highlighted by our patients. We also bring to attention the importance of reverse phenotype when evaluating a patient with a neurodevelopment disorder and a pathogenic variant in *ARID1B* gene.

PrgmNr 2576 - Factors influencing the chance of a genetic diagnosis in >13,000 individuals with developmental disorders

View session detail

Author Block: **P. Campbell**[1,2], V. K. Chundru[1], H. V. Firth[2], D. R. FitzPatrick[3], C. F. Wright[4], M. E. Hurles[1], H. C. Martin[1]; [1]Wellcome Sanger Inst., Cambridge, United Kingdom, [2]Cambridge Univ. Hosp. Fndn. Trust, Addenbrooke's Hosp., Cambridge, United Kingdom, [3]Univ. of Edinburgh, Edinburgh, United Kingdom, [4]Univ. of Exeter, Exeter, United Kingdom
Disclosure Block: **P. Campbell:** None.
The Deciphering Developmental Disorders (DDD) study is a UK-wide project that has, over the past 10 years, collected genomic and phenotypic data for >13,000 children with severe undiagnosed developmental disorders and their parents. Using whole exome sequencing and exon-arrayCGH, the overall diagnostic yield to date is around 31% - similar to that reported for comparable cohorts. Some factors are known to influence the chance of an individual patient receiving a diagnosis, such as whether they are sequenced in a trio. However, other factors influencing the chance of reaching a genetic diagnosis have not yet been explored in depth. We performed multiple logistic regression to see how various demographic, clinical, phenotypic, maternal and ancestral factors affect the chances of gaining a diagnosis within the DDD study. This model explained ~13% of the variance in chance of getting a diagnosis. We find that trio status has the largest impact on the chance of gaining a diagnosis (OR: 4.5, 95% CI 4.0 - 5.1). Other factors significantly increasing the chance of diagnosis include: being the only affected family member (OR: 1.7, 95% CI: 1.6 - 1.9), having severe developmental delay (OR: 2.4, 95% CI: 2.1 - 2.7) and having increasing number of organ systems affected (OR: 1.1, 95% CI: 1.1 - 1.1). In the DDD cohort, male sex (OR: 0.7, 95% CI: 0.7 - 0.8), increasing consanguinity (OR: 0.7, 95% CI: 0.6 - 0.8) and African ancestry (OR: 0.5, 95% CI: 0.3 - 0.8) reduce the odds of finding a diagnosis. We find evidence of a non-linear interaction between trio status and African ancestry (P

PrgmNr 2577 - Human patient SFPQ homozygous mutation is found deleterious for brain and motor development in a zebrafish model

SFPQ (Splicing factor proline- and glutamine-rich) encodes a DNA and RNA binding protein involved in transcription and pre-mRNA splicing. Loss of *sfpq* causes defects in neuronal development, and rare variants in this gene have been previously implicated in neurodegenerative disorders. In this study, we identified a homozygous p.Ser660Asn variant in *SFPQ* through whole exome sequencing (WES) of an Italian family affected with a complex neurological phenotype characterized by intellectual disability, peripheral neuropathy, vacuolar myopathy, parkinsonian features and neuroradiological anomalies resembling neurodegeneration with brain iron accumulation (NBIA). Rescuing a zebrafish *SFPQ* homozygous null mutant with this human SFPQ^{S660N} variant revealed robust defects in the developing central nervous system (CNS) of the embryos, including microcephaly, misfolding of the posterior brain neuroepithelium and abnormal branching of the motor axons innervating body muscles. The defects identified in the SFPQ^{S660N} zebrafish model provide evidence supporting a contribution of SFPQ^{S660N} to the patientsâ complex pathology and suggest that *SFPQ* mutations may contribute to different broad clinical and neuroradiological degenerative features in humans.

PrgmNr 2578 - Identification of rare copy number variants in a family with high prevalence of psychosis

View session detail

Author Block: **F. Francis**; UCR, San Jose, Costa Rica
Disclosure Block: **F. Francis:** None.
Psychotic disorders are a relevant subject of public health because of their prevalence, economic significance and emotional suffering to families and patients. However, due to their complex disease nature, among others, they are difficult to study. Currently, Copy Number Variants (CNVs), have become more relevant, not only for their contribution to the genome variability among individuals, but also because some of these variants increase the risk of SZ, BPD and autism spectrum disorders (ASD). These variants tend to have much larger effect size than SNPs, however the bioinformatic complexity for the analysis of these variants remains high. In addition, rare variants, are most commonly found in families or individual cases, usually have a larger effect, and are of recent origin, which gives them an important role to characterize the disease. Despite this, those variants are underrepresented in the current databases. We identified a family in Costa Rica with 219 individuals (121 women, 96 men), of whom 56 have presented some psychotic disorder (31 women, 25 men) such as bipolar disorder, unspecified affective psychosis, schizo-affective disorder and unspecified psychosis according to the DSM-IV, confirmed by a personal interview and the process of best estimate diagnosis. Since studies with related individuals help reduce the sample size required to maintain statistical power, increasing the probability of capturing the association between rare variants and phenotype, we analyzed 114 whole genome sequences of individuals from the family described above. The sample includes 48 cases (27 women and 21 men) and 66 controls (38 women and 28 men), the sequence is paired ends, with a minimum read length of 2x100bp and minimum of 30x average coverage. We present the workflow used to identify a wide range of CNVs using a combination of software and algorithms to estimate CNVs breakpoints. The competencies of 15 CNV detection software packages, that are currently in use, were analyzed (CLAMMS, ReadDepth, CNAseg, XHMM, cn.mops, Seq Gene, SeqCNV, BreakDancer, Hadoop CNV, SurVIndel, GATK, Genome STRiP, RDXplorer, LUMPY, CNVnator), of these, CNVnator and GATK were selected, for various reasons. Currently the pipeline has a total time of 80m8.083s, paralleling by sample and not by Jobs, with GNU parallel and Samtools, instead of Sambamba. The pipeline was standardized with 6 .cram files, in which the average RD per Bin was 174.4 Â± 17.0 before the GC correction and we estimated in average 1991 Â± 127 CNVs per sample. This is the first study to identify CNV of risk for psychotic disorders in a Costa Rican population.

ALS2-related disorders are rare monogenic disorders that have variable affection of upper and lower motor neurons usually presenting with upper motor neuron and cranial nerve involvement. Most patients are described within the clinical spectrum of motor neuron disorders subdivided into three main diseases: Infantile ascending hereditary spastic paraplegia (IAHSP), juvenile primary lateral sclerosis and juvenile amyotrophic lateral sclerosis. However, other forms such as dystonia have been described. *ALS2*-related disorders are caused bi-allelic variants in the gene *ALS2* encoding for alsin mostly described in consanguineous communities.

Here, we describe a family with two affected members presenting with IAHSP from the indigenous toba community from the Chaco region of Argentina. We present two siblings that began early in life with delayed motor milestones. One male and one female, both had late sitting and walking, and lost this ability after a few years. They later evolved to tetraparesis and bulbar involvement with anarthria. Although given the language difficulties the cognitive assessment is limited, they understand complex commands, they know how to read and manage independently with telephones and computers. The older sibling, currently 21 years old has mild swallowing difficulties, but his younger 14-year-old sister does not have swallowing difficulties. They belong to the indigenous toba community, parents are consanguineous and have other unaffected siblings.

Through a collaborative next generation sequencing study a homozygous variant in *ALS2* was detected in both patients: NM_020919:c.T2531A(p.L844H). This variant is predicted to be pathogenic and previously reported in another patient from Argentina. They are not known to be from the same community but both parents are originally from a small remote town. This second family had two first cousins affected, and we are currently following up the family origin to determine if they belong to a related indigenous community.

In summary, we describe an interesting consanguineous toba family with 2 members affected by a homozygous pathogenic variant in *ALS2* presenting in childhood with IAHSP. Diagnosis for this family was established after two decades of symptom onset and was essential for genetic counselling. Achieving a molecular diagnosis in such rare disorders is essential for family planning and the development of biomarkers and targeted therapies.

PrgmNr 2580 - Inherited variants in *CHD3* demonstrate variable expressivity in Snijders Blok-Campeau syndrome

Disclosure Block: **J. den Hoed:** None.

Interpretation of next-generation sequencing data of individuals with an apparent sporadic neurodevelopmental disorder (NDD) often focusses on *de novo* variants in genes known for autosomal or X-linked dominant inheritance, or on bi-allelic variants in genes described with recessive inheritance. As a consequence, inherited variants in genes associated with dominant disorders may be overlooked when the transmitting parent is clinically unaffected. While *de novo* variants explain a substantial proportion of cases with NDDs, still a significant number remains undiagnosed. Various factors may explain the inability to diagnose these individuals, including coding variants associated with reduced penetrance and variable expressivity. Here, we characterized 18 families with inherited missense or protein-truncating variants (PTV) in *CHD3*, a gene in which *de novo* variants were recently described to cause a neurodevelopmental syndrome, characterized by intellectual disability, speech delay and recognizable facial features (Snijders Blok-Campeau syndrome; MIM#618205). With in-depth analysis, including computational facial and human phenotype ontology-based comparisons, we demonstrated that the phenotypic features of probands with inherited *CHD3* variants overlap with the phenotype previously associated with *de novo* variants in the gene, while carrier parents are mildly or not affected, suggesting variable expressivity. Additionally, we demonstrated, both in healthy carriers and in a related affected proband with a *CHD3* PTV, similarly reduced expression levels of CHD3 protein in cells, suggesting that allelic compensation is unlikely to be an underlying mechanism. Our results point to a role of inherited variation in well-described NDDs previously associated almost exclusively to *de novo* variants, a finding that is critical for genetic counseling and warrants further investigation towards understanding the broader contributions of such variation to the landscape of human disease.

PrgmNr 2581 - Methylation status of chromosome 5 in *Cri du Chat*Syndrome: new insights for clinical variability?

View session detail

Author Block: **V. Almeida**[1], G. Carvalho[1], S. Chehimi[1], Y. Gasparini[1], A. Nascimento[1], C. Kim[2], L. Kulikowski[1]; [1]Faculdade de Med. da Univ.e de SÃ£o Paulo, Sao Paulo, Brazil, [2]Inst. da Crianca, Hosp. das Clinicas, Faculdade de Med., Sao Paulo, Brazil
Disclosure Block: **V. Almeida:** None.
Cri Du Chat Syndrome (SCDC) or 5p- Syndrome (OMIM #123450) is characterized by a genomic loss in the short arm of chromosome 5 and variable clinical manifestations, that include highâ□□pitched cry in newborns, facial asymmetry, microcephaly, hypotonia, ocular hypertolorism, micrognathia, neurological and behavioral changes. Different cytogenomics rearrangements, family history and environmental factors may hinder genotype - phenotype association. Thus, phenotypic variability in this syndrome may not be limited only to variations in gene structure, such as deletions, duplications, inversions, insertions and translocations, being possible that others mechanisms related to promoters activation or inactivation and/or exons of actively transcribed genes, including DNA methylation, which occurs mainly in the â□□CpG Islandsâ□□. In this sense, we studied the profile of methylation status of chromosome 5 in 10 patients and investigated regions around the chromosomal breakpoint at 5p to verify the differentially methylated status. DNA samples from seven SCDC patients with similar breakpoints and three previously genotyped control samples (HumanCyto850K BeadChip) were evaluated using the chip Infinium MethylationEPIC BeadChip (Illumina, Inc., San Diego, CA). The analysis was performed with RStudio software. The patient's heatmaps show greater heterogeneity of methylated probes for the 5p region compared to control samples also the results reveals that some genes important to the SCDC phenotype have hypermethylated methylation status, consistent with the patient's phenotype.

PrgmNr 2582 - Modeling a neuropathy-associated *GARS1* mutation in *C. elegans*

View session detail

Author Block: **J. Pierluissi**[1], A. Antonellis[2,3]; [1]Dept. of Human Genetics, Univ. of Michigan, Ann Arbor, MI, [2]Univ. of Michigan, Ann Arbor, MI, [3]Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI
Disclosure Block: **J. Pierluissi:** None.
Charcot-Marie-Tooth disease (CMT) is a heritable peripheral neuropathy that is characterized by motor and sensory defects in the distal extremities. Mutations in five genes encoding aminoacyl-tRNA synthetases (ARSs)â□□a family of enzymes that ligate amino acids to cognate tRNA molecules during the beginning stages of protein translationâ□□have been implicated in dominantly inherited CMT. One of these implicated enzymes is glycyl-tRNA synthetase (GARS1), the enzyme responsible for ligating glycine to cognate tRNA molecules. It has been demonstrated that there is wide allelic and clinical heterogeneity of *GARS1*-mediated neuropathy. We recently reported a 12-base-pair, in-frame deletion in *GARS1*, (E245_Q248; or Î□ETAQ) in a patient with a severe form of peripheral neuropathy that is similar to infantile-onset spinal muscular atrophy. The Î□ETAQ mutation ablates enzyme activity *in vitro*, reduces viability in yeast complementation assays, and is dominantly toxic to mouse neurons. To further determine the pathological significance of the Î□ETAQ mutation and to establish a pipeline by which disease-causing ARS mutations may be systematically studied in a robust model organism, we employed a CRISPR/Cas9 method to generate a *C. elegans* model of *GARS1*-mediated disease. Here, we provide characterization of the first *C. elegans GARS1*-mediated neuropathy model, which supports a loss-of-function effect of the patient variant. Pharmacological characterization of the neuromuscular junction of mutant worms indicates a degenerative defect in synaptic transmission, specifically implicating the presynaptic terminal of the cholinergic motor neurons. Here, I will present our unpublished data and plans to improve the phenotype observed in worm toward developing patient therapeutics. This work contributes to our understanding of the role of *GARS1* in peripheral neuropathy and provides a framework for studying the pathogenicity of other ARS mutations of interest.

PrgmNr 2583 - Monoallelic variants in *TFAP2E* are implicated in craniofacial and central nervous system anomalies

TFAP2E encodes the transcription factor AP-2. The potential role of TFAP2E (AP-2) transcription factor in development and the formation of the central nervous system (CNS) and craniofacial structures has not been systematically investigated . Here, we report 3 individuals with novel heterozygous missense variants in *TFAP2E*, all presenting with CNS malformations and craniofacial anomalies. For one family, parental samples were available to confirm *de novo* occurrence of the variant allele. Variants were identified by exome sequencing (ES). We initiated functional characterization in zebrafish larvae using splice and translational blocking morpholinos (MO) in different transgenic zebrafish lines. Fluorescent signals of neuronal, glial and neural crest cells at 2 days post fertilization (dpf) were analysed *in vivo* using a twoâ□□photon point scanning microscope and subsequent 3D modelling with IMARIS analysis software. Alcian blue cartilage staining was performed at 3 dpf. Shared clinically observable phenotypic features among patients comprised malformations of the CNS (3/3) and craniofacial anomalies (3/3) including micrognathia or microcephaly. MO knockdown of *tfap2e* in zebrafish larvae showed microcephaly, hydrocephalus und craniofacial anomalies and thus partially recapitulate the human phenotype. Major effects on vasculogenesis were excluded after MO injections into vascular reporter lines, suggesting the tissue specificity of the observed effects. Our findings implicate *TFAP2E* in CNS and neural crest development and suggest *TFAP2E* as a novel candidate gene for human CNS malformations and craniofacial anomalies. Grant: J.C.K: BonnNI grant Q614.0754 and BONFOR grant O-167.0023. HR and HT: German Research Foundation (Deutsche Forschungsgemeinschaft, DFG) (RE 1723/5-1, and TH 1327/2-1). Neurodevelopmental disorders (NDD) is a broad term that includes Autism Spectrum Disorders (ASD), intellectual disability (ID), and epilepsy. Advances in sequencing technology have greatly expanded our understanding of the NDD genetics. More than 100 rare Mendelian diseases have been associated with NDDs. Given the high-level of phenotypic and genotypic heterogeneity, the correct molecular diagnosis requires not only up-to-date sequencing/bioinformatic tools but also a detailed clinical investigation. We collected and deeply phenotyped 212 pediatric NDD cases from Macedonia (NeuroWES-Macedonia) affected by ASD/ID (82/212, 39%), complex syndromes (74/212; 35%), and isolated ASD (55/212; 26%). We performed trio-Whole Exome Sequencing (WES) within the Autism Sequencing Consortium (ASC) international collaborative network. Currently, we analysed 151 trios. We found pathogenic/likely pathogenic variants in 39 (26%), with the highest diagnostic rate among syndromic cases (21/44; 47%), and the lowest in the isolated ASDs (3/31; 9%). Most causative variants were *de novo* (dn, 25/39, 65%); the remaining autosomal recessive (7/39, 18%) or X-linked inherited (7/39, 18%). Among syndromic cases we found pathogenic variants in exceedingly rare disease-associated genes: truncating variants in *HIST1H1E* (MIM 617537)*, PQBP1 (*MIM 309500), *USP9X* (MIM 300968) and missense variants in *EZH2 (*MIM 277590), *HDAC8* (MIM 300882*)*, *PHF6 (*MIM 301900). Being these genes involved in chromatin-remodeling pathways, an â□□epigenetic signatureâ□□ analysis is ongoing within the EpiSign consortium. Dual molecular diagnoses were found in 2 cases (4%). In one family, we found two similarly affected brothers: one had a causative *dn* frameshift in *TRIP12* (*604506)*,* the other the dn recurrent missense p.A1728V in *FBN1*. In a case with microcephaly, short stature, and impaired glucose metabolism (MIM 616817), we found a homozygous p.R658H in *PPP1R15B,* the third missense pathogenic variant described in this gene. We also found 4 novel strong candidate NDD genes: a *dn* frameshift in *PRMT8* (*610086); a *dn* missense in *PHLPP1* (*609396); a *dn* missense in *OSBPL8* (* 606736) in a proband with a Lenz-Majewski-like clinical presentation; finally, a homozygous missense in *AARSD1* likely disrupting the function of this alanyl-tRNA editing activity protein highly related to brain myelinations processes. We realized that deep phenotyping combined with trio-WES genetic data is a key strategy to solve undiagnosed NDD cases, and go beyond clinical complexity. We suggest novel possible NDD genes which we will study in the near future.

PrgmNr 2585 - Paediatric neurogenetic disorders in Bangladesh: First tier exome sequencing in previously unexplored population

View session detail

Author Block: **H. Morsy**[1], S. Efthymiou[1], M. Zaman[2], V. Salpietro[1], SYNaPS Study Group, J. Vandrovcova[1], S. Banu[2], H. Houlden[1]; [1]UCL Inst. of Neurology, London, United Kingdom, [2]Khan Shishu Hosp. and ICH, Dhaka, Bangladesh
Disclosure Block: **H. Morsy:** None.
Background: Peadiatric neurogenetic disorders are highly heterogenous both on phenotypic and molecular basis. Identification of underlying etiology is highly significant for clinical care of the patients. In Bangladesh, these disorders have not been previously characterized. We describe clinical and genomic data from a large cohort of Bangladesh comprising 230 families recruited from 2018 to 2020.
Methods: All patients were deeply phenotyped and assigned a diagnostic group based on Genomics England clinical classification. Whole Exome Sequencing (WES) was applied as a first-tier diagnostic testing for 230 affected individuals, of which 78 probands were sequenced as duo/trio. Exome data were screened for ultra-rare deleterious variants in known and candidate genes in Neurology and Neurodevelopmental Panel according to Genomics England. Applying additional bioinformatics pipelines such as SpliceAI and Conifer for calling of splice altering variants, CNVs and small Indels is currently ongoing.
Results: Our cohort compromised patients mainly with Inherited epilepsy syndromes or Neurodevelopmental disorders with frequency of 47.8 % and 34.7%, respectively. More than 1/3 of the patients were younger than 2 years old and almost half of the cohort were born to first degree cousin parents. We had a definitive or likely genetic diagnosis at 31.3 % (72/230) of cases. Interestingly, more than 2/3 of the solved cases was caused by monoallelic variants (68.05%). Even more, ultra-rare monoallelic variants in our cohort which is highly consanguineous (49.1 %) compromised 52.46 % of all protein coding variants in Neurology and neurodevelopmental gene panel.
Conclusion: We describe the challenges facing WES data analysis in previously unexplored population and how good phenotyping and additional Bioinformatics pipelines can improve the diagnostic yield. We highlight the significant proportion of ultra-rare monoallelic deleterious variants in Paediatric neurogenetics disorders even in highly consanguineous population.

PrgmNr 2586 - Phenotypic characteristics of a family with distal arthrogryposis type 2B (Sheldon-Hall syndrome) due to*TNNT3*pathogenic variant

View session detail

Author Block: **D. GERMAIN**[1], I. DABAJ[2], R. Y. CARLIER[3], O. AILIOAIE[3], S. QUIJANO-ROY[3]; [1]Paris Saclay Univ., Montigny, France, [2]CHU Rouen, Rouen, France, [3]APHP - Paris Saclay Univ., Garches, France
Disclosure Block: **D. Germain:** None.
Background: Distal arthrogryposis (DA) is a group of rare, clinically and genetically heterogeneous disorders characterized by congenital contractures of the limb joints. Sheldon-Hall syndrome (SHS or DA2B) is a rare multiple congenital contracture syndrome characterized by contractures of the distal joints. SHS is intermediate to DA1 and DA2A (Freeman-Sheldon syndrome) and was found to be due to mutations in genes encoding the fast-twitch skeletal muscle contractile myofibers complex.
Patients and methods: A 16-year old boy with a history of congenital distal arthrogryposis presented to our multidisciplinary consultation with severe kyphoscoliosis and respiratory insufficiency. Both his mother and younger sister, who had not previously diagnosed, were found to have a milder phenotype. Diagnostic work up included physical exam, whole body muscular MRI (WBMRI) in all three patients, together with ENMG studies and muscle biopsy in the index case. DNA sequencing was used to confirm the clinical diagnosis. **Results:** Physical examination suggested the clinical diagnosis of SHS. No major abnormalities were found in WBMRI for all three individuals. Neurogenic changes were observed on needle EMG and on muscle biopsy in the index patient. DNA sequencing revealed a missense pathogenic variant in *TNNT3* (c.187C>T; p.Arg63Cys). This variant was found to segregate with the SHS phenotype in affected individuals. **Discussion:** This is the first report of neurogenic involvement in a patient with DA2B. A missense mutation was identified at codon 63 a mutational hotspot of the *TNNT3* gene. While *TNNT3* encodes the fast-twitch skeletal muscle contractile myofibers complex, our data suggests additional chronic nerve injury in this arthrogryposis syndrome.

PrgmNr 2587 - Recessive burden analysis and gene discovery in ~40,000 developmental disorder trios with diverse ancestries

View session detail

Author Block: **V. Chundru**[1], Z. Zhang[2], K. E. Samocha[1], R. Torene[2], M. E. Hurles[1], K. Retterer[2], H. C. Martin[1]; [1]Wellcome Sanger Inst., Hinxton, United Kingdom, [2]GeneDx, Gaithersburg, MD
Disclosure Block: **V. Chundru:** None.
Previous work in the Deciphering Developmental Disorders (DDD) study has estimated that ~3% of White British cases and ~30% of British South Asian cases could be attributed to recessive coding variants. The difference in burden of recessive coding variants between these populations is driven by differing rates of autozygosity due to consanguinity (Martin *et al*., Science, 2018). About half of this burden was previously attributed to as-yet-undiscovered genes, as gene discovery was limited due to lack of power in the predominantly European ancestry, and non-consanguineous DDD cohort.
Here, we present the largest multi-ancestry study to date for the discovery of novel recessive genes in developmental disorders (DDs). Combining the DDD study and GeneDx, we will analyse ~40,000 DD trios. However, rules around patient confidentiality preclude sharing complete raw data for patients. Despite this, we developed a federated approach to quality control, followed by data harmonisation based on comparing summary statistics, in order to be able to undertake mega-analyses of rare variant data from the two largest cohorts of DD patients.
Since properly calibrated burden analysis for recessive variants relies on population-specific allele frequency estimates, we use PCA and UMAP to examine fine-scale population structure. We identified 20 distinct ancestry groups, each with at least 100 trios, from European, African, South Asian, East Asian, South American, and Middle Eastern populations, which we are analysing individually. For example, we identify a homogeneous European group with ~25,000 trios (~0.08% with >1.56% autozygosity - corresponding to offspring of second cousins), a South Asian group with ~1,800 trios, and a Middle Eastern group with ~1,000 trios (both of which have >50% with >1.56% autozygosity). Using a burden testing framework accounting for levels of autozygosity and parental haplotype frequencies, we will estimate the excess of protein-truncating and damaging missense variants in each gene within each ancestry group. Summing these values across genes will allow us to estimate the recessive burden of DDs. We will leverage this larger sample size to discover new recessive genes for DDs through statistical burden analysis. Additionally, we will develop a simulation-based statistical enrichment test, weighting biallelic genotypes by their degree of exome-wide enrichment, to further increase our power to detect recessive DD genes.

PrgmNr 2588 - Recessive inactivating variants in *DMAP1* in an intellectual disability syndrome

Disclosure Block: **D. Li:** None.

DMAP1 encodes a versatile protein that is involved in different complexes responsible for maintenance of DNA methylation when directly interacting with DNMT1, regulation of histone acetylation when coupled with the TRRAP/Tip60 complex, and catalysis of histone H2A.Z deposition in conjunction with the SRCAP complex. Despite DMAP1â□□s essential role in multiple transcriptional processes, it has not been implicated in human diseases. By exome sequencing and international matchmaking, we identified six unrelated individuals with a syndromic neurodevelopmental disorder carrying homozygous or compound heterozygous variants in *DMAP1*. Besides two truncating and one splice-altering variants, we uncovered five missense variants [c.291G>C, p.(Trp97Cys); c.338A>G, p.(His113Arg); c.371A>G, p.(Tyr124Cys); c.511T>C, p.(Phe171Leu), and c.581G>A, p.(Arg194Gln)] residing in or around the SANT domain, suggesting they may affect its interaction with DNA and/or histone. All six individuals have global developmental delay, intellectual disability, feeding difficulty, hypotonia, and craniofacial dysmorphic features, although the reported findings varied. Detailed clinical assessment demonstrated that an additional feature, such as microcephaly, short stature, seizures, and brain malformation, was concomitant in at least two individuals. Using the Gal4-UAS system in *Drosophila*, we expressed two independent *Dmap1* RNAis (RNAiBL63666, and RNAiv103734) under the control of *elav-Gal4*, a pan-neural driver, and found that both led to pupal lethality. Dissection of larval brains further demonstrated structural defects of the mushroom body (MB), the learning and memory center of fly. Compared to control, the volume of vertical lobe was significantly reduced after *Dmap1* knockdown, while the horizontal lobe was marginally affected, highlighting an underappreciated role of *Dmap1* in the MB development. Preliminary transcriptome analyses from *Drosophila* RNAi brains (N = 6) identified dysregulation of hundreds of genes implicated in transcription processing, neuronal function, and brain development. Together, our findings suggest that the *DMAP1* variants we discovered may exert a loss of function effect. To test our hypothesis, we are currently conducting rescue studies with the identified missense variants. In summary, we demonstrate that recessive variants in *DMAP1* are associated with a novel neurodevelopmental disorder.

Disclosure Block: **C. Engel:** None.

BRAT1 bi-allelic mutations have been associated with two distinct clinical pictures: the rigidity and multifocal seizure syndrome (RMFSL) and a neurodevelopmental disorder associating cerebellar atrophy with or without seizures syndrome (NEDCAS). To our knowledge, 37 patients from 26 families have already been described with recessive variations in *BRAT1*. We report here clinical and molecular findings of 51 patients from 39 families with bi-allelic pathogenic variants in the *BRAT1* gene. Prenatal features were observed in 3 patients (3/39; 8%). Microcephaly was observed in 22 of 41 patients (54%) and was already present at birth in 6 of 45 patients (13%). Hypotonia was noted in 28 of 44 patients (64%) and hypertonia of the limbs in 23 patients (46%). Intellectual disability was noted in all patients, except one. All but this one showed developmental delay, without any psychomotor acquisition for 41% of them (21/51). Only 48% of patients (24/50) acquired walking. Ataxia was present in 41% of cases (21/51). Epilepsy was present in 51% of patients (26/51). Mean age of onset was around one year of life (358 days) ranging from in utero to 13 years old. First seizures occurred before the age of one year in 81% of cases (21/26), and in 50% of cases (13/26) in the first week of life. In the majority of cases, epilepsy was drug resistant (20/26 ; 77%). Brain MRI showed cerebral atrophy in 13 patients (13/49; 27%) and cerebellar atrophy in 34 patients (34/49; 69%). Death occurred in 18 patients (35%), before the age of 1 year for 14 of them (28%). The phenotype of our patients seems less severe than that described in the literature. This might be

explained by the difference in the representation of truncating and missense mutations. We therefore suggest that biallelic *BRAT1* variants are not associated with two distinct clinical presentations but rather with a broader phenotypic spectrum. The most severe end of this disorder, mainly seen in patients with two truncating variations, is associated with profound intellectual disability, drug-resistant epilepsy, cerebral atrophy and early death. At the other end of the spectrum, a phenotype of mild ID, cerebellar atrophy, ataxia, nystagmus and higher life expectancy is observed in patients with at least one missense variant.

PrgmNr 2590 - The pleiotropy of neurodegenerative repeat expansions in ALS

View session detail

Author Block: **J. Hengeveld**[1], A. Vajda[2], M. Heverin[2], R. L. McLaughlin[1]; [1]Smurfit Inst. of Genetics, Trinity Coll. Dublin, Dublin, Ireland, [2]Academic Unit of Neurology, Trinity BioMed. Sci. Inst., Trinity Coll. Dublin, Dublin, Ireland

Disclosure Block: **J. Hengeveld:** None.

ALS is a fatal neurodegenerative disorder which causes the death of neurons controlling voluntary muscles. ALS has no cure, and its underlying cause is mostly unknown, although a strong genetic component is known to play a role. Repeat expansions (REs) underlie more than 40 diseases, most of them affecting the nervous system. The most common neurodegenerative repeat expansions (NDREs) diseases are Huntingtonâ□□s Disease (HD), Spinocerebellar Ataxias (SCA), Frontotemporal Dementia (FTD) and Amyotrophic Lateral Sclerosis (ALS). Several REs are pleiotropic; for example, GGGCC RE in *C9orf72* is associated with FTD/ALS and CAG RE in *ATXN2* causes SCA2/ALS. Previous studies on *ATXN2* showed that harbouring intermediate-length repeat expansions are significantly associated with the risk of ALS. Therefore, pleiotropy might be common in ALS. This study aims to genotype 34 neurodegenerative genes that harbour REs, in a cohort of 1000 controls and 1000 patients from the Irish ALS bank to assess the association between expanded genotypes and ALS. The length measurement of each NDRE gene and its possible repeat expansion was done by PCR, Repeat Primed-PCR (RP-PCR), agarose gel electrophoresis and fragment length capillary electrophoresis (FLA). In an Irish population, ALS might be driven by multiple intermediate-length repeat expansion in likely 8 NDREs genes: *ATXN1*, *ATXN2*, *DIP2B*, *FRA11AC1*, *HTT*, *NUTM2B-AS1*, *PABN1* and *ZNF713*. This study will give a better understanding of ALS mechanisms. ALS is a very complex disease that might be caused by pleiotropy of multiple REs and multiple factors.

PrgmNr 2591 - Whole exome sequencing of consanguineous individuals reveals rare coding variants in known and novel genes that contribute to neurological disorders

View session detail

Author Block: **W. Koomson**[1,2], A. E. Schaffer[2], M. Gunel[1]; [1]Yale Univ., New Haven, CT, [2]Case Western Reserve Univ., Cleveland, OH
Disclosure Block: **W. Koomson:** None.
Neurologic disorders can cause structural, connective, biochemical or electrical abnormalities in the nervous system. We analyzed 1,500 patients including 70 trios and 3 quads, with neurological/neurodevelopmental disorders of varying severity including structural brain malformations from a network of 28 clinical centers in Turkey, with a high degree of consanguinity. Autosomal recessive diseases are more frequently observed in consanguineous unions, therefore homozygosity analysis allows for gene mapping of recessive mutations. Our cohort consists of 60% consanguineous families with 46% female and 54% male affected individuals. Structural brain malformations occur in 45% of patients in our cohort, often presenting with clinical phenotypes such as autism, intellectual disability, dysplasia, cerebellar malformations, epilepsy, microcephaly, lissencephaly, neurodegenerative disorders, and neurological syndromes. Whole-exome sequencing enabled us to identify known disease-causing variants in a subset of the cohort, including: C19orf12 in patients with Hallervorden-Spatz disease, CACNA1A and CACNA1B in patients with epilepsy and intellectual disability, COL18A1 in patients with Knobloch Syndrome and Frontal Pachygyria, KIAA1211L in neurodevelopmental disorders, and WDR62 in patients with microcephaly and lissencephaly. Nevertheless, the majority of disease causing variants currently remain unidentified in our cohort. In addition to our continued analysis of homozygous variants, we will also explore the role of de novo mutations, which have been shown to be increased in neurodevelopmental disorders. Finally, we will identify gene co-expression module profiles, and perform gene enrichment analysis to identify categories of genes that may have an association with disease phenotypes.

PrgmNr 2592 - Clinical implementation of RNA sequencing for Mendelian disease diagnostics

View session detail

Author Block: **V. A. Yepez**[1], M. Gusic[2], R. Kopajtich[3], J. Gagneur[4,5], H. Munich, Munich, Germany, [4]Technical Univ. of Munich, Garching, Germany, [5]Inst. of Computational Biology, Munich, Germany, [6]Helmholtz Zentrum Muenchen, Neuherberg, Germany
Disclosure Block: **V.A. Yepez:** None.
Lack of functional evidence hampers variant interpretation, leaving a large proportion of cases with a suspected Mendelian disorder without genetic diagnosis after whole exome sequencing (WES). Research studies advocate to further sequence transcriptomes to directly and systematically probe gene expression defects. However, collection of additional biopsies, and establishment of lab workflows, analytical pipelines, and defined concepts in clinical interpretation of aberrant gene expression are still needed for adopting RNA-sequencing (RNA-seq) in routine diagnostics. We implemented an automated RNA-seq protocol and developed a computational workflow, DROP, with which we analyzed skin fibroblasts of more than 300 individuals with a suspected mitochondrial disease which previously underwent WES. We detected on average 12,500 genes per sample including around 60% disease genes - a coverage substantially higher than with whole blood, supporting the use of skin biopsies. We prioritized genes demonstrating aberrant expression using OUTRIDER, aberrant splicing using FRASER, or mono-allelic expression. The pipeline required less than one week from sample preparation to result reporting and provided a median of eight disease-associated genes per patient for inspection. A genetic diagnosis was established for 16% of the 205 WES-inconclusive cases. Detection of aberrant expression was a major contributor to diagnosis including instances of 50% reduction, which, together with mono-allelic expression, allowed for the diagnosis of dominant disorders caused by haploinsufficiency. Moreover, calling aberrant splicing and variants from RNA-seq data enabled detecting and validating splice-disrupting variants, of which the majority fell outside WES-covered regions. We share DROP, which besides integrating all analysis steps, it also includes quality control, can leverage parallel computing infrastructures and generates browsable web page reports. Together, these results show that streamlined experimental and computational processes can accelerate the implementation of RNA-seq in routine diagnostics.

PrgmNr 2594 - Dietary nutritional recommendations in patients with phenylketonuria in Ecuador

View session detail

Author Block: **A. Campodonico**[1], E. Haro[1], B. Bahamonde[1], J. Pozo[1], V. I. Romero[2]; [1]USFQ, Quito, Ecuador, [2]Univ. San Francisco de Quito, Quito, Ecuador
Disclosure Block: **A. Campodonico:** None.
Phenylketonuria (PKU) is an autosomal recessive disease due to an enzymatic deficit to convert the phenylalanine into tyrosine, a crucial component in neurodevelopment from the fetal stage. Without treatment it results in irreversible intellectual disability. The Ecuadorian neonatal screening tests for PKU, however it does not provide nutritional recommendations or meal guides including available products. Our study aims to assess the PKU individual nutritional status, develop nutritional guidelines with Ecuadorian products and educate the families with them.
First, we performed a 24-hour diet reminder in patients diagnosed with PKU. The test recorded a day of complete feeding, allowing a real starting point in the amount of phenylalanine consumed daily. The results indicated higher levels of phenylalanine than recommended, since they do not have a personalized nutrition guide.
Second, we performed a systematic literary review in English and Spanish of the nutritional databases available in Latin America, however we didnÂ´t find any regional guideline. Therefore, we used nutritional guidelines from North America and Europe to develop a Latin American nutritional recommendation guide with products from our region.
In conclusion, we identified that Ecuadorian patients with PKU do not have a nutritional counseling for their condition and are consuming higher levels of phenylalanine than recommended. We did not find Latin American nutritional guidelines, so we are developing one, with products from our regions.

PrgmNr 2595 - Dysosteosclerosis in an individual harboring a homozygous nonsense variant in *TNFRSF11A*: further considerations on genotype-phenotype correlation

View session detail

Author Block: **M. Castro**[1], B. D. W. Linnenkamp[1], C. R. Gama[2], T. M. Ali[3], L. A. N. Oliveira[1], R. S. Honjo[1], G. L. Yamamoto[4], C. A. Kim[1], D. R. Bertola[1]; [1]Inst. da Crianca HCFMUSP, Sao Paulo, Brazil, [2]Inst. Disclosure Block: **M. Castro:** None.
Dysosteosclerosis and osteopetrosis are both sclerosing skeletal dysplasias with overlaping radiographic signs and classified in the group 23 of the nosology of genetic skeletal disorders. They are classically differentiated by the findings of platyspondyly and increased submetaphyseal radiolucency, associated only to dysosteosclerosis, and by the presence of bone marrow failure, a hallmark complication of osteopetrosis. Although they present genetic heterogeneity with variants in distinctive genes, recently they converged, as both could be caused by biallelic variants in *TNFRSF11A*. A previously proposed hypothesis for genotype-phenotype correlation states that variants leading to synthesis of truncated or elongated RANK proteins lead to the milder dysosteosclerosis phenotype, while total loss of expression of all isoforms could be associated to osteopetrosis. We report on an adult individual with clinical and radiological findings compatible with dysosteosclerosis and absence of hematological abnormalities, harboring the nonsense variant NM_003839.4(*TNFRSF11A*):c.1325G>A:p.(Trp442*) in a homozygous state. This variant creates a stop codon only in isoforms 1 and 2, predicted to be degraded by nonsense-mediated mRNA decay, and does not affect splice site predictions. Thus, isoforms 3, 4 and 5 are probably not affected. We have noticed that in all patients with dysosteosclerosis reported so far, there is total or partial preservation of isoforms 4 and 5. Therefore, our case illustrates that only the maintenance of the expression of these two isoforms (not necessarily the presence of truncated or elongated proteins) could explain the lack of hematologic abnormalities, or at most, cause a mild compromise.

PrgmNr 2596 - Expanding the clinical spectrum of *NDUFAF3*-related disorders: Prolonged survival and unusual course in a patient with compound heterozygous *NDUFAF3* variants

Disclosure Block: **A. van der Ven:** None.
Mitochondrial disorders most frequently originate from impaired oxidative phosphorylation (OXPHOS) activity. Mitochondrial complex I (CI) is the largest OXPHOS component. It is composed of three functional modules: the Q-, the P- and the N-module. NDUFAF3 (NADH: Ubiquinone Oxidoreductase Complex Assembly Factor-3) is one of 13 proteins known to aid the correct assembly of this large multienzyme complex. Recent investigations have advanced the understanding of NDUFAF3 for CI biogenesis, pinpointing it to the step were the Q- and the P-module are joined. Recessive disease-causing variants in *NDUFAF3* have previously been described as the cause of a distinct mitochondrial disease condition (OMIM # 618240). The seven patients reported to date exhibited severe neurologic symptoms and lactic acidosis, followed by death within the first two years of age in six cases. We present a 10-year-old patient with developmental delay, exercise intolerance, dystonia, basal ganglia abnormalities, and elevated lactate concentration in blood. Trio-exome sequencing revealed a paternally inherited splice site variant and a maternally inherited missense variant in *NDUFAF3*, classified as pathogenic and likely pathogenic, respectively, according to ACMG criteria. Spectrophotometric analysis of fibroblast-derived mitochondria demonstrated isolated and relatively mild reduction of CI in our patient. Complexome analysis revealed undetectable levels of NDUFAF3 and a severely decreased amount of fully assembled CI. Furthermore, an unusual occurrence of the assembly factors ACAD9 and ECSIT was noted on fully assembled complex I. With this untypical presentation of a patient with onset of symptoms during early childhood and comparatively attenuated course, we provide further insight into the phenotypic spectrum of NDUFAF3-related mitochondrial disease. The relatively mild phenotype of our patient is likely a result of the paternally inherited splice-site variant. This variant is relevant for only one of the four coding *NDUFAF3* transcript-isoforms, accounting for approximately 25% of NDUFAF3 expression across human tissues. The data obtained via complexome analysis are in line with the previously defined role of NDUFAF3 for CI biogenesis. Beyond that, the abnormal occurrence of the assembly factors ACAD9 and ECSIT additionally indicates an incomplete maturation of CI in our patient.

PrgmNr 2597 - Gut microbiome affects human bone mass, microarchitecture, and strength: The Framingham Study

View session detail

Author Block: **P. Okoro**[1], E. Orwoll[2], M. Bouxsein[3], S. Sahni[1], D. P. Kiel[1]; [1]Hebrew SeniorLife, Boston, MA, [2]Oregon Hlth.& Sci. Univ, Portland, OR, [3]Beth Israel Deaconess Med. Ctr., Boston, MA
Disclosure Block: **P. Okoro:** None.
The gut microbiome has been shown to affect the inflammatory environment through effects on the T-cell landscape, which influence the production of soluble immune mediators and inflammatory cytokines that stimulate osteoclastogenesis and bone loss in mice. However, there is a lack of large human studies of the gut microbiome and skeletal health. Thus, we explored the relationship between the gut microbiome and measures of volumetric bone mineral density (vBMD), microarchitecture, and strength in humans.
We used 16S rRNA amplicon sequencing and high resolution peripheral quantitative computed tomography (HR-pQCT) phenotypes from men and women in the Framingham Study (n=1310). The 16S data were processed into operational taxonomic units (OTUs) and matched to the Greengenes 16S database. After QC and sequencing batch correction, the resulting OTU counts were converted into relative abundances. HR-pQCT scans of the distal radius and tibia generated volumetric density and architecture of cortical (porosity & thickness) and trabecular bone (thickness & number), and biomechanical estimates of failure load.
To probe for the association between microbial genera and bone measures using generalized linear model, we normalized and transformed the OTU abundances, and adjusted the bone measures for age, sex, BMI, smoking and diabetes status. At FDR â¤ 0.05, 10 unique genera were associated with one or more bone measures. We found interesting patterns of associations across the skeletal phenotypes. First, 75% of the associations were at the tibia; in the majority of these, greater abundance was associated with worse bone measures. The remainder (25%) of the associations at the radius were equally bad for radial skeletal site measures. Additionally, all bone-taxa associations at the radius were observed only with trabecular measures while those at the tibia were observed mostly with cortical measures. We did observe two microbes, *Eubacterium dolichum* and *Coprobacillus cateniformis*, for which greater abundances were associated with lower measures of bone density, worse micro-architecture (lower cortical thickness) and bone strength (reduced failure load).
In summary, these early results from a moderately large cohort study show evidence of significant relationships between gut microbiota and bone measures that differ between cortical and trabecular bone and in weight bearing tibial and non-weight bearing radial sites. Several microbes demonstrated deleterious associations across measures of density, microarchitecture and strength, thus supporting the importance of the gut microbiota in skeletal homeostasis and health.

PrgmNr 2598 - Novel *RUNX2* gene variation associated with cleidocranial dysplasia-like phenotype

View session detail

Author Block: **J. Aponte**[1], J. Pascual[2], Y. Mojica[3], C. I. Hernandez[4], S. Carlo[5], A. S. Cornier[6]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Ponce Hlth.Sci. Univ. Sch. of Med., Ponce, Puerto Rico, [3]Univ. of Puerto Rico Rio Piedras Campus, San Juan, Puerto Rico, [4]Natl. Children's Hosp., Pediatrics Dept., Washington D.C., DC, [5]Ponce Hlth.Sci. Univ., Cabo Rojo, PR, [6]San Jorge Children's Hosp. / Ponce Hlth.Sci. Univ., San Juan, PR

Disclosure Block: **J. Aponte:** None.

The *RUNX2* gene has been recognized to play an important role in the formation of bone, cartilage, and teeth, while several variations have been associated with the development of cleidocranial dysplasia (CCD). CCD affects the development of the bones, skull, and teeth. Signs and symptoms include underdeveloped or absent clavicles, dental abnormalities, and delayed closing of the fontanelles. Other symptoms may include osteopenia, hearing loss, bone abnormalities of the hands, and recurrent sinus and ear infections. People with CCD may develop curvature of the spine (scoliosis), osteoporosis, and may be shorter than average in stature. *RUNX2* is inherited in an autosomal dominant pattern. DNA sequence analysis of an 18-year-old patient with severe progressive scoliosis, webbed neck, clavicle dysplasia, fragile teeth and brachydactyly revealed a novel variation within one copy of the *RUNX2* gene (c.228_260dup) which results in the insertion of 11 amino acids to the RUNX2 protein (p.Ala79_Ala89dup). The presence of this genetic variation, along with the patient's clinical presentation, suggests a novel phenotype-genotype association, characterized by the appearance of both typical and unusual signs and symptoms of cleidocranial dysplasia in this individual.

PrgmNr 2599 - Novel variants of PAH gene in Ecuadorian phenylketonuria patients: Do we need new molecular panels for metabolic disorders for Latin American populations?

View session detail

Author Block: **E. Haro**[1], A. CampodÃ³nico[1], B. Bahamonde[1], J. Pozo[1], V. I. Romero[2]; [1]USFQ, Quito, Ecuador, [2]Univ. San Francisco de Quito, Quito, Ecuador
Disclosure Block: **E. Haro:** None.
The heterogeneity of the molecular variants of the *phenylalanine hydroxylase (PHE)* gene results in a spectrum of enzyme deficiency and mild to severe phenotypes. PKU is part of the nationwide neonatal screening, however molecular analysis is not covered or studied.
We identified the molecular variant on previously diagnosed individuals with PKU and report novel variants. Ecuador is a country with an admixed population between African, European, and Native American groups. Therefore, we found both common and novel molecular variants in our patients linked to these populations in literature and databases. Most of genetic databases have limited participants from minorities, we concluded that the novel variants arise from Indigenous populations of the region
Our findings highlight the importance of developing population-related molecular panels in Latin American. We correlate the molecular variants and the complexity of nutritional treatment, demonstrating the importance to offer molecular analysis to patients with PKU to optimize their management.

PrgmNr 2600 - Sensorineural hearing loss is an early indicator of mitochondrial disease

View session detail

Author Block: **A. Koleilat**, G. L. Poling, S. C. Ekker, V. S. Pureza, L. A. Schimmenti, L. Hasadsri; Mayo Clinic, Rochester, MN
Disclosure Block: **A. Koleilat:** None.
Disorders of energy metabolism are multisystem conditions characterized by dysfunctional mitochondria caused by genetic mutations in either mitochondrial DNA (mtDNA) or nuclear DNA (nDNA) and are collectively known as Mitochondrial Disease (MD). Tissue distribution (replicative segregation) and heteroplasmy contribute to the multiple system nature of MD and impact age of clinical presentation. Sensorineural hearing loss (SNHL) occurs in MD and can range in severity and age of onset. It is estimated that over half of patients with MD will develop some hearing impairment and of those individuals, more than 50% experienced hearing loss prior to age 40. In this retrospective study, we evaluated patients referred to a large reference laboratory who were identified to have diagnostic testing supportive of MD and reviewed medical records for the presence, type, and age of onset of SNHL. The goal of this study was to determine if a genetic investigation occurred at the onset of hearing loss would an earlier diagnosis of MD occurred, and furthermore, if hearing loss can be used as an early indicator for MD. Of the 50 total patients identified with a confirmed molecular MD diagnosis, 42% were diagnosed between the ages of 21- 40. Within this cohort 72% had a missense variant in mtDNA, 16% had a deletion in mtDNA and12% had a missense pathogenic variant in nDNA. Medical records were searched for evidence of a SNHL diagnosis prior to a mitochondrial disease diagnosis. Thirty-six percent of this cohort presented with SNHL prior to the diagnosis of MD. Of the 36, audiometric data (1-8 kHz) was available for 18 individuals. In all 18, mild to moderate hearing loss at lower frequencies and moderate hearing loss at 2 kHz and higher was identified. In individuals where a specific age was recorded for the onset of hearing loss, there was an average difference of 15 years between discovery of hearing loss and the diagnosis of mitochondrial disease. In conclusion, we discovered that over one-third of individuals with a molecular MD diagnosis presented with SNHL, on average, over a decade prior to being tested for and diagnosed with MD. This observation supports the need for a clinical genetics evaluation that includes consideration of MD in the work up of individuals who present with early adult onset of SNHL This suggests that SNHL could be an early indicator of MD in a subset of patients.

PrgmNr 2601 - The role of seryl-tRNA synthetase in mitochondrial biology and disease

View session detail

Author Block: **C. Del Greco**[1], J. Kitzman[2], A. Antonellis[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Univ MICHIGAN, Ann Arbor, MI
Disclosure Block: **C. Del Greco:** None.
Aminoacyl-tRNA synthetases (ARSs) are essential, ubiquitously expressed enzymes that charge tRNA molecules with amino acids in the cytoplasm and mitochondria. All 37 human ARSs are nuclear-encoded: 17 function in the cytoplasm, 17 function in the mitochondria, and three function in both cell compartments. Importantly, all 17 mitochondrial ARSs have been implicated in human recessive disease with a broad range of clinical phenotypes that often affect tissues with high energy demands. Mitochondrial seryl-tRNA synthetase (*SARS2*) has been implicated in disease phenotypes ranging from progressive spastic paresis to HUPRA (hyperuricemia, pulmonary hypertension, renal failure in infancy, and alkalosis) syndrome, but there is no explanation for this variability. Additionally, the number of patient variants, all of which map to the catalytic domain of the protein, is limited, and the full allelic spectrum of potentially pathogenic *SARS2* mutations remains unknown. To expand the allelic spectrum of *SARS2*-related disease, I will perform a massively parallel assessment of *SARS2* exons encoding key functional domains by performing saturation genome editing on haploid (Hap1) human cells. First, I will develop a Hap1 cell line that harbors an integrated, doxycycline-inducible copy of *SARS2*; the *SARS2* transgene will be engineered to be resistant to subsequently used gRNAs. Second, I will engineer all possible *SARS2* missense and nonsense mutations in 8 exons of interest; this will result in a total of 2934 *SARS2* variants studied. Third, I will use CRISPR/Cas9 genome editing to introduce the mutation library into a population of Hap1 cells and will determine mutation integration frequencies in the presence of doxycycline (*i.e.*, during expression of the wild-type *SARS2* transgene). Finally, I will remove doxycycline treatment, allow the cells to grow for 4 days, and sequence DNA from the resulting population. Variants that are reduced in frequency after doxycycline removal will represent loss-of-function variants that impair cell viability. In parallel, I will model known patient variants in Hap1 cells and investigate their effects on mitochondrial protein translation and oxygen consumption to correlate mitochondrial function with clinical severity. Here, I will present my plans to study *SARS2* variants and our unpublished, preliminary data. This study will inform our understanding of essential regions of SARS2, broaden our understanding of the allelic heterogeneity of pathogenic *SARS2* alleles to assist in assessing newly identified patient mutations, and deepen our understanding of how mitochondrial ARSs lead to diverse disease phenotypes.

PrgmNr 2602 - A digital health approach to rare disease diagnosis; identifying patients with feature combinations warranting further evaluation for a possible diagnosis of 22q11.2 deletion syndrome from UK primary care electronic health records

View session detail

Author Block: **L. Menzies**, O. Buendia, W. Evans; Mendelian, London, United Kingdom
Disclosure Block: **L. Menzies:** Consultant/Consulting Fees/Other Remuneration; Mendelian Ltd.
Introduction: 22q11.2 deletion syndrome is a rare disease with multi-systemic features including congenital cardiac malformations, velopharyngeal insufficiency, parathyroid hypoplasia and intellectual disability (prevalence of ~25/100,000). Rare disease diagnosis is challenging due to disease complexity and low physician awareness. The 2021 UK Rare Diseases Framework highlights a global need for faster diagnosis, to improve clinical outcomes.
Methods: We developed a digital health tool to facilitate earlier diagnosis of rare diseases. The tool scans pseudo-anonymised Electronic Health Records (EHR) to highlight patients for further investigation for a given syndrome. Peer-reviewed disease criteria are mapped to the appropriate SNOMED CT codes to create a digital criteria algorithm. An algorithm for 22q11.2 deletion syndrome was derived from a published diagnostic criterion. The tool identifies patients who breach a defined threshold depending on the diagnostic significance of SNOMED CT codes. This digital algorithm was applied to 501,188 primary care EHR. Matched cases were subject to internal review to consider appropriateness for further evaluation. EHR of patients that matched the 22q11.2 algorithm and those already diagnosed with 22q11.2 deletion syndrome were reviewed.
Results: 25 patientsâ EHR had a diagnosis of 22q11.2 deletion syndrome. The digitised criteria algorithm identified 5 of these patients; 3 of whom matched the digitised criteria in advance of the diagnostic code being assigned. For example, 1 patient met the digitised criteria threshold for suspected diagnosis 11 years prior to recorded diagnosis. 112 undiagnosed patientsâ EHR also matched the digitised criteria; 102 of these were deemed appropriate for further evaluation after an internal manual review.
Conclusions: This digital approach has the potential to identify patients with a possible diagnosis of 22q11.2 deletion. Improved (earlier) diagnosis has important implications for clinical care, for example enabling surveillance for disease complications and genetic counselling. Further prospective studies are planned to evaluate this digital approach and its implementation as an adjunctive tool in primary care.

PrgmNr 2603 - Association of missense variants in the transthyretin *TTR* gene with hereditary transthyretin-mediated hATTR amyloidosis in 454,782 UK Biobank whole exome sequences

View session detail

Author Block: **M. Plekan**[1], R. Hoffing[1], L. D. Ward[2], A. Deaton[1], A. Flynn-Carroll[1], C. Willis[1], G. Hinkle[1], P. Nioi[2], M. M. Parker[2]; [1]Alnylam Pharmaceuticals, Cambridge, MA, [2]Alnylam, Cambridge, MA
Disclosure Block: **M. Plekan:** Salary/Employment; Alnylam Pharmaceuticals.
ObjectiveOver 100 distinct missense variants in the TTR gene are known to cause hereditary transthyretin-mediated (hATTR) amyloidosis, a progressively debilitating life-threatening disease. We aimed to characterize missense TTR variants in a cohort of 454,782 exomes and test their association with hATTR amyloidosis. MethodsMissense TTR variants were identified in 454,782 exomes from the UK Biobank, a population-based prospective study where patients are followed to age 68 on average. Variants were classified as pathogenic, likely pathogenic, benign, conflicting interpretation, uncertain significance or novel based on CLINVAR. â□□Novelâ□□ indicates the variant had not been previously assessed for pathogenicity. In carriers of known pathogenic variants, the prevalence of an hATTR amyloidosis diagnosis and common hATTR symptoms (polyneuropathy, carpal tunnel syndrome, heart failure and cardiomyopathy) were characterized. In carriers of variants with uncharacterized/uncertain pathogenicity, we assessed diagnoses for evidence of hATTR amyloidosis.Results We identified 84 missense TTR variants including 10 pathogenic variants (N=423), 20 variants of uncertain or conflicting interpretation (N=740), and 51 novel variants (N=125). The most prevalent pathogenic variants were V122I (N=358), V30M (N=25), T60A (N=19) and I68L (N=12). Ten of 423 pathogenic variant carriers (2.4%) had an amyloidosis diagnosis (ICD10 code â□□E85â□□). Of pathogenic variants with >1 carrier, the mutation with the highest frequency of amyloidosis diagnosis was T60A (15%) followed by V122I (2%). By age 75, 12.1% (95% CI = 6.7-17.2%) of carriers had at least one common symptom of hATTR amyloidosis. Phenome-wide association analysis of the common missense variant Gly6Ser (rs1800458, MAF=8%, N=64,353) in the white British population (N=363,973) revealed no significant associations supporting its benign CLINVAR designation. Analysis of carriers of missense TTR variants with uncharacterized pathogenicity revealed no evidence of novel pathogenic hATTR amyloidosis variants. Lastly we identified 15 heterozygous carriers of high confidence predicted loss of function mutations, none of whom had an amyloidosis diagnosis.ConclusionsWe identified 84 missense TTR variants in 454,782 UKBB exomes, including 10 known pathogenic variants and 71 variants of unknown pathogenicity. Despite a low frequency of amyloidosis diagnosis among pathogenic variant carriers, many have diagnoses of common hATTR symptoms, suggesting an underdiagnosis of disease. No evidence of additional hATTR amyloidosis pathogenic variants among missense variants of unknown pathogenicity was found.

PrgmNr 2605 - Increasing the diagnostic yield through post-report reanalysis of exome data in subjects with immune disorders

View session detail

Author Block: **M. A. Walkiewicz**[1], M. Similuk[2], B. Seifert[3], J. Yan[4], A. Borges[1], M. Setzer[5], C. Jodarski[6], M. Kamen[4], D. Veltri[1], S. Holland[1], R. Ghosh[2]; [1]NIAID/NIH, Bethesda, MD, [2]NIH, Bethesda, MD, [3]Natl. Inst. of Allergy and Infectious Diseases (NIAID), Bethesda, MD, [4]Natl. Inst. of Allergy and Infectious Diseases, Bethesda, MD, [5]Med. Sci. and Computing/NIAID, Bethesda, MD, [6]
Disclosure Block: **M.A. Walkiewicz:** None.
Background & Rationale:The rate of molecular diagnosis within immunology by exome sequencing ranges between 15%-79% depending on the population and technical approach. Several studies have shown that periodic reanalysis yields additional diagnoses. Initial analysis of the first 1000 probands of our cohort of immunology patients referred to the National Institute of Allergy and Infectious Diseases (NIAID) Centralized Sequencing Program (CSP) yielded 341 molecular diagnoses among 314 probands (31.4%). Here, we present our reanalysis of the first 1000 probands. Methods:Research-based exome sequencing was performed on 1000 study probands. In addition, chromosomal microarray was performed in 374 of these probands. The data was then analyzed, and relevant findings were reported to the subjects. Semi-automated reanalysis of the data was performed between 1-3 years after the initial review and focused on new gene-disease associations, new HGMD-cataloged variants present in our database, as well as updates in clinical presentation or inclusion of additional relatives in the analysis. Results:Reanalysis yielded 21 new molecular diagnoses in 20 probands (2.0%), six of whom already had at least one molecular diagnosis. In this group, there were 23 variants which now constituted or contributed to a molecular diagnosis. Nine diagnoses were made from newly described gene-disease associations. Among these, 3 patients with variants in *SASH3* were initially identified through the CSP and published in collaboration with NIAID investigators, one patient with a truncating variant in *IL6ST* contributed to the original research report, and one diagnosis came from a new CNV-disease association. In addition, 11 molecular diagnoses were made from re-assessment of the variant due to new publications, data on relatives or updated clinical history. Lastly, two molecular diagnoses were made from the updated ACMG incidental findings gene list. Conclusion:In summary, our reanalysis of 1000 probands yielded an additional 21 diagnoses, increasing our diagnostic rate to 32.8% (328 probands with 362 molecular diagnoses). With the fast pace of new gene-disease discoveries, incorporating newly reported genes into reanalysis is important in maintaining the most up to date analysis pipeline. Periodic review of new literature of variants in disease genes and inclusion of family members for segregation studies proved to be important factors contributing to new diagnoses. Additionally, reanalysis of CNV data should be considered as the contribution of CNVs to immune disorders is not fully understood. Lastly, scalability should remain a key consideration for all re-analysis methods.

Background: *TNNC1* encodes for cardiac troponin C, a subunit of the troponin complex which constitutes thin filaments and regulates muscle contraction. It is known to be associated with a rare form of autosomal dominant cardiomyopathy. Nevertheless, after reviewing the published case reports, about one third of patients had pediatric onset cardiomyopathies.

Material and methods: We diagnosed a *TNNC1* pathogenic variant in a patient with dilated cardiomyopathy detected at one-month-old. Therefore, we set up a national collaboration call with the five French referent molecular laboratories for hereditary cardiomyopathies. We requested the number of patients diagnosed with pediatric onset cardiomyopathy out of their cohort of *TNNC1* mutated patients. Genetic analysis was performed by targeted Next-Generation Sequencing and/or Sanger sequencing.

Results: A cohort of ten children out of thirty-seven patients with *TCCN1* variants (27%) was isolated in France. Genetic investigations identified seven patients with a heterozygous variant in *TNNC1* and three patients with homozygous variants, including one brother and one sister. All were missense mutations, two of which were newly described: p.(Phe27Val) and p.(Pro54Arg) and four previously published: p.(Ala8Val), p.(Asp149Asn), p.(Asp88Asn) and p.(Asp25Asn). The three homozygous probands had the same p.(Ala8Val) mutation. Clinical assessment was only available for eight

patients. It showed that first signs mostly began before the age of one year, ranging from antenatal onset to 8-year-old. Predominant symptoms consisted of dilated (6/8) or hypertrophic cardiomyopathy (3/8). Additional conditions comprised restrictive cardiomyopathy (2/8), ventricular (2/8) or atrial septal defect (1/8) and myocardial bridge (1/8). In the majority of cases, clinical presentation was severe. It rapidly led to transplantation in one homozygous proband at 2 years old and in one heterozygous proband at 4 years old. Death occurred in three children at ages 1, 6 and 12 months, including the other two homozygous patients.
Conclusion: Neonatal or early pediatric onset cardiac phenotypes seem to be found in one third of patients with *TNNC1* mutations. Homozygous or compound heterozygous variants appeared to be responsible, in absence of transplantation, for a lethal outcome. Further reports and delineation of the genotype-phenotype correlations of this gene should improve disease management and genetic counselling.

Introduction: Autosomal dominant polycystic kidney disease (ADPKD) is caused primarily by variants in *PKD1*, and *PKD2.* Disease severity ranges from *in-utero* onset to preserved kidney function into old age. It is well established that the type of diagnostic ADPKD variant can influence disease severity and variants have been identified which modify disease severity or can cause autosomal recessive disease. Here we demonstrate, using robust statistical analyses, that rare variant burden in the gene *PKD1* contributes to ADPKD phenotypic variability.

Methods: Patients (n=449) with an established genetic diagnosis of ADPKD due to a pathogenic variant in *PKD1* or *PKD2* were recruited from five international centres (Dublin Ireland, Genomics England/ Royal Free Hospital London UK, Leipzig Germany, Bologna Spain, Sydney Australia). The association between the presence of rare, additional *PKD1* variants and age at end-stage renal disease (ESRD) was tested using a Cox mixed-effect regression model.

Results: The presence of non-diagnostic, rare, predicted damaging *PKD1* variants was associated with a lower age at ESRD, in patients with an established genetic diagnosis (hazard ratio: 1.62 (1.15-2.29), p=5.2x10^{-3}).

Conclusions: Rare, additional predicted damaging *PKD1* variants impact disease severity in ADPKD. Patients with an additional, rare, predicted damaging *PKD1* variant reached ESRD a median of 3-7 years earlier than those lacking such qualifying variants. These findings have important implications for patient counselling and the assessment of variant pathogenicity in clinical genetics services.

Disclosure Block: **F. Privitera:** None.
Retinoblastoma (RB) is an ocular tumor of the pediatric age caused by biallelic inactivation of the RB1 gene (13q14). About 10% of cases are due to gross-sized molecular deletions. The deletions can involve the surrounding genes delineating a contiguous gene syndrome characterized by RB, developmental anomalies and peculiar facial dysmorphisms. Overlapping deletions previously found by traditional and/or molecular cytogenetic analysis allowed to define some critical regions for intellectual disability (ID) and multiple congenital anomalies, with key candidate genes. In the present study, we characterized by array-CGH seven new patients with interstitial 13q deletion involving RB1. Among these cases, three patients with medium or large 13q deletions did not present psychomotor delay. This allowed to define a minimal critical region for ID that excludes the previously suggested candidate genes (HTR2A, NUFIP1, PCDH8 and PCDH17). The region contains 36 genes including NBEA, which emerged as the candidate gene associated with developmental delay. In addition MAB21L1, DCLK1, EXOSC8 and SPART haploinsufficiency might contribute to the observed impaired neurodevelopmental phenotype. In conclusion, this study adds important novelties to the 13q deletion syndrome, although further studies are needed to better characterize the contribution of different genes and to understand how the haploinsufficiency of this region can determine ID.

PrgmNr 2609 - 7q36.1q36.2 deletion in a child with intellectual disability, developmental delay, short stature, and a Chiari 1 malformation

View session detail

Author Block: **E. Cordell**, Y-C. Hou, C. Gooch, J. Neidich; Washington Univ. Sch. of Med., St. Louis, MO
Disclosure Block: **E. Cordell:** None.
Introduction: Distal monosomy 7q36 is a rare chromosomal syndrome with symptoms including holoprosencephaly, growth restriction, developmental delay, intellectual disability, and facial features. In patients with distal monosomy 7q36, the partial deletion of the long arm of chromosome 7 includes the *SHH* gene located in 7q36.3 resulting in holoprosencephaly. Deletions in the proximal part of 7q36 are even less common. A case study from 2008 described a 9-year-old girl with a 5.27Mb deletion in 7q36.1q36.2 with a phenotype characterized by intellectual disability, facial features, renal hypoplasia, and long QT syndrome. Here we present a 12-year-old female with a 3.19MB *de novo* deletion in the 7q36.1q36.2 region. The patient presented with ADHD, autistic features, facial findings, intellectual disability, tremors, short stature, and a Chiari 1 malformation.
Methods: A chromosomal microarray analysis (CMA) was performed using the CytoScan HD array. Copy-number variant (CNV) interpretation guidelines were used for the evaluation and interpretation of CNVs. Results were confirmed using fluorescence *in situ* hybridization (FISH).
Results: The CMA test revealed an interstitial deletion of the long arm of chromosome 7 at band q36.1q36.2, arr[GRch37] 7q36.1q36.2(149828686-153017182)x1, approximately 3.18Mb in length. FISH analysis showed only one signal located at 7q36.1q36.2 confirming the terminal 7q deletion. The parental FISH were normal. This loss contained 45 protein-coding RefSeq genes and 7 disease-associated genes, *ASB10, CDK5, KCNH2, KMT2C, NOS3, PRKAG2* and *XRCC2*. Similar size losses have been documented as pathogenic or likely pathogenic in DECIPHER database in three individuals. Phenotypes included cardiac defects, congenital microcephaly, facial dysmorphisms, global developmental delay, and renal dysplasia. *KCNH2* and *KMT2C* genes have sufficient evidence for haploinsufficiency by ClinGen Dosage Sensitivity Map.
Discussion: The clinical features matched those of reported individuals with similar deletions encompassing the 7q36.1q36.2. She displays intellectual disability, short stature, and facial features consistent with the reported case. The patient has not developed long QT syndrome associated with loss of the *KCNH2* gene. Her recent ECG was normal. The patient has phenotypes associated with loss of the *KMT2C* gene, including autistic features, intellectual disability, short stature, and dysmorphic features. The patient has Chiari 1 malformation, not described previously. Our report contributes to the genotype-phenotype correlation in 7q36.1q36.2 deletion cases.

PrgmNr 2610 - Diagnostic yield of exome sequencing in neurodevelopmental disorders in a Brazilian clinical laboratory

View session detail

Author Block: **J. Sobreira**[1], D. Cupertino[1], D. Bermeo[1], T. Loureiro[1], D. Villela[1], G. Yamamoto[1], M. Gomes[1], R. Guarischi[1], C. de Souza[1], J. Silva[1], A. Bonaldi[1], A. Paes[1], G. Pereira[1], B. Schmabel[1], K. Endo[1], M. Milanezi[1], N. L. Sobreira[2], M. Migliavacca[1]; [1]LaboratÃ³rio GeneOne, SÃ£o Paulo, Brazil, [2]Johns Hopkins Univ, Baltimore, MD
Disclosure Block: **J. Sobreira:** None.
Neurodevelopmental disorders (NDDs) are a genetically heterogeneous set of conditions that affect 1-3% of children and is characterized by a wide range of phenotypic features, including intellectual disability (ID), autism spectrum disorder (ASD) and global developmental delay as the most common. Whole exome sequencing (WES), along with advanced bioinformatics capabilities, have created opportunities to use WES in a variety of medical situations, including for the molecular characterization of rare diseases such as neurodevelopmental disorders. A diagnostic rate between 25-38% has been reported for isolated NDD and between 41-64% for the syndromic NDDs. The diagnostic rate ranges from 29 to 50% among patients with ID, from 11 to 24% among patients with ASD and from 29 to 46% for patients with ID and ASD combined. Here we analyzed the diagnostic rate of WES performed by a Brazilian clinical laboratory in a cohort of 251 Brazilian patients with NDD. Among the 251 patients, 188 had the WES analyzed for the investigation of CNVs also. The patients were selected by searching the medical records for the following terms: 1) intellectual disability; 2) delay in global development, motor skills or speech, and; 3) hypotonia or muscle hypertonia or seizure (neonatal patients). The proportion between male and female was 143 (56.9%): 108 (43.1%), and the ages ranged from 29 days to 70 years. An overall diagnostic rate of 31.4% (79/251) was achieved, with the identification of two CNVs. The pathogenic variants were observed in 64 genes, with 59.7% related to autosomal dominant node of inheritance, 27.2% to autosomal recessive mode of inheritance and 13.1%. The diagnostic rate for CNV was 1%. Our data are consistent with previous reports and we observe that a better diagnostic rate is reported in cohorts where trio-WES sequencing is performed. The low diagnostic rate for large CNVs was already expected, since, in Brazil, investigation of patients with NDD using techniques such as array is required before performing WES.

PrgmNr 2611 - Genetic evaluation of children born with very low birth weight

View session detail

Author Block: **A. Jorge**[1], B. L. Freire[1], T. K. Homma[1], A. M. Lerario[2], I. J. P. Arnhold[1]; [1]Faculdade de Med. da Univ.e de SÃ£o Paulo (USP), Sao Paulo, Brazil, [2]Univ. of Michigan, Michigan, MI
Disclosure Block: **A. Jorge:** Consultant/Consulting Fees/Other Remuneration; NovoNordisk, Biomarin.
Very low birth weight (VLBW) children are defined as those infants with birth weight Patients and Methods: Forty-two children born VLBW referred for short stature investigation in a tertiary care hospital. Fourteen children were diagnosed based on clinical findings of a known condition and were submitted to a candidate gene approach: 6 patients were evaluated by a MS-MLPA due to clinical suspicion of Silver-Russel syndrome (SRS); and 8 cases were clinically diagnosed with a monogenic condition. Patients with a negative result in the candidate gene approach (n=5) or without clinical suspicion (n=28) were evaluated by chromosome microarray analysis (CMA; n=15) and/or whole exome sequencing (WES; n=25). Twelve patients had CMA negative results before performing WES. **Results:** All patients were born VLBW, 66% were VP, 74.5% born SGA and 72.5% has syndromic features. From the 42 patients who were selected for genetic analysis, a syndromic genetic condition was confirmed in 43% (18/42). A candidate gene approach confirmed the clinical diagnosis in 64.3% (9/14): SRS (n=4); pseudohypoparathyroidism (*GNAS*), resistance to IGF-1 (*IGF1R*), Bloom (*BLM*), Aarskog-Scott (*FGD1*) and Noonan (*SOS1*) syndromes (one each other). Twenty-eight patients without clinical suspicion and five patients with negative target analysis were selected to do genomic approaches. Among these patients, we diagnosed 27% (9/33) cases. Three patients had pathogenic CNVs and 6 patients had rare monogenic conditions: resistance to IGF1 (*IGF1R*), Microcephalic Osteodysplastic Primordial Dwarfism type II (*PCNT*), Centronuclear myopathy (*DNM2*), Baraitser-Winter (*ACTB*), Silver-Russell (*HMGA2*) and Hoyeraal-Hreidarsson (*TERT*) syndromes. **Conclusion:** A significant proportion of children born VLBW have a monogenic syndromic condition, with great heterogeneity of diagnoses including several rare conditions. The use of WES is an approach that allows the diagnosis of most cases, excluding patients with suspected epimutations defects.

PrgmNr 2612 - Lung Pathology in Takenouchi-Kosaki Syndrome: Expanding the phenotypic spectrum

View session detail

Author Block: **A. Ahmed**, R. Morgan, C. M. Oermann, I. Thiffault; Children's Mercy Hosp., Kansas City, MO
Disclosure Block: **A. Ahmed:** None.
Background: Takenouchi-Kosaki syndrome is a congenital malformation syndrome characterized by severe developmental delay, macrothrombocytopenia, camptodactyly, hearing loss and dysmorophic facial features associated with mutations in the *CDC42* gene. Lung pathology has not been previously described in the few cases that have been reported. **Case Report**: A female infant with past history of congenital heart disease, intestinal malrotation and developmental delay presented at 15 months of age with fever and respiratory distress. She was subsequently diagnosed with RSV bronchiolitis at 2 years of age. Work-up revealed chronic thrombocytopenia with giant platelets and immune deficiency with decreased numbers of T-lymphocytes and NK cells. Genomic sequencing from the patient and parents revealed the patient was heterozygous for a de novo pathogenic variant in *CDC42*, c.203G>A (p.Arg68Gln). She had frequent hospital admissions to intensive care for chronic respiratory distress, acute exacerbations and multiple episodes of viral infections. CT scan of the lung highlighted diffuse interstitial lung disease with prominent subpleural cystic changes. A wedge lung biopsy was processed for histopathology and ultrastructural morphology. There was diffuse interstitial fibrosis with patchy areas of chronic inflammation and emphysematous cystic changes. The dilated alveolar spaces displayed diffuse type II pneumocyte hyperplasia and increased alveolar macrophages. There was proteinaceous material associated with cholesterol clefts. Electron microscopy revealed many lamellar bodies, some of which showed electron dense deposits. Some lamellar bodies were abnormally small and dense and composite lamellar bodies were present. Although some of the lung pathology could be attributed to repeated infections, the presence of alveolar proteinosis, desquamative interstitial pneumonitis-like areas and ultrastructurally abnormal lamellar bodies suggested a surfactant deficiency disorder. The patient did not have any pathogenic variants in the known surfactant genes and other clinical and genetic features were more consistent with Takenouchi-Kosaki syndrome. **Conclusion**: This is the first case of the syndrome to be associated with severe chronic interstitial lung disease and morphologic surfactant abnormalities. The novel mutation site and the lung pathology further expand the genetic and phenotypic spectrum of this disease.

PrgmNr 2613 - Missense variants at a conserved 14-3-3 binding site in HDAC4 result in a novel intellectual disability syndrome

Histone deacetylases (HDACs) have a central role in the regulation of chromatin structure and gene expression in the eukaryotic cell. Disruption of their activity has been shown to cause a wide range of developmental disorders. Loss-of-function alleles of *HDAC4*, a class IIa deacetylase, have been reported in Brachydactyly-mental retardation syndrome (BDMR). Loss of HDAC4 function usually occurs as part of longer deletions of chromosome 2q37 and BDMR is also known as Chromosome 2q37 deletion syndrome. The precise role of HDAC4 within this phenotype remains uncertain. Eight unrelated patients with a novel phenotype distinct from BDMR and heterozygous *de novo* missense variants in *HDAC4* gene were identified. Common features in these patients include severe intellectual disability, epilepsy, swallowing difficulties, scoliosis and distinctive facial features. All eight have variants within a key regulatory site spanning residues 242-248 of HDAC4. This site binds to 14-3-3 proteins and regulates nucleocytoplasmic shuttling of HDAC4. Six individuals carried variants affecting Pro248, altering a key residue for 14-3-3 binding. Two patients carried variants p.(Thr244Lys) and p.(Glu247Gly) which were shown by immunoprecipitation assay to impair 14-3-3 binding. We propose that reduced 14-3-3 binding results in enhanced nuclear import, in turn leading to a novel gain-of-function effect. Two further individuals were identified with variants in the C-terminal region of *HDAC4*, in or immediately before the nuclear export signal (p.(Glu1049Lys), p.(Thr1055Lys)). Both patients have a similar phenotype, including severe developmental delay and intellectual disability. Our hypothesis is that these two variants give rise to a similar increase in nuclear HDAC4, as a result of impaired nuclear export. Overall these findings suggest that increased nuclear activity of HDAC4 is the underlying cause of a newly characterised developmental disorder.

PrgmNr 2614 - Molecular and clinical diagnosis of 17p11.2 microduplication described as Potocki-Lupski Syndrome: Case Report

View session detail

Author Block: **M. Mesa**[1], D. NuÃ±ez[2], C. Lattig[3], A. Lopez[4]; [1]Facultad de Med., Univ. de los Andes, BogotÃi D.C, Colombia, [2]Univ. de los Andes, BogotÃi D.C, Colombia, [3]Univ. de los Andes, Bogota, Colombia, [4]FundaciÃ³n Santa Fe de BogotÃi, Bogota, Colombia
Disclosure Block: **M. Mesa:** None.
Background: Potocki-Lupski Syndrome (OMIM #610883) is a rare genetic disorder that affects 1 in 25,000 people and is genetically associated with a heterozygous duplication at chromosome 17p11.2 that encompasses *RAI1.* This syndrome is autosomal dominant, but it has been reported that most cases arise from de novo mutations. Phenotypically, it presents as a developmental disorder characterized by congenital anomalies along with neurodevelopmental delays such as hypotonia, failure to thrive, mental retardation and pervasive developmental disorders, accompanied with growth hormone deficiency.
Case Presentation: We report the clinical and molecular characterization of a 13 year old girl with 17p11.2 microduplication associated with atypical autism spectrum disorder, mental retardation and renal agenesia. Initially, the patient was tested for Angelman-gene *UBE3A* (FISH) with a negative result due to a phenotype characterized by unmotivated laughs, stereotyped movements, and sleep disorder. The patient was evaluated by the CGH + SNP array which revealed chromosomic alteration consistent with a mosaic duplication of 3.6mpb in chromosome 17p11.2 that encompasses 61 genes compatible with Potocki-Lupski syndrome. It was until one year after her Potocki-Lupski Syndrome diagnosis, that her parents reported symptoms of urinary incontinence throughout her entire life and along with diagnostic images she was diagnosed with renal agenesia, so she was referred to other specialists to keep the follow up of her disease.
Discussion: Here we present a patient diagnosed with Potocki-Lupski Syndrome where molecular testing played a big role in the diagnosis and the further follow up of the patient. The patient was referred to other specialists along with clinical genetics to follow up her condition and give her the best type of care. Although, our patient was diagnosed at 13 years-old, it is important to start testing for chromosomic alterations along with other complementary tests in patients that present phenotypic anomalies as soon as possible to give them an interdisciplinary treatment in order to improve their symptoms and their quality of life.

PrgmNr 2615 - Automated variant classification workflows of known and novel variants can be used to maintain quality standards, support standardization and reduce turn-around times in a rare disease laboratory

View session detail

Disclosure Block: **H. Savage:** Salary/Employment; Congenica Ltd.
As demand for genomic testing increases, driven by greater accessibility and falling sequencing costs, variant analysts are encountering increasingly complex patients in addition to their routine cases. While increased access to testing is to be celebrated, the use of exome and genome testing for a wider range of disorders means variant interpretation is a key bottleneck, as even highly skilled and experienced analysts are not experts on all genes/disorders encountered. Yet this is the daily interpretation challenge we face.
Achieving a timely diagnosis has a huge impact on patients and their families; from providing answers to questions such as â□□why am I or my child different?â□□, to informing reproductive choice, providing access to support for patients, information about prognosis and early treatment leading to improved patient outcomes. However, the increased amount of time needed to familiarize analysts with novel genes and variants can increase turnaround times and may lead to delays in reporting results. With a finite workforce laboratories may face a situation where lack of resources for analysis of complex cases could lead to an extended diagnostic odyssey for patients and their families. This issue was recently confirmed in a survey of Clinical Laboratories which identified that 71% are at, or approaching, capacity.
Automated processes are commonplace in the diagnostic laboratory; from liquid-handling robotics to automated bioinformatics pipelines processing large volumes of data, however automated interpretation is yet to be widely adopted. As clinical variant analysis can take up 11 hours in just simple rare disease cases, with complex cases taking up to 16 hours, unsupported manual interpretation is not a scalable solution. Is it time to embrace automation of pre-classified variants, automated assignment of ACMG criteria to novel variants, and integration of powerful HPO-driven ranking algorithms to support timely diagnosis for even the most complex of patients?
Here I present the case for automating standardized analysis of cases to rapidly generate high quality, relevant results to support the diagnosis of patients with rare genetic disease, without compromising the diagnostic yield or quality of each analysis.

Rare diseases (RD) are estimated to affect between 3.2 and 13.2 million individuals in Brazil. The Rare Genomes Project (RGP) is a Brazilian initiative for whole genome sequencing (WGS) of patients with RD recruited from centers for rare diseases of the National Unified Health System (SUS). RGP initiated in 2020 and will sequence the genomes of 7755 patients with RD until the end of 2023, allowing the creation of the largest Brazilian genomic database of patients with RD and hereditary cancer. RGP also aims to study the clinical and social burden of RD in Brazil, provide valuable information for cost-effective national health policies for a population generally underrepresented in previous genomic studies and improve diagnosis, therapy, prevention, genetic counseling and the quality of life of patients. The ongoing project has recruited 1486 probands from nine centers of four out of five macroregions of the country. Among those, approximately 1300 have already had their genomes sequenced, and for 163 clinical reports were returned to attending physicians.The most prevalent disorders are neurological (n=402, average age:11.8 years), congenital malformations (n=376, average age:10.6 years), hereditary cancer (n=343; average age:45), inborn errors of immunity (n=145; average age:19.6 years) and clinical genetic syndromes (n=114; average age:10.9 years). Out of the 163 reports released, molecular diagnosis was established for 57 patients (34,9%). In 43 patients, no candidate variants were detected (26,38%). The remaining 63 (38,7%)patients presented variants of unknown significance (VUS) in heterozygous or homozygous state, heterozygous state for a recessive phenotype or pathogenic/likely pathogenic (P/LP) variants in heterozygous state and a VUS in the same gene for a recessive phenotype. Among the positive cases, the higher diagnostic rates were seen in the neurological (18 cases; 36%), clinical genetic syndromes (10 cases; 17.6%), inborn errors of metabolism (7; 12.3%), immunodeficiencies (5; 8.8%), and hereditary cancer syndromes (5;8.8%) cohorts. A total of 81 variants were detected in the 57 positive patients (67 SNVs and 14 large-scale CNVs/SVs), 69 (85.2%) being annotated as (P/LP) (57 SNVs and 12 CNVs/SVs). Interesting to mention that 112 positive cases (21.1%) had P/LP CNVs or SNVs in regulatory regions which would not be identified by whole exome sequencing (WES). In summary, the RGP is the largest rare disease sequencing effort in Brazil, and the preliminary results demonstrate a high diagnostic rate.

PrgmNr 2617 - Clinical relevance of the study of pigmentary mosaicism using genomic *array*

View session detail

Author Block: **Y. G. Gasparini**[1], M. M. Montenegro[1], A. M. Nascimento[1], V. T. Almeida[1], G. F. S. Carvalho[1], S. N. Chehimi[1], B. M. Wolff[1], M. S. Caravante[1], C. A. Kim[2], L. D. Kulikowski[1]; [1]Laboratorio de Citogenomica, Departamento de Patologia, Faculdade de Med. FMUSP, Univ.e de Sao Paulo, Sao Paulo, Brazil, [2]Inst da Crianca, Sao Paulo, Brazil
Disclosure Block: **Y.G. Gasparini:** None.
The mosaicism is a usual event in the world population and is defined by the presence of two or more genetically different cell lines in the same individual, providing for the same zygote. However, the identification and characterization of mosaicism is the big challenge of the area laboratorial medicine, because maybe the tissue canâ□□t reveal the variant in mosaicism. This is associated with mosaicism confined to tissue or pigmentary mosaicism, that constitutes a heterogeneous group of skin pigmentation alterations associated with multisystem involvement. Thus, the nuances of these clinical observations were prescient and resulted in the construction of several hypotheses based on the idea that the concomitant genomic alterations in different tissues could explain unusual patterns of phenotype within the same disease. We report on an eleven-year-old boy with mild intellectual disability, short neck, congenital cervical block, hyperchromic spots in Blaschko lines, JUP stenosis on the left, intestinal constipation, clinodactyly of the hands and enlarged halluces. We have collected samples from peripheral blood, saliva and skin fibroblasts. Results from cytogenetic analysis (GTG Band) performed in fibroblasts obtained from spots and peripheral blood were normal. Unexpected results from skin fibroblasts, peripheral blood and saliva using genomic array (cytoSNP850k-Illumina) revealed a pathogenic duplication in 17q21.31 in mosaic. The region that involving the duplication in 17q21.31 contemplate the two important genes, KANSL1 and KANSL1-AS1, that associated a Koolen-De-Vries syndrome (#610443) and 17q21.31 Duplication Syndrome (#613533) and in both is related the clinical phenotype similar to that presented by the patient is reported like as constipation intestinal, JUP stenosis, clinodactyly and mild intellectual disability. Our results highlight the importance of genomic arrays to investigate patients with pigmentary mosaicism to assess genomic variation among, and increasingly within, individuals and improve the genotype-phenotype correlations.

PrgmNr 2618 - Fold-back mechanism originating an inv dup del rearrangement in chromosome 15

View session detail

Author Block: **B. Burssed**, F. T. Bellucco, M. Zamariolli, B. P. Favilla, M. I. Melaragno; Div. of Genetics, Dept. of Morphology and Genetics, Univ.e Federal de SÃ£o Paulo, SÃ£o Paulo, Brazil
Disclosure Block: **B. Burssed:** None.
Inverted duplications associated with terminal deletions characterize a family of rearrangements known as inv dup del. Four mechanisms have been proposed to explain their formation and three of them lead to the appearance of a normal copy number region (spacer) between the two copies of the duplicated segment. In this study, we investigated a patient with facial dysmorphisms, underdeveloped nasal alae, micrognathia, hypothyroidism, hearing loss, hydrocephalus, and brachydactyly with an intra-arm rearrangement in chromosome 15q. Karyotyping and CytoScan HD Array (Affymetrix) revealed a de novo 19.5 Mb duplication and a 5.5 Mb deletion in 15q, as follows: arr[GRCh37] 15q24.3q26.2(77348331_96973582)Ã□3,15q26.2q26.3(96973928_102429040)Ã□1. Custom array (Agilent), with enrichment of probes from chromosome 15, was performed to determine the putative breakpoint with more precision and presented the following result: arr[GRCh37] 15q24.3q26.2(77338889_96963865)Ã□3,15q26.2q26.3(96966519_102263635)Ã□1. A normal copy number region was found between the duplication and the deletion for both catalog and custom arrays, with sizes of 346 bp and 2,654 bp, respectively. Long-range PCR revealed an inversion of the duplicated segment, and Sanger sequencing confirmed that the patient has an inv dup del(15q) with the presence of a 2,743-bp spacer. The breakpoint between the end of the spacer (chr15:96966212) and the start of the inverted duplication (chr15:96963469), which were much closer to the ones shown by the custom array than to the catalog array, presented four nucleotides of microhomology. Based on these results, we proposed that the rearrangement was formed through the Fold-back mechanism, in which a double-strand break leads to a 5' resection, which then exposes microhomologies in the 3' free end, allowing the chromosome to fold onto itself. This fold-back loop region that facilitates the intrastrand pairing within a sister chromatid corresponds to the spacer. DNA replication forms an unstable dicentric, which will later be broken to form the inv dup del chromosome. The precise determination of the genomic regions subjected to copy number variation enabled a better understanding of the patient's phenotype. Financial support: SÃ£o Paulo Research Foundation (FAPESP), Brazil.

PrgmNr 2620 - Incorporating a risk modifying SNP (rs143838139) to increase the detection of [2+0] carriers for Spinal Muscular Atrophy

View session detail

Author Block: **G. Ware**[1], C. Miller[1], D. Jones[1], m. avenarius[2]; [1]The Ohio State Univ., Columbus, OH, [2]The Ohio State Univ., Columbus, OH
Disclosure Block: **G. Ware:** None.
Spinal muscular atrophy (SMA) is an autosomal recessive motor neuron disease that most commonly presents in infancy with hypotonia. SMA is caused by biallelic inactivation of the survival motor neuron 1 (*SMN1*) gene, with most patients showing homozygous deletions and up to 10% showing one intragenic mutation and one deletion. The severity of this disease is inversely modified by increasing copies of *SMN2*, a hypofunctional paralog of the *SMN1* gene. Recently, SMN-enhancing therapies have become available and are linked to remarkable improvements in clinical presentation. With a prevalence of ~1 in 10,000 live births (carrier frequency of ~1:50), SMA is one of the most common severe childhood-onset diseases; therefore, current guidelines recommend SMA carrier screening before or during pregnancy. At our institution, we employ a competitive quantitative PCR method, including *SMN1* and *SMN2* standards and a co-amplified control gene. This gene dosage assay detects ~96% of all SMA carriers but not the remaining 4% of carriers who harbor two copies of *SMN1* arrayed in -cis. Although definitive detection of these [2+0] carriers is challenging, it has been noted that the c.*3+80T>G (rs143838139) variant is positively correlated with this chromosomal configuration the degree to which depends upon racial/ethnic background. Bayesian analysis is used to calculate the residual risk of being a carrier with counseling and paternal testing offered to those couples with higher risk. In July 2020, we enhanced our standard SMA carrier testing by adding detection of this risk-modifying SNP. Detection of this SNP relies on *SMN1*-specific amplification of intron 7, restriction digestion with HpyCh4III, and fragment sizing by capillary electrophoresis. Since implementing this enhanced assay, we have screened 1,117 patients. 21 (1.9%) patients tested positive for a single copy of *SMN1* and 163 showed the rs143838139 variant (14.6%). Among the latter group, 36 (22%) harbored two copies of *SMN1* and were reported as potential [2+0] carriers for SMA. The remaining risk-modifier positive patients (n=127) showed a range of *SMN1* copy numbers including 1 patient with 1 copy of *SMN1*, 98 patients with 3 copies of *SMN1*, and 28 patients with 4 copies of *SMN1*. At this time, the risk-modifying SNP is not informative for these individuals and was not reported for these patients. As allele frequency data is limited for this SNP, our study may contribute additional population-level genetic data to help increase the detection of carriers for SMA in other patient populations. Additionally, studies are ongoing to understand how our enhanced SMA carrier screen is utilized in clinical practice at our institution.

PrgmNr 2622 - The ACMG SF v3.0 gene list increases actionable variant detection by 25% over v2.0 in the ClinSeqÂ® cohort

View session detail

Author Block: **J. J. Johnston**, M-L. Brennan, K. B. Radenbaugh, S. Yoo, S. Hernandez, K. L. Lewis, A. Katz, T. A. Manolio, L. G. Biesecker; NHGRI, Bethesda, MD
Disclosure Block: **J.J. Johnston:** None.
Background: The American College of Medical Genetics and Genomics (ACMG) recommends interrogation of a minimum gene list for return of secondary findings from clinical exome and genome sequencing. The ACMG has recently released the third version of this list (ACMG SF v3.0) with the addition of 14 genes that meet the ACMG Secondary Findings Working Groupâ□□s requirements for actionability, severity, penetrance, and impact or burden of treatment and/or screening. These genes, known to be causative of disorders with defined phenotypes that are clinically actionable, are associated with cardiovascular (*TTN*, *FLNC*, *TRND*, *CASQ2*), cancer susceptibility (*PALB2*, *MAX*, *TMEM127*), inborn errors of metabolism (*GAA*, *BTD*), and other (*ACVRL1*, *ENG*, *RPE65*, *HFE*, *HNF1A*) phenotypes. **Methods:** To determine the additional variant yield in a cohort of unselected individuals we interrogated the ClinSeqÂ® cohort (~1450 individuals, 57% White, 32% African American or Black, 10% other) for variants in these 14 genes. We restricted our analyses to coding variants, +1,+2/-1,-2 splice site variants, and the pathogenic *GAA* variant, NM_000152.5:c.-32-13. Variants were assessed according to ACMG/AMP guidelines, including manual curation of 305 unique variants for evidence of pathogenicity. Forty-three individuals had potential loss of function variants in *TTN* (33 unique variants) which far exceeded the expected frequency based on the prevalence of dilated cardiomyopathy. Nineteen *TTN* variants in exons included in less than 80% of transcripts were excluded from the analysis. Another 11 *TTN* variants were excluded due to low coverage resulting in the variant being represented by a single paired-end read. **Results:** A total of 27 unique variants (in 185 individuals) were classified as pathogenic/likely pathogenic (P/LP). Nine individuals had P/LP variants identified in the heterozygous state in genes associated with disease with autosomal dominant inheritance, *FLNC* (1), *HNF1A* (1), *PALB2* (3), *TMEM127* (1), *TTN* (3). *HFE*, p.Cys282Tyr was identified in the homozygous state in four individuals. Seventeen P/LP variants (in 172 individuals) were identified in the heterozygous state in genes associated with disease inherited in an autosomal recessive pattern and were not considered for return. Excluding the four individuals with *HFE*, p.Cys282Tyr, which is known to be more common in individuals with European ancestry, the frequency of returnable P/LP variants did not differ by ancestry. **Conclusion:** Using the updated ACMG v3.0 gene list, the number of individuals with a returnable P/LP variant increased in the ClinSeqÂ® cohort by 25%, from 3.7% (n=53, ACMG SF v2.0) to 4.5% (n=65, ACMG SF v3.0).

PrgmNr 2623 - The knowns and unknowns: Challenges of Genes of Uncertain Significance in the era of high-throughput sequencing and lessons from Matching Tools

View session detail

Author Block: **I. Thiffault**[1], E. G. Farrow[2], C. Saunders[2], A. S. Cohen[3], J. Alaimo[1], F. Del Viso[1], V. Paolillo[1], T. Zion[1], S. Neal[1], T. Pastinen[3]; [1]Children's Mercy Hosp., Kansas City, MO, [2]Children's Mercy Hosp, Kansas City, MO, [3]Children's Mercy Kansas City, Kansas City, MO
Disclosure Block: **I. Thiffault:** None.
Gene-disease associations continue at a high rate in the era NGS testing. However, many genes lack sufficient evidence to be considered clinically-relevant. A scoring system for gene-disease associations was proposed by ClinGen, considering experimental/genetic evidence, such as the number of probands with compelling variants. Extremely rare variants, including de novo, in candidate genes may be implicated in disease, but are reported as â□□genes of unknown significanceâ□□ (GUS) in our center when evidence is lacking. In the context of a health system wide genomic medicine program Genomic Answers for Kids (GA4K) and our clinical NGS testing program at Childrenâ□□s Mercy, we performed a retrospective study of variants detected in GUS of all patients/families (>5000) tested for suspected genetic disorder. Since 2015, we submitted >550 GUS in GeneMatcher. The rate of GUS detection has significantly increased with ~ 3 GUS per week and an annual Matching tools-related publication rate of 10 manuscripts a year. We submitted >1 GUS in a subset of proband [â□¥2 (11%); â□¥3 (2%)] for which the variants were de novo and/or more than one genetic etiology were suspected. The variants included in this study are all absent or nearly absent from databases. More than 75% of the GUS were associated with de novo variant and only 2% were recurrent in unrelated families within our cohort â□□highlighting the need for data sharing. We experienced a high rate of â□□Matching hitsâ□□ (Nâ□¥10) only for GUS with de novo and/or loss-of-function variants. There is a positive correlation with the number of matching entries and the rate of publication. X-linked (XL) or autosomal recessive (AR) GUS (~25% of our entries) are underrepresented in Matching tools with an ~ 0-3 hits. Moreover, XL and AR hits had ~ 2.5 years length for functional characterization and publication. A subset of GUS (5%) are OMIM genes with novel phenotype/inheritance. The vast majority of our cohort were referred for neurological disorder with or without congenital anomalies (~75%). Many of the genes have only been reported in large autism cohorts where limited phenotypic information is available. The sharing of carefully vetted GUS, as in this study, is highly important to establish solid gene-disease relationships and molecular diagnosis. Thus, additional cases with phenotypic data are imperative to upgrade GUSs to disease causing status but also to expand phenotypic spectrum of known-OMIM genes. We propose that speed and yield of new gene discovery can be enhanced by additional methods of data sharing, which we are currently implementing via a registered access phenotype/genotype GA4K rare disease resource on a cloud-based PhenoTips platform.

PrgmNr 2624 - What does a 45,X karyotype add to 5p- syndrome literature?

View session detail

Author Block: **S. Chehimi**[1], V. Almeida[1], A. M. Nascimento[1], Y. G. Gasparini[2], G. S. Carvalho[2], B. M. Wolff[1], M. M. Montenegro[1], N. A. Assuncao[3], C. A. Kim[4], L. D. Kulikowski[5]; [1]Faculdade de Med. da Univ.e de SÃ£o Paulo, Sao Paulo, Brazil, [2]Faculdade de Med. da Univ.e de SÃ£o Paulo, SÃ£o Paulo, Brazil, [3]Escola Paulista de Med., Univ.e Federal de Saì□o Paulo, Sao Paulo, Brazil, [4]Inst da Crianca, Sao Paulo, Brazil, [5]Univ. de Sao Paulo, Sao Paulo, Brazil
Disclosure Block: **S. Chehimi:** None.
Rearranged chromosomes may often lead to distress in a genetic diagnosis. Some specific monosomies, such as in 5p- syndrome, with a well-described phenotype, may undergo undiagnosed when there are other autosomes or sexual chromosomes involved. Here we describe a rearrangement between chromosomes 5 and Y that could only be seen with the combination of different molecular techniques that characterized the chromosomes rearrangements. The patient investigated was 5-years old and presented with a normal male genitalia. The first molecular approach was the karyotype that indicated the result of 45,X. MLPA and FISH indicated that there were deletions in 5p and Yq probes with a positive SRY signal in 5p region (FISH result was 45,X.ish X(DXZ1+),der(5)(SRY+)). Array was a complementary molecular test that confirmed previous results and defined the size of the deletions (arr[GRCh37] 5p15.33p15.1(22149_17812007)x1; Yq11.21q12(14852740_59335913)x0). Gathering all the results, we have inferred that one of the pair of chromosomes 5 was derived from 5p- chromosome and Yq- chromosome and this rearrangement probably generated a stable dicentric derivative chromosome. We could only find two reports on patients with t(Y;5) and both were published more than 30 years ago (Vignetti et al., 1977; Weber et al., 1987) with no molecular characterization. Generally, microdeletions on the Y chromosome are associated with male infertility and azoospermia, but previous studies involving translocations between chromosomes 5 and Y do not point to any specific changes associated with the Y deletion (including reports mentioning normal external male genitalia and no other abnormalities). Previous studies also pointed to phenotypic characteristics commonly associated with 5p-, such as hypertelorism and micrognathia. In conclusion, we have observed that 5p- syndrome was already described in other rearrangements with different autosomes and chromosomes but this case is unique, so far, indicating the need for a complete molecular characterization to follow a proper genetic familiar counseling.

PrgmNr 2625 - *APOE4* increases astrocyte reactivity in cells with local European ancestry

View session detail

Author Block: **O. Oron**[1], J. P. Rodgers[1], Y. Akvan[1], M. L. Vasquez[1], K. Celis[1], K. S. Maddy[1], C. M. Chambers[1], B. E. Feliciano-Astacio[2], G. W. Beecham[1], M. L. Cuccaro[1], H. N. Cukier[1], M. Blurton-Jones[3], M. A. Pericak-Vance[1], J. M. Vance[1], D. M. Dykxhoorn[1]; [1]John P. Hussman Inst. for Human Genomics, Univ. of Miami Miller Sch. of Med., Miami, FL, [2]Univ. Central del Caribe, BayamÃ³n, PR, [3]Dept. of Neurobiology and Behavior, Univ. of California, Irvine, Irvine, CA

Disclosure Block: **O. Oron:** None.

Recently we demonstrated that local genomic ancestry (LA) drives the difference in AD risk between European (EU) and African (AF) carriers of *APOEÎµ4/4*. As a follow-up study using single-nuclei RNAseq, we found that AD *APOEÎµ4* homozygotes with EU Local Ancestry (LA) had a significantly increased *APOEÎµ4* expression compared to AD *APOEÎµ4* homozygotes with AF LA. In two of the EU LA brains, an astrocyte cluster which showed the highest *APOEÎµ4* expression was observed, also expressed a panel of genes consistent with A1 Reactive Astrocytes (A1RA). No such cluster was seen in the AF LA brains. A previous study in mice suggested *APOEÎµ4* maybe a contributor to A1RA development. We sought to explore the relationship of increased *APOEÎµ4* expression and A1RA using inducible Pluripotent Stem Cells (iPSC)-derived astrocytes.

iPSC lines were reprogrammed from PBMCs derived from one EU LA patient, and one AF LA patient, bearing the *APOEÎµ4/4* genotype. They were subsequently validated for pluripotency by Immunocytochemistry (ICC) of NANOG, SOX2 and OCT4, and genomic stability. Following differentiation into astrocytes, they were validated by GFAP and Î²S100 ICC. Upon maturity (Day 54 in-vitro), astrocytes were treated with either a cytokine cocktail (IL-1a, hTNFa, C1q) or overexpressed with *APOEÎµ4* by lentiviral transduction for 14 days (two replicates per line). mRNA was extracted and qPCR was performed to measure changes in *APOEÎµ4* and markers of A1RA (C3, GBP2, IFITM3). Astrocytes treated with the cytokine cocktail had a 100- and 600-fold increase in C3 in EU and AF LA astrocytes, respectively. Upon transgenic *APOEÎµ4* overexpression (OE), a significant increase in C3 was observed in the EU LA astrocytes, while no increase was observed in the AF LA astrocytes.

Our preliminary results support the hypothesis that APOEÎµ4 OE can increase the conversion of astrocytes to the toxic A1RA state in EU LA astrocytes. Additional EU LA and AF LA astrocytes are currently being investigated to further investigate this initial finding.

PrgmNr 2626 - A murine model lacking *Lyst* displays progressive neurodegeneration and recapitulates Chediak-Higashi Syndrome

View session detail

Author Block: **S. Greene**[1], J. D. Burke[1], E-R. Nicoli[2], M. Morimoto[2], P. M. Zerfas[3], L. Garrett[4], G. Elliot[4], C. Toro[5], W. A. Gahl[6], W. J. Introne[7], M. Malicdan[5]; [1]Human Biochemical Genetics Section, Med. Genetics Branch, NHGRI, NIH, Bethesda, MD, [2]Undiagnosed Diseases Program, Common Fund/ NHGRI, NIH, Bethesda, MD, [3]Diagnostic & Res. Services Branch, OD, NIH, Bethesda, MD, [4]Transgenic Mouse Core, NHGRI, NIH, Bethesda, MD, [5]NIH, Bethesda, MD, [6]NHGRI (NIH), Bethesda, MD, [7]NIH, Bethesda, MD

Disclosure Block: **S. Greene:** None.

Background: Chediak-Higashi Syndrome (CHS) is a rare autosomal recessive disease with congenital immunodeficiency, bleeding diathesis, partial oculocutaneous albinism, and progressive neurologic impairments that include parkinsonism, ataxia, and sensorimotor neuropathies. CHS is due to bi-allelic mutations in the lysosomal trafficking regulator gene (*LYST*), which encodes a 429-kDa protein. Patient-derived cells are noted to have enlarged lysosomes clustered in the perinuclear region, indicating LYST might be involved in lysosomal fusion or fission. Despite *LYST* mutations being recognized as the cause of CHS more than a decade ago, a knowledge gap remains on the exact function of LYST and how mutations in *LYST* cause CHS. This knowledge gap is likely due to several factors, including the absence of an animal model that faithfully recapitulates all aspects of CHS. **Methods:** We generated a knockout mouse model ($Lyst^{-/-}$) that lacks a functional murine *Lyst* homologue. Using CRISPR/Cas9 technology, we deleted exons 4-53, creating a *Lyst* knockout mouse model, $Lyst^{-/-}$. Phenotypic characterization was performed to establish the molecular, biochemical, and histological consequences of deleting the majority of the *Lyst* gene. We compared our results to the phenotype of the existing $Lyst^{bg}$/J, a spontaneous murine mutant that has a homozygous 3 bp deletion in the penultimate exon of the gene but lacks a robust neurologic phenotype. Extensive murine behavioral tests were employed, focusing on the neurological impairments in mice. **Results:** $Lyst^{-/-}$ mice are viable, present with lighter pigmentation of the coat and skin of the ears and tail, and exhibit prolonged bleeding times. Measurement of mRNA expression in multiple tissues revealed markedly reduced *Lyst* levels. Mouse embryonic fibroblasts from $Lyst^{-/-}$ mice depict enlarged, perinuclear lysosomes and polymorphonuclear leukocytes contain enlarged granules. $Lyst^{-/-}$ mice develop ataxia and declining motor coordination with signs of an intention tremor by 9 months of age, compared to the late onset of ataxia in $Lyst^{bg}$/J mice (17 months). Histologically, $Lyst^{-/-}$ mice show significant Purkinje cell loss at 12 months of age, and evidence of a progressive peripheral neuropathy from 3 months to 24 months of age. **Conclusions:** Our $Lyst^{-/-}$ model replicates many important aspects of the human CHS phenotype, most notably neurological manifestations that parallel the human disease. Our $Lyst^{-/-}$ mice represent a system on which to study the basis of neurodegeneration and explore the potential therapeutic efforts for this devastating disease.

PrgmNr 2627 - A splice site SNP in *Gabra2* is a modifier of *Scn8a* encephalopathy in the mouse

View session detail

Author Block: **W. Yu**[1], M. K. Mulligan[2], R. W. Williams[2], M. H. Meisler[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN
Disclosure Block: **W. Yu:** None.
De novo gain-of-function mutations of *SCN8A* are responsible for early onset developmental epileptic encephalopathy (OMIM #614558). Severely affected individuals exhibit refractory seizures, developmental delay, and cognitive disabilities, often accompanied by impaired movement. Patients carrying the same variant can differ in clinical course, suggesting a role for modifier genes in disease severity. We used a mouse model of the patient *SCN8A* mutation p.Arg1872Trp in the C57BL/6J strain background to screen for genetic modifiers by carrying out crosses with other inbred strains. In an F2 cross with strain SJL/J, we observed mice with increased age of seizure onset and prolonged survival. QTL analysis identified a modifier that mapped to an 15 Mb region of mouse chromosome 5 containing the *Gabra2* gene (Yu et al, *Epilepsia* 61:2847-2856, 2020). C57BL/6J mice carry a hypomorphic mutation at the exon 5 splice acceptor site of *Gabra2* that results in a 4x reduction of transcript abundance (Mulligan et al, *Front. Genet.* 10:188, 2019). Homozygosity for the hypomorphic C57BL/6J allele was associated with early seizure onset and shortened life span in the F2 mice. We have now confirmed *Gabra2* as the modifier gene by analysis of a cross with a corrected line of C57BL/6J in which the deleted T nucleotide at position -5 upstream of exon 5 has been replaced (Mulligan et al, *Front. Genet.* 10:188, 2019). Correction of the deletion restores transcript abundance and also restores the later age of seizure onset. *Gabra2* encodes the alpha2 subunit of the GABA receptor that provides inhibitory input to the axon initial segment of excitatory neurons. Reduced inhibitory input due to the hypomorphic C57BL/6J allele is consistent with elevated neuronal excitability and the enhanced seizure phenotype in homozygotes. The 'private' mutation of *Gabra2* in strain C57BL/6J could influence other studies of neurological phenotypes. There is a potential role for quantitative variation in human GABA receptor expression on the severity of genetic epilepsies as well as therapeutic interventions.

PrgmNr 2628 - Characterization of the genetic architecture of neurodevelopmental disorders using Duchenne Muscular Dystrophy as a model

View session detail

Author Block: **C. Samogy Costa**[1,2], L. Madanelo[2], E. Zachi[2], G. Yamamoto[2], A. Girardi[2], J. Y. T. Wang[2], E. Vadasz[3], G. Campos[1], A. C. Krepischi[1], M. Zatz[1,2], M. R. Passos-Bueno[1,2]; [1]Inst. de BiociÃªncias, Univ.e de SÃ£o Paulo, SÃ£o Paulo, Brazil, [2]Centro de Estudos do Genoma Humano e CÃ©lulas-Tronco, Univ.e de SÃ£o Paulo, SÃ£o Paulo, Brazil, [3]Inst. de Psiquiatria - Hosp. das Clinicas da Faculdade de Med., Univ.e de SÃ£o Paulo, SÃ£o Paulo, Brazil
Disclosure Block: **C. Samogy Costa:** None.
Duchenne muscular dystrophy (DMD) is a muscular disease caused by loss of function variants in the *DMD* gene. In addition to the muscle phenotype, neurodevelopmental disorders, such as intellectual disability (ID) and autism spectrum disorders (ASD) are more frequent among DMD individuals than in the general population. In this context, different studies have shown the relevance of rare variants of moderate effect in the genetic background for the manifestation and variability of NDDs, compatible with an oligogenic inheritance model. Our work aims to investigate whether mutations in *DMD*, associated with an accumulation of rare variants with moderate effect on neurodevelopmental genes, are responsible for the development of ASD and/or ID in these individuals. To achieve this goal, we are setting up a group of 57 DMD individuals for which ASD and ID were evaluated. Clinical evaluation was based on previous diagnosis, medical records, evaluation by a psychiatrist and/or Childhood Autism Rating Scale (CARS) and Raven's Progressive Matrices results. Whole exome sequencing was performed for two quartets and 10 trios (seven ASD/ID individuals and seven non ASD/ID DMDs) and rare exonic variants that reached minimum quality scores of coverage and allele balance were selected. Variant exclusion criteria included synonymous variants, nonsynonymous variants (CADD TRIO, *EBF3*, *CACNA1C* and *HEPACAM*. Two of them were classified as pathogenic variants based on ACMG guidelines and literature data (*HEPACAM* and *EBF3*), while only one variant was found in the Non-ASD DMDs (*CDK13*). Preliminary, these data suggest that ID and/or ASD-DMD individuals present a higher number of damaging variants in genes associated with neurodevelopment, compared to Non-ASD DMD individuals, suggesting the relevance of the genetic background for ASD/ID in DMD.
Financial support: CEPID/ FAPESP.

PrgmNr 2629 - Effects of somatic mutations on cellular differentiation outcomes and outlier behaviour in iPSC models

View session detail

Induced pluripotent stem cells (iPSC) are an important tool for disease modelling. In particular, they offer unique opportunities to study the cellular basis of developmental disorders, as cell types and lineages relevant to human neurogenesis can be accessed through differentiation. Combining pooled iPSC-based experiments with single-cell sequencing has helped to tackle some of the heterogeneity of in vitro differentiation systems and is a powerful design to compare wild-type and mutant cells. However, differentiation outcomes of individual cell lines remain variable and not well understood. We explored whether somatic mutations acquired during reprogramming might affect the capacity of iPSC lines to differentiate. We leveraged exome sequencing data from the HipSci Project, available for iPSC lines as well as the fibroblasts from which they were derived, and analysed differentiation outcomes from four published experiments using HipSci iPSCs: dopaminergic neurons (DN; n=352 lines), macrophages (n=102), sensory neurons (n=85) and endoderm (n=86). While the total burden of acquired somatic mutations was not associated with the ability of iPSCs to differentiate, we observed significant differences in burden at key developmental gene-sets (pi1>0.8), such as known developmental disorder genes (DDD, www.ddduk.org) and cancer-associated genes (COSMIC-Tier1), between lines that differentiated successfully or failed. We then analysed pooled scRNA-seq data from the DN differentiations (Jerber et al. 2021 Nat Genet), which includes cell-lines profiled at three time points (days 11, 30, 52). We found that cell-type composition differences between failed and successful lines were already observed at the progenitor stage (d11), yet again likely driven by expression differences in developmental gene sets modulating commitment towards DN. We also found that expression of such genes correlates with early progenitor abundance. In order to study the effects of known disease mutations, their effects need to be distinguishable from cell line outlier behaviour caused by other factors. To this end, we identified outlier cell-lines with abnormal patterns of differentiation in the DN single-cell dataset that did not show any shift on mutational burden compared to non-outlier cell lines. We are currently characterising the differentiation behaviour of seven iPSC lines with individual CRISPR-engineered knock-outs of known DDD genes included in the DN experiment. Our study constitutes the first attempt to assess the feasibility and constraints to detecting effects of pathogenic genetic variants in iPSC-based, pooled single-cell experiments.

PrgmNr 2630 - Pathogenic *SPTBN1* variants cause an autosomal dominant neurodevelopmental syndrome

SPTBN1 encodes Î²II-spectrin, the ubiquitously expressed member of the Î²-spectrin family that forms micrometer-scale networks associated with plasma membranes. Î²II-spectrin is abundantly expressed in the brain, where it is essential for neuronal development and connectivity. Previous studies have shown that mice deficient in neuronal Î²II-spectrin have defects in cortical organization, global developmental delay, dysmorphisms, and behavioral deficiencies. These phenotypes, while less severe, are observed in haploinsufficient animals, suggesting that individuals carrying heterozygous variants in this gene may also present with measurable compromise of neural development and function. In this study, we report the identification of *de novo SPTBN1* variants in 29 individuals as a cause of a neurodevelopmental syndrome characterized by global developmental, language and motor delays, mild to severe intellectual disability, autistic features, seizures, behavioral and movement abnormalities, hypotonia, and variable dysmorphic facial features. Twenty-eight unique variants were identified (one individual has two *de novo* variants in cis) of which 22 are missense, three are nonsense, and three are canonical splice-site variants. Missense variants in codons Gly205, Thr268, Arg411 and Arg1003 were identified in more than one individual. Using cell-based systems including heterologous cell lines, primary mouse cortical neuron culture, and human induced pluripotent stem cell (iPSC) lines reprogrammed from peripheral blood mononuclear cells (PBMCs), we show that these *SPTBN1* variants lead to loss-of-function, gain-of-function, and dominant negative effects that affect protein stability, disrupt binding to key protein partners, and disturb cytoskeleton organization and dynamics. We further investigated the molecular rationale for these observations using in silico molecular modeling. Lastly, we assessed Î²II-SpHet mice and the results suggest that Î²II-spectrin LOF impairs global development and has a selective impact on social motivation and reward that may contribute to the autistic features and social behavior impairments manifested in some affected individuals. Our studies define *SPTBN1* variants as the genetic basis of a neurodevelopmental syndrome, expand the set of spectrinopathies affecting the brain and neural development, and underscore the critical role of Î²II-spectrin in the central nervous system.

PrgmNr 2631 - Schizophrenia risk mediated by microRNA target genes in 22q11.2 deletion syndrome

View session detail

Author Block: **S. Ying**[1], Z. Zhang[1], R. K. Yuen[2], A. S. Bassett[3]; [1]Univ. of Toronto, Toronto, ON, Canada, [2]The Hosp. for Sick Children, Toronto, ON, Canada, [3]Univ of Toronto, Toronto, ON, Canada
Disclosure Block: **S. Ying:** None.
Background: 22q11.2 deletion syndrome (22q11.2DS) is associated with an over 20-fold increase in risk for schizophrenia. The 22q11.2 deletion region contains *DGCR8*, encoding a protein in the miRNA biogenesis pathway; global miRNA dysregulation imparted by *DGCR8* haploinsufficiency may play a role in mediating increased risk for schizophrenia. There is also evidence that rare genome-wide copy number variants (CNVs) increase schizophrenia risk in 22q11.2DS, and in the general population. We hypothesized that, within 22q11.2DS, in those with schizophrenia, there would be an enrichment of miRNA target genes that are overlapped by rare genome-wide CNVs.
Methods: We derived experimentally supported miRNA target genes (n=8464) from DIANA-TarBase, and obtained data available on rare genome-wide CNVs that overlapped genes in 22q11.2DS. We compared results for the miRNA target genes overlapped by these CNVs in 218 individuals with 22q11.2DS, with and without schizophrenia.
Results: Consistent with our hypothesis, among the 22q11.2DS cohort, we found a higher proportion of subjects in the schizophrenia group to have one or more miRNA target genes overlapped by a rare CNV (odds ratio (OR)=2.29, p=0.004). The miRNAs whose target genes contributed most to this differential target gene burden included miR-17-5p, miR-124-3p, and miR-342-3p, miRNAs with previous evidence for differential expression in 22q11.2DS experimental models and/or in schizophrenia and related neuropsychiatric disorders. Gene set enrichment results supported a role for miRNA target genes that belonged to several sets previously implicated for schizophrenia in the general population, including targets of FMRP and post-synaptic density (PSD)-related, when compared to all genes in the genome (FDR**Conclusion**: These data are the first to support a possible synergistic disruption of gene expression involving the target genes of dysregulated miRNAs and genome-wide rare CNVs as part of the complex mechanisms that increase risk for schizophrenia in 22q11.2DS. A comparable mechanism may be relevant to individuals with idiopathic schizophrenia and could therefore have implications for proposed novel miRNA-based therapeutics.

PrgmNr 2632 - Telomere length analysis in amyotrophic lateral sclerosis using large-scale whole genome sequence data

View session detail

Author Block: **A. Al Khleifat**, The Project MinE Consortium; Kingâ□□s Coll. London, London, United Kingdom
Disclosure Block: **A. Al Khleifat:** None.
Background Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by the loss of upper and lower motor neurons, leading to progressive weakness of voluntary muscles, with death following from neuromuscular respiratory failure, typically within 3 to 5 years. There is a strong genetic contribution to ALS risk. In 10% of cases or more, a family history of ALS or frontotemporal dementia is obtained, and the Mendelian genes responsible for ALS in such families have now been identified in about 80% of cases. Only about 14% of apparently sporadic ALS is explained by known genetic variation, suggesting that other forms of genetic variation are important. Telomeres maintain DNA integrity during cellular replication, differ between sexes, and shorten naturally with age. Gender and age are risk factors for ALS and we therefore investigated telomere length in ALS.
Methods: Samples were from Project MinE, an international ALS whole genome sequencing consortium that includes phenotype data. For validation we used donated brain samples from motor cortex from people with ALS and controls. Ancestry and relatedness were evaluated by principal components analysis and relationship matrices of DNA microarray data. Whole genome sequence data were from Illumina HiSeq platforms and aligned using the Isaac pipeline. We estimated telomere length by applying a bioinformatics analysis to the data. We tested the association of telomere length with ALS and ALS survival. **Findings**: There were 6,580 whole genome sequences, reducing to 6,195 samples (4,315 from people with ALS and 1,880 controls) after quality control, and 159 brain samples (106 ALS, 53 controls). Accounting for age and sex, there was a 20% (95% CI 14%, 25%) increase of telomere length in people with ALS compared to controls ($p = 1.1 \times 10^{-12}$), validated in the brain samples ($p = 0.03$). Those with shorter telomeres had a 10% increase in median survival ($p = 5.0 \times 10^{-7}$). Although there was no difference in telomere length between sporadic ALS and familial ALS ($p=0.64$), telomere length in 382 people with ALS due to expanded *C9orf72* repeats was less than in those without expanded *C9orf72* repeats ($p = 5.0 \times 10^{-4}$). **Interpretation:** Although telomeres shorten with age, longer telomeres are a risk factor for ALS and worsen prognosis.
Conclusions: It is likely that longer telomeres increase risk for ALS.

PrgmNr 2633 - Understanding the role of CLP1 in mammalian mRNA transcription and cleavage in neurodegeneration

Disclosure Block: **G. LaForce:** None.

Tight regulation of mRNA isoform expression is essential for neuronal development, maintenance, and function; however, the factors governing this process are largely unknown. We show the RNA kinase, CLP1, regulates mRNA isoform diversity through suppression of proximal transcription termination to promote expression of long mRNA isoforms. We generated human stem cell-derived motor neurons with CLP1 knockout, the motor neuron disease-associated CLP1 p.R140H variant, and the kinase-deficient CLP1 p.K127A variant, and performed transcriptome analyses. We identified distinct patterns of polyadenylation site usage resulting in imbalanced mRNA isoform expression of long genes important for neuronal development and function. We show similar mRNA misprocessing signatures in the CLP1 knockout and CLP1 p.K127A that differ from the CLP1 p.R140H, providing evidence that the disease-associated p.R140H allele exhibits toxic gain-of-function properties and kinase activity is required for CLP1 function in mRNA 3â□□-end processing. Together, these results identify a role for CLP1 in regulating mRNA isoform diversity and balance, of which perturbation causes broad transcriptional dysregulation and neurodegeneration.

PrgmNr 2634 - Wnt/beta-catenin pathway and cell adhesion deregulation in CSDE1-related intellectual disability and autism spectrum disorders

Among the genetic factors playing a key role in the etiology of intellectual disabilities (IDs) and autism spectrum disorders (ASDs), several encode RNA-binding proteins (RBPs). In this study, we deciphered the molecular and cellular bases of ID-ASD in a patient followed from birth to the age of 21, in whom we identified a de novo *CSDE1* (Cold Shock Domain-containing E1) nonsense variation. CSDE1 encodes an RBP that regulates multiple cellular pathways by monitoring the translation and abundance of target transcripts. Analyses performed on the patient's primary fibroblasts showed that the identified *CSDE1* variation leads to haploinsufficiency. We identified through RNA-seq assays the Wnt/Î²-catenin signaling and cellular adhesion as two major deregulated pathways. These results were further confirmed by functional studies involving Wnt-specific luciferase and substrate adhesion assays. Additional data support a disease model involving APC Down-Regulated-1 (APCDD1) and cadherin-2 (CDH2), two components of the Wnt/Î²-catenin pathway, CDH2 being also pivotal for cellular adhesion. Our study, which relies on both the deep phenotyping and long-term follow-up of a patient with CSDE1 haploinsufficiency and on ex vivo studies, sheds new light on the CSDE1-dependent deregulated pathways in ID-ASD.

PrgmNr 2635 - An epigenome-wide view of osteoarthritis in primary tissues

Osteoarthritis (OA) is a complex disease clinically characterized by chronic joint pain, stiffness and progressive deformity. Affecting more than 40% of people over the age of 70, OA contributes substantially to public health burden. Yet in spite of its high prevalence, there is no cure, and current treatment methods are limited to pain management and joint replacement. To promote the development of novel, efficient therapeutic approaches, it is first necessary to unravel the genomic architecture of osteoarthritis. Here, we investigate matched genotype and methylation profiles from macroscopically intact (low-grade) and degraded (high-grade) osteoarthritis cartilage, as well as synovium tissue from a total of 98 knee osteoarthritis patients undergoing joint replacement surgery.We conducted an epigenome-wide association study (EWAS) comparing matched low-grade and high-grade osteoarthritis cartilage within the same individual to identify methylation markers of cartilage degeneration. We further constructed random forest-based classifiers of cartilage degeneration. We generated genome-wide cis-methylation QTL (mQTL) maps in synovium, low-grade, and high-grade osteoarthritis cartilage. We used Mendelian randomization (MR) and colocalisation to identify epigenetic mechanisms mediating the effects of genotype on disease risk.The EWAS discovered 15,328 differentially methylated sites and 2,477 regions linked to cartilage degeneration. These regions were mapped to genes enriched in 76 Gene Ontology terms including a potential novel process linked to epithelium development. Using machine learning approaches, we derive methylation models of cartilage degeneration, which we validate with 82% accuracy in independent data. The mQTL analysis revealed widespread associations between genetic variants and methylation in all three examined joint tissues. Furthermore, mQTLs colocalised with 18 osteoarthritis-associated genetic loci, potentially elucidating their regulatory targets. Applying MR identified 19 methylation loci with a putative causal influence on osteoarthritis.In this study, we identify widespread epigenomic profile changes related to cartilage degeneration. We provide the first genome-wide map of mQTLs in knee OA affected tissues. This map enabled us to identify likely effector genes of GWAS signals, thus enhancing our understanding of the mechanisms underpinning disease development and progression in OA.

PrgmNr 2636 - Concurrence of Incontinentia pigmenti and thrombophilia increases the risk of Recurrent Early Pregnancy Loss

View session detail

Author Block: **M. V. Ursini**[1], E. Spinosa[1], M. B. Lioi[2], C. Casale[1], A. Pescatore[1], F. Fusco[1]; [1]IGB ABT CNR, Naples, Italy, [2]Univ. of Basilicata, Potenza 85100, Italy, Italy
Disclosure Block: **M.V. Ursini:** None.
Pregnancy loss, also referred to as miscarriage or spontaneous abortion, is generally defined as a nonviable intrauterine pregnancy up to 20 weeks of gestation. Here, we report the observation of recurrent miscarriages occurred in females with two diseases: Incontinentia Pigmenti (IP, MIM308300), a rare X-linked dominant disorder, and thrombophilia, an inherited disorder of blood clotting. The miscarriages are associated to both IP disease and thrombophilia. In IP the pregnancy loss in male fetus is due to the *NEMO/IKBKG* Loss of Function (LoF) mutations. In the thrombophilia it is due to hypercoaguable state which leads to arterial and/or venous thrombosis at the site of implantation or in the placental blood vessels.Three cases of IP females also suffered by thrombophilia. Two showed an history of Recurrent (>4) Early Pregnancy Loss (REPL) of both male and female fetus at less than 20 weeks of gestation. Each carried a different LoF mutation in exon 5 of *NEMO/IKBKG* gene (*c.523dup; c.646del; c.628_651insTG*). In addition, they carried mutations in genes of thrombophilia (Factor V Leiden_*FVL*, *MTHFR* mutation_*c.677C>T*, a prothrombin mutation_*G20210A* or *prothrombin II_PTII* mutation, or a protein S and/or C deficiency). Maternal comorbidities increase the risk of pregnancy loss. Thus we hypothesize that the co-occurrence of these two diseases in the same patient increases the risk of REPL. Here, we describe the IP and thrombophilic conditions and we perform genotype/phenotype correlation based on the genomic information of each patient to reveal shared genes and underlying functional systems. All patients belong to Incontinentia Pigmenti Genetic Biobank (IPGB; http://www.igb.cnr.it/ipgb/).

PrgmNr 2637 - Neonatal onset and severe complicated phenotype caused by heterozygous or homozygous new *ATL1* gene mutations

View session detail

Author Block: **A. Hamamie-Chaar**[1], M. Renaud[2], A-L. Bruel[3], C. Philippe[4], G. Banneau[5], V. Des Portes[6], N. Hadouiri[7], Q. THOMAS[8], L. Lambert[2], A. Hocquel[2], C. Disclosure Block: **A. Hamamie-Chaar:** None.

Hereditary spastic paraplegias (HSP) are clinically and genetically heterogeneous group of neurodegenerative diseases, characterized by a progressive spasticity of the lower limbs. Spastic paraplegia (SPG) A3 is the second most common form, mainly associated with an early age of onset, before the end of the first decade, and a pure phenotype. SPG3A is caused by heterozygous variants in *ATL1*, a gene which encodes atlastin GTPase 1.

One article has mentioned that autosomal recessive inheritance might exist.Indeed, Khan et al (2014) reported a large consangineous pakistani family with the segregation of a homozygous novel missense variant p.Arg118Gln in *ATL1* in six family members, affected by pure HSP, with no clinical signs in seven heterozygous carriers. We describe here two patients with an unusually neonatal onset and complex phenotype.

Patient 1 is a 6-year-old boy with severe axial hypotonia, dystonia and moderate spastic quadriplegia with a *de novo ATL1* mutation p.Lys406Glu detected by exome sequencing. He could not hold his head, he could not sit unassisted or walk, mobility required a wheelchair but he cannot use it himself. He also had swallowing disorders and was non-verbal. Intellectual abilities were difficult to assess was not affected. Patient 2 is a 7-year-old boy with spastic diplegia, cognitive impairment and epilepsy. He was not stable sit at 4yo, and he currently can only make few steps with human help. HSP panel gene revealed a homozygous novel mutation p.Arg403Glu. Probandâ□□s parents are consanguineous, they are asymptomatic and both carrier of the mutation at a heterozygous state.

In the literature, such severe clinical presentations are extremely rare. Regarding heterozygous patients, 3 mutations in *ATL1* (i.e., p.Pro344Ser, p.Met408Thr and p.Gly409Asp) resulted in very early-onset and severe complicated SPG3A. These codons were located in the linker or three-helix bundle region of atlastin 1. This part of the protein provides a structural basis for conformational changes and dimerization in homotypic ER membrane fusion. The patient 2 gives arguments in favor of a potential autosomal recessive inheritance, even if other patients should be described to confirm this hypothesis.

In conclusion, we report two further patients with neonatal onset HSP with complex phenotypes, both with heterozygous or homozygous *ATL1* variants. Further clinical descriptions will help defining the full clinical spectrum and mode of inheritance of *ATL1*-related phenotypes.

PrgmNr 2638 - Perturbation in hepatic lipid metabolism associated with altered TM6SF2 gene expression in HuH-7 cells

View session detail

Author Block: **A. Pant**[1], Y. Chen[1], A. Kuppa[1], X. Du[1], B. Halligan[1], E. Speliotes[1,2]; [1]Div. of Gastroenterology and Hepatology, Univ. of Michigan, Ann Arbor, MI, [2]Dept. of Computational Med. and Bioinformatics, Univ. of Michigan Med. Sch., Ann Arbor, MI

Disclosure Block: **A. Pant:** None.

Nonalcoholic fatty liver disease (NAFLD) is caused by accumulation of excess lipids in hepatocytes and can cause liver damage. Although NAFLD has become the leading cause of liver disease worldwide, few effective treatments exist for NAFLD making it a large unmet medical need. Genome wide association studies have identified strong association of NAFLD with non-synonymous E167K amino acid mutation in transmembrane 6 superfamily member 2 (TM6SF2) protein. The E167K mutation affects TM6SF2 stability and its carriers display increased hepatic lipids levels and lower serum triglycerides. While similar phenotype is evident in mice with TM6SF2 knockdown, effects of TM6SF2 on hepatic lipid metabolism is not completely understood. Here, we overexpressed wild-type or E167K variant of TM6SF2 or knocked down TM6SF2 expression in lipid-treated Huh-7 cells. We used biochemical assays, untargeted lipidomic analysis, RNAseq transcriptome analysis and high-throughput fluorescent imaging to determine changes in lipid metabolism and investigated molecular function of TM6SF2 in hepatocytes. Both knockdown and E167K overexpression increased acylglyceride levels which was decreased by wild-type TM6SF2 overexpression. Characterization of lipid droplets profile through high-content image analysis showed that overexpression of the E167K variant and TM6SF2 knockdown similarly affects lipid droplet phenotype to significantly increase the mean intensity while wild-type TM6SF2 had no effects. Although we did not see changes across lipid classes, we observed lipid chain remodeling for acylglycerides by TM6SF2 knockdown leading to a relative increase in species with shorter and more saturated side chains. Importantly, TM6SF2 knockdown and overexpression of wild-type TM6SF2 lead to significant changes in the abundance of several lipid species, including phosphoplipids, lysophospholipids, and acylglycerides. RNA sequencing revealed differential expression of several lipid metabolizing genes, including genes belonging to AKR1 family and lipases, primarily in cells with TM6SF2 knockdown. Taken together, our data shows that overexpression of TM6SF2 gene or its loss-of-function changes hepatic lipid species composition and expression of lipid metabolizing genes. Further, overexpression of E167K variant and TM6SF2 knockdown similarly increased hepatic lipid accumulation and lipid droplets profile further confirming a loss-of-function effect for variant. These results help us to understand how TM6SF2 and the E167K variant protect and promote NAFLD.

PrgmNr 2639 - Phenotypic Consequences of Variation in Elastin

View session detail

Author Block: **M. S. Williams**[1], A. Justice[1], M. A. Kelly[1], J. D. Green[1], R. Zaidi[1], B. A. Kozel[2]; [1]Geisinger, Danville, PA, [2]NIH, Bethesda, MD
Disclosure Block: **M.S. Williams:** Royalty(ies)/Honoraria; Prevention Genetics.
Introduction: Elastic fibers provide recoil to tissues that stretch, including the skin, blood vessels, and lungs. Haploinsufficiency for elastin (*ELN*) causes supravalvar aortic stenosis (SVAS OMIM#185500), characterized by arterial narrowing and stiffness, as well as hypertension, while missense changes in the C-terminal part of the gene lead to autosomal dominant cutis laxa (OMIM#123700). We hypothesize that variation in *ELN* may contribute more widely to connective tissue disease in the general population than is currently appreciated. Methods: Participants in the MyCode Community Health Initiative with exome sequence data were analyzed for common and rare sequence variation within *ELN*. ClinVar was interrogated for variants identified. In silico predictors were used to further identify variants of potential interest. Participants with variants of interest underwent dual chart review using a standardized abstraction tool that encompassed phenotypic findings in relevant organ systems (e.g. cardiovascular, pulmonary, renal). Reviewers were blinded to variant type. A Phenome-wide Association Study (PheWAS) was conducted with the participants carrying an *ELN* variant defined as cases and participants without an *ELN* variant defined as controls. Standardized and validated phenotypes (PheCodes) were developed and used for the analysis of electronic health records. Results: 115 living participants with a variant in *ELN* were identified from 145,000 MyCode participants. Roughly half of these had a variant (NM_000501.4:c.659C>T (p.Pro220Leu)) that has been annotated in ClinVar as likely pathogenic based on segregation of SVAS with the variant in several families. The other half had variants that were predicted to impact splicing. Chart review did not identify any patients with a diagnosis of SVAS or cutis laxa. 30 of the 115 participants (26%) had findings potentially consistent with elastinopathy, mostly related to vascular aneurysm. Conclusions: Preliminary analysis suggests that variation in *ELN* contributes to disease affecting elastic tissue function beyond classic phenotypes. Further studies will include expanding sequence analysis to 180,000 participants, PheWAS, enhancing variant annotation, functional variant analysis, and deep phenotyping.

PrgmNr 2640 - Saturation-scale functional evidence supports clinical variant interpretation in Lynch Syndrome

View session detail

Author Block: **A. Scott**[1], F. Hernandez[2], C. Horton[2], A. C. Chamberlin[2], X. Jia[1], S. Jayakody[1], B. Bharathi Burugula[1], T. Pesaran[2], E. C. Chao[2], R. Karam[2], J. Kitzman[1]; [1]Dept. of Human Genetics, Univ. of Michigan, Ann Arbor, MI, [2]Ambry Genetics, Aliso Viejo, CA
Disclosure Block: **A. Scott:** None.
Lynch Syndrome (LS) is a cancer predisposition syndrome affecting more than 1 in every 300 individuals worldwide. Tumorigenesis in LS is driven by germline loss-of-function variants in DNA mismatch repair (MMR) genes. Clinical genetic testing for LS can be life-saving but is complicated by a large burden of variants of uncertain significance (VUS), especially missense changes. We previously applied deep mutational scanning to measure functional effects for >94% of the 17,746 possible missense variants in the key LS gene *MSH2* (Jia et al, *AJHG*, 2021). Here, to establish the clinical validity of these functional data, and demonstrate their utility in large-scale variant reclassification, we overlaid them on clinical databases comprising >15,000 individuals with MMR gene variants detected by paired tumor and germline testing at a clinical genetic testing laboratory. To gauge the strength of evidence provided by our functional data, we curated a list of *MSH2* germline missense variants previously classified as Pathogenic (N=23) or Benign (N=26) as controls. To avoid redundant application of evidence, these validation variantsâ classifications were derived without use of any functional data. Our functional measurements agreed with the clinical interpretation for all 49 variants. Following recommendations for application of the functional evidence criterion using the ACMG/AMP variant interpretation framework (Brnich et al, *Genome Med*, 2019), our *MSH2* function map can be used with PS3/BS3 evidence codes given its observed strong concordance with these prior clinical interpretations. We next identified 720 standing VUS missense variants in *MSH2*. While most of these are predicted to have a neutral impact on gene function, 29 (4.0%) scored as deleterious in our function map, consistent with previously published rates among other cancer predisposition genes. We are pursuing reclassification for these variants, combining functional evidence with family history and tumor characteristics consistent with Lynch Syndrome. Additionally, in addition to retrospective VUS reclassification, to date these functional data have enabled resolution of five newly detected missense *MSH2* VUSs. High-throughput assays for mismatch repair loss of function provide a scalable method for VUS resolution, and serve as strong evidence criteria for variant classification.

PrgmNr 2642 - Spatial analyses of complement factor genes in AMD: Clarifying known genetic relationships and creating prediction models

View session detail

Author Block: **E. Palmer**[1], S. de Jong[2], M. Grunin[1], B. Jin[1], D. C. Rinker[3], C. Moth[3], J. A. Capra[4], W. S. Bush[5], J. L. Haines[5], A. den Hollander[6], IAMDGC; [1]Case Western Reserve Univ., Cleveland, OH, [2]Radboud Univ. Med. Ctr., Nijmegen, Netherlands, [3]Vanderbilt Univ., Nashville, TN, [4]Univ. of California San Francisco, San Francisco, CA, [5]Case Western Reserve Univ, Cleveland, OH, [6]Radboud Univ Nijmegen MC, Nijmegen, Netherlands

Disclosure Block: **E. Palmer:** Salary/Employment; CVS/Aetna.

Age-related macular degeneration (AMD) is the leading cause of blindness worldwide. Variants in complement factor genes are known risk factors for AMD, and potential therapeutic targets. Therefore, identifying if a given patient has a functional variant in one of these genes could aide in disease treatment stratification. Here, we incorporated protein 3D spatial context into interpretation of rare missense variants from the HRC-imputed International AMD Genomics Consortium (IAMDGC) dataset, containing 16,144 cases and 17,832 controls. We applied our protein spatial statistics algorithm (PathProx) to characterize variants that are more proximal to known AMD risk variants than observed presumed neutral variants from gnomAD. To evaluate the effect of rare missense variants on protein stability, we also calculated each variantâ□□s predicted free energy change (ddG). Variants proximal to known AMD variants or with a ddG>|2| were retained for gene-based testing using seqMeta. We also performed an orthogonal protein-based test that uses a structural kernel method (Pokemon) to identify spatial patterns of variants associated with case-status. Nominal p-values of 0.05 were considered significant in all tests. Finally, given the availability of protein expression data from cell *in vitro* experiments of *CFI* missense variants, we created a binary variable indicating if the variant caused a reduction in expression to C9, *CFH*, and *CFI*; ddG identified *CFI*, with *CFH* also suggestive of a possible association (p=0.051); Pokemon identified *C9*, *CFB*, *CFH*, and *CFI*. Finally, our model predicting a reduction in CFI protein had an area under the curve (AUC) of 0.76, thereby outperforming the model using CADD scores which had an AUC of 0.69. We have demonstrated that AMD risk variants in complement genes cluster within protein structures. This information may be useful in building predictive models that classify variants identified in AMD patients as benign or pathogenic. Further, we have shown that computationally predicted stability via ddG is a better indicator of a variantâ□□s potential to impact protein expression of CFI than CADD scores. Future work iterating bench validation and model training will allow us to identify which protein disruptions are most critical. This in turn will inform therapeutic development and enhance efforts to rapidly identify and validate the pathogenicity of novel variants identified in AMD patients.

PrgmNr 2643 - A network-based deep learning framework translates GWAS and multi-genomics findings to pathobiology and drug discovery for Alzheimerâ□□s disease

View session detail

Author Block: **J. Xu**[1], F. Cheng[1,2,3]; [1]Genomic Med. Inst., Lerner Res. Inst., Cleveland Clinic, Cleveland, OH, [2]Dept. of Molecular Med., Cleveland Clinic Lerner Coll. of Med., Case Western Reserve Univ., Cleveland, OH, [3]Case Comprehensive Cancer Ctr., Case Western Reserve Univ. Sch. of Med., Cleveland Clinic, OH

Disclosure Block: **J. Xu:** None.

Human genome sequencing studies have identified numerous loci associated with complex diseases, including Alzheimerâ□□s disease (AD). Translating human genetic findings (i.e., Genome-wide association studies [GWAS]) to biological mechanisms and therapeutic discovery, however, remains a major challenge. To address this critical problem, we present a **net**work **t**opology-based deep learning framework to identify disease-**a**ssociated **g**enes (NETTAG). NETTAG is capable of integrating multi-genomics data along with the protein-protein interactome to accurately infer likely risk genes and potential drug targets impacted by GWAS loci. Specifically, we leverage non-coding GWAS loci effects on expression quantitative trait loci (eQTLs), histone-QTLs, and transcription factor binding-QTLs, enhancer and promoter regions, open chromatin, and promoter flanking region from GTEx, NIH RoadMap and FANTOM5 databases.The key premises of NETTAG are that the disease risk genes: i) exhibit distinct functional characteristics compared to non-risk genes and therefore can be distinguished by their aggregated genomic features, and ii) converge to a limited number of pathobiological pathways captured by the human protein interactome. Via applying it to the latest AD GWAS data, we identified a set of likely risk genes (e.g., *APOE*, *BIN1*, *IL6* and *PICALM*) that are consistent with leading pathophysiological hypotheses of AD. NETTAG-predicted risk genes are: (1) significantly enriched in multiple AD-related pathobiological pathways; (2) more likely to be differentially expressed in single-nuclei RNA-sequencing data of AD patient brains in cell type-specific manners (including disease-associated microglia and astrocytes); and (3) are enriched in drug targets with available approved medications. In summary, our findings suggest that understanding of human pathobiology and therapeutic development could benefit from a network-based deep learning methodology that utilizes GWAS findings under the multimodal genomic analyses and the human protein interactome model. From a translational perspective, if broadly applied, the network-based deep learning tools could minimize the translational gap between genetic/genomic findings and precision medicine, is a significant challenge in genomic medicine.

PrgmNr 2644 - A pipeline for the identification of rare variants in multigenerational families with high prevalence of complex disorders

View session detail

Author Block: **E. RodrÃguez**, G. Chavarria-Soley, H. Raventos; Univ. de Costa Rica, San JosÃ©, Costa Rica
Disclosure Block: **E. RodrÃguez:** None.
Genome-wide association studies have been widely used for the identification of common variants associated with various diseases, however these variants only explain a small portion of the inheritance in complex diseases.
On the other hand, studies with extended pedigrees are valuable for the identification of novel rare variants that are transmitted to affected individuals. This rare variants are considered important factors for complex diseases.
However, many of the possible novel rare variants are usually filtered out by various tools whose filtering processes prioritize the permanence of known variants over unknown variants, minimizing the number of false positives but generating high rates of false negatives.
Here we aim to establish a practical pipeline that favors the identification of high-quality rare variants for germline variants calling in multigenerational families with high prevalence of complex disorders. The pipeline was tested using 114 WGS from members of a large multigenerational Costa Rican family with a high prevalence of complex psychiatric phenotypes. In addition, to reduce the needs of computational infrastructure, as well as execution times, a specific interval was applied in which the *Disrupted in schizophrenia 1* (*DISC1*) gene is located. This gene is found in a region in which a balanced chromosomal translocation t(1;11)(q42.1;q14.3) was previously reported linked to schizophrenia and psychosis in a Scottish family.
As a result, the pipeline allows to carry out a call for common and rare variants for genetic studies in multigenerational pedigrees with complex disorders, applying best practice procedures, genotypic refinement by pedigree and filtering of variants that prioritize the identification of high-quality rare variants.
Once the variants have been obtained and identified, they are available for later analysis in an association study.

PrgmNr 2645 - Aberrant splicing prediction across human tissues

View session detail

Author Block: **N. Wagner**[1], M. Ã□elik[2], F. HÃ¶lzlwimmer[1], V. YÃ©pez[1], C. Mertes[1], H. Prokisch[3], J. Gagneur[1]; [1]Technical Univ. of Munich, Garching, Germany, [2]Univ. of California Irvine, Irvine, CA, [3]Helmholtz Zentrum Muenchen, Neuherberg, Germany
Disclosure Block: **N. Wagner:** None.
Aberrant splicing is a major cause of genetic disorders but its direct detection in transcriptomes is limited to clinically accessible tissues such as skin or body fluids. While DNA-based machine learning models allow prioritizing rare variants, their performance on predicting tissue-specific aberrant splicing remains unknown. Here, we generated the first benchmark dataset for aberrant splicing prediction by applying the aberrant splicing caller FRASER [1] on 6,931 RNA-seq samples from 48 human tissues from the GTEx dataset, comprising 5 million rare variants in paired genotype data from 635 individuals. At 20% recall, state-of-the-art DNA-based models [2,3] cap at 2% precision. We constructed a tissue-specific splicing map (SpliceMap) by mapping and quantifying tissue-specific splice site usage genome-wide and modeling isoform competition. Using SpliceMap together with state-of-the-art DNA-based models increased precision by ten fold. Integrating RNA-sequencing data of clinically accessible tissues brought precision to 50%. Furthermore, we developed tissue-specific aberrant gene expression predictors with similar performance by leveraging that aberrant splicing often results in nonsense mediated decay. These findings, replicated in an independent cohort, substantially contribute to non-coding loss-of-function variant identification and have implications for non-invasive genetic diagnostics design and analytics.

PrgmNr 2646 - Analysis of 5â□□UTR Variation in Rare Disease Patients Reveals Variants of Potential Disease Relevance

View session detail

Author Block: **B. Bowles**[1], R. Olson[2], S. Senum[3], C. Schmitz[2], K. Clark[4], P. C. Harris[3], E. Klee[2]; [1]Mayo Clinic Dept. of Clinical and Translational Sci., Rochester, MN, [2]Mayo Clinic Ctr. for Individualized Med., Rochester, MN, [3]Mayo Clinic Polycystic Kidney Disease Discovery Lab., Dept. of Biochemistry and Molecular Biology, Rochester, MN, [4]Mayo Clinic Dept. of Biochemistry and Molecular Biology, Rochester, MN

Disclosure Block: **B. Bowles:** None.

Correct diagnosis is imperative to treating patients with idiopathic, suspected genetic conditions, yet current sequencing approaches leave up to 70% of these patients undiagnosed, significantly complicating both their medical care and genetic counseling. These remaining undiagnosed patients often suffer protracted diagnostic odysseys as they seek effective treatment. Variants within the 5â□□ untranslated region (UTR), particularly in upstream open reading frames (uORFs) that can act as regulatory elements, represent an especially under-examined source of disease. uORFs are short regions, typically 30bp - 600bp, that influence downstream gene translation through a variety of mechanisms, such as sequestering ribosomes or initiating nonsense-mediated decay of their associated mRNA. uORFs are present upstream of an estimated 54% of human transcripts. To better understand the range of human uORF variation and to evaluate the feasibility of uORF analysis as a part of clinical sequencing workflow, we retrospectively analyzed whole exome sequencing (WES) results from 469 idiopathic rare disease patients and 129 polycystic kidney disease (PKD) patients, as well as panel based sequencing results for an additional 979 PKD patients. We annotated sequencing files with variant interpretation information from a variety of sources, including population allele frequency, Combined Annotation Dependent Depletion (CADD) score, and evolutionary conservation score, and applied two deep learning tools to predict variant impacts on transcript ribosome load (TITER and FramePool). Our pipeline identified a median of 5 variants per patient that were predicted to have a deleterious impact on protein translational efficiency. These variants create new uORFs out of frame with the downstream coding sequence (CDS), are predicted to create N-terminal extensions in frame with the downstream CDS, or alter the function of existing uORFs. From these results, we have identified 5â□□UTR variants of uncertain significance upstream of *CTNND1*, *DPF2*, *HEPACAM*, *HSP90B1*, *NOTCH2*, *OTOF*, and *SMARCC2*, which have a potential role in initiating or modifying patient disease. This work demonstrates that analysis of 5â□□UTR variants can be incorporated into existing WES pipelines, and identifies a subset of variants with potential significance to patient disease. Further experimental evidence is necessary to ascertain the pathogenicity of these variants.

PrgmNr 2647 - Characterization of complex genomic rearrangements detected with long reads sequencing: two chromothripsis cases

View session detail

Author Block: **Y. Duffourd**[1], s. verdez[2], C. Martin[1], L. Faivre[3], C. Philippe[4], T. Christel[1], N. Chatron[5], S-B. Caroline[6], P. Callier[7], D. Sanlaville[8], A. Vitobello[9]; [1]CHU DIJON - INSERM U1231, DIJON, France, [2]CHU Dijon, Dijon, France, [3]Hosp d' Enfants, Dijon, France, [4]Ctr. Disclosure Block: **Y. Duffourd:** None.
Background: Genome sequencing (GS) and especially long reads sequencing (LRS) become the efficient approach to identify complex rearrangements involving multiple breakpoints and low complexity regions. In order to test this method, we choose to study cases of chromothripsis, which is a brutal chromosome rearrangement involving multiple chromosomes. To characterize each complex events consecutive to chromothripsis, we choose to reconstruct the sequence of derivative chromosomes using a hybrid pipeline involving long reads and short reads sequencing.
Method: We deployed 30X short reads GS and 20X SMRT sequencing (Pacific Biosciences) to resolve complex SV in 2 patients with syndromic intellectual disability. Three others samples from same LRS batch were used for filtration. We established a new pipeline using information provided by frequency, depth and genomic phase to filter breakpoints identified by long-reads. We used Dnarrange[1] pipeline to analyze the position and sequences at breakpoints (BPs). Retained BPs were independently validated by PCR, Sanger sequencing, fluorescent in situ hybridization (FISH).
Results: We obtained 1794 and 1652 BPs for the first and the second patient respectively. After filtration we narrowed that list to 263 and 210 respectively. Dnarrange-link reconstructed 29 and 27 pieces of derivative chromosomes. We confirmed eight BPs by PCR and Sanger sequencing nine sequences involving 24 blocks with FISH.
Conclusions: This pipeline allowed us to filter, analyze and reconstruct the sequence of derivative chromosomes, highlighting 180 blocs involving chromosomes 3, 10, 12 for the first patient and 115 blocks involving chromosomes 4, 11, 13, 14, 15, 21 for the second patient. Overall the combination of short reads GS and LRS permitted to characterize structural variation at single nucleotide resolution with a small number of samples.

PrgmNr 2648 - Improved detection of allele-specific expression using Personalised ASE Caller (PAC)

View session detail

Author Block: **A. Saukkonen**[1,2], H. Kilpinen[3,2,4], A. Hodgkinson[1]; [1]Molecular and Med. Genetics, King's Coll. London, London, United Kingdom, [2]UCL Great Ormond Street Inst. of Child Hlth., Univ. Coll. London, London, United Kingdom, [3]Helsinki Inst. of Life Sci., Univ. of Helsinki, Helsinki, Finland, [4]Wellcome Sanger Inst., Cambridge, United Kingdom
Disclosure Block: **A. Saukkonen:** None.
A key finding in complex trait genetics is that most variants associated with disease are in non-coding regions of the genome and overlap significantly with variants modulating gene expression, thus making a strong case for the role of gene regulation in disease. On a population scale, variants influencing gene expression are identified through expression quantitative trait loci (eQTL) mapping, but this is not possible in cases where sample sizes are small, or variants are rare. For this reason, the detection of an imbalance in the expression of two alleles within a gene (allele specific expression, ASE) is potentially more informative about genes that are undergoing genetic regulation in *cis*, but detection of these events needs particular care, since technical features such as RNA-seq mapping biases can lead to false positives.
Here, we present a mapping and filtering pipeline, Personalised ASE Caller (PAC), that minimises errors in ASE detection through multiple steps incorporating better phasing of genetic data utilising RNA reads, parental genome mapping, reallocation of multi mapping reads, selecting optimal mapping parameters and incorporating haplotype level information. We apply PAC to simulated data and show that it assigns reads more accurately and in higher numbers than standard single genome mapping and other â□□gold standardâ□□ ASE methods, particularly in genomic regions close to indels and other genetic variants. We also use PAC to quantify ASE in population level data, using 670 whole blood samples from the GTEx project. Within these data, we find that ASE signals recapitulate eQTL effect sizes well, and the correlation between allelic fold change (aFC) measured from ASE and eQTL data is higher using PAC compared to standard mapping and other ASE methods. PAC is a standalone pipeline written in Nextflow and is available to use via https://github.com/anna-saukkonen/PAC

PrgmNr 2649 - MRSD: a novel quantitative approach to predict tissue-specific feasibility of RNA-seq in the investigation of splicing diversity

Hosp. Southampton NHS Fndn. Trust, Coxford Rd, Southampton, United Kingdom, [6]Faculty of Med., Univ. of Southampton, Duthie Building, Southampton Gen. Hosp., Tremona Road, Southampton, United Kingdom

Disclosure Block: **C. Rowlands:** None.

Background: RNA-seq is a highly powerful technology allowing the examination of the transcriptomic landscape in individual tissues or cell types. It may, for example, allow discernment of key changes at the transcript level between cells in healthy and diseased states, or unstressed and stressed states. However, few resources exist to allow researchers to identify which genes and transcripts can be feasibly investigated in a given tissue.

Aims: To develop an approach that quantifies, for a given tissue, the experimental feasibility of using RNA-seq to investigate given genes or transcripts. Further, to develop an online resource through which these predictions can be accessed and visualized.

Methods: We leveraged publicly-available RNA-seq datasets generated through the Genotype-Tissue Expression (GTEx) project to derive a novel metric, the minimum required sequencing depth, or MRSD, for all human genes genome-wide. For a given tissue, MRSD represents the number of uniquely mapping RNA sequencing reads required to yield a user-specified level of coverage of a given transcript or splice junction.

Results: We evaluate that MRSD predicts transcript coverage from the RNA sequencing depth of a given sample with a high positive predictive value (90.1-98.2%, dependent on parameters). Through cross-referencing with human disease genes listed in the Genomics England PanelApp gene panel repository, we also demonstrate that, for 58.0% of Mendelian disease genes, a sequencing depth of 100 million RNA-seq reads or fewer is likely to be sufficient to observe the majority of pathogenic mis-splicing events in at least one of three tissues: whole blood, lymphoblastoid cell line (LCL) and skeletal muscle. Finally, we have created an online portal that allows users to rapidly query lists of genes or variants of interest and receive a prediction for the minimum RNA sequencing depth required to scrutinize their features of interest.

Conclusions: We have developed a robust predictive metric that will allow researchers to make informed decisions about the likely feasibility of RNA-seq-based analyses at the level of individual genes and transcripts, and across all manner of research questions. We anticipate that integration of MRSD scores into experimental planning will reduce redundant sequencing runs and improve the efficiency of transcriptomic investigations.

PrgmNr 2650 - Re-genotyping and tool combinations improve detection accuracy of Copy Number Variants in Whole Genome Sequencing data

View session detail

Author Block: **E. Iovino**, D. Paola, M. Seri, P. Tommaso; Univ. of Bologna, Bologna, Italy
Disclosure Block: **E. Iovino:** None.

Copy Number Variants (CNVs) are defined as the duplication (Dup) or deletion (Del) of DNA material larger than 50bp. Although CNVs are a clinically important class of genomic variation, their detection is known to be highly affected by different factors, such as the sequencing coverage, the size of the event and the underlying reference sequence structure (e.g. segmental duplications and/or DNA repeats). With the growing use of Whole Genome Sequencing (WGS) in the clinical setting, >70 tools for the detection of structural variants, including CNVs, have been developed; however, none of them achieves good call accuracy over the entire spectrum of CNV sizes and types (duplications/deletions), displaying false positive rates as high as 89%.The combination of different approaches is therefore indicated as a solution to increase accuracy, but there is currently no clarity on how several tools should be used together. Here, we evaluated the impact of combining different state-of-art tools and variant re-genotyping on achieving high call accuracy for high-coverage WGS data from 1KG NA12878 sample. To this end, we chose five tools (Delly, ERDS, Lumpy, Manta, Svaba) based on different detection methods (split-reads, read-depth, paired-reads, de-novo assembly) and previously assessed to be among the best performing approaches (Kosugi et al., 2019). We performed re-genotyping of CNVs with assigned PASS filter using SV2 and subsequently merged variant calls from each of the tools with SURVIVOR. We assessed False Positive (FP) and True Positive (TP) rates for re-genotyped as well as non re-genotyped variants called by each tool independently and for each of their combinations, using the call-set by Kosugi et al., 2019 as a gold-standard. We observed that successful re-genotyping (SRG;Dels=2998, Dups=487) improves power to discriminate between TP and FP calls both for deletions and duplications: 84% and 71 % SRG Dels (n=2534) and Dups (n=347), respectively were TP, against only 22 % Dels and 7% Dups with failed re-genotyping (FRG; Dels= 7169, Dups=9849). TP SRG rate increases to 90 % Dels and 80% Dups if large CNVs (> 50 kb) and each tool exclusive calls were excluded. As for FRG Del calls, but not Dups, TP rate rises to 83% by combining at least four tools. However, no difference was noticed between FRG CNVs larger and smaller than 50 kb. Our results suggest that SRG/FRG and tool combination may represent valuable parameters for increasing detection accuracy of small/medium (50 kb) CNVs identified in WGS data.

PrgmNr 2651 - A large-scale cohort metagenomic study of the Brazilian miscegenated population: building gut microbiome profiles of healthy and unhealthy individuals

View session detail

Author Block: **G. M. Novo-Filho**[1], G. F. S. Carvalho[1], E. A. Zanardo[1], G. S. Lemos[1], M. A. Zonta[1], G. A. Janaudis[1], L. D. Kulikowski[2,1]; [1]INSIDE RESEARCH AND DEVELOPMENT DIAGNOSTICS S.A., Sao Paulo, Brazil, [2]Univ. de Sao Paulo, Sao Paulo, Brazil
Disclosure Block: **G.M. Novo-Filho:** None.
The human organism hosts a wide variety of microorganism species that, through a mutualistic interaction, can provide biological advantages. The set of species of microorganisms that composes a given microbiota, what is called microbiome, is highly adaptable to nutrition and individual health status. Thus, microbiome profile studies can be used as a marker for quality of life and individual clinical condition. However, since the environment is one of the factors associated with the microbiome variability, population characteristics must be considered in individual and large-scale metagenomic studies. Thus, we sequenced the 16S gene (V3/V4 region) of fresh stools samples form 449 patients in a large-scale cohort metagenomic study, aiming to build a gut microbiome profile from healthy and unhealthy Brazilian population. Individuals with any clinical complaint or pre-diagnosed clinical condition, including diarrhea, dyspepsia, celiac disease, ulcerative colitis, Crohn's disease and others, were included in the non-healthy group (NH), while individuals with no complaints nor pre-diagnosed diseases were included in the healthy group (H). Thereafter, we compared the average representation of the great phylum in both groups. We identified a significant variability in the average proportion of 4 large phylum between the H and NH groups. The greatest variability occurred between the Firmicutes (F) and Bacteroidetes (B) phylum, with 2.10 of F/B ratio in the H group and 1.56 in the NH group. Furthermore, in the healthy group we identified a greater abundance of the Actinobacteria phylum in relation to the Verrucomicrobia phylum, whereas in the non-healthy group there is a greater abundance of Verrucomicrobia. Increased abundance of Proteobacteria phylum, which includes several inflammatory species, is broadly associated with an unhealthy microbiota, however, in this study, the abundance of this phylum between the H and NH groups was similar, suggesting that Brazilian population characteristics may influence increased abundances of bacteria in the Proteobacteria phylum even in healthy individuals. The average phylum representation in a gut microbiome study can be used as a marker for individual health status. In addition, metagenomic tools may allow a better follow-up of the clinical course and effectiveness in the treatment of patients with different clinical conditions.

PrgmNr 2653 - High yield depletion for an RNA-seq application using an innovative benchtop platform for workflow automation and miniaturization

View session detail

Author Block: **S. Aguilar**; INOREVIA, Paris, France
Disclosure Block: **S. Aguilar:** None.

Massively parallel sequencing of RNAs has unlocked the study of the transcriptome, enabling genome wide transcriptional profiling. While mRNAs are of great interest as they encode for proteins, they make up only 3-5% of total RNAs, with the majority (80%) comprising ribosomal RNAs (rRNAs). Therefore, RNA-seq applications face the challenge of efficiently enriching mRNA species prior to library preparation. To improve transcriptomic applications, Magelia, a disruptive automated multi-OMICs platform combines patented technologies for sample and reagent volume reduction, and efficient bead manipulation.Here, we have evaluated the advantages of using the platformâ□□s rRNA depletion application for RNA-seq. Equal amounts of human control total RNA were treated in parallel manually and in the Magelia for rRNA depletion using Illuminaâ□□s Ribo-Zero Plus rRNA Depletion Kit. After depletion, treatment in the platform allowed us to recover 3x more mRNAs. This impacted library preparation, where 10x more sequencing ready material was recovered for samples treated in the instrument. Importantly, sequencing revealed superior depletion for the instrument treated samples as 27,5x less rRNA reads were counted. As the control RNA used for the study was extracted from a well characterized cell line, the Harmonizome database was used to identify highly transcribed genes across studies. All top 20 expressed genes were identified in the top 15% of transcription levels, corroborating the biological validity of these data. Finally, more gene fusion events were detected in samples treated in the platform, emphasizing the improved level of enrichment achieved with this benchtop solution. This multi-OMICs platform provides unprecedented transcriptome resolution by improving rRNA depletion levels, this, with a 5x reagent volume reduction. Harnessing the strengths of its patented technologies, this depletion solution has also been recently applied to provide unprecedented resolution into a bat virome study in collaboration with researchers of the University of Chile. Fully automated RNA-seq library preparation is currently being validated downstream of this depletion application. This adds to the platformâ□□s ever-growing portfolio of NGS applications, including WGS library preparation with up to 50x DNA input reduction when compared to kitâ□□s limits. In addition to significant hands-on time reduction, the platform provides a smart combination of miniaturization and automation. This unique combination of benefits puts the platform in a unique position to become the leader in miniaturized sample preparation for modern biology and medicine.

Disclosure Block: **C. Fernandez-Rozadilla:** None.

Colorectal cancer (CRC) is the third most commonly diagnosed cancer. Despite recent success of genome-wide association studies (GWAS) and discovery of common genetic variants in over 150 loci associated with CRC risk, much of the heritable risk and the biology underpinning CRC susceptibility remain unexplained.

To gain additional insights into CRC genetics, we conducted a GWAS meta-analysis totalling 100,204 CRC cases and 154,586 controls of European (73% of total) and East Asian (27%) ancestry. We identified 46 new loci associated with CRC risk at PWe therefore integrated the gene expression and methylation data from 1,077 and 488 samples of normal colorectal mucosa from 6 in-house datasets plus the transverse colon data from the Genotype-Tissue Expression (GTEx) project v8 into GWAS summary statistics to perform transcriptome- (TWAS) and methylome-wide association studies (MWAS). TWAS analyses identified 136 candidate risk genes, of which 18 at 11 loci lay over 1Mbp away from a GWAS-identified risk SNP, and were thus considered novel. Conditional TWAS analyses showed these 11 loci to be independent of GWAS SNPs and identified a further 2 genes independent of a GWAS locus within 1Mb. Likewise, MWAS analyses identified 15 CRC-associated CpGs annotated to 11 new risk loci previously undiscovered by GWAS or TWAS.

TWAS and MWAS have successfully identified 24 novel CRC susceptibility regions, highlighting the potential of multiomic data for discovering missing heritability. Moreover, TWAS and MWAS also provide a list of candidate genes to test for causal effects on disease risk, and this may be helpful for identifying new relevant CRC molecular pathways. We identified novel candidate target genes linked to microbiome, insulin pathway, hyperlipidaemia, and prostaglandin metabolism, which could lead to new drug targets for chemoprevention.

PrgmNr 2655 - Lipid pathway signatures discriminate subgroups linked to race/ethnicity in metabolomic and proteomic analysis from the TOPMed Study

View session detail

Author Block: **M. Sevilla**[1], A. K. Manning[1], K. D. Taylor[2], TOPMed Diabetes Working Group, TOPMed Multi-Omics Working Group; [1]Massachusetts Gen. Hosp., Boston, MA, [2]The Lundquist Inst. for BioMed. Innovation, 1124 W. Carson Street, Torrance, CA 90502, Torrance, CA
Disclosure Block: **M. Sevilla:** None.
The advent of omics studies offers an unparalleled opportunity to understand the processes involved in the development of complex diseases. Insights from diverse study samples are necessary to understand health disparities but omics profiles correlated with race/ethnicity or ancestry could be caused by environmental exposures or differences in allele frequencies. The objectives of this study were to identify and describe metabolomic and proteomic profiles that correlate to race/ethnicity or ancestry in two multi-ethnic cohorts from the NHLBIâ□□s TOPMed Study. Studying 2,398 individuals with proteomic and metabolomic data from the Multi-Ethnic Study of Atherosclerosis (MESA) and Womenâ□□s Health Initiative (WHI) cohorts, we defined both cohort-reported race/ethnicity subgroups and ancestry subgroups derived from allele differences linked to continent-specific haplotypes. Our labels were African-American (AA), East Asian (EA), European (EU), and Hispanic (HS) for the cohort-reported race/ethnicity subgroups. We used Orthogonal Projection to Latent Structures of Discriminant Analysis (OPLS-DA) to identify the proteomic or metabolomic profiles that distinguished each subgroup from the rest of the sample. We then used pathway analysis for the biological classification of these signatures. The metabolomic profile of the AA subgroup was characterized by both high carbon-number and low double-bond Diacylglycerols (DAGs) and Triacylglycerolâ□□s (TAGs) without any significant pathways, whereas the EA subgroup was characterized by high carbon-number and high double-bond DAGs and TAGs implicating the glycerophospholipid pathway (q=0.03). The same pathway was highlighted in the EU subgroup (q=0.03). The HS subgroup profile was also characterized by Phosphatidylethanolamines (PEs). We found more significant metabolites in the MESA cohort compared to WHI, but remarkably almost all of the metabolites identified in the WHI cohort were identified in the MESA cohort. Proteomic signatures that showed good discriminatory capability and were unique to a subgroup were Ephrin-A4 in the AA subgroup, and Lymphotoxin b R and Ephrin-A5 in the EA subgroup, and Transgelin-2 in the EU subgroup. Our results suggest that lipid profiles comprised DAGs, TAGs, and PEs are signatures of our subgroups. Such signatures could be important to understand health disparities but also could be included in models linking genetic variants and omics values to complex diseases to leverage larger sample sizes and correct for potential confounding due to these subgroup signatures.

PrgmNr 2656 - MED13L knockout in cerebral organoids disrupts retinal gene expression regulation

View session detail

Author Block: **J. Ghoumid**[1,2], R. Ziffra[2], D. Laboy Cintron[2], J. Sige[1], N. Ahituv[3]; [1]ULR7364 RADEME, Univ. of Lille, Lille, France, [2]Dept. of Bioengineering and Therapeutic Sci., Univ. of California San Francisco,, San Francisco, CA, [3]Dept. of Bioengineering and Therapeutic Sci., Univ. of California San Francisco, San Francisco, CA
Disclosure Block: **J. Ghoumid:** None.
The Mediator is a large coregulator complex conserved from yeast to human, taking part in the recruitment of RNA Polymerase II. It has emerged as a master coordinator of development and cell lineage determination through interactions with various transcription factors and epigenetic regulators. Mediator Complex is organized into four modules, i.e. Tail, Middle, Head, and the kinase-module. In vertebrates, the kinase-module comprises four proteins: CDK8, CCNC, MED12, and MED13, or their respective paralogs: CDK19, MED12L, and MED13L. Rare variants of the genes encoding this module have been linked to human neurodevelopmental disorders.
We developed a *MED13L*-knockout cerebral organoids from hIPSc (human Induced Pluripotent cells). We characterized *MED13L* KO and wild-type cerebral organoids through gene expression and chromatin accessibility analysis at the single-cell level.
We found in wt cerebral organoids, development of mature cortical neurons of both upper and deep layers (*BCL11B*, *SATB2*), glutamatergic and GABAergic neurons with apparently functional synapses (*GRIA1*, *GRIA2*, *GABRB3*). In *MED13L* KO cerebral organoids, gene expression analysis revealed that *MED13L* knockout led to a retinal commitment, with robust expression of retinal markers (*RAX*, *VSX2*) and photoreceptors (*USH2A*). Combining single-cell chromatin accessibility data allowed identification of co-accessible pairs of DNA elements, connecting regulatory elements to their putative target genes. Comparatively to the wt cerebral organoids, we found in the *MED13L* KO cerebral organoids a larger number of accessible regulatory elements driving high expression of genes critical for retinal development, including *PAX6*, *NEUROD1*, and *VSX2*. Basing on these data, *MED13L* is probably critical in the negative control of early genes inducing a retinal fate. This mechanism is likely to be critical to allow a proper cortical commitment to the developing neurons.

PrgmNr 2657 - Same role but different actors in the genetic regulation of post-translational modification of two distinct proteins

View session detail

Post-translational modifications (PTMs) are ubiquitous mechanisms used by cells to diversify and extend their protein functions beyond what is dictated by the genome. While PTMs are known to be involved in regulating almost all cellular events, genetic regulation of PTMs themselves has not been extensively investigated. Protein glycosylation, one of the major PTMs, has been linked to the ageing process and a wide variety of diseases, ranging from rheumatoid arthritis, type 2 diabetes, Crohnâ□□s and Parkinsonâ□□s disease to cancer. Nevertheless, genetic regulation of glycosylation is yet not fully understood. In this study, we compared for the first time the genetic regulation of the same post-translational modification of two distinct proteins -glycosylation of transferrin and immunoglobulin G (IgG). By performing genome-wide association analysis of transferrin glycome, we identified 10 significantly associated loci (P MGAT5, ST3GAL4, B3GAT1; IgG - *MGAT3, ST6GAL1*) as well as shared associations (*FUT6, FUT8*). Colocalization analyses of the latter suggest that distinct causal variants in FUT genes regulate fucosylation of the two proteins. We propose that these variants affect the binding of different transcription factors in different tissues, with fucosylation of IgG being regulated by IKZF1 in B cells and fucosylation of transferrin by HNF1A in liver. Uncovering the genes responsible for transferrin glycosylation and comparing them with those underlying IgG glycosylation, our results are beginning to unravel the genetic regulation of glycosylation, one of the most common PTMs. We show that both unique and shared genes are involved in glycosylation of two proteins, and suggest that different underlying causal variants in the same gene are regulating glycosylation of distinct proteins in a tissue-specific manner.

PrgmNr 2658 - Understanding the genetic contribution to neuroinflammatory cell traits using iPSC-derived microglia

View session detail

Author Block: **M. Perez-Alcantara**[1], Y. Chen[1], S. Washer[2], J. Steer[1], D. Ebner[3], S. Cowley[2], G. Trynka[1], A. Bassett[1]; [1]Wellcome Sanger Inst., Hinxton, United Kingdom, [2]William Dunn Sch. of Pathology, Oxford, United Kingdom, [3]Target Discovery Inst., Nuffield Dept. of Med., Oxford, United Kingdom

There is mounting genetic evidence, both from common and rare variants, that implicates microglia in neurodegenerative disease. Microglia perform various immunological functions in the brain as sentinels, housekeepers and mediators of neuroinflammatory response: these include cellular signalling, migration and phagocytosis. Our aim is to assess how these cellular functions might be perturbed in neurodegenerative disease (particularly Alzheimerâ□□s but also Parkinsonâ□□s, amyotrophic lateral sclerosis and frontotemporal dementia), and the genetic contribution to these phenotypes. To achieve this, we will examine the role of neurodegeneration-associated variants and loci in the gene expression and cellular phenotypes of iPSC-derived microglia differentiated *in vitro*. We will perform pooled differentiations towards microglia of iPSCs from ~250 donors from the human pluripotent stem cell initiative (hipSCi), as well as candidate gene KOs and disease relevant mutant lines on isogenic background. This will be followed by phenotyping (for functions such as phagocytosis and chemotaxis) and single cell RNA-seq (scRNA-seq) to assess gene expression. Finally, we will perform expression and phenotypic Quantitative Trait Locus (QTL) mapping and colocalization with common variants identified by genome-wide association studies of neurodegenerative traits, with the aim of linking these variants to their target genes.We are improving the *in vitro* microglia maturation protocols to achieve cells more phenotypically and transcriptomically similar to primary microglia. Phenotyping protocols are adapted for pooled designs (10-20 donors/pool) e.g. with FACS-based outcomes and whole genome sequencing followed by deconvolution of donor identity for phenotypic QTL analysis. Expression QTL analysis of pooled microglia (using established methods such as tensorQTL) will be performed on scRNA-seq from microglial subpopulations under resting and stimulated (e.g. with LPS) conditions, to map the transcriptomic changes that occur during immune response. We will also perform a targeted single cell CRISPR KO screen and phenotyping of known and candidate disease-relevant mutants highlighted by previous prioritization studies. Finally, a subset of phenotypic assays will be applied to a genome-wide CRISPR screening to identify more genes involved in microglial processes.

Disclosure Block: **H. Hou:** None.

Background: RNA sequencing (RNA-seq) has the potential to improve our ability to interpret the functional and clinical significance of the genetic variants identified by Whole Exome Sequencing (WES) and Whole Genome Sequencing (WGS). A cohort of 134 pediatric patients with heterogeneous phenotypes collected through the SickKids Genome Clinic (Centre for Genomic Medicine) underwent testing by gene panels, microarray, and subsequently WGS. This resulted in the identification of pathogenic or plausibly causative variants in 44% of the samples. In this study, we set out to assess the utility of blood RNA-seq for the diagnosis of patients with diverse clinical indications and develop an interpretation schema to identify candidate genes.
Methods: We developed a clinical-grade, automated, scalable, and robust end-to-end RNA-seq library preparation platform capable of processing up to 96 samples at one time. We generated whole-blood RNA-seq from 134 individuals using this automated RNA-seq platform. Using a bioinformatics pipeline that incorporates various published tools and custom scripts, we identified expression outliers, aberrant splicing events, and allele-specific expression. We then took a disease gene-centric interpretation approach to identify clinically relevant transcriptional aberrations.
Results: Despite samples being archived for >3 years, we were able to generate good-quality RNA-seq data from all samples. With a median sequencing depth of 115M, we detected >70% of genes in curated genes panels related to phenotypes observed in our cohort. We identified expression outliers and/or aberrant splicing events in clinically relevant genes in 23.1% (31/134) blood RNA-seq data from our patient cohort. Specifically, we found RNA evidence supporting previously identified genetic variants in 30.5% (18/56) patients and proposed candidate genes in 16.6% (13/78) cases with negative WES/WGS findings. For example, we identified a known Joubert syndrome gene CEP120 as a decreasing expression outlier that contained a deep intronic splicing alteration in a patient with global developmental delay, abnormality of brain morphology, and dysmorphic facial features.
Conclusion: Our results support the use of clinical blood RNA-seq to facilitate genome diagnostics in pediatric patients with diverse phenotypes.

PrgmNr 2660 - *de novo* variant calling identifies cancer mutation profiles in the 1000 Genomes Project

Detection of *de novo*â¯variants (DNVs) is critical for studies of disease-related variation and mutation rates and have been shown to occur at 50 to 100 DNVs per individual per generation. In developing a GPU-based workflow to expedite DNV calling, we applied the 602 parent-child sequenced trios from the publicly available 1000 Genomes Project as a set of controls. The DNA that was used for whole-genome sequencing from these individuals was derived from lymphoblastoid cell lines (LCLs). We detected 445,711 total DNVs with a bimodal distribution of DNVs, having a first peak at approximately 200 DNVs per child and a second peak at 2,000 DNVs. While the DNA from these individuals may contain cell line artifacts, these artifacts are propagating additional DNVs every cell passage, implying that the controls are not static. Evidence to support this finding include reduction in DNVs at CpG sites and in percent of DNVs with a paternal parent-of-origin with increasing number of DNVs. Detailed assessment of individual NA12878 across multiple genome datasets from 2012 to 2020 reveals increasing number of DNVs over time. Mutation signature analysis across this control set revealed individuals had either 1) age-related, 2) B-cell lymphoma, or 3) no prominent signatures.â¯ Additionally, clinically-relevant DNVs associated with twelve diseases were identified in individuals in this cohort. We also applied the DNV GPU workflow to 4,216 parent-child trios from the Simons Simplex Collection (SSC) with DNA derived from blood. This was in contrast to the 1000 Genomes dataset with DNA from LCLs. When testing our approach on the SSC data, we saw the expected results confirming the quality of our DNV workflow. The average DNV count was 78 per individual in the 4,216 trios. We also saw that an average of 18.3% of the DNV sites were found at CpG sites across the trios, which is close to the expected 20%. Our approach allows for fast and accurate detection of DNVs, which is especially important when analyzing large disease datasets, such as when studying autism. Our approach also shows that cell line artifacts present in lymphoblastoid cell lines are not always random but rather are associated with cancer mutation profiles with important implications for use of the variant data as a control.

PrgmNr 2661 - Building a predictive matrix model for autism genotype-phenotype associations

View session detail

Author Block: **E. Sams**, T. N. Turner; Dept. of Genetics, Washington Univ. Sch. of Med., St. Louis, MO
Disclosure Block: **E. Sams:** None.
Characterizing the structure and function of the human genome in association with phenotypic presentation at the molecular and organismal level is critical for advancing our understanding of human health and disease. In this study, we constructed a predictive matrix model for genotype-phenotype associations using previously collected genotypic and phenotypic data. The genetic event used to build this model is the presence of a copy number variant (CNV) in the 16p11.2 region. Recurrent CNVs in this region are strongly associated with autism and other developmental disorder phenotypes. The relevant data was obtained from the Simons Foundation Autism Research Initiativeâ□□s (SFARI) Simons Searchlight Project cohort of families affected by a 16p11.2 CNV. This cohort contains probands as well as affected and/or unaffected family members and thus includes both *de novo* and inherited 16p11.2 CNVs. The genotype section of the matrix for each sample was constructed by listing the copy number for each of the 52 genes in the 16p11.2 critical region using coordinates for CNVs confirmed by two technologies (microarray and whole exome sequencing). Every sample in the matrix also received a score indicating if they are diagnosed with autism or other related developmental disorder phenotypes, including coordination disorder, intellectual disability, and behavioral disorders. In addition to this 16p11.2 model, a genome-wide matrix was built in which the copy number for every protein coding gene in the genome was recorded for each sample. Both the 16p11.2-specific and genome-wide matrices were statistically analyzed to determine which factors decisively distinguish individuals with autism from those without. This analysis revealed that autism diagnosis is more commonly associated with 16p11.2 deletions than duplications or no 16p11.2 CNV. Analysis of the matrices also unveiled a key distinction: while autism diagnosis prediction using the 16p11.2 matrix is driven by the related developmental phenotypes, prediction using the genome-wide matrix is driven by the copy number of genes in the 16p11.2 region. It is our hope that this prototype model can be utilized in the clinic for additional phenotypes and disorders arising from genetic variants.

PrgmNr 2662 - CoverageMaster: a clinical grade and user oriented copy number variant caller

Copy number variation (CNV) is the most frequent structural alteration in the human genome. Aberrant number of copies of specific genes or genomic regions (deletion: 0 or 1 copy, gain: >2 copies) are known to be implicated in pathogenic conditions such as Mendelian diseases and cancer. In clinical applications, while advances in next generation sequencing (NGS) have provided a standardized way for accurate coding variant analyses through whole exome sequencing (WES), CNV detection still relies on probe-based methods, such as array Comparative Genomic Hybridization (array CGH) and Multiplex Ligation-dependent Probe Amplification (MLPA). These technologies are complementary to NGS approaches in clinical diagnostics but limited array CGH resolution, poor MLPA scalability and additive costs are pushing for WES to become the primary strategy for identifying CNVs. However, WES technical issues such as lack of continuity of the target regions and biases due to the hybridization processes made it difficult so far to standardize a procedure for CNV detection. In particular, current WES based methods for CNV calling suffer from high false positive rates and reduced sensitivity for micro CNVs (

PrgmNr 2663 - Highly sensitive transcriptomic-based pooled CRISPR screening on 1 million cells enabled by spatial molecular imager

Broad Inst., Cambridge, MA, [4]NanoString Technologies, Seattle, WA
Disclosure Block: **S. Spisak:** None.
Pooled single-cell CRISPR-based screens present a powerful strategy to functionally link regulatory elements to their target genes. To date, most screens rely on readouts that can be robustly measured, such as proliferation and strong transcriptional responses. Measuring individual transcripts would be an ideal readout; however, accurate measurement of transcripts of interest at single cell resolution remains challenging.
Droplet and flow cytometry technologies coupled with next generation sequencing have been extended to detect mRNA and CRISPR guide (gRNA) sequences from the same cell for perturbation studies; however they tend to work optimally for high-expressing transcripts and for perturbations affecting pathways, limiting its broad applicability. Moreover, dropout rates impact efficiency and cost. Here, we describe a novel method using SMI (spatial molecular imaging), which precisely and quantitatively measures gRNAs and transcripts of interest within the same cell. This method is not restricted to polyadenylated transcripts and can accurately measure medium- and low-expressing transcripts at single cell resolution with throughput of hundreds of thousands to one million cells per experiment.
Methods: We performed pooled CRISPR-based screens by targeting an androgen receptor (AR) enhancer in the LNCaP prostate cancer cell line using SMI to investigate performance characteristics. LNCaP-modified lines were transduced by two gRNA pools (enhancer-targeting, positive/negative controls). AR and related target gene levels (N=37) were measured by SMI in a million cells and RT-PCR.
Results: Using SMI, we demonstrated quantitation of gene expression for AR and related target genes on over 90% of the cells analyzed (**Conclusion:** SMI enables simultaneous visualization of gRNA and accurate detection of low- and medium expressed transcripts at the single cell level. Looking forward, this platform has the potential to further improve resolution in pooled CRISPR screens by distinguishing transcript variants; analyzing multiple perturbation within single cells at throughput of hundreds of thousands of cells; and decreasing 3`-end transcript bias in gene expression readout.
Spatial molecular imager is for research use only and not for use in diagnostic procedures.

PrgmNr 2664 - Longitudinal multiomics data responses aid the detection of collective phenotypic characteristics in prediabetic/diabetic monitoring

View session detail

Author Block: **M. Zheng**[1], G. Mias[2]; [1]Biochemistry and Molecular Biology, IQ Ctr., Michigan State Univ., East Lansing, MI, [2]Michigan State Univ., East Lansing, MI
Disclosure Block: **M. Zheng:** None.
Longitudinal multiomics profiling, which combines data from biomolecular, physiological, environmental and clinical measures, presents great promise for precision health. Detecting temporal phenotypic characteristics across individuals by comparing the longitudinal multiomics is important for understanding and predicting disease outcomes based on molecular measures. A main challenge of comparing longitudinal multiple omics across individuals is data heterogeneity, including different scales, missing datapoints, uneven sampling, etc. We addressed this challenge by applying network-based analyses to categorize single individual's multi-omics, and use these to create multi-individual similarity clusters directly from their longitudinal multiomics profiles. These clusters revealed variability of phenotypic characteristics associated to immune responses in individualized multiomics from prediabetic and diabetic individuals.
We analyzed individualized multiomics profiles from public data for 69 individuals using spectral methods. We generated periodograms for individual subject omics signals, to construct within-person omics networks and analyze personal-level immune changes. We compared periodograms across all individuals to identify network clusters of individuals with similarities across their common omics temporal patterns.
Our analysis discovered both intra- and inter- individual characteristics differences. The inter-individual longitudinal omics clusters show pattern changes corresponding to the individualâ□□s physiological state changes. We identified similar individual-level responses to immune perturbation. The multi-individualsâ□□ similarity network revealed different classes within which the molecular behavior was linked to phenotypic differences, including body mass index and insulin resistance, with the immune response dominating differences attributed to diabetic status.
We detected collective phenotypic differences in prediabetic and diabetic individuals by creating intra- and inter- individual temporal multiomics networks. We captured common immune responses across diabetic and pre-diabetic individuals in response to immune perturbation (vaccination/infection). Based on collective temporal omics responses we identified individualsâ□□ clusters with differences in body mass index and insulin resistance. Our findings utilizing personal temporal omics to identify collective responses across individuals associated with macroscopic characteristics, can potentially help predict disease responses and outcomes towards clinical implementations.

PrgmNr 2665 - Meta-Learning on Next-Generation Sequencing data to Improve Cell Type Annotation

View session detail

Author Block: **Y. Park**, D. Heider, A-C. Hauschild; Philipps-Univ. of Marburg, Marburg, Germany
Disclosure Block: **Y. Park:** None.

Tremendous advances in next-generation sequencing technology during the last decade allowed the accumulation of vast amounts of omics data in various research areas. However, study limitations of small sample sizes, particularly in clinical research of rare diseases, technical heterogeneity, and batch effects, narrow the applicability of traditional statistics and machine learning analysis. Here, we present a meta-learning approach to transfer knowledge from large-scale data and reduce the search space in the data with small sample sizes. Few-shot learning algorithms integrate meta-learning to overcome data scarcity and data heterogeneity by transferring molecular pattern recognition models from datasets of unrelated domains. We investigate few-shot learning models with TCGA (The Cancer Genome Atlas) data and demonstrate its potential as a molecular pattern recognition model for small datasets. Our results show that transfer learning is very effective for datasets of limited sample sizes. Furthermore, we demonstrate that our approach can transfer knowledge across technological heterogeneity, e.g., bulk-cell to single-cell data. Our approach can overcome study size restrictions, batch effects, and technological limitations in single-cell data analysis by utilizing existing bulk-cell sequencing data.

PrgmNr 2667 - OUTRIDER2: A generalized framework for context-dependent outlier detection in omics data

Author Block: **I. Scheller**[1], S. Loipfinger[2], D. Smirnov[3,4], R. Kopajtich[5], F. Brechtmann[2], H. Prokisch[6,3], J. Gagneur[7,1]; [1]Inst. of Computational Biology, Helmholtz Zentrum MÃ¼nchen, Neuherberg, Germany, [2]Faculty of Informatics, Technical Univ. of Munich, Garching, Germany, [3]Inst. of Human Genetics, Technical Univ. of Munich, Munich, Germany, [4]Inst. of Human Genetics, Helmholtz Zentrum Muenchen, Neuherberg, Germany, [5]Technical Univ. of Munich, Munich, Germany, [6]Helmholtz Zentrum Muenchen, Neuherberg, Germany, [7]Technical Univ. of Munich, Garching, Germany
Disclosure Block: **I. Scheller:** None.
The detection of aberrant gene expression events in RNA-seq data has recently been shown to be a promising complementary avenue to DNA sequencing both in rare disease diagnostics and in understanding effects of rare variants in common diseases. To this end, we have earlier adapted denoising autoencoders to RNA-seq data and implemented the method into the R package OUTRIDER [1]. OUTRIDER models expected RNA-seq gene read counts while controlling for latent confounders, and then performs significance based outlier detection using negative-binomial p-values. Here, we describe OUTRIDER2, an extension and generalization of OUTRIDERâ□□s denoising autoencoder and p-value based outlier detection method to continuous measurement and demonstrate it on mass-spectrometry based proteomics data. OUTRIDER2 adds support for modelling data with a Gaussian distribution and provides different data preprocessing and transformation options as well as a modularized model building procedure. It introduces a python backend and command line interface to the frontend R package which provides a flexible design that allows for an easy inclusion of additional distributions, data processing options and latent space fitting and decoding methods in the future. It furthermore supports the consideration of known covariates in addition to the data driven learning of the latent space during model fitting, and provides an improved runtime performance compared to the original R package for datasets with larger sample sizes. We demonstrate OUTRIDER2 by applying it to both transcriptomics and proteomics measurements within a rare disease cohort of 135 samples, enabling the joint analysis of aberrant RNA and protein expression events in the context of rare genetic variation [2]. Across all cutoffs, enrichments of rare variants suspected to disrupt protein abundance (missense, frameshift, stop gains) for outliers ranked by OUTRIDER2 is 100% higher than for rankings based on z-scores from regression on covariates (batch, sex) and 50% higher than for rankings p-values of differential expression tests (one-against-all, limma). In conclusion, this genome-wide observations highlight the complementarity of considering outlier events in different omics measurements to capture the functional impact of rare genetic variation, and showcases OUTRIDER2 as an easy-to-use tool that enables the study of aberrant events in a wider range of data modalities.

Introduction: Many patients with suspected muscular dystrophies remain genetically undiagnosed despite clinical diagnostic testing via second-generation short read sequencing and standard variant analyses of this sequence data. We propose that a significant proportion of these undiagnosed individuals harbor structural variants (SVs) that are not easily detected with this approach. Nanopore long-read whole genome sequencing, a form of third-generation sequencing, is a powerful technique that can be used to identify and resolve a higher proportion of such SVs, further identifying causal variants in these unsolved families. We optimized protocols to yield long reads from pre-existing DNA extractions and developed an analytical workflow to test our hypothesis. We detected a likely pathogenic SV that was initially undetected by short read sequencing in one family, and determined the relative positions of the copies of a multi-exon duplication in a second family.

Results: LAMA2-related dystrophies resulting from partial or complete merosin deficiency are one of the most common forms of recessive congenital muscular dystrophies. Clinical whole exome sequencing identified a single heterozygous pathogenic variant in *LAMA2* (c.2962C>T, p.Gln988X) in an individual with a sporadic congenital muscular dystrophy phenotype suggestive of merosin deficiency. Nanopore sequencing identified a 3,463 bp duplication (chr6:129660157-129663620) that includes all of exon 30, likely resulting in a frameshift and premature termination. We confirmed the presence of this duplication in 120-1 (proband) and 120-2 (mother) using PCR primers that span the boundaries of the duplicated region.

A second individual (1466-1) was found to have a duplication of exons 10-26 in *DMD* during a genetic evaluation for an unrelated issue. He is a 40-year-old construction worker with a normal CK and no weakness on physical examination, thus it was suspected that the duplication may be non-tandem. Nanopore sequencing was used to pinpoint the breakpoint locations, and determined that the duplication was indeed in tandem. This suggests that this SV may not be pathogenic for a Duchenne or Becker muscular dystrophy phenotype, but cardiac surveillance may be warranted. We confirmed the breakpoints of this duplication in 1466-1 using PCR and Sanger sequencing.

Conclusion: This study highlights the utility of nanopore sequencing to identify and characterize previously cryptic or incompletely defined SVs, potentially providing a more complete molecular diagnosis for patients, and increasing our understanding of the distribution of pathogenic variants in the setting of muscular dystrophy.

PrgmNr 2669 - Using deep learning to detect Noonan syndrome from electronic health records

View session detail

Author Block: **Z. Yang**, A. R. Shikany, G. Zhang, K. N. Weaver, J. Chen; Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH
Disclosure Block: **Z. Yang:** None.
Background: Noonan syndrome (NS) is a genetic disorder that affects an estimated 1 in 1000 to 2500 people. Common clinical features include short stature, heart defects, and congenital malformations. Variable expressivity is common making it difficult to obtain a timely diagnosis. Genetic testing can be used to confirm a diagnosis but many individuals do not get tested due to a lack of recognition and referral. Our study sought to investigate the utility of using electronic health records (EHR) to build deep learning models and to identify patients at high risk of NS.
Methods: Using diagnosis description text from Cincinnati Children's Hospitalâ□□s de-identified EHR database, we constructed deep learning models from 162 NS cases and 32400 presumable controls. Models were optimized using 6-fold cross-validation. The final models were tested with an independent test set, consisting of 28 NS cases and 28000 presumable controls.
Results: We found all deep learning models performed significantly better than our previously developed statistical method, Genetic Disease Diagnosis based on Phenotypes (GDDP). Convolutional neural net (CNN) had the best performance on NS classification among all techniques, with a 0.5 recall at 0.42 precision and 0.55 area under precision-recall curve.
Conclusion: The deep learning models based on diagnosis description text from EHR were able to classify NS patients and provide clinically relevant explanations. The results suggested the validity of this approach as a screening method for NS, and demonstrated the value of EHR data and machine learning methods for diagnostics of rare genetic diseases.

PrgmNr 2670 - Using transcriptomic analysis to identify pathogenic variants in rare Mendelian diseases missed on conventional genomic testing

The implementation of next-generation exome or genome sequencing (ES/GS) in clinical practice allows the rapid identification of causative genetic variants responsible for Mendelian diseases. However, a large part of patients with rare genetic disorders, and in particular with neurodevelopmental disorders (NDDs), remains without a molecular diagnosis, indicating that the genetic information alone is sometimes insufficient to identify causative variants. GS allows the analysis of regions not enriched by ES, and in particular intronic regions and poorly covered exons. Intronic, structural genomic variants and exonic variants not well covered by ES account for an additional diagnostic yield of about 10% as compared to ES. However, the challenge remains the clinical interpretation of the high amount of variants, especially those located within deep-intronic regions. Recently, it has been demonstrated that using of RNA sequencing (RS) as a complement of GS can improve diagnosis of patients with negative ES results. Indeed, RS can detect splicing anomalies that may be associated with aberrant gene expression (outliers).Here, we describe our experience about the implementation of RS in the laboratory practice for the analysis and the interpretation of transcriptome data in NDDs. We applied RS from whole blood and skin fibroblasts coupled with GS in a cohort of 100 patients with NDDs remained without molecular diagnosis despite standard genomics analysis (ES/GS). We implemented workflow to detect outliers in gene expression and splicing anomalies. Starting from sample handling to the generation of analysis report we describe potential caveats and pitfalls associated with RS. Our analyses identified cases with deep-intronic variants causing cryptic exon activation, expression down-regulation identified via transcriptomic sequencing and structural variants not previously identified by our GS pipeline.In conclusion, new diagnoses could be raised in our cohort of undiagnosed individuals with NDD and suspected rare Mendelian diseases using transcriptomic analysis.

PrgmNr 2671 - Clinical pharmacogenomic test reporting preferences among adult and pediatric providers

View session detail

Author Block: **A. Cera**[1], H. Naik[1], R. M. Wasserman[2], B. Duong[3], A. Owusu Obeng[1,4], K. J. Cook[5,6], N. Seligson[5,6], N. Cody[1,7], V. F. Funanage[3], K. V. Blake[5], S. A. The increasing availability of practice guidelines has resulted in growing interest in implementing clinical pharmacogenomic testing; however, there is ongoing regulatory debate whether clinical pharmacogenomic test reports should include therapeutic recommendations. Previous studies have concluded that most providers do not feel equipped to independently interpret pharmacogenomic results. Therefore, we aimed to assess provider preferences on clinical pharmacogenomic report content. Adult (36%) and pediatric (60%) providers participated in an anonymous online national survey, including physicians (54%), pharmacists (22%), nurse practitioners (12%), and other providers (22%), which were diverse in age and gender, largely white (75%) or Asian (16%), and concentrated in urban and suburban medical centers in the Eastern U.S (n=105). Half of all respondents (54%) identified as being somewhat familiar with pharmacogenomics; however, only 36.5% had previously heard of the Clinical Pharmacogenetics Implementation Consortium (CPIC). Importantly, the majority (66%) of providers agreed that clinical pharmacogenomic reports should include identified genotypes, metabolizer phenotypes, potentially impacted medications and therapeutic recommendations, compared to only 7.7% who disagreed. Moreover, most providers agreed that all potentially impacted medications should be reported, including those with FDA label recommendations and from other sources (e.g., CPIC). Similarly, 72% of providers indicated that the therapeutic recommendations should include contraindicated medications, dosing information, and patient monitoring recommendations when applicable. Interestingly, physicians preferred more therapeutic recommendations and dosage guidance information than pharmacists (p=0.0007), suggesting that pharmacists may feel more confident than clinicians to translate pharmacogenomic results into therapeutic recommendations. Regarding panel testing, the majority (72%) of providers indicated they were not worried about including panel results in patient medical records. However, only ~30% of providers indicated they were not worried about their clinical responsibility for panel results beyond the original indication for the test or for panel results ordered by a different provider. Taken together, these data indicate that the majority of clinical providers prefer to have explicit therapeutic recommendations included in clinical pharmacogenomic test reports; however, additional resources are necessary to support the delivery of pharmacogenomic panel results to providers through electronic medical records.

PrgmNr 2672 - Common statin intolerance variants in *ABCB1* and *LILRB5* show synergistic effects in statin response: an observational study using electronic health records

View session detail

Author Block: **A. Melhem**[1], M. Chourasia[1], M. Bigossi[1,2], C. Maroteau[1], A. Taylor[1], R. Pola[2], A. Dawed[1], A. Tornio[1,3], C. N. Palmer[1], M. K. Siddiqui[1]; [1]Univ. of Dundee, Dundee, United Kingdom, [2]Fondazione Policlinico Univ.rio, Rome, Italy, [3]Univ. of Turku, Turku, Finland

Statin intolerance impacts approximately 10% of statin users, with side effects ranging from mild myalgia to extreme intolerance resulting in myopathy and rhabdomyolysis. Statin intolerance results in poor adherence to therapy and can impact statin efficacy. Many genetic variants are associated with statin intolerance. The effect of these variants on statin efficacy has not been systematically explored. Using longitudinal electronic health records and genetic biobank data from Tayside, Scotland, we examined the effect of nine genetic variants with previously reported associations with simvastatin or atorvastatin intolerance on the outcome of statin response. Statin response was measured by the reduction achieved when comparing pre-and post-statin non-HDL-cholesterol. Post-treatment statin response was limited to non-HDL-cholesterol measured within six months of therapy initiation. Univariate and multivariable linear regression models were used to assess the main and adjusted effect of the variants on statin efficacy. 9,401 statin users met study inclusion criteria, of whom 8,843 were first prescribed simvastatin or atorvastatin. The average difference in post-treatment compared to pre-treatment non-HDL-cholesterol was 1.45 (Â±1.04) mmol/L. In adjusted analyses, only two variants, one in the gene *ABCB1* (rs1045642) and one in *LILRB5* (rs12975366), were associated with statin efficacy. In *ABCB1*, homozygous carriers of the C allele at rs1045642 had 0.05 mmol/L better absolute reduction in non-HDL-cholesterol than carriers of the T allele (95%CI: 0.01,0.1). In *LILRB5* (rs12975366), carriers of the C allele had 0.05 mmol/L better absolute reduction compared to those homozygous for the T allele (95%CI: 0.01,0.08). When combined into a two-variant risk score, individuals with both the rs1045642-CC genotype and the rs12975366 -TC or CC genotype had a 0.05 mmol/L greater absolute reduction in non-HDL-cholesterol compared to those with rs1045642-TC or TT genotype and the rs12975366 -TT genotype (95%CI: 0.02, 0.08; P=0.002). We report two genetic variants for statin adverse drug reactions that are associated with statin efficacy. While the *ABCB1* variant has been shown to have an association with statin pharmacokinetics, no similar evidence for *LILRB5* has been reported. These findings highlight the value of genetic testing to deliver precision therapeutics to statin users.

PrgmNr 2673 - DrugnomeAI: An exome-wide machine-learning framework for druggability prediction and ranking of drug target candidates by stochastic semi-supervised learning

View session detail

Author Block: **A. Raies**, E. Tulodziecka, J. Stainer, A. R. Harper, S. Petrovski, D. Vitsios; AstraZeneca, Cambridge, United Kingdom
Disclosure Block: **A. Raies:** Salary/Employment; Arwa Raies is an employee of AstraZeneca.
Target selection is paramount to the overall success of clinical development activities. Targets with genomic support are more likely to succeed with large-scale genomic studies now yielding many putative targets. Target selection requires consideration for many aspects, including the druggability, or tractability, of a target. However, predicting druggability, using standard machine learning (ML) approaches, is challenging due to the small number of known targets, lack of robust negative data, and extreme data imbalance.To address these challenges, we developed drugnomeAI, an automated ML framework based on a previously published method (Vitsios & Petrovski, 2020) that has been re-purposed for estimating a druggability likelihood for every protein-coding gene in the human exome. DrugnomeAI implements a positive-unlabeled learning approach by randomly segregating the dataset into smaller balanced datasets of positive and unlabeled genes. DrugnomeAI provides specialised models stratified by both disease type (oncology and non-oncology) and therapeutic modality (small molecules or antibodies). The tool employs the Tclin annotation from PHAROS, as a labelled set of known drug targets, and integrates gene-level properties from 13 sources, including PHAROS, String, CTD and DGIdb as well as protein-protein interaction network data, resulting in a set of >350 features. The best performing model, based on gradient boosting, identifies known drug targets with 98% accuracy. Some key features contributing to the predictions include: protein-protein interactions from DGIdb, STRING, InWeb and Reactome, RNA specificity from Human Protein Atlas, monoclonal antibodies, as well as processes from CTD, such as apoptosis and phagosomes for the oncology-specific model.Investigation of the top ~1,000 drugnomeAI ranked genes shows that 74% have been previously selected for clinical development programs (48% in Phase IV). We found the top 5% of drugnomeAI gene target predictions to be significantly enriched for genes that achieved study-wide significance in a large PheWAS adopting 455K exomes from the UK Biobank. When compared to another ML tool (TargetDB), drugnomeAI demonstrates higher statistical enrichment in ranking genes from the Open Targets tractability data, both for small molecules (Fisherâ□□s exact: OR=4.1; $p=9.1x10^{-28}$) and antibodies (Fisherâ□□s exact: OR=3.7; $p=1.7x10^{-35}$).DrugnomeAI supports targets discovery by improving our understanding of the properties of druggable genes and prioritizing novel targets most amenable to small molecule and antibody modalities to further accelerate drug discovery.

PrgmNr 2674 - Pharmacogenetics for precision cardiovascular therapy: a novel GRS for *SLCO1B1* as a predictor of statin intolerance

View session detail

Author Block: **M. Bigossi**[1,2], C. Maroteau[3], A. Melhem[2], R. Pola[1], C. N. A. Palmer[2], M. K. Siddiqui[2]; [1]Section of Internal Med. and Thromboembolic Diseases, Dept. of Med., Fondazione Policlinico Univ.rio A. Gemelli IRCCS, L.go A. Sch., Univ. of Dundee DD1 9SY, Dundee, Italy
Disclosure Block: **M. Bigossi:** None.
Statin intolerance impacts approximately 10% of statin users with side effects ranging from mild myalgia to myopathy and rhabdomyolysis. *SLCO1B1* has been extensively studied in relation to statin-associated muscle symptoms as it encodes OATP1B1, the main influx transporter of statins. However, studies have mostly focused on a single loss of function (LOF) variant (Val174Ala). Here we present findings that use several variants in *SLCO1B1* to produce a genetic risk score (GRS).
Using longitudinal electronic health records and genetic biobank data from Tayside, Scotland, we examined the effect of four common *SLCO1B1* variants with MAF > 0.05 on statin intolerance. Using *SLCO1B1* missense variants: Val174Ala, Asn130Asp, Pro155Thr, and Leu643Phe, an unweighted non-additive GRS for LOF was developed. The GRS was tested on two intolerance phenotypes: general statin intolerance (GSI), defined as having raised creatine kinase (CK) and 3 or more switches in statin therapy or discontinuation, and statin-induced myopathy/rhabdomyolysis (SIM) defined as statin users having CK levels â¥10 times the upper limit of normal in the ambulatory setting. These were compared to statin tolerant controls who had no recorded raised CK measures, were on therapy for a minimum of 5 years, had at least 90% daily coverage, had no more than 1 switch and no discontinuation of therapy. Logistic regressions were used to assess adjusted effect of the variants on statin intolerance phenotypes. Models were adjusted for statin type and dose, prior cardiovascular events, age and sex.
From 15,543 statin users, 521 individuals (3.4%) had GSI, while 108 (0.7%) had SIM. These were compared to 1901 statin tolerant individuals (12.2%). Individuals homozygous for Val174Val were classified as level 8 of the GRS. Risk alleles in other variants were treated additively with a maximum level of 7 (median 6, range 2-8). Individuals with GRS â¥7 (7% of study population) had significantly higher odds of GSI and SIM compared to those who had GRS â¤ 6. Individuals with GRS â¥7 had 2.42 times the odds of GSI compared to those with GRS â¤ 6 (95% CI 1.24-4.46, p 0.006). Similarly, individuals with GRS â¥7 had 3.50 times the odds of SIM compared to those with GRS â¤ 6 (95% CI 1.25-8.30, p 0.008). In contrast, Val174Ala alone is associated with a non-significant increase of both GSI (OR 1.94, 95% CI 0.64-5.88, p 0.24) and SIM (OR 2.76, 95% CI 0.64-12.0, p 0.18).
Impaired OATP1B1 function is associated with higher risk of statin intolerance. At present, Val174Ala in *SLCO1B1* is the only pharmacogenetic variant tested in clinical practice. This study shows that a comprehensive GRS of *SLCO1B1* is better able to predict risk of statin intolerance than Val174Ala.

PrgmNr 2675 - Sanford Health Preemptive Population Genetic Screening - A Comparison of Military Veterans and non-Veterans

View session detail

Author Block: **J. Leonhard**[1], A. Massmann[2], B. Tucker[3], J. Van Heukelom[2], K. Jacobsen[2], J. Kippley[2], A. Schultz[2], C. Hajek[2]; [1]Sanford Hlth., Bemidji, MN, [2]Sanford Hlth., Sioux Falls, SD, [3]Denver, CO
Disclosure Block: **J. Leonhard:** None.
Background: Population genetic screening programs for healthy adults are becoming more common even though guidelines regarding such testing are scant; however, considerations for implementation were recently published (1,2,3,4). Military veterans are a unique demographic of patients with complex healthcare needs (5). Mental health issues may be common, occurring in up to 33% of veterans (5). Many veterans take medications that have Clinical Pharmacogenetics Implementation Consortium guidelines (6,7). Efforts to implement pharmacogenomic (PGx) testing are underway in the Veterans Health Administration (6). In addition, up to 3% of veterans are expected to have secondary findings reported through the Sanford Health preemptive genetic screening program (Sanford Chip) (8). We present a comparison of results for military veterans and non-veterans from the Sanford Chip.
Methods: The Sanford Chip detects PGx and medically actionable predisposition (MAP) variants. Using a genotyping platform, we report the genotype/phenotype for up to 11 PGx genes as well as Sanger-confirmed pathogenic and likely pathogenic variants in 57 genes. Pharmacists review all PGx results, enter summaries in the electronic medical record (EMR), and notify providers of actionable results. Programmed decision support informs future medication or dose changes in the EMR. Patients with MAP-positive results are contacted and referred for clinical genetic counseling.
Results: During the period from 9/16/2020 through 5/15/2021, 437 veterans and 719 non-veterans had PGx results. All patients in this cohort had at least one PGx variant. Actionable drug-gene variants were present in 33.8% of veterans and 27.9% of non-veterans (p p = 0.21) were associated with an increased risk to develop disease, and the remainder were positive for carrier status or association with moderate disease risk.
Conclusion: Meeting the complex needs of veterans can be facilitated by implementing a personalized approach to their healthcare. Preliminary data presented here suggests preemptive genetic screening of veterans compared to non-veterans could impact medical management recommendations for veterans, especially with prescribing practices.

PrgmNr 2676 - Transcriptomic effects of propranolol and primidone uncover important pathways for tremor reduction in essential tremor

View session detail

Author Block: **C-E. Castonguay**[1], C. Liao[1], A. Khayachi[1], G. Houle[1], J. P. Ross[1], P. A. Dion[1], G. A. Rouleau[2]; [1]McGill Univ., Montreal, QC, Canada, [2]Montreal Neurological Inst.-Hosp., Montreal, QC, Canada

Disclosure Block: **C. Castonguay:** None.

Essential tremor (ET) is one of the most common movement disorders, with nearly 1% of the worldwide population suffering from the disease. Despite its high prevalence and heritability, few genetic risk factors for ET have been identified. Previously, studies of drug effects have been leveraged to uncover genes related to complex traits, particularly for disorders with subsets of drug-responsive patients. ET notably presents patients who are responsive to two tremorolytic drugs: propranolol and primidone. Genes targeted by these tremor reducing agents might be implicated in the pathophysiology of ET. The objective of this study was to identify convergent propranolol and primidone transcriptomic targets in cerebellar DAOY cells and cortical neural progenitor cells (NPCs) in order to inform on ET related genes. To achieve this, DAOY cells and NPCs were treated for 5 days with clinical concentrations of propranolol and primidone, followed by RNA-sequencing to identify differentially expressed genes (DEGs). A meta-analysis approach was used to identify convergent genes across the different cell lines and treatments. The expression of genes previously associated with ET, such as *TRAPPC11*, were significantly affected by treatment with propranolol. Furthermore, Reactome and Gene Ontology (GO) pathway enrichment analysis identified axon guidance, vascular endothelial growth factor (VEGF) signalling and endosomal sorting complex required for transport (ESCRT) as significant. Weighted gene co-expression network analysis (WGCNA) also revealed co-expression modules related to neurite and cell projection morphogenesis in NPCs as well as endosomal trafficking in DAOYs. Gene-set enrichment analysis in human cerebellar single-cell data also showed an enrichment of propranolol and primidone targeted genes in granule cells and endocytes. Loss-of-function analysis using observed/expected ratio (o/e) scores from gnomAD revealed that convergent primidone and propranolol DEGs had significantly higher mutational constraint than all protein coding genes, suggesting that these drugs affect the expression of genes that might carry rare deleterious variants. Our results therefore highlight important pathways by which propranolol and primidone might reduce tremor, as well as identify potential genes to test for rare variance in ET.

SCYL2 is an evolutionary conserved pseudokinase that binds to clathrin and AP2, a plasma membrane adaptator. It phosphorylates the beta 2 adaptin subunit with a role in regulating excitatory receptor in the synapse. SCYL2 is important for neuronal survival in the developing brain. In mice, targeted disruption of *Scyl2* results in increased perinatal lethality, growth retardation and severe sensorimotor deficits (Gingras *et al. (*2015)). In humans, *SCYL2* bi-allelic nonsense and frameshift pathogenic variants were recently involved in arthrogryposis multiplex congenita 4, neurogenic, with agenesis of the corpus callosum (AMC4, OMIM : # 618766). Seidahmed et *al.(*2020) reported 8 individuals with AMC4 in 2 unrelated consanguineous families. Six of the 8 patients died in infancy or early childhood. Prenatal ultrasound included reduced fetal movements, polyhydramnios, clenched hands, fixed flexion of upper and lower limb joints, clubfeet, agenesis of the corpus callosum and dilated brain ventricles. At birth, the patients presented with arthrogryposis, microcephaly, facial dysmorphology, shortening of the femurs, fractures of the long bones. Most patients had seizures and peripheral neuropathy. We describe here an additionnal case of a male fÅtus from unrelated parents with AMC4. Ultrasonography at 24 weeks of amenorhea showed reduced fetal movements, corpus callosum agenesis, microretrognathia, clubfeet and clenched hands. No chromosomal abnormalities were detected by array CGH. Prenatal trio exome sequencing showed the fÅtus carried two compound heterozygous pathogenic variants in *SCYL2* (NM_001317784.1:c.97delG, p.Asp33Metfs* and c.176dup, p.Glu60Glyfs*8). None of these variants are found in a homozygous state in the GnomAD database. Ultrasonographic signs in this fÅtus are compatible with the diagnosis of AMC4 confirming these variants are implicated in the phenotype. Our study reports the first case of AMC4 diagnosed in the prenatal period and gives additionnal support for the involvement of *SCYL2* in autosomal recessive arthrogryposis in humans.

PrgmNr 2678 - Association between acute maternal infections during pregnancy and birth defects in Bogota and Cali, Colombia 2001-2018

Infectious diseases occur frequently during pregnancy and their teratogenic role is well established in TORCH (Toxoplasmosis, other infections, Rubella, Cytomegalovirus, and Herpes simplex). However, the intrauterine development consequences of the rest of the infectious diseases that affect gravid women are unknown. We described a cohort of patients with major congenital defects (CD) and the exposure to infectious diseases during pregnancy using the information of Congenital Defects Surveillance Programs of Bogota and Cali (Colombia) between 2001 and 2018. We evaluated associations between groups of maternal infectious diseases and CD among 3,096 cases and 7,446 controls. CD presentation was more frequent as isolated (64.3%), polymalformed (23.2%), and syndromic (12.4%). 52.5% of cases and 44.6% of controls presented infectious diseases during pregnancy. The most common polyinfection was vaginal and urinary tract infection. The most common single infection was vaginal infection between cases and controls. We found an association between CD and gastrointestinal infections with an odds ratio (OR) 2.06 (IC 1.18 - 3.59), urinary tract infections OR 1.16 (IC 1.05 - 1.30), viral infections OR 1.88 (IC 1.18 - 3.0), respiratory infections OR 1.56 (IC 1.28 - 1.9), and vaginal infections OR 1.18 (IC 1.08 - 1.30). Comprehending the teratogenic effect of infectious diseases is relevant to promote prevention, screening, timely diagnosis, and appropriate treatment to gravid women.

PrgmNr 2679 - Evidence for genetic imprinting and a causal role of fetal insulin and diastolic blood pressure in regulation of placental weight

Introduction The placenta plays an essential role in fetal development. Placental weight can be indicative of efficacy; lowered by poor placentation, or increased under excessive gestational weight gain or diabetes. Very high or low placental weights associate with adverse outcomes such as preeclampsia, reduced fetal growth, and preterm birth. Despite this, little is known about genetic underpinnings of human placental growth. **Methods** We meta-analysed genome-wide association statistics on placental weight adjusted for sex and gestational age at 11,217,023 SNPs in 65,651 offspring, 60,886 mothers and 52,400 fathers of predominantly European ancestries in 19 cohorts. We used these results in Mendelian Randomization analyses to examine the causality of maternal exposures on placental weight. **Results** We identified 32 fetal, 4 maternal and 2 paternal loci at genome-wide significance (p-8). One paternal locus was distinct from the nearby fetal locus, the other colocalised with a fetal signal. Of the 37 independent loci, 17 are either novel or distinct from nearby birth weight SNPs. We estimated independent parental and fetal effects at the loci using a novel weighted linear model, providing evidence that the maternally-, but not paternally-inherited C allele at rs2237892 (KCNQ1 fetal locus) was associated with lower placental weight. Mendelian Randomization showed that higher maternal glucose and lower maternal insulin secretion causally increase placental weight, with opposite effects using fetal SNPs. Using blood pressure SNPs, we found evidence that higher fetal, but not maternal, genetically instrumented diastolic blood pressure lowers placental weight. **Conclusion** We identified 37 loci associated with placental weight, the majority having only direct fetal effects. Substantial overlap exists with loci previously associated with birth weight, with evidence of imprinting at locus KCNQ1. Imprinting effects at this locus have previously been shown for Type 2 Diabetes (T2D risk allele lowers placental weight). Mendelian Randomization supported the role of fetal insulin in regulation of placental growth and, in contrast to what we previously observed for birth weight, fetal but not maternal genetically predicted diastolic blood pressure potential alters placental weight.

PrgmNr 2680 - Genome-wide genetic control of fetal placental genomics shows multiple associations with health and disease across the life course, informing the Developmental Origins of Health and Disease

The placenta is the master regulator of the intrauterine environment and is central to the Developmental Origins of Health and Disease (DOHaD). Studies show that fetal genetics and placental genomics can influence child health traits. An integrative analysis of genetics, placental genomics, and child health traits has not been done and would yield insight into the DOHaD hypothesis. Recently, we developed Multi-Omic Strategies for Transcriptome-Wide Association Studies (MOSTWAS), which uses mediation analysis to scan variants genome-wide, detect gene-trait associations (GTAs), and develop hypotheses for trait-associated gene regulation. Here, using genetic, transcriptomic, and methylomic data from the Extremely Low Gestational Age Newborn (ELGAN) Cohort Study (N = 272), we applied MOSTWAS to train genetic models of expression of all genes on the ELGAN RNA-seq panel, 2,994 of which showed strong in- and out-sample accuracy. With these models, we conducted TWAS for 40 traits from 5 categories (autoimmune, metabolic, cardiovascular, perinatal, neuropsychiatric) and identified 264 GTAs across 176 TWAS genes and potential transcription (TFs) or epigenomic factors regulating their expression. Of the 176 genes, 50 were associated with multiple traits, many not genetically correlated (e.g., *IDI1* with BMI and schizophrenia). Genetically-regulated placental expression, in aggregate, explained significant portions of three neonatal traits (total puberty growth, childhood BMI, start of puberty) at 5-8% of total SNP heritability. In addition, 91 GTAs showed significant associations through distal variants, with many mediated through 8 TFs associated with multiple TWAS genes. For example, *EPS15*, a maternally imprinted placental TF associated with fetal growth, showed a negative association with waist-hip ratio (WHR) and was negatively associated with two genes: *SPATA13* and *FAM214A*, both showing positive TWAS associations with WHR. In human placenta-derived trophoblasts, FANA silencing of *EPS15* led to upregulation of both *SPATA13* and *FAM214A*, providing evidence for placental TF regulation of these genes. Further transcriptomic and functional consequences of *EPS15* knockdown are under evaluation. Our study reveals potentially shared placental pathways associated with many traits across the life course. GTAs with traits across categories and different life periods suggest that placental dysregulation affects fundamental early-in-life traits, and these effects compound and manifest in later-in-life traits. Our work motivates increased sample sizes for early childhood trait GWAS and the placenta as a key tissue of study.

PrgmNr 2681 - Investigating the influence of fetal growth on maternal blood pressure in pregnancy

View session detail

Res. Council Integrative Epidemiology Unit, Univ. of Bristol, Bristol, United Kingdom
Disclosure Block: **C. Decina:** None.
Raised maternal blood pressure (BP) confers a higher risk of pregnancy complications such as preeclampsia and fetal growth restriction. The role of fetal growth variationâ□□s contribution to maternal BP variation is not well understood. Prior evidence includes (i) cases of Beckwith-Wiedemann syndrome (fetal abnormalities of chr11p15) associated with fetal overgrowth and maternal gestational hypertension and (ii) recently published work demonstrating that fetal birth weight (BW)-increasing alleles were associated with higher maternal BP. We aimed to further explore fetal influence on maternal BP in pregnancy by (1) testing its association with fetal sex given the known difference in BW (males ~130g heavier than females) and (2) testing its association with a fetal genetic score (GS) for BW in further samples.

We performed multivariable linear regression to explore the association between fetal sex and maternal systolic and diastolic BP (SBP & DBP) measured at 28 wk gestation from term, singleton births, in women from the HAPO (n=12,185) and ALSPAC (n=11,875) studies. We adjusted models for maternal age, parity, gestational age (GA), and a BW z-score either adjusted for sex and GA at delivery or unadjusted. We meta-analysed effects across cohorts. We also built a fetal BW GS using 190 BW SNPs adjusted for maternal effects and meta-analysed its association with maternal SBP and DBP in HAPO (n=915) and ALSPAC (n=7,499) mother-child pairs of European-ancestry.

Male fetal sex was associated with a 2.9 mmHg/kg higher maternal SBP [95%CI: 1.2 - 4.7], the 95%CI including the estimated coefficient for BW of 1.9 mmHg/kg higher SBP [95%CI: 1.7 - 2.2] in the adjusted BW model, with no sex association with SBP in the unadjusted BW model (P=0.31), consistent with mediation of a sex effect by BW. Male fetal sex was associated with a 2.9 mmHg/kg higher DBP [95%CI: 1.7 - 4.2], similar to a BW effect of 3.7 mmHg/kg higher DBP [95%CI: 3.1 - 4.3] in the adjusted model, with a possible small independent sex effect seen in the unadjusted model (P=0.005). Our fetal BW GS analyses found a 0.1 mmHg higher maternal SBP [95%CI: 0.0 - 0.3] and DBP [95%CI: 0.0 - 0.2] per 1 SD higher GS.

Maternal BP contributes to pregnancy complication risk, thus understanding whether fetal sex is a contributor alongside other risk factors could inform clinical care. Results found here suggest that male sex is associated with higher maternal SBP and DBP, and that these effects are likely driven by larger male size. Evidence of a sex effect on DBP independent of BW requires further investigation. We found fetal alleles that increase BW show weak evidence of association with higher maternal BP, but larger samples are needed to confirm this.

Disclosure Block: **S. JuÃirez-PeÃ±alva:** None.

Progeroid syndromes are rare, monogenic disorders that present with clinical features resembling accelerated aging. Hutchinson-Gilford progeria syndrome (HGPS) is the most common form, typically developing in childhood and causing premature death within the first two decades of life. Most HGPS cases are autosomal dominant, caused by a single *de novo* synonymous change causing altered splicing in exon 11 of the *LMNA* gene. *LMNA* encodes for lamin A, an essential protein for nuclear structure and function.

We report a male patient presenting with intrauterine growth retardation, hand contractures, microcephaly and microretrognathia. There is no family history of neurological problems; parents are Caucasian and unrelated. The patient presented with low birth weight (##1800g), erythroderma, thin and transparent skin, lagophthalmos, sparse scalp hair and mandibular underdevelopment. Hematological findings were high platelet count and anemia. Perinatally, there were difficulties in weight gain with poor suction during breastfeeding, precipitating nasoenteric feeding. At age 6 months, the patient continued to require nasoenteric feeding.

Genomic investigations included a normal karyotype and normal array-CGH. Whole exome sequencing revealed a heterozygous missense variant in exon 6 of the *LMNA* gene. The variant, NM_170707.2:c.973G>A,p.(Asp325Asn), was not present in publicly available databases (gnomad, exome variant server, 1000 genomes), was well conserved across species and predicted to be pathogenic *in silico*. According to the ASHG variant classification guidelines (2015), it was catalogued as a variant of unknown significance. However, The Progeria Research Foundation (International Progeria Registry and Cell and Tissue Bank) has identified an as yet unreported previous case with the same variant and neonatal presentation, whereby the patient had similar clinical features and passed away at age 9 months.

In summary, we describe an interesting patient presenting in fetal life with a progeroid syndrome associated with a novel *LMNA* variant. Early diagnosis and molecular characterization of such unusual diseases are essential for genetic counselling, the participation of patients in clinical trials, and the development of biomarkers and targeted therapies. Current and future substantial advances in diagnosis and management of progeria are only possible through international clinical and scientific collaborations.

PrgmNr 2683 - Mining NIPT data of 108.349 Dutch pregnant women: cfDNA based viral analysis and GWAS

View session detail

Author Block: **E. Sistermans**, J. Linthorst; Amsterdam UMC, Amsterdam, Netherlands
Disclosure Block: **E. Sistermans:** None.
Objectives: Non Invasive Prenatal Testing aims at detecting fetal aneuploidies using maternal plasma. The sequencing data generated for NIPT can be repurposed for other goals, such as the detection of viral DNA and the imputation of SNPs, thereby allowing GWAS. As viral infections during pregnancy are a major health concern to both mother and fetus, our first goal was to characterize the DNA virome in a cohort of 108.349 pregnant women. These data will enable future implementations for the early detection of specific viral infections during pregnancy. Next, we performed different genome-wide association studies. We confirmed our method by performing a GWAS targeted at length and BMI. Consequently, we looked for novel loci that associate with factors that affect NIPT performance such as the fraction of fetal cfDNA and the overall concentration of cfDNA. Finally, we combined the viral and GWAS studies to discover genes that associate with the previously detected viral infections. **Results**: In our anonymized cohort, we identified the presence of several viral species that are potentially harmful to mother or fetus or both, including Herpesvirus 5 (Cytomegalovirus), Parvovirus B19 and Hepatitis B. For each viral species detected we report an estimate of the prevalence in our Dutch cohort. Most viruses were detected at a low abundance, but we also observed cases with an exceptionally high viral load of Parvovirus B19 and Hepatitis B. DNA fragments originating from different viruses were found to have distinct fragmentation patterns, presumably caused by nucleosome remodeling, topology and timing of the infection. The GWAS analysis targeted at BMI and height replicated many known loci, while our GWAS into factors that affect NIPT performance highlighted genes involved in DNA degradation and autoimmune disease. Finally, by combining the most commonly detected viral infections with the imputed variants, we identified genes that potentially drive the susceptibility to viral infections including specific viral receptor genes and the HLA locus. **Conclusion**: We demonstrate that with a straightforward approach, we are able to detect viral DNA from typical genome-wide NIPT cfDNA sequencing data and to report the main characteristics of the virome in our cohort. We also demonstrate that SNPs imputed from low coverage NIPT sequencing data can be used for GWAS analyses. Future efforts are directed at elucidating genes that are involved in pregnancy associated problems such as pre-eclampsia and preterm birth.

PrgmNr 2684 - Small supernumerary marker chromosome 15 in Prenatal Diagnosis: A clinical challenge

View session detail

Author Block: **J. Catanho da Silva**[1], S. Lemos Ferreira[2], M. Santos Melo[2], T. Kay[1], M. VenÃ¢ncio[1], I. Carvalho[1]; [1]Dept. of Med. Genetics, Hosp. Dona EstefÃ¢nia, Centro Hosp.ar UniversitÃirio Lisboa Central, Lisbon, Portugal, [2]

Disclosure Block: **J. Catanho da Silva:** None.

Background: Small supernumerary marker chromosomes (sSMCs) are rare cytogenetic abnormalities, present in less than 0.08% of all pregnancies. sSMCs are extra chromosomes with structural anomalies whose size is smaller than or equal to that of chromosome 20 on the same metaphase spreads. Reportedly, about 70% of cases of sSMCs are *de novo* and most frequently derived from chromosome 15. Uniparental disomy (UPD) is the inheritance of both homologous chromosomes from the same parent. The most prominent clinical outcome of UPDs are imprinting disorders, and when affecting chromosome 15, is associated with Prader Willi or Angelman syndromes.

Case Presentation: We report a 39-year-old woman that underwent amniocentesis at 16 weeks of gestation, due to high risk for trisomy 21 (1/88) at first trimester combined screening. Ultrasound performed at 21 weeks and 5 days of gestation showed bilateral clubfoot. Conventional cytogenetics identified an abnormal fetal karyotype: 47,XY,+mar[7]/46,XY[10]. Parents had normal karyotypes. Fetal chromosomal microarray (CMA) analysis was normal. Fluorescence *in situ* hybridization (FISH) revealed a marker chromosome del(15)(q10), consisted exclusively of heterochromatic material. UDP studies indicated maternal UDP of chromosome 15, establishing the diagnosis of Prader-Willi syndrome. After genetic counseling, parents decided on the termination of pregnancy.

Discussion: Identification of sSMC is a difficult task in prenatal diagnosis (PND). Conventional karyotype analysis can detect numerical and structural chromosomal abnormalities but cannot determine the origin and genetic content of sSMCs. The identification of a sSMC in prenatal settings must alert clinicians to a possible UPD. Prenatal UPD testing should be considered, among other criteria, when a structurally abnormal chromosome 15 or a *de novo* sSMC with no apparent euchromatic material in the fetus are identified.

Conclusion: We bring to attention the importance of combining cytogenetic and molecular genetic techniques to the detailed characterization of marker chromosomes in PND. It allows proper genetic counseling, facilitates informed decision-making, prevents uncertainty, and provides proper prognostic assessments.

PrgmNr 2685 - A computationally efficient clustering linear combination approach to jointly analyze multiple phenotypes for GWAS

View session detail

Author Block: **M. Wang**, S. Zhang, Q. Sha; Mathematical Sci., Michigan Technological Univ., Houghton, MI
Disclosure Block: **M. Wang:** None.
There has been an increasing interest in joint analysis of multiple phenotypes in genome-wide association studies (GWAS) because jointly analyzing multiple phenotypes may increase statistical power to detect genetic variants associated with complex diseases or traits. Recently, many statistical methods have been developed for joint analysis of multiple phenotypes in genetic association studies, including the Clustering Linear Combination (CLC) method. The CLC method works particularly well with phenotypes that have natural groupings. In the CLC method, one first clusters individual statistics from the association tests for each phenotype into positively correlated clusters, then the CLC test statistic was developed to combine the individual statistics linearly within each cluster and combine the between-cluster terms in a quadratic form. It was theoretically proved that if the individual statistics can be clustered correctly, the CLC test statistic is the most powerful test among all tests with certain quadratic forms. Due to the unknown number of clusters for a given data, the final test statistic of CLC method is the minimum p-value among all p-values of the CLC test statistics obtained from each possible number of clusters. Therefore, a simulation procedure must be used to evaluate the p-value of the final test statistic. This makes CLC method computationally demanding. We develop a new method called computationally efficient CLC (ceCLC) to test the association between multiple phenotypes and a genetic variant. Instead of using the minimum p-value as the test statistics in CLC, ceCLC uses the Cauchy combination test to combine all p-values of the CLC test statistics obtained from each possible number of clusters. The test statistic of ceCLC follow a standard Cauchy distribution, so the p-value can be obtained from the cumulative density function without the need of the simulation procedure. Through extensive simulation studies and application on the COPDGene data, the results demonstrate that the type I error rates of ceCLC are effectively controlled in different simulation settings and ceCLC either outperforms all other methods or has statistical power that is very close to the most powerful method with which it has been compared.

PrgmNr 2686 - A method for estimating personalized causal genomic variants of disease

View session detail

Author Block: **M. A. Rahman**[1], C. Cai[2], N. Bo[3], D. McNamara[4], Y. Ding[3], G. F. Cooper[2], X. Lu[2], J. Liu[1,5]; [1]Dept. of Engineering Management and Systems Engineering, Missouri Univ. of Sci. and Technology, Rolla, MO, [2]Dept. of BioMed. Informatics, Univ. of Pittsburgh, Pittsburgh, PA, [3]Dept. of Biostatistics, Univ. of Pittsburgh, Pittsburgh, PA, [4]Dept. of Med., Univ. of Pittsburgh, Pittsburgh, PA, [5]Dept. of Biological Sci., Missouri Univ. of Sci. and Technology, Rolla, MO
Disclosure Block: **M.A. Rahman:** None.
Genomic variants of disease are often discovered nowadays through population-based genome-wide association studies (GWAS). These genomic variants are not necessarily present in each individual with the disease due to inter-individual genomic heterogeneity. Such individual-level genomic variation is important for designing personalized treatment, which is, however, not generally captured well by population-level models, such as GWAS. In addition, GWAS typically requires a large sample to detect low-frequency genomic variants with sufficient power. To help address these challenges, we have developed an instance-specific causal inference (ICI) algorithm for estimating the causal genomic variants that influence traits at the level of an individual (e.g., patient). In particular, ICI is a Bayesian method for learning instance-specific causal Bayesian networks from observational data; to our knowledge, it is unique in doing so. By modeling at the level of an individual, ICI is capable of finding low-frequency or rare genomic variants that may exist only in a small number of individuals. We compared the ability of ICI to find causal genomic variants of clinical phenotypes, relative to GWAS. In particular, from the Framingham Study (FHS; dbGaP Study Accession: phs000007.v30.p11) we used whole genome data from Affymetrix HuGeneFocused50K measurements and harmonized phenome data of blood pressure measurements and plasma lipid levels. ICI and GWAS identified a significant number of shared variants; the unique variants identified only by ICI have a much lower minor allele frequency (MAF) than those identified by GWAS. In addition, we observed that ICI discovered more individualized and diverse variants with higher likelihood ratios among the hypertension patients than did GWAS. Also, ICI identified top-ranked causal variants that predicted hypertension better than did GWAS, according to the area under the ROC curve. Finally, ICI found several well-known low-frequency causal variants of serum lipid levels that were missed by GWAS. Overall, the results provide support for ICI as a promising approach for learning personalized causal genomic variants of clinical traits and disease to help advance precision medicine.

PrgmNr 2687 - A powerful test of ancestral heterogeneity in the effects of gene expression on complex traits

View session detail

Author Block: **K. Knutson**[1], W. Pan[2]; [1]Div. of Biostatistics, Univ Minnesota, Minneapolis, MN, [2]Univ Minnesota, Minneapolis, MN
Disclosure Block: **K. Knutson:** None.
The Transcriptome Wide Association Study (TWAS) is a widely used approach which integrates expression and GWAS data to study the role of cis-regulated gene expression (GEx) in complex traits. TWAS models GEx as a function of cis-eQTL genotypes. However, strong evidence suggests that the genetic architecture of GEx varies across populations. Furthermore, recent findings point to possible ancestral heterogeneity in the effects of GEx on complex traits, heterogeneity which may be amplified in TWAS by modeling GEx as a function of cis-eQTLs. We present a novel extension to TWAS which models heterogeneity in the effects of cis-regulated GEx which are correlated with ancestry. By jointly analyzing samples from multiple populations, our multi-ancestry TWAS framework can improve power to detect genes with shared expression-trait associations across populations through increased sample sizes, as compared to existing stratified TWAS approaches. Under our proposed model, we derive score tests for homogeneous, heterogeneous, and total GEx effects on a complex trait. Our preliminary simulations reveal conserved Type-I error rates and high power across a number of scenarios, holding promise for further simulations on larger simulated datasets. We apply our test to case-control genotypes from the Alzheimer's Disease Sequencing Project (ADSP) and publicly available prediction models from the Multi-Ethnic Study of Atherosclerosis (MESA) study. We identify a number of genes with suggestive heterogeneous effects between African American and Caucasian subjects on Alzheimerâ□□s Disease (AD), including *ASPHD2*, *SDSL*, *ZNF589*, *PGM2L1*, and *PPIL3*. Our preliminary application further identifies many putative AD risk genes which were not discovered through ancestry-stratified TWAS analyses, many of which have well established or biological plausible links to AD, including (but not limited to) *RTP4*, *ORAI2*, and *TOMM40L*. In forthcoming work, we will apply our test to a larger sample from ADSP, anticipating a greater number of significant findings due to the increased sample size. Additionally, we will apply our proposed test of heterogeneity to continuous endophenotypes from the UK Biobank (n â□□ 500,000), specifically considering a set of imaging derived phenotypes with strong associations to AD.

PrgmNr 2688 - An ensemble tool to predict health outcomes using microbiome data

View session detail

Author Block: **T. Wang**[1], B. Li[2], H. Xu[3], Y. Miao[1], M. Qian[1], S. Wang[1]; [1]Columbia Univ., New York, NY, [2]Brown Univ., Providence, RI, [3]Univ. of Sci. and Technology of China, Hefei, China
Disclosure Block: **T. Wang:** None.
Research in microbiome studies have been centered around the goals to examine whether the entire microbiome community or some taxa are associated with or predictive of a health outcome. Majority of the statistical methods developed for microbiome data are distance-based that begin by computing pairwise distances between microbiome communities of two samples. In these methods, multiple microbiome distance matrices that capture various information in microbiome were examined one by one and the 'optimal' one was selected. That is, only one form of association is used in the final model. However, microbiome studies have suggested that a health outcome usually is associated with multiple taxa in multiple forms. That is, the outcome is associated with some taxa that are phylogenetically-related, while some other associated taxa might be phylogenetically-unrelated, when no single prediction model can capture this complex and mixture forms of association between taxa and an outcome. Here we propose an ensemble prediction method that creates a weighted combination of predictions from three categories of commonly-used prediction methods including i) non-parametric machine learning methods, e.g., random forest (RF), ii) semi-parametric kernel regressions, and iii) linear models. Before ensemble, we propose to enhance RF taking into account the special characteristics of microbiome data through re-weighting contributions of samples using multiple microbial distance metrics in order to capture various aspects of associations between microbiome and a health outcome. We similarly utilize multiple microbial distances in semi-parametric kernel regressions, and then construct the ensemble estimate based on all learners from the three categories. Our simulation studies suggested that the proposed ensemble estimate always has the best prediction performance and a much improved prediction performance than that of any of the ensembled learners when different associations between microbiome and health outcomes were considered. We applied the proposed method to the American Gut Project (EBI: ERP012803) and found that it consistently outperforms competing methods in predicting both binary and continuous microbiome-related health outcomes.

Introduction: Phylogenetic analysis can provide information about the demography and genetic diversity of a population. Identifying haplogroups in phylogenetic reconstructions of human mitochondrial DNA (mtDNA) sequences is often an iterative task. While the addition of an automated algorithmic program can be used to establish a baseline phylogeny, a phylogenetic tree must often be reconstructed while accounting for known back-mutations and non-continuous variants. The aim of this study was to use a Bayesian Analysis of Population Structure (BAPS) algorithm to identify haplogroups by the partitioning of individual mtDNA sequences into cluster and explore the phylogenetic implications of this clustering.
Methods: hierBAPS is a Bayesian algorithm that assigns a set of haploid DNA sequences to clusters at different levels using an expected total number of groupings for the set of sequences as input, nested within levels over which the clustering should be performed, increasing the total number of groupings. After specifying a number of groupings (K), the algorithm clusters the sequences into as many groupings as possible (up to Kmax groupings). The algorithm then attempts to maximize the posterior probability of an allocation over other possible allocations, generating a data frame that indicates the assignment of sequences to specific clusters. We conducted three different grouping and level combinations using 874 whole mitogenome sequences from haplogroup U5, including 2 levels (4 groupings), 3 levels (11 groupings), and 4 levels (24 groupings) To test whether these groupings were consistent with a maximum likelihood phylogeny, we projected the BAPS clusters onto a phylogeny generated with IQ-tree, which also finds the best nucleotide substitution model. We then predicted haplogroups based on polymorphisms consistent with the most recent version of Phylotree (Build 17).
Results: We found that that using hierBAPS to evaluate human mitogenome sequences accurately predicted the haplogroups for these samples. At the four groupings level, the haplogroups were predicted up to 3-digits. The haplogroup predictions were most optimal at the 24-grouping level, and corresponded to exact haplogroups presented in Phylotree. Through this analysis, we also identified a sublineange of U5b3e1 that had not yet been represented in Phylotree.
Conclusion: Using the hierBAPS algorithm, we defined human mtDNA haplogroups at different resolutions which accurately corresponded to phylogenetically determined clusters. This methodology is also able to identify potenitally new phylogenetic branches that could be added to the known library of mtDNA haplogroups.

PrgmNr 2690 - Combining the strengths of inverse-variance weighting and Egger regression in Mendelian randomization using a mixture of regressions model

With the increasing availability of large scale GWAS summary data on various traits, Mendelian randomization (MR) has become commonly used to infer causality between a pair of traits, an exposure and an outcome. It depends on using genetic variants, typically SNPs, as instrumental variables (IVs). The inverse-variance weighted (IVW) method (with a fixed-effect meta-analysis model) is most powerful when all IVs are valid; however, when horizontal pleiotropy is present, it may lead to biased inference. On the other hand, Egger regression is one of the most widely used methods robust to pleiotropy, but it suffers from loss of power. We propose a two-component mixture of regressions to combine and thus take advantage of both IVW and Egger regression; it is both more efficient (i.e. higher powered) and more robust to pleiotropy (i.e. controlling type I error) than either IVW or Egger regression alone by accounting for both valid and invalid IVs respectively. We propose a model averaging approach and a novel data perturbation scheme to account for uncertainties in model/IV selection, leading to more robust statistical inference for finite samples. Through extensive simulations and applications to the GWAS summary data of 48 risk factor-disease pairs and 63 genetically uncorrelated trait pairs, we showcase that our proposed methods could often control type I error better while achieving much higher power than IVW and Egger regression. We expect that our proposed method will be a useful addition to the toolbox of Mendelian randomization for causal inference.

PrgmNr 2691 - Congenica A.I.: A High Scalable Machine Learning Decision Support Framework for Improving the Diagnostic Yield

View session detail

Author Block: **S. Morganella**, Y. Dahman, L. Ponting, J. R. Filby, N. Trump, H. Savage, E. Serra, S. Drury, A. Haworth, N. J. Lench; Congenica, Cambridge, United Kingdom

Rare genetic conditions impact more than 400 million people globally with each individual affected by at least one of the ~7,000 recognized rare diseases. Despite the technological advance in DNA sequencing, the characterization of the one or two actionable variants amongst the hundreds of thousands of mutations in an individualâ□□s genome remains a very complex task and hence the identification of an accurate diagnosis for the patient can take several years. One of the main challenges for the clinicians is the lack of enough evidence for delivering a clear classification resulting in variants of uncertain significance (VUS). In this scenario, machine learning can play a key role for delivering reliable and efficient prediction models for the characterization of the diagnostic variants. Here, we present an innovative high scalable machine learning framework that can accurately predict the pathogenicity of the variants, reclassify VUS, and identify the diagnostic variants by using an ad-hoc computational framework that combines patient phenotypes with the information contained in the Online Mendelian Inheritance in Man (OMIM) database. Our model is trained using a unique and well curated set of data generated by expert users of the Congenica platform. The training data includes ~35,000 variants observed in more than 10,000 unique patients and spanning more than 50 rare disease phenotypes. We validated our pathogenicity model on ClinVar 3 and 4 stars variants reviewed by expert panels showing a compelling 95.5% accuracy in predicting the correct pathogenicity. In addition, we showed that we were able to correctly reclassify 92.8% of variants that were previously considered VUS by our clinical team. Finally, we retrospectively assessed our ability to detect the diagnostic variants in 73 singletons, showing that we returned the causative variant as top candidate in 63% of cases and in the top 10 in 85% of cases. We have also analysed 126 singletons obtained from two external research institutes showing that in 48% of cases the diagnostic variant was at the top of the list and in 77% of cases in the top 10. The presented results strongly suggest that by using our machine learning-based decision support framework into clinical settings would help clinicians in increasing the diagnostic yield and improve the diagnosis and treatment even for the most complex cases.

PrgmNr 2692 - Cost-effective Low-Coverage Sequencing Imputation from Millions of Haplotypes

View session detail

Author Block: **S. Rubinacci**[1,2], R. Wertenbroek[1,2,3], O. Delaneau[1,2]; [1]Dept. of Computational Biology, Univ. of Lausanne, Lausanne, Switzerland, [2]Swiss Inst. of Bioinformatics, Lausanne, Switzerland, [3]Univ. of Applied Sci. and Arts Western Switzerland, Yverdon-les-bains, Switzerland
Disclosure Block: **S. Rubinacci:** None.
The last decade saw an unprecedented growth of genetic data with the recent establishment of projects such as TOPMed and GnomAD as a major milestone in human genetics. Despite the significant drop in DNA sequencing costs, SNP arrays are still a common practice to genotype large cohorts of individuals. In the last few years, several studies showed that Low-Coverage Whole Genome Sequencing (LC-WGS) offers a cost-effective alternative to SNP arrays while being less susceptible to ascertainment biases and more powerful to capture rare variations. These results suggest that a shift from SNP arrays to LC-WGS would be beneficial for the next generation of disease and population genetics studies.
In this context, we propose GLIMPSE2, a method for LC-WGS imputation, that is highly accurate while being able to leverage information from millions of reference samples and genetic positions in running times comparable to the last generation of imputation methods designed for SNP arrays.
We show the versatility of our tool by using more than 260 individuals from 127 populations as part of the Simonâ□□s diversity project with coverages ranging from 0.1x to 8x. We report imputation performance at both autosomes (chromosomes 1 to 22) and allosomes (chromosomes X and Y), for different types of small genetic variations (SNPs and indels), and extensively validate that our pipeline offers a solid strategy for genotyping most human populations compared to commonly used SNP array models.
In order to demonstrate the ability of GLIMPSE2 to efficiently leverage information in large reference panels, we performed imputation using simulated data, and showed that GLIMPSE2 is able to scale to reference panels containing millions of haplotypes and hundreds of millions of genetic positions. GLIMPSE2 makes imputation from large reference panels actually so efficient that the main bottleneck now becomes reading files from disk.
Overall, the computational performance reached by GLIMPSE2 makes the tool perfectly suited to perform high throughput imputation from modern high-coverage reference panels in an imputation server setting.

PrgmNr 2693 - Deep Learning in microbiome: Hybrid CNN-LSTM model for disease prediction using longitudinal microbiome data

View session detail

Author Block: **D. Sharma**[1], W. Xu[1,2]; [1]Princess Margaret Cancer Ctr., Toronto, ON, Canada, [2]Dalla Lana Sch. of Publ. Hlth., Univ. of Toronto, Toronto, ON, Canada
Disclosure Block: **D. Sharma:** None.
Researchers have shown that changes in the microbiome composition over time, either transiently or long term, through infections or environmental factors can be potentially associated with risk of various diseases. In this work, we propose a hybrid deep learning framework for disease prediction from longitudinal microbiome data, which integrates Convolutional Neural Networks (CNN) for feature extraction and Long Short-Term Memory Networks (LSTM) for analyzing temporal dependency in longitudinal microbiome data along with the hostâ□□s environmental factors. Main points of novelty are: (1) a multi-step approach consisting of step 1: pre-processing microbiome data based on correlation provided by the inherent taxonomic hierarchy in Operational Taxonomic Units (OTUs), to satisfy CNNs requirement for spatial similarity in the input, step 2: incorporating a stratified approach to group OTUs into clusters based on their phylum and training ensemble of CNNs within each of the clusters individually to capture OTU features efficiently and step 3: forwarding the extracted features to the LSTM module at each timepoint to learn temporal dependency; (2) handling irregular observation times and missing data in repeated measures through padding-masking operation in LSTM without the explicit requirement of data imputation and (3) incorporating a weighted loss function in the LSTM learning to handle case-control imbalance, thus, mitigating biased network learning when case-control ratio is highly skewed in microbiome studies. We validated the modelâ□□s performance on a set of 100 simulation studies across multiple time points with drop-off nature in subjects along time in the study design. We further implemented the framework into two real longitudinal human microbiome studies: (i) DIABIMMUNE three-country cohort with four food allergy outcomes (785 samples; 534 OTUs), (ii) DiGiulio study with preterm delivery outcome (3767 samples; 1420 OTUs). Extensive comparison of our proposed model to conventional machine learning methods provided encouraging performance with an Area Under the Curve (AUC) of 0.897 (95% Confidence Interval (CI): [0.891 - 0.905]) on simulated studies and AUCs of 0.762 (95% C.I: [0.758 - 0.765]) on the overall food allergy outcome and 0.713 (95% CI: [0.705 - 0.720]) on the preterm birth outcome for the two real longitudinal microbiome studies showing an improvement of 5%, 19% and 8% respectively, in comparison to the next best performing method. In summary, our analysis provides deeper insights on the efficiency of hybrid CNN-LSTM modelling to understand the associations between longitudinal microbial composition changes and disease outcomes.

PrgmNr 2694 - Detecting differential isoform splicing from single-cell long-read RNA sequencing

View session detail

Author Block: **Y. Hu**[1], K. Wang[2]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]CHOP, Philadelphia, PA
Disclosure Block: **Y. Hu:** None.
Unlike conventional single-cell short-read RNA-Seq that only assays gene expression at the 3â end of transcripts, the emergence of single-cell long-read RNA-seq technology has made it possible to measure isoform expression variations at cellular level. This breakthrough enables the investigation of a wider range of research problems including analysis of splicing heterogeneity among individual cells. However, compared to bulk RNA-seq, single-cell long-read RNA-seq data are much noisier due to high technical variability and low sequencing depth. We previously developed LIQA (long-read isoform quantification and analysis) for accurate isoform quantification from long-read bulk RNA-Seq data that accounts for different read (or alignment) quality and different levels of 5â degradation via a survival model. Here we propose LIQA-drop for differential splicing analysis in single-cell long-read RNA-seq, which achieves high sensitivity at low coverage by accounting for technical noises. LIQA-drop explicitly models technical noise by accounting for capture efficiency and amplification bias and further accounts for transcriptional burstiness, which are all unique features encountered in single-cell data. A key aspect of LIQA-drop is a Bayesian-based model to account for prior knowledge of splicing regulation from primary sequence information via deep neural network, making it possible to detect differential isoform usage at low sequencing depth. To evaluate the performance of LIQA-drop, we analyze both simulated and real scRNA-seq datasets. In simulation data, we weaken the true splicing difference between conditions by introducing technical noise through a generative model. We show that LIQA-drop has well-controlled type I error rate (3.2% at 0.05 significance level), and is powerful in detecting differential splicing isoform, especially when splicing difference is small (power = 0.76 when splicing ratio difference = 10%). Also, we show that LIQA-drop accurately estimates isoform usage at cellular level than bulk-level approaches (R^2=0.81). We also apply LIQA-drop to a mouse brain single-cell long RNA-seq dataset with ~1,200 single cells. LIQA-drop identifies unique differential splicing events with subtle difference across 7 cortical cell types, which are consistent with observed junctions reads in IGV sashimi plots. We are currently applying LIQA-drop to multiple real single-cell long-read RNA-seq datasets. With the increasing applications of long-read RNA-seq, we believe LIQA-drop will be well-suited for various isoform splicing studies at cellular level.

PrgmNr 2695 - Distinguishing different psychiatric disorders using polygenic prediction

View session detail

Author Block: **W. Peyrot**[1], A. L. Price[2]; [1]Amsterdam UMC, location VUmc, Amsterdam, Netherlands, [2]Harvard Sch Pub Hlth, Boston, MA
Disclosure Block: **W. Peyrot:** None.
Despite great progress on methods for case-control polygenic prediction (e.g. schizophrenia vs. control), there remains an unmet need for a polygenic method that distinguishes different psychiatric disorders (e.g. schizophrenia (SCZ) vs. bipolar disorder (BIP) vs. depression (MDD) vs. control); such a method would have key clinical value, as symptoms of psychiatric disorders are often shared, in particular at disorder onset. Here, we present a new method for distinguishing different disorders using polygenic prediction.
Our method computes probabilities of each possible diagnosis (e.g. SCZ=60%, BIP=20%, MDD=10%, control=10%) using case-control polygenic risk scores (PRS) for each disorder (computed using existing methods) and prior clinical probabilities for each diagnosis. First, we transform the case-control PRS to their respective liability scales. Second, we use bivariate LD score regression to estimate the genetic correlation among disorders and sample-overlap across the respective discovery GWAS samples. Then, we include all of this information in a multivariate liability threshold model to compute probabilities of each possible diagnosis. To assess prediction accuracy, we compute for each diagnosis the AUC for distinguishing this diagnosis (e.g. SCZ) versus the rest (e.g. BIP, MDD, control) in an independent validation sample.
We simulated data at realistic genetic architectures, genetic correlations and training sample sizes with equal proportions of SCZ, BIP, MDD and controls (25%, 25%, 25% and 25%). In these data, our method yielded well-calibrated results (the predicted probability of each diagnosis was equal to the true probability on average), whereas naÃ¯ve approaches were poorly calibrated. Furthermore, our method attained AUC for distinguishing each diagnosis vs. rest that were comparable to the AUC of published methods for distinguishing cases vs. controls of each disorder, an easier task: 0.70 for SCZ vs. rest, 0.61 for BIP vs. rest, 0.63 for MDD vs. rest, and 0.63 for control vs. rest. These simulation results suggest that our new method could be clinically useful for differential diagnosis, particularly as training sample sizes increase. We will present results of application of the method to empirical psychiatric disease data sets.

PrgmNr 2696 - Exploiting public GWAS databases to identify and adjust for heritable confounding in Mendelian randomization studies

View session detail

Author Block: **J. Morrison**; Univ. of Michigan, Ann Arbor, MI
Disclosure Block: **J. Morrison:** None.
Mendelian randomization (MR) is a widely used causal inference method which promises tests of causal effects derived only from genetic associations. When applied carefully, MR can yield valuable insight. However, pleiotropy and heritable confounding remain common sources of MR false positives. The most reliable MR studies rely on pre-existing evidence and expertise to identify and control for possible sources of confounding. However, for many promising applications of MR, little prior information is available. In lieu of such information, we propose an automated method that exploits the deep and growing resources of publicly available GWAS summary statistics. Our method identifies potential confounders by querying the IEU Open GWAS database for all other known phenotype associations with candidate MR instruments. We then identify traits that explain substantial heterogeneity in per-instrument MR estimates. Our method returns to the investigator a list of potential confounders as well as adjusted estimates of the causal effect. The investigator can then apply their domain knowledge to accept or reject potential confounders, or propose new causal hypotheses. This strategy can serve a dual role of providing more robust MR results and suggesting new candidates for further investigation. We demonstrate an application of this method to an exploration of the relationship between obesity and heart disease, hypertension, and type 2 diabetes.

PrgmNr 2697 - Gene selection by incorporating genetic networks into case-control association studies

View session detail

Author Block: **X. Cao**[1], X. Liang[2], S. Zhang[1], Q. Sha[1]; [1]Michigan Technological Univ., Houghton, MI, [2]Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN
Disclosure Block: **X. Cao:** None.
There is strong evidence shown that when genes are functionally related to each other in a genetic network, statistical methods utilizing prior biological network knowledge can outperform other methods that ignore the genetic network structures. Therefore, statistical methods that can incorporate genetic network information into association analysis in human genetic association studies have been widely used since 2008. The most recent published work in this area is by Kim K and Sun H [BMC Bioinformatics]. They developed an approach to incorporate genetic networks into case-control association studies with high-dimensional DNA methylation data. Given a biological network, their approach combines one of data dimension reduction techniques with network-based regularization to identify outcome-related genes. Motivated by their work, we propose a gene selection approach by incorporating genetic networks into case-control association studies with DNA sequence data or DNA methylation data. Instead of using traditional dimension reduction techniques such as principal component and supervised principal component, we use a linear combination of genotypes at SNPs or a linear combination of methylation values at CpG sites in each gene to capture gene-level signals. We develop three approaches for the linear combination: optimally weighted sum (OWS), LD-adjusted polygenic risk score (LD-PRS), and beta-based weighted sum (BWS). OWS and LD-PRS are supervised approaches that depend on the effect of each SNP or CpG site on the case-control status, while BWS can be extracted without using the case-control status. After we use one of the linear combinations of genotypes or methylation values in each gene to capture gene-level signals, we regularize them to perform gene selection based on the biological network. Simulation studies show that the proposed approaches have higher true positive rates than using traditional dimension reduction techniques. We also apply our approaches to Illumina HumanMethylation450 BeadChip array data for DNA methylation and UK Biobank data for DNA sequence of rheumatoid arthritis patients and normal controls. The results show that the proposed methods can select potentially rheumatoid arthritis related genes that are missed by existing methods.

PrgmNr 2698 - Genetic fine-mapping with dense linkage disequilibrium blocks

View session detail

Author Block: **C. Mo**; Univ. of Maryland Sch. of Med., Columbia, MD
Disclosure Block: **C. Mo:** None.
Background: Fine-mapping is an analytical step for causal prioritization of the polymorphic variants in a trait-associated genomic region observed in genome-wide association studies (GWAS). Prioritization of causal variants can be challenging due to linkage disequilibrium (LD) patterns among hundreds to thousands of polymorphisms associated with a trait. Hence, we propose an L0 graph norm shrinkage algorithm to disentangle LD patterns by dense LD blocks consisting of highly correlated single nucleotide polymorphisms (SNPs). We further incorporate the dense LD structure for fine-mapping. From graph theory, the concept of 'dense' refers to that a block is composed mainly by SNPs highly correlated with each other. We demonstrated the application of our new fine-mapping method using a large UK Biobank (UKBB) sample related to nicotine addiction. We also evaluated and compared its performance with existing fine-mapping algorithms using simulations. Results: Our results suggested that polymorphic variances in both neighboring and distant variants can be consolidated into dense blocks of highly correlated loci. Results from simulations demonstrated that this method outperformed comparable fine-mapping methods with increased sensitivity and reduced false-positive error rate for causal variant selection. The application of this method to the smoking severity trait in the UKBB sample replicated previously reported loci and suggested the causal prioritization of genetic effects on nicotine dependency.Conclusion: We found that the dense LD block structure can guide fine-mapping and accurately determine a parsimonious set of potential causal variants. Our approach is computationally efficient and allows fine-mapping of thousands of polymorphisms.

PrgmNr 2699 - Identifying clinically-relevant circulating protein biomarkers for type 1 diabetes: A two-sample Mendelian randomization study

Disclosure Block: **N. Yazdan panah:** None.

Type 1 diabetes is a chronic autoimmune disorder causing destruction of the insulin-producing pancreatic beta cell. Other than HLA haplotypes and polygenic risk scores, very few biomarkers exist that could predict development of type 1 diabetes before pancreatic auto-antibodies emerge. Such biomarkers might inform us on the pathophysiology of loss of self-tolerance to type 1 diabetes and serve as tools for early screening for individuals at high-risk for the disease. A relatively underexplored source of biomarkers is circulating proteins in the blood, which are drug-binding sites and as such may also represent potential drug targets. Here, we aimed to identify circulating proteins causally linked to type 1 diabetes susceptibility using Mendelian randomization (MR). We employed a large-scale two-sample MR study to screen circulating proteins outside the major histocompatibility complex (MHC) for causal association with risk of type 1 diabetes. To do this, we used cis genetic determinants of up to n=1,611 circulating proteins from five large genome-wide association studies to estimate their causal effects on type 1 diabetes risk amongst 9,684 cases with type 1 diabetes and 15,743 controls. We found that a standard deviation increase in genetically predicted Signal Regulatory Protein Gamma (SIRPG) level was associated with increased risk of type 1 diabetes risk (MR OR = 1.66, 95% 1.36- 2.03; P = 7.1 x 10-7). The risk of type 1 diabetes increased almost two-fold per standard deviation increase in genetically predicted interleukin-27 Epstein-Barr Virus Induced 3 (IL27-EBI3) protein levels (MR OR=1.97, 95% CI = 1.48 - 2.62, P= 3.7 x10-6). Conversely, a standard deviation increase in genetically predicted chymotrypsinogen B1 (CTRB1) was associated with decreased risk of type 1 diabetes (MR OR=0.84, 95% CI = 0.77 - 0.90, P= 6.1 x10-6). In summary, we identified three novel protein biomarkers associated with type 1 diabetes risk using an unbiased MR approach. These biomarkers inform us on the pathophysiology of type 1 diabetes, and, if validated in cohorts of individuals with type 1 diabetes and controls, they may represent promising targets for development of drugs and enhance screening for individuals at high risk for type 1 diabetes.

PrgmNr 2700 - Incorporating family disease history and controlling case-control imbalance for population based genetic association studies

View session detail

Author Block: **Y. Zhuang**[1], B. N. Wolford[2], K. Nam[3], W. Bi[1,4], W. Zhou[5], C. J. Willer[2], B. Mukherjee[1], S. Lee[1,3]; [1]Biostatistics, Univ. of Michigan, Ann Arbor, MI, [2]Univ. of Michigan, Ann Arbor, MI, [3]Seoul Natl. Univ., Seoul, Korea, Republic of, [4]Dept. of Med. Genetics, Sch. of Basic Med. Sci., Peking Univ., Beijing, China, [5]Massachusetts general Hosp., Broad Inst., Boston, MA
Disclosure Block: **Y. Zhuang:** None.
In the genome-wide association analysis of population-based biobanks, the low prevalence in most diseases results in low detection power. If a family disease history is collected, the power can be improved by inferring the disease risks in control samples, which will be used as phenotypes in association analysis. In the presence of related samples, however, the existing methods, such as LT-FH, fail to address increased phenotypic correlation among closely related samples due to similar family history. In addition, existing approaches cannot adjust for the unbalanced phenotypic distribution. We propose a new method, TAPE (mixed-model-based Test with Adjusted Phenotype and Empirical saddlepoint approximation), which controls for increased phenotype correlation by introducing an additional variance component for closely related samples and accounts for case-control imbalance by using empirical saddlepoint approximation. We show through simulation studies that TAPE is computationally efficient and gains greater power than common GWAS without using family disease history (SAIGE) while controlling type I error. In power simulation, TAPE showed 21.0% increase in average chi-square statistics and 12.1% increase in causal SNP detection than SAIGE. While LTFH also had increased power over SAIGE, it suffered type I error inflation especially when analyzing related samples with low disease prevalence and MAF (118 times inflation at alpha=5E-8). We applied TAPE to 10 binary traits in UK Biobank among 408,898 white British samples and identified 659 genome-wide significant clumped variants, among which 127 were with MAF

PrgmNr 2701 - Inter-cohort heterogeneity significantly undermines fine-mapping a meta-analysis

View session detail

Author Block: **M. Kanai**[1,2], R. Elzur[1,2], Global Biobank Meta-analysis Initiative, M. J. Daly[2,1,3], H. K. Finucane[1,2]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Massachusetts Gen. Hosp., Boston, MA, [3]Inst. for Molecular Med. Finland (FIMM), Helsinki, Finland
Disclosure Block: **M. Kanai:** None.
Meta-analysis is commonly used to combine multiple genome-wide association studies (GWAS) and has identified thousands of loci associated with complex traits. To resolve causal variants for these loci, previous meta-analysis studies have applied fine-mapping methods as if they are applied to a single-cohort study. However, it is understudied how heterogeneous characteristics of each cohort (e.g., phenotyping, genotyping, or imputation) affect fine-mapping. Indeed, due to such inter-cohort heterogeneity, we observed spurious fine-mapped variants in the recent COVID-19 Host Genetics Initiative meta-analysis when we naively applied existing methods.

Here, we first demonstrate the effect of inter-cohort heterogeneity in meta-analysis fine-mapping via simulations. Using HAPGEN2 with the 1000 Genomes Project Phase3 (1000GP3), we simulated multiple cohorts (n = 10,000 each) from different 1) ancestries (African, East Asian, European, or South Asian); 2) genotyping arrays (Illumina Omni 2.5, MEGA, GSA, or Affymetrix UKB); and 3) imputation panels (1000GP3_hg19, HRC_hg19, or TopMed_hg38). We assigned true phenotypes by assuming the same causal variants and effect sizes across cohorts where each locus has a single causal variant. We then conducted GWAS, meta-analyzed five random cohorts, applied the Approximate Bayes Factor, and evaluated fine-mapping accuracy.

We observed fine-mapping calibration was significantly undermined when we include different genotyping arrays or imputation panels. When multiple genome builds exist, we observed a particularly high number of false positives due to liftover (mean false positive rate: ~18%). With the same array and imputation panel, ancestry does not affect calibration. However, including Africans significantly improves power compared to other ancestries, likely due to shorter length of linkage disequilibrium (LD).

To identify likely problematic loci for meta-analysis fine-mapping, we develop a statistical method using summary statistics and gnomAD LD matrices. Briefly, because marginal association statistics for tagging variants correlate with r2 values to a causal variant, our method regresses chi-squared statistics on r2 to the index variant and identifies outlier variants with unexpected chi-squared, potentially due to inter-cohort heterogeneity. We apply it to 14 disease endpoints from the Global Biobank Meta-analysis Initiative and use the results to guide its fine-mapping effort. Although a principled solution requires complete synchronization across cohorts, our study provides the best practices in meta-analysis fine-mapping and will help prevent spurious results in the future.

PrgmNr 2702 - Joint analysis model of multiple high-throughput sequencing data

View session detail

Author Block: **Y-S. Kim**[1], G. D. Johnson[2], T. Cowart[1], A. S. Allen[2], A. Ochoa[1], A. Barrera[1], T. E. Reddy[1]; [1]Duke Univ., Durham, NC, [2]Duke Univ, Durham, NC
Disclosure Block: **Y. Kim:** None.
Functional genomic assays are commonly used to identify shared and distinct gene regulatory states between diverse collections of cell types and cell states. However, identifying shared regulatory states across the genome becomes challenging as the number of different cell types or cell states becomes large, for example the number of tissues assayed by RNA-seq in the Genotype-Tissue Expression (GTEx) project or the number of different cell models assayed in ENCODE. In particular, as the number of samples increases, the traditional condition-by-condition analysis do not reliably capture commonalities across many samples. To address the challenge of identifying shared gene regulatory states or responses, we developed JAMMYâ a Joint analysis model of multiple biology data. JAMMY is a statistical model that jointly analyzes functional genomics assays across many different cell types and cell states, and identifies responses common and unique to those cells. We demonstrate that JAMMY is highly flexible, able to identify common and unique responses across collections of RNA-seq, ChIP-seq, and even high throughput reporter assay datasets such as STARR-seq.Specifically, we demonstrate that JAMMY can identify cell-shared gene regulatory responses among groups of tissues in GTEx RNA-seq and novel co-binding between transcription factors in ENCODE ChIP-seq data. We also observe, by applying JAMMY to STARR-seq data, our model can identify differences in DNA sequences that contribute to cell-shared or cell-specific regulatory states, and gene regulatory elements that had shared and unique responses to diverse steroid hormones and that contributed to T cell differentiation. We also demonstrate that a joint analysis approach increases statistical power over the traditional pairwise comparisons to discover novel gene regulatory events. Together, these outcomes highlight substantial advantages to joint analysis models for integrating genomic datasets across many cell models.

Background: The current analytical paradigm for genome-wide association studies (GWAS) is to evaluate each single nucleotide polymorphism (SNP) with a specific disease risk. Although this method has successfully identified susceptibility SNPs across cancers, it does not consider possible multi-way and non-linear SNP-SNP interactions. ML algorithms can incorporate interactions without inflating the multiple testing issue by adopting advanced predictive modelling approaches. Herein, we propose to apply these techniques to our existing Mayo GWAS data of patients with CLL to compare ML risk prediction models.
Objective: This project aims to implement advanced ML approaches to GWAS of CLL to compare ML prediction models.
Methods: We genotyped 765 CLL cases and 639 controls with GWAS data from the Mayo Clinic CLL study. Using these data, we implemented a two-step approach by first applying feature selection, which narrows down to the SNPs that have the potential to be highly predictive for CLL risk, followed by a classification step that trains the ML algorithms to classify whether the selected SNPs are associated with CLL risk. We evaluated three types of ensemble algorithms: random forest (RF), extreme gradient boosting machines (XGBoost), and light gradient boosting machines (LightGBM). The performance of their prediction probability was evaluated using the area under the curve (AUC). The more robust algorithm in selecting relevant risk-associated SNPs was chosen. In the second step, we implemented ML classifiers to handle high dimensional data in performing predictions. We evaluated two classifiers, support vector machines (SVM) and regularized logistic regression (RLR) algorithms, on the selected SNPs.
Results: Our feature selection approach showed that LightGBM outperformed both RF and XGBoost and the feature importance score indicated that LightGBM was robust in selecting SNPs with high-risk predictive potential for developing CLL. Algorithm comparisons showed that integrating LightGBM with SVM gives a higher AUC of 63.4% with radial basis function kernel versus an AUC of 60.4% at the baseline SVM, while integrating LightGBM with RLR obtains a higher AUC of 63.6% with elastic-net penalty term when compared to the baseline RLR AUC of 59.4%.
Conclusion: Our preliminary results showed promise that integrating ML techniques for feature selection and classification improves the predictive performance when compared with baseline ML techniques. Our next steps are to incorporate another set of CLL GWAS data of 1,100 CLL cases and 15,000 controls from the Mayo Clinic CLL study and compare the ML findings to that obtained known CLL loci.

PrgmNr 2704 - Leveraging summary statistics fromEuropean GWAS to improve discovery of non European populations accounting for heterogeneity in effect sizes

View session detail

Author Block: **P. Orozco del Pino**[1], S. Zollner[2]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Univ Michigan, Ann Arbor, MI
Disclosure Block: **P. Orozco del Pino:** None.
Polygenic risk scores (PRS) aim to quantify disease risk that non-genetic tools can not identify raising interest in clinical application These PRS are based on a weighted sum of the number of risk variants found on their genome; weights and risk variants are identified using summary statistics from Genome-Wide Association Studies (GWAS). Since most GWAS samples are of European ancestry, current PRS have lower predictive ability for populations more genetically distant from the European, which means that health disparities will increase if diagnosing and treating tools are based on current PRS.One of the factors for the lack of transferability of PRS is the heterogeneity of effect sizes that arises from differential environmental exposure distributions. However, knowledge of the right environment variables is rare and challenging. In addition, heterogeneity might not be uniform across the genome, which poses the need to account for heterogeneity per region. Finally, combining summary statistics from different populations without accounting for heterogeneity can be more detrimental than beneficial.We develop a method to leverage information from the European sample to reduce the MSE in the estimation of effect size in the non-European sample. To manage the risk of using different populations as discovery and target populations is that the large sample size of the discovery population might hinder the estimation of population-specific effect sizes, we use a power prior distribution to calibrate the discovery population's influence on the posterior distribution of the effect size in the target population. We parametrize this prior based on LD patterns and heterogeneity. We present a model to combine European summary statistics and non-European individual-level data for continuous traits that uses a Bayesian sparse linear mixed model and incorporates the power prior. By modeling the heterogeneity at a variant granularity, we claim that we can increase the estimation of shared effect sizes without compromising the discovery of population-specific effect sizes, which will improve the predictive ability of PRS.

PrgmNr 2705 - M-DATA: A statistical approach to jointly analyzing *de novo* mutations

View session detail

Author Block: **Y. Xie**[1], M. Li[1], W. Dong[2], W. Jiang[1], H. Zhao[1]; [1]Dept. of Biostatistics, Yale Univ., New Haven, CT, [2]Dept. of Genetics, Yale Univ., New Haven, CT
Disclosure Block: **Y. Xie:** None.
Recent studies have demonstrated that multiple early-onset diseases have shared risk genes, based on findings from *de novo* mutations (DMNs). Therefore, we may leverage information from one trait to improve statistical power to identify genes for another trait. However, there are few methods that can jointly analyze DNMs from multiple traits. In this study, we develop a framework called M-DATA (Multi-trait framework for *De novo* mutation Association Test with Annotations) to increase the statistical power of association analysis by integrating data from multiple correlated traits and their functional annotations. Using the number of DNMs from multiple diseases, we develop a method based on an Expectation-Maximization algorithm to both infer the degree of association between two diseases as well as to estimate the gene association probability for each disease. We apply our method to a case study of jointly analyzing data from congenital heart disease (CHD) and autism. Our multi-trait model was able to identify 23 genes including 12 novel genes, which is substantially more than single-trait analysis. Among the 12 novel genes, our analyses suggest *POGZ*, *KDM5B* and *NAA15* may be considered as new candidate CHD genes, leading to novel insights into CHD disease etiology.

PrgmNr 2706 - Modeling transcription factor binding in statistical tests of common and rare non-coding regulatory variants

View session detail

Author Block: **N. Patel**[1], b. jin[2], W. S. Bush[3]; [1]Inst. for Computational Biology, Case Western Reserve Univ, Cleveland, OH, [2]case western reserve Univ., cleveland, OH, [3]Case Western Reserve Univ, Cleveland, OH

Disclosure Block: **N. Patel:** None.

Non-coding variants altering transcription factor(TF) binding can significantly affect gene expression regulation, which has been shown to be associated with complex diseases. Despite the development of transcriptome-wide association study(TWAS) approaches, integrating TF binding information into models of variant influence on gene expression is limited and the inclusion of rare variants (MAF cis-regulatory TF scores for common variants to generate TWAS gene expression prediction models. TFKin is a kernel-based variance component test for performing association between a phenotype and an estimated *cis*-regulatory genetic kinship matrix generated using rare non-coding variant-TF scores. To validate these approaches, we used whole blood genotype and expression data from the Depression Genes Network (N = 922) and GTEx(N =313). We compared the performance of TFXcan with EpiXcan, a TWAS approach that uses broad epigenetic priors generated using eQTL summary statistics to weight variants. We obtained a statistically significant percent improvement(PI) in average cross-validation R^2 for the expression, across all the genes, for TFXcan models compared to the EpiXcan models(PI_{DGN} = 5%, PI_{GTEx} = 10%). This improvement was also seen in average prediction R^2 , when we used models trained using one dataset to impute expression for the other($PI_{DGN â¶ GTEx}$ = 19%; $PI_{GTEx â¶ DGN}$ = 8%). The TFKin approach, besides producing a power of 87%, generated higher percent enrichment(PE) of significant genes replicating in an independent dataset ($PE_{DGNâ¶GTEx}$ = 45%; $PE_{GTExâ¶DGN}$ = 83%), compared to a SKAT based framework weighting rare variants based on their MAF ($PE_{DGNâ¶GTEx}$ = 41%; $PE_{GTExâ¶DGN}$ = 80%). Both, TFXcan and TFKin take advantage of biologically relevant TF based regulatory information to estimate genetic variant influence over gene expression. Furthermore, these methodologies can be easily applied to find genes dysregulated in any complex disease trait.

PrgmNr 2707 - Optimising Polygenic Score Portability Across Ancestral Populations

View session detail

Author Block: **O. Pain**[1], T. Kono[1], R. Arathimos[1], J. R. Coleman[1], K. B. Hanscombe[1], D. Howard[1], G. D. Breen[1], L. Folkersen[2], C. M. Lewis[1]; [1]King's Coll. London, London, United Kingdom, [2]Danish Natl. Genome Ctr., Copenhagen, Denmark
Disclosure Block: **O. Pain:** None.
Introduction: The predictive utility of polygenic scores (PGS) is increasing as the sample sizes within genome-wide association studies (GWAS) become larger and as novel PGS methodology is developed. However, the vast majority of GWAS are based on European ancestry individuals, and PGS have a low portability when applied to non-European populations (portability = $R^2_{\text{non-European}} / R^2_{\text{European}}$). In this research, we compared the portability of PGS across polygenic score methods, and assessed how similarity in allele frequency and linkage disequilibrium (LD) patterns might improve portability. **Methods**: We compare PGS methodology using Height and Body Mass Index (BMI) in unrelated UK Biobank participants (N = 394,434) genetically mapped to the five 1000 Genomes super populations. PGS were calculated using European-based GWAS summary statistics for Height (Wood *et al*. 2014) and BMI (Lock *et al*. 2015). We used previously developed PGS methods, including pT+clump, LDpred2, lassosum, PRScs, SBayesR, and DBSLMM, as well as two novel approaches called imputed gene-expression risk scoring (GeRS), and cross-population similarity weighted polygenic scoring (CrossPop). GeRS integrates multi-SNP predictors of gene expression in the PGS. CrossPop PGS reweight genetic effects according to their similarity in allele frequency and linkage disequilibrium (LD) across populations. **Results**: Previously developed PGS methods showed a similar portability across populations, with relative performance of each method being similar in European and non-European populations. The best prediction was achieved using models containing LDPred2 or lassosum PGS based on a range of shrinkage parameters. Both novel methods, GeRS and CrossPop PGS, provided substantially improved prediction in specific scenarios. For example, using GeRS for BMI in East Asians, the variance explained increased from 3.9% to 7.1% ($p=1.02x10^{-7}$), with a corresponding the portability increase from 0.53 to 0.93 compared to Europeans (baseline value 1.0). Using CrossPop, the variance explained increased from 4.3% to 10.1% ($p=6x10^{-9}$) for Height in Admixed Americans, corresponding to a portability increase from 0.42 to 1.05 compared to Europeans. **Conclusion**: These results indicate that commonly applied polygenic scoring approaches have similar values of portability across ancestral populations. Furthermore, these findings suggest integration of functional annotations, such as effects of gene expression, and allele frequency and LD similarity information, can improve PGS portability across populations. We are currently expanding this study to evaluate these PGS methods in a wider context.

PrgmNr 2708 - Ordinal regression with gene-based aggregation tests in the UK Biobank

View session detail

Gene-based variant aggregation is an important strategy to increase power to detect associations between rare variants and phenotypes of interest. Traditionally these methods have been used when testing for associations with either categorical or quantitative traits. Here we perform burden testing with regression on ordinal traits. Much of the data in the UK Biobank is not accurately captured by binary or quantitative measurements, including many answers to the touch-screen questionnaire. Performing ordinal regression allows for the inclusion of a wider set of data into burden testing. To demonstrate this method, we tested exome-wide gene-based variant aggregations in 363973 individuals against eight ordinal phenotypes, with a minimum of 100 carriers per phenotype, and found type 1 error to be well controlled. The following phenotypes were tested: chronotype, frequency of insomnia, frequency of daytime napping, alcohol intake frequency, overall self-assessed health rating, relative age of first facial hair, usual walking pace, and frequency of recent lack of interest or pleasure in doing things. We found known associations between *ADH1C* predicted loss of function variants (pLOF) with alcohol intake frequency ($p = 4.1 \times 10^{-24}$, beta = 0.23 SD decrease in drinking) and *PER2* pLOF with chronotype ($p = 2.1 \times 10^{-13}$ beta = 1.17 SD increase in morningness). We also found novel associations between *GIGYF1* pLOF and alcohol intake frequency (p-value = 3.5×10^{-14}, beta= 1.14 SD decrease in drinking), *ANKRD12* with alcohol intake frequency (p-value = 5.8×10^{-11}, beta = 0.70 SD decrease in drinking), usual walking pace (p-value = 4.67×10^{-8}, beta = 0.69 SD decrease in walking pace) and overall health rating (p-value = 1.39×10^{-9}, beta = 0.73 SD decrease in overall health), as well as *KDM5B* with daytime napping frequency (p-value = 1.80×10^{-7}, beta = 0.74 SD increase in daytime napping). All three of these genes were previously reported to associate with cognitive function (Chen et al., presentation at ASHG 2020), and we recently reported *GIGYF1* to associate with type 2 diabetes (Deaton et al., medRxiv 2021). These results highlight the importance of including ordinal phenotypes in burden tests of rare variants.

PrgmNr 2709 - PathWAS reveals biologically relevant pathways in complex traits

View session detail

Author Block: **S. M. May-Wilson**[1], E. Macdonald-Dunlop[1], J. F. Wilson[2], N. Pirastu[1]; [1]Univ. of Edinburgh, Edinburgh, United Kingdom, [2]Univ Edinburgh, Edinburgh, United Kingdom
Disclosure Block: **S.M. May-Wilson:** None.
Rationale: With the aim of understanding the biology underlying the genetics of complex traits and multifactorial disease it is increasingly common to incorporate omics, such as in TWAS, to improve the power of discovery and biological relevance of GWAS. However, these studies could be limited by examining the effects of individual genes acting in isolation and not in the context of broader biological networks. Here we present an alternative and novel method for incorporating the information of multiple genes grouped by pathways, in an attempt to predict pathway functionality and to find associations of pathways with complex traits.
Method: We grouped genes from known biological pathways obtained from databases, such as KEGG, and created polygenic risk scores (PRS) for these genes using SNPs from QTL data. These PRS were created using effect sizes weighted by LD structure, using the statistical method LDpred2. The relative contribution of each gene on overall pathway functionality was estimated by fitting a multivariable Mendelian randomisation (MR) analysis, using the QTL SNPs as exposures against one of 184 proteomics â□□end-pointsâ□□ from the SCALLOP consortium, measured in 26000 individuals. The PRS and MR results were then combined to create an overall pathway PRS, validated in an independent sample. The significant pathway scores were then used to search for associations with traits in UK Biobank via PheWAS. We then also conducted additional PheWAS analyses, with the removal of individual genes from the pathway PRS in order to determine if the pathways were the associated factor rather than any individual gene.
Results: Our method successfully predicted the end-point protein level in 12 pathways. These pathways are primarily immune response pathways, such as NOD-like receptor signalling and Toll-like receptor signalling. From these results, PheWAS identified numerous associations between these pathways and traits recorded in UK Biobank, such as lymphocyte and leukocyte count, as well as height, weight and lung-function traits. Removal of individual gene scores resulted in 8 significant pathway-trait associations, several of which are supported by the existing literature.
Conclusion: Pathway scoring offers the prospect of a more powerful and holistic analysis of GWAS results, with the potential to discover relevant causal pathways for complex traits. By incorporating additional QTL and proteomics datasets, along with improvements made in definition of pathways, in future it may be possible to improve the prediction of pathway functionality for any individual, thus allowing potential examination of pathway relevance in many complex traits and diseases.

PrgmNr 2710 - Penalized mediation models for multivariate data

View session detail

Author Block: **D. J. Schaid**[1], O. Dikilitas[1], J. Sinnwell[1], I. J. Kullo[2]; [1]Mayo Clinic, ROCHESTER, MN, [2]Mayo Clinic, Rochester, MN
Disclosure Block: **D.J. Schaid:** None.
Statistical methods to integrate multiple layers of data, from exposures to intermediate traits to outcome variables, are needed to guide interpretation of complex data sets about which variables are likely contributing in a causal pathway from exposure to outcome. Statistical mediation analysis based on structural equation models provide a general modeling framework, yet they can be difficult to apply to high-dimensional data and they are not automated to select the best fitting model. To overcome these limitations, we developed novel algorithms and software to simultaneously evaluate multiple exposure variables, multiple intermediate traits, and multiple outcome variables. Our penalized mediation models are computationally efficient and simulations demonstrate that they produce reliable results for large data sets. Application of our methods to a study of vascular disease demonstrate their utility to identify novel direct effects of single nucleotide polymorphisms (SNPs) on coronary heart disease and peripheral artery disease, while disentangling the effects of SNPs on the intermediate risk factors including lipids, cigarette smoking, systolic blood pressure, and type2 diabetes.

PrgmNr 2711 - Pleiotropy testing identifies genetic variants with pleiotropic evidence in Alzheimerâ□□s disease

View session detail

Author Block: **N. Lorincz-Comi**[1], X. Zhu[2]; [1]PQHS, Case Western Reserve Univ., Cleveland, OH, [2]Case Western Reserve Univ, Cleveland, OH
Disclosure Block: **N. Lorincz-Comi:** None.
Mendelian randomization (MR) analysis can estimate the causal effect of a given exposure on an outcome while identifying pleiotropic variants among instrumental variables via a t-test. The t-test can then be applied to genome-wide variants to search for associations with both the exposure and outcome given the MR causal estimate, and the associations can be interpreted as potential pleiotropy.
In the present study, we studied the causal contributions of brain regions of interests (ROIs) obtained from brain imaging on Alzheimerâ□□s disease (AD) using GWAS summary statistics. Among 101 ROIs, we identified the top 12 ROIs genetically correlated with AD after strict QCs. We estimated causal effects of the top 12 ROIs genetically correlated with AD and performed genome wide pleiotropy analysis. MR results indicate a positive causal effect of hippocampal volume on AD risk (OR=1.02, P=0.015), and a negative effect of the caudate (OR=0.51, P=0.024) on AD risk. From MR models for all 12 brain regions, one SNP (rs35283920, 16:70687195:T:C, 31.3% MAF) was genome-wide significant in pleiotropy testing but had no genome-wide significant associations in the AD GWAS in a 1 Mb window. As such, rs35283920 tagged a novel locus that was undetected in the original AD GWAS. This SNP had associative evidence (effect size=0.01, P=0.048) in respective ROI GWAS (ventral diencephalon). The gene closest to this SNP, *IL34*, was thus not originally identified by the AD GWAS of >425,000 participants, cases defined as having AD or a family history of AD. However, this gene was identified in a smaller GWAS (nâ□□315,000) of AD family history only, this study including additional clinical covariates in their GWAS analyses.
We demonstrated that the MR pleiotropy t-test can be used to identify novel SNP associations undetected by standard GWAS analysis. The identified associations potentially have pleiotropic effect. We additionally aim to cluster the 101 ROIs into a small number of distinct groups based on genetic correlations and treat these groups as exposures in MR analysis with AD, educational attainment, and cognition.

PrgmNr 2713 - scRegMap: A statistical framework for mapping context-specific regulatory variants using single cell RNA-sequencing

View session detail

Author Block: **A. Cuomo**[1,2], T. Heinen[3], D. Vagiaki[4], D. Horta[2], J. C. Marioni[2,1,5], O. Stegle[3,4,1];
[1]Wellcome Sanger Inst., Hinxton, United Kingdom, [2]European Bioinformatics Inst. (EMBL-EBI), Hinxton, United Kingdom, [3]DKFZ, Heidelberg, Germany, [4]EMBL, Heidelberg, Germany, [5]Cambridge Inst. Cancer Res. UK (CRUK), Cambridge, United Kingdom
Disclosure Block: **A. Cuomo:** None.
Single cell RNA sequencing (scRNA-seq) is widely applied to assess cellular heterogeneity in human tissues and cell-based models. Technological advances and exponential reduction in cost have enabled the first population-scale scRNA-seq studies, which have assayed single-cell transcriptomes in hundreds of genetically diverse individuals. However, current workflows to analyse these data remain largely based on principles for analysing conventional bulk expression quantitative trait locus (eQTL) studies, and hence fail to fully exploit complex scRNA-seq readouts. A critical limitation of current methodology is the need to define cell types for eQTL mapping a priori, which limits novel opportunity to chart continuous and unbiased landscapes of regulatory variants. To address this, we here proposed scRegMap, a statistical framework to map regulatory variants across the continuous manifold of cellular environments estimated from scRNA-seq. scRegMap allows to test for and quantify genetic effects on gene expression at the resolution of individual cells, while flexibly sharing statistical strength related cell states. Our framework provides a principled strategy to identify and characterize heterogeneous genetic effects that vary across cell states and cell types. We validate scRegMap using simulated data and apply it in the context of recent single-cell eQTL studies of differentiating iPS cells from our lab [1,2] where we demonstrate its power to map context-specific genetic effects and identify the cellular subpopulations where they are active. By clustering single-cell allelic effects, we identify regulatory modules as eQTLs with shared response patterns across cell states. Moreover, using our approach, we identify novel colocalization signals that connect a subpopulation of dopaminergic neurons to schizophrenia risk.

PrgmNr 2714 - Simulated data provides insight on optimal control method for confounders

View session detail

Author Block: **L. Breidenbach**[1], L. K. Davis[2]; [1]Vanderbilt, Maple Grove, MN, [2]Vanderbilt Univ Med Ctr., Nashville, TN
Disclosure Block: **L. Breidenbach:** None.
Case/control studies are a common method to study how an exposure affects an outcome. However, population stratification, environmental variables, and other confounders often obscure results. Different control methods can be employed to correct for these problems. One popular approach is regression, where each confounder is accounted for by weighting its impact on the exposure and outcome. Another popular approach is matching, which matches controls and cases on potential confounding variables. There are many subtypes of analyses within these two general approaches, thus creating a multitude of options for controlling confounding. However, there is little guidance for choosing an appropriate control method for a given data set. Here we hypothesize that the choice of a control method has a significant impact on results, and that knowing which one to choose will lead to more accurate, reproducible science. To test this, we simulated data of various sample sizes (N=100 through N=10,000) using Bayesian Networks (BNs). Th BNs allowed us to embed complex relationships between the exposure, the outcome, and confounders, modeled after directed acyclic graphs (DAGs). Next, we varied the effect strength the exposure had on the outcome. We then tested the ability of various regression and matching methods of confounding control to recover the inputted effect strength. We compared the regression-based control methods to matched control methods to determine which approach yielded the most accurate estimate of the true effect size.

PrgmNr 2715 - Simulations to understand potential miscalibration in fine-mapping algorithms

View session detail

Author Block: **R. Elzur**[1,2], R. Cui[3,2], M. Kanai[1,2], J. C. Ulirsch[1,2], Z. Fan[4], H. K. Finucane[5,1,2]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Analytic and Translations Genetics Unit, Massachusetts Gen. Hosp., Boston, MA, [3]Broad Inst, Cambridge, MA, [4]Yale Univ., Dept. of Statistics and Data Sci., New Haven, CT, [5]Harvard T. H. Chan Sch. of Publ. Hlth., Cambridge, MA
Disclosure Block: **R. Elzur:** None.
Genetic fine-mapping uses genome-wide association study results to select variants with a high probability of being causal for a trait. State of the art algorithms such as SuSiE and FINEMAP have led to biological insights; however, we have found that these and other algorithms produce posterior inclusion probabilities (PIP) for variants that differ greatly at different sample sizes. Specifically, when fine-mapping a range of well-powered phenotypes in the UK Biobank using sample sizes of 360k versus 100k individuals, we see a high replication failure rate (RFR) of up to 36%, that is, a high proportion of variants reported at N=100k as putatively causal (PIP>0.9) reported as not putatively causal (PIPWe have re-created replication failure in small-scale simulations. First, in simulations with variant effect sizes drawn from a uniform distribution instead of a normal distribution, as specified by the prior, RFR for SuSiE approached 12% due to false positives at the smaller sample size. Second, in loci with 2 causal variants with similar effect size in linkage disequilibrium r = 0.9, SuSiE and Approximate Bayes Factors RFRs exceeded 10%. However, these and other simulations that achieve RFRs approaching those observed in real data do not align with what are considered realistic genetic architectures for complex traits.

To better understand what might be driving miscalibration, we simulated larger, more realistic data. We drew random genotypes from UK Biobank imputed genotype probabilities. We then sampled causal variants and effect sizes from the SuSiE posterior distributions obtained by fine-mapping genome-wide significant loci for Height in 360k individuals from the UK Biobank. We randomly selected additional causal variants in accordance with polygenic models for complex traits, and we simulated uncorrected population stratification. After simulating phenotypes, we applied quality control thresholds and excluded some simulated causal variants. Ongoing work involves conducting an association study, fine-mapping significant loci, and assessing calibration on this data.

PrgmNr 2716 - Spatially Aware Dimension Reduction for Spatial Transcriptomics

View session detail

Author Block: **L. Shang**[1], X. Zhou[2]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Univ MICHIGAN, Ann Arbor, MI
Disclosure Block: **L. Shang:** None.
Spatial transcriptomics are a collection of genomic technologies that have enabled transcriptomic profiling on tissues with spatial localization information. Analyzing spatial transcriptomic data is computationally challenging, as the data collected from various spatial transcriptomic technologies are often noisy and display substantial spatial correlation across tissue locations. Here, we develop a spatially aware dimension reduction method, SpatialPCA, that can extract a low dimensional representation of the spatial transcriptomics data with enriched biological signal and preserved spatial correlation structure, thus unlocking many existing computational tools previously developed in single-cell RNAseq studies for tailored and novel analysis of spatial transcriptomics. We illustrate the benefits of SpatialPCA for spatial region detection, trajectory inference on the tissue, and high-resolution spatial map construction in multiple spatial transcriptomic datasets. In these applications, SpatialPCA identifies key molecular and immunological signatures in a newly detected tumor surrounding microenvironment including a tertiary lymphoid structure that shapes the gradual transcriptomic transition during tumorigenesis and metastasis, detects the past neuronal developmental history that underlies the current transcriptomic landscape across tissue locations in the cortex and cerebellum, and reveals fine-resolution structural and transcriptomic architectural details underpinning the functionality of complex tissues.

PrgmNr 2717 - Spatially Informed Cell Type Deconvolution for Spatial Transcriptomics

View session detail

Author Block: **Y. Ma**[1], X. Zhou[1,2]; [1]Dept. of Biostatistics, Univ. of Michigan, Ann Arbor, MI, [2]Ctr. for Statistical Genetics, Univ. of Michigan, Ann Arbor, MI
Disclosure Block: **Y. Ma:** None.
Various spatially resolved transcriptomic technologies have enabled gene expression profiling on complex tissues with spatial localization information. The majority of these technologies, however, are currently of limited spatial resolution and effectively measure on each tissue location the average gene expression from a mixture of cells of potentially heterogeneous cell types. Consequently, deconvoluting cell types on tissue locations measured in spatial transcriptomics becomes a key for identifying the spatial localization of different cell types and characterizing the structural and functional organization of complex tissues. Here, we introduce a deconvolution method, CARD, that leverages cell type specific expression information from single cell RNA sequencing (scRNA-seq) for the deconvolution of spatial transcriptomics. A unique feature of CARD is its ability to model the spatial correlation in cell type composition across tissue locations, thus enabling spatially informed cell type deconvolution. Modeling spatial correlation allows us to borrow the cell type composition information across locations on the entire tissue to accurately infer the cell type composition on each individual location, achieve robust deconvolution performance in the presence of mismatched scRNA-seq reference, impute cell type compositions and gene expression levels on unmeasured tissue locations, and facilitate the construction of a refined spatial tissue map with a resolution much higher than that measured in the original study. We demonstrate the benefits of CARD through extensive simulations and in-depth analysis of four spatial transcriptomics data sets with distinct technologies. In the real data applications, CARD revealed refined tissue structures with enhanced spatial resolution and identified novel marker genes that underlie the functional and structural organization of the olfactory bulb and hippocampus. CARD also identified multiple cell types and molecular markers with distinct spatial localization that define the progression, heterogeneity and compartmentalization of pancreatic cancer.

PrgmNr 2718 - Stacking Method to Improve Polygenic Risk Prediction in Admixed Individuals using Population Specific GWAS Effect Sizes

View session detail

Author Block: **K. S. Liao**[1], S. Zollner[2]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Univ Michigan, Ann Arbor, MI

Disclosure Block: **K.S. Liao:** None.

Polygenic risk score (PRS) predictions for admixed individuals, in whom genomic segments trace back to multiple ancestries, perform poorly when constructed from European-ancestry GWAS. Incorporating GWAS effect size estimates from each population represented in a sampleâ□□s admixture may improve polygenic prediction. Here, we propose a machine learning stacking method to improve polygenic risk prediction in admixed individuals that leverages population specific GWAS effect sizes. Our stacking method uses a window-based framework to account for heterogeneity in local admixture across samples. In training data, a local European (EUR) and African (AFR) PRS are computed in each window across the genome via clumping and thresholding (C+T) using their respective population GWAS. We then â□□stackâ□□ local PRSs across windows from the training data in a penalized regression model using all local PRSs as covariates. Stacking in a penalized framework provides an efficient data-driven approach to learn which populationâ□□s effect sizes maximize prediction in a local region. In testing data, learned weights from the penalized regression model are used to compute a stacked PRS as a linear combination of local PRSs. For a baseline comparison, we compute a â□□traditionalâ□□ EUR and AFR PRS using genome wide C+T. To validate our method, we simulate admixed African Americans (AA) and GWAS effect sizes for EURs and AFRs under a shared genetic architecture. Method performance is assessed using the Pearson correlation between the â□□trueâ□□ PRS (PRS using only the designated GWAS causal variants) and estimated PRS for each method. Across simulations, the average overall correlation between the stacked PRSs and true PRSs was 0.79 compared to 0.58 and 0.57 for the traditional EUR and AFR PRSs, respectively. When stratifying by EUR ancestry quantiles, the stacked PRSs outperformed both traditional PRSs with correlation increases to the true PRS ranging from 26.1% to 52.2%. Furthermore, while the performance of the traditional PRSs showed ancestry dependence (correlations for the EUR and AFR PRSs linearly increased by 3.24% and decreased by 1.58% respectively for each EUR ancestry quantile increase), our stacking approach removed the relationship between PRS performance and global ancestry with a mere 0.65% correlation increase across quantiles.

We based our work on simulations to ensure high-powered GWAS effect sizes in the understudied African population. With ongoing efforts to fund larger genetic studies in diverse populations, our approach will allow for a simple data-driven method for polygenic risk prediction in individuals of all admixture types in the near future.

PrgmNr 2719 - Testing Mendelian Randomization methods via zero-relevance analysis of COVID-19 traits

View session detail

Author Block: **T. Bond**[1,2,3,4], T. Palmer[1,4], D. Evans[2,5,6], G. Davey Smith[5,4], D. Lawlor[1,4]; [1]MRC Integrative Epidemiology Unit at the Univ. of Bristol, Bristol, United Kingdom, [2]Univ. of Queensland Diamantina Inst., Brisbane, Australia, [3]Dept. of Epidemiology and Biostatistics, Imperial Coll. Disclosure Block: **T. Bond:** None.
Background: Mendelian randomization (MR) is an increasingly used group of methods which exploit genetic association data to improve causal inference. The validity of MR is undermined when genetic variants affect the outcome independently of the exposure, particularly via confounders of the exposure-outcome relationship (correlated horizontal pleiotropy). The COVID-19 pandemic provides an opportunity to test the robustness of recent MR methods which aim to overcome this limitation. Participants of GWAS conducted prior to 2020 constitute a â□□zero-relevanceâ□□ group, in which COVID-19 traits cannot conceivably have had causal effects on any outcomes. We tested whether MR methods correctly infer this, using COVID-19 traits as negative control exposures. **Methods:** Using Linkage Disequilibrium Score Regression (LDSC) we estimated genetic correlations (rG) between a range of socioeconomic and biomedical traits in the UK Biobank (UKB), and two COVID-19 Host Genetics Initiative phenotypes: hospitalized COVID-19 cases, and cases with COVID-19 or SARS-CoV-2 infection, each versus separate control groups (comprising all non-case individuals). We then applied numerous MR methods in a Two-Sample MR Phenome-Wide Association analysis (MR-PheWAS), testing effects of liability to COVID-19 traits on 869 outcome traits. As a positive control, we conducted an MR-PheWAS in the opposite direction, testing effects of 869 traits on COVID-19 outcomes. **Results:** LDSC provided strong evidence for genetic correlation between COVID-19 traits and numerous socioeconomic-related traits, raising the prospect that COVID-19 traits are subject to pervasive correlated pleiotropy via socioeconomic confounders. MR-PheWAS analyses indicated that the MR-Egger, weighted median and weighted mode-based estimators inferred more statistically significant causal effects of COVID-19 liability on other traits than would be expected by chance. Widely used pleiotropy detection methods did not provide evidence for horizontal pleiotropy. **Conclusions:** Our results suggest that commonly used MR methods may have limited robustness to pleiotropic bias, so should not be viewed as definitive evidence for a causal effect in isolation. COVID-19 traits may provide valuable negative control exposures for studies developing or applying MR methods.

PrgmNr 2720 - The construction of multi-ethnic polygenic risk score using transfer learning

View session detail

Author Block: **Z. Zhao**[1], B. Mukherjee[1], S. Lee[2]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Seoul Natl. Univ., Seoul, Korea, Republic of
Disclosure Block: **Z. Zhao:** None.
Methods for polygenic risk scores (PRS), including pruning and thresholding (PT), lassosum (lsum) and PRS-CS, have been extensively investigated in recent years. As most existing GWAS were conducted in European or East Asian individuals, the existing PRS models have limited transferability to minority populations such as Africans and South Asians. Although recent studies have developed multi-ethnic PRS models that linearly combine multiple PRS trained with different ancestry GWAS, they remain under-powered.
Here we propose a novel multi-ethnic PRS using transfer learning from machine learning literature. Our approach, TL-PRS, fine-tunes the potentially biased model trained with GWAS summary statistics from the majority ancestry to the target dataset of the minority ancestry. TL-PRS can use any existing PRS methods (such as lsum and PRS-CS) as a baseline method for fine-tuninge. Using the potentially biased baseline parameter estimates as initial values, TL-PRS iterates the gradient descent algorithm to adapt the parameters for the target ancestry group. In the presence of multiple GWAS summary statistics from different ancestries, TL-PRS combines fine-tuned PRS using the linear combination. Through simulation studies, we show that TL-PRS improved the performance of PRS with a wide range of genetic architectures and cross-population genetic correlations. TL-PRS was most effective when genetic correlations between populations and samples used for calculating summary statistics discovery GWAS sample sizes were small and the genetic architecture was less polygenic. For example, when genetic correlation was 0.4, TL-PRS-lsum attained on average a 228% and 36% relative improvement in prediction accuracy compared to lsum when the causal variants were 0.1% and 1% respectively, while TL-PRS-CS attained on average a 26% and 20% relative improvement compared to PRS-CS.
In the application of 8,168 Africans of UK Biobank data, TL-PRS substantially improved the prediction accuracy of all six quantitative and two dichotomous traits. Compared to lsum, TL-PRS-lsum attained a 21% and 26% average relative improvement in prediction accuracy when using Biobank Japan and UK Biobank GWAS summary statistics, respectively; the average relative improvement of TL-PRS-CS over PRS-CS was 40% and 9%, respectively. When combining summary statistics from Biobank Japan and UK Biobank, the TL-PRS-lsum and TL-PRS-CS outperformed the linear combination of PT and PRS-CSx. By improving the polygenic risk prediction in non-European individuals, our approach will increase the usefulness of PRS and reduce potential health disparities.

PrgmNr 2721 - The METRO method improves identification of gene-disease associations through multi-ancestry transcriptome-wide association studies

Disclosure Block: **Z. Li:** None.
Transcriptome-wide association studies (TWAS) integrate genome-wide association studies (GWAS) with gene expression mapping studies for identifying gene-trait associations. So far, almost all existing TWAS methods have focused on using expression studies collected on individuals from a single genetic ancestry, typically European ancestry, for building expression prediction models that are necessary for the subsequent TWAS analysis. However, due to the differences in allele frequencies and linkage disequilibrium patterns, SNP effects on gene expression can vary, sometimes quite substantially, across populations with diverse genetic backgrounds. Consequently, the expression prediction models constructed in one genetic ancestry may not necessarily benefit or transfer to another, thus hindering the application of TWAS towards underrepresented populations. In addition, the expression prediction models constructed in different groups of genetic ancestry may capture distinct genetic architectures underlying gene expression and thus may provide complementary information that could otherwise improve the effectiveness of TWAS. Here, we develop a new computational method, METRO (Multi-ancEstry TRanscriptOme-wide analysis), that leverages expression data collected from multiple genetic ancestries to enhance TWAS. METRO incorporates expression prediction models constructed in multiple genetic ancestries through a likelihood-based inference framework, producing calibrated test statistics with substantially improved TWAS power. We illustrate the benefits of METRO through comprehensive simulations and applications to four GWAS datasets that include two of primarily European ancestry and two of primarily African ancestry. In the real data applications, we leverage expression data measured on 1,032 African Americans and 801 European Americans from the Genetic Epidemiology Network of Arteriopathy (GENOA) study to identify a substantially larger number of gene-trait associations as compared to existing TWAS approaches. Among the newly identified associations are *ABCA1* and *SIK3* with high density lipoprotein and *MAPT* with type II diabetes. These new associations highlight the critical role of cellular transportation and homeostasis in regulating lipid metabolism and provide evidence that the pathology in microtubule-associated protein tau may act as a key trigger of impaired insulin sensitivity and secretion in the etiology of type II diabetes.

PrgmNr 2722 - Ultrahigh dimensional learning of polygenic risk scores for Mendelian randomization studies

View session detail

Author Block: **X. Zhang**, D. Kong, L. Wang, S. Volgushev; Univ. of Toronto, Toronto, ON, Canada
Disclosure Block: **X. Zhang:** None.

Mendelian randomization (MR) is a statistical method by which genetic variants, usually single nucleotide polymorphisms (SNPs), are leveraged as instrumental variables (IV) to examine the causal relationship between modifiable exposure or risk factor and a clinically relevant outcome from observational data, while control for any unobserved confounder. Finding appropriate genetic variants is crucial to make convincing causal conclusions from MR analysis. Previously, selection of genetic variants replies on expert knowledge. Nowadays, explosion of modern data collection has facilitated access to a larger set of genetic variants associated with risk factors and disease-related outcomes. Current methods work well when candidate instruments are of moderate size. However, for the identification of valid IVs under ultrahigh dimensional setting, normal in practice, empirical evidence implies that existing procedures may miss many or even all the valid IVs, due to inclusion of irrelevant variables that have non-negligible correlation with the exposure.

In response to this challenge, we propose a novel approach to first remove irrelevant variants from the candidate set. Some variants in the remaining set might not be valid instruments due to pleiotropic effects, linkage disequilibrium and so on. To address this problem, we then apply existing methods that aims to make valid causal inference in the presence of invalid IVs to identify valid instruments. To obtain more accurate causal effect estimate, we aggregate the effect of each estimated valid IV by constructing polygenic risk score (PGS), which may explain a considerable proportion of variation in the exposure and thus produce an adequately powered MR analysis. In addition, we provided theoretical guarantee of the proposed procedure.

To evaluate the performance, we investigate the causal relationship between tau protein and Alzheimerâ□□s Disease (AD). The data we use comes from the Alzheimerâ□□s Disease Neuroimaging Initiative (ADNI) database. In our analysis, we consider 357 subjects and approximately 3 million SNPs as candidate instruments. The proposed method has identified a new set of genetic variants that were missed by existing approaches.

Introduction: Preterm birth (PTB) is the main condition related to perinatal morbimortality worldwide. The aim of this exploratory study was to identify associations of genetic variants with spontaneous PTB considering maternal environmental exposures.

Methods: We carried out a retrospective case-control study including sociodemographic, neighborhood, and obstetric data of women who gave birth at a maternity hospital from TucumÃin, Argentina, between 2005 and 2010. Using the Ion Torrent S5 platform, we sequenced the exons of *KCNN3*, *CRHR1*, *COL4A3*, *PON1*, and *F3* genes from blood samples of 69 preterm (case) and 61 term newborns (control). We identified genetic variants and performed quality controls using the Ion Torrent procedure. We studied the association of genetic variants with PTB using two methodologies, in both we used an additive genetic model. On the one hand, we used a penalized logistic regression including variants, ancestry, fetal sex, and 48 variables related to maternal exposures (sociodemographic, neighborhood, diseases, health care, and obstetric). We selected the penalized model based on binomial deviance using leave-one-out cross validation. On the other hand, we performed a multiple correspondence analysis (MCA) on maternal exposure variables. Then we performed logistic mixed models for each variant including covariates related to ancestry, fetal sex, and increasing the inclusion of MCA components from 0 to 10 as covariates. We used Wald test to get effect size estimates and analyzed these models using quantile-quantile plots and genomic control.

Results: In the studied sample we identified 57 genetic variants. The T allele of rs4845397 (*KCNN3*) variant was included in the selected model with the penalized logistic regression while in all logistic mixed models, it had an odd ratio lower than 1 with a 95% confidence interval. The genomic control of the logistic mixed model that included the first 3 MCA components, which explain 19.4% of the variance of maternal exposures, was 1.02. In this model the variant odd ratio was 0.25 (CI 95% 0.10 - 0.62, P 0.0025, false discovery rate 0.14). The models that included 4 or more MCA components reported a genomic control greater than 1.10. In the studied sample the frequency of the T allele was 16.5%.

Conclusions: The results of this exploratory study suggest that the *KCNN3* variant would be

associated with spontaneous PTB considering 19.4% of the variance of maternal exposures. Future studies with a larger sample size are necessary to confirm these findings and to analyze a greater number of exposures.

PrgmNr 2725 - A phenome-wide association study of telomere length using combined qPCR and whole genome sequencing data in 136,597 UK Biobank participants

View session detail

Author Block: **O. Burren**, S. V. V. Deevi, Q. Wang, H. Olsson, K. J. Carss, A. S. Platt, S. Petrovski; AstraZeneca, Cambridge, United Kingdom

Variation in telomere length (TL) between individuals has been associated with a range of human diseases, including cancer and idiopathic pulmonary fibrosis (IPF). Previous population-based studies have successfully used either qPCR[1] or whole-genome sequencing[2] (WGS) measurements to characterise phenotypic and genetic associations with TL. In this pilot study we compared qPCR and WGS TL estimates for 136,597 UK Biobank (UKB) participants, finding only partial correlation (r=0.41) between the two measures. We hypothesised that a PCA-derived linear combination[3] of both WGS and qPCR measurements might optimise biological signal and boost power for phenotypic and genetic association analyses. For the same ~137K UK Biobank participants, we compared GWAS statistics of our combined PCA TL score with those derived from qPCR and WGS measurements, identifying 64, 55 and 42 common variant loci, respectively. And, in support of the combined PCA TL approach all but two of the 64 loci from our PCA TL score replicated in a larger ~470,000 qPCR-only UKB study[1]. Using our PCA TL score we examined over 33,000 binary clinical endpoints finding 106 significant associations that included known positive (e.g., prostate cancer $P_{pc1}=1.7 \times 10^{-15}$, $\hat{I}^2_{pc1}=1.6$) and negative (e.g., IPF $P_{pc1}=7.8 \times 10^{-43}$, $\hat{I}^2_{pc1}=-0.6$) relationships with TL. By applying a rare variant collapsing approach, we identified ten genes that when genetically aberrated significantly associated with decreased or increased TL. These included three genes where carrying a rare protein-truncating variant associated with maintaining a significantly increased TL compared to the non-carriers. Our pilot study highlights not only the utility of WGS to robustly measure TL at scale but also the value of combining orthogonal TL measurements to demonstrably increase power in downstream analyses. Ongoing work will leverage the WGS and qPCR TL measurements of over 450,000 UKB participants, serving as a platform to both define novel telomere biology genetics and connect this with underlying disease pathogenesis.

Background Phenome-wide association studies conducted in electronic health record (EHR)-linked biobanks have uncovered a large number of genomic loci associated with traits and diseases. However, interpretation of the complex relationships of associated genes and phenotypes is challenging. **Results** We constructed a tissue-level phenome-wide network map of colocalized genes and phenotypes. First, we generated colocalized expression quantitative trait loci from 48 tissues of the Genotype-Tissue Expression project and from publicly available genome-wide association study summary statistics from the UK Biobank. We identified 9,151 colocalized genes for 1,411 phenotypes across 48 tissues. Then, we constructed a bipartite network using the colocalized signals to establish links between genes and phenotypes in each tissue. The majority of links are observed in a single tissue whereas only a few are present in all tissues. Finally, we applied the biLouvain clustering algorithm in each tissue-specific bipartite network to identify co-clusters of non-overlapping genes and phenotypes. The majority of co-clusters contains a small number of genes and phenotypes, and 88.6% of co-clusters are found in only one tissue. To demonstrate functionality of the phenome-wide map, we tested if these co-clusters were enriched with known biological and functional gene classes and observed several significant enrichments. Furthermore, we observed that tissue-specific co-clusters are enriched with reported drug side effects for the corresponding drug target genes in clinical trial data. **Conclusions** The phenome-wide map provides links between genes, phenotypes and tissues across a wide spectrum of biological classes and can yield biological and clinical discoveries. The phenome-wide map is publicly available at https://rstudio-connect.hpc.mssm.edu/biPheMap/.

Purpose/Introduction: Natural history studies of rare diseases permit genotype-phenotype correlations, combining clinical descriptions and molecular diagnostics. The Rate of Progression in *USH2A* Related Retinal Degeneration (RUSH2A) study evaluated genotype-phenotype correlations among patients with disease-causing variants in *USH2A*.**Materials and Methods:** We assessed molecular genetic findings and the visual, auditory, and olfactory phenotypes of 127 participants with Usher syndrome (USH2) (n=80) or non-syndromic autosomal recessive retinitis pigmentosa (ARRP) (n=47) due to *USH2A* variants.**Results:** *USH2A* truncating alleles were associated with USH2 and had a dose-dependent effect on hearing loss severity with no effect on visual loss severity. A group of missense alleles, in an inter-fibronectin domain, appeared to be hypomorphic for photoreceptor degeneration in ARRP. These alleles were associated with later age of onset, larger visual field area, better sensitivity thresholds, and better electroretinographic responses. No effect of missense variants on auditory or olfactory deficit severity was observed. **Conclusion:** This study expands our knowledge of a tissue-specific *USH2A* allelic hierarchy and adds important prognostic implications for genetic counseling and treatment trial endpoints. Genotype-driven predictions of clinical outcomes may inform clinical trials for allelic disorders with pleiotropic phenotypes.

PrgmNr 2728 - Assisted reproductive technologies reduce fetal growth and alter maternal and fetal DNA methylation

Disclosure Block: **D. William:** None.
Numerous observational studies have reported associations between assisted reproductive technologies (ART) and perinatal outcomes. However, the causal nature of these associations remains unclear.
We performed a Mendelian randomization study using a Norwegian cohort of 27,368 genotyped mother-father-newborn trios (613 were ART-conceived children) and investigated the causal effects of ART on birth weight, birth length, maternal and fetal DNA methylation (DNAm). Among these 27368 trios, 745 trios with naturally conceived children and 480 trios with children born via ART have DNA methylation (DNAm) information from Illumina 850K. We estimated the effect of ART using a new unbiased one-sample MR method we have developed called â□□Cross-fitting for Mendelian Randomizationâ□□ (CFMR). We assessed the causality of ART using a powerful pleiotropy-free polygenic risk score as an instrument for ART (area under the curve=0.77 in the test set) using paternally non-transmitted genotypes. We performed an epigenome-wide MR of ART on maternal and fetal DNAm.
We detected 89 CpGs and 158 CpGs causally associated with ART in the children and the mothers, respectively (FDR

PrgmNr 2729 - Enigmas of *TRAF3*: Toward a mechanistic understanding of world differences in gallstone prevalence

View session detail

Author Block: **O. Clay**, S. A. Dingsdag, G. A. Quintero; Univ. del Rosario, BogotÃi, Colombia
Disclosure Block: **O. Clay:** None.
Introduction. An association of the pleiotropic *TRAF3* locus (TNF receptor-associated factor 3) with gallstone prevalence/disease has been observed for a Chilean, largely Mapuche (Native American) population; searches for a similar association in Europe failed (Bustos *et al.*, 2019). Native-ancestry American populations have highest gallstone (and/or type 2 diabetes) prevalence worldwide; if the link is causal, it begs the question of the underlying mechanism(s). Recent attention has been given to potential roles of the bacterial microbiome in gallstone lithogenesis as bacteria are frequently found in the bile and gallstones of patients undergoing cholecystectomy. TRAF3 has roles in innate immune defense against infecting microbes as well as in orchestrating exocyst-mediated extraction of pathogenic bacteria from (bladder) epithelial cells, for removal by immune clearance or body fluids (Miao *et al.*, 2016).
Materials and Methods. Data from 1000 Genomes, including new end-to-end sequences (Ebert *et al*., 2021), were analyzed to identify and characterize the haplotype blocks overlapping and flanking the *TRAF3* gene.
Results. On the basis of a strong CpG island, a corresponding repeat structure varying structurally among haplotype classes, and published methylation data, the promoter region of the 5â gallstone-associated haplotype block of *TRAF3* could be a prime channel allowing common natural variation to influence gallstone prevalence by modulating *TRAF3* transcription. The key structural features (e.g., zinc finger pattern) of the TRAF3 protein and 3â region are encoded by a different haplotype block, located immediately downstream of the promoter blockâs lead SNPs for gallstone association, suggesting independent modulating of the two blocks by common variation. Inter-population differences among the shared haplotypesâ frequencies do not explain why the gallstone effect is observed in Chile but not in Germany.
Conclusion. The salient features of the *TRAF3* promoter haplotype suggest involvement of CpG density-dependent CpG methylation, an epigenetic effect that could be locally modulated, as a likely causal mechanism for the population-specific gallstone association observed and then consolidated by *TRAF3* expression differences in gallbladder and duodenum (Bustos *et al.*, 2019). This partly epigenetic control route could have coevolved with (post)-transcriptional regulation after the Beringian epoch, and with different microbiome backgrounds and dysbioses affecting the biliary tract. A picture emerges of how TRAF3 might act to deter or influence gallstone etiologies through a very different route than other known gallstone genes.

PrgmNr 2730 - Gene expression differences by race and genetic ancestry in B-cell acute lymphoblastic leukemia

Disclosure Block: **F. Barragan:** None.

There are documented differences in clinical presentation and survival by race/ethnicity in children with B-cell acute lymphoblastic leukemia (B-ALL) in the United States: typically, African American (AA) children present with more aggressive cancers than their European American (EA) and Latinx (LAT) counterparts and have worse survival despite EA and LAT children being more frequently diagnosed with B-ALL. Prior work has indicated that racial/ethnic differences in B-ALL outcomes cannot be wholly explained by differences in socioeconomic status or access to care. Related work has also suggested that there may be some genetic factors that could partially explain these residual differences. Using gene expression data generated via microarray and RNA-sequencing on children with B-ALL from the National Cancer Instituteâ□□s TARGET Database (N=324) and St. Judeâ□□s PeCan Server (N=303), we perform differential gene expression analyses by reported race/ethnicity in both datasets, using Limma and DESeq2 with Benjamini-Hochberg (BH) corrections for multiple comparisons. In PeCan using RNAseq data, we identify 374, 198, and 50 statistically significantly differentially expressed (DE; BH adjusted-p

PrgmNr 2731 - Genetic Management in Benign Prostatic Hyperplasia

Lipids metabolism is implicated in neurological diseases and underlying mechanisms suggest modulating cholesterol could be beneficial for neurological disorders, but the effects haven't been thoroughly explored. We used Mendelian Randomization (MR) to evaluate causal effects of lipids in multiple neurological and psychiatric diseases, as well as several brain-related traits. In total, five lipids, HDL, LDL, triglycerides, apolipoprotein A (ApoA), apolipoprotein B (ApoB), and 10 diseases, Alzheimer's (AD), Parkinsonâ□□s, multiple sclerosis (MS), autism, epilepsy, schizophrenia (SCZ), ADHD, bipolar disorder, FTD and major depressive disorder, were included in the analysis. We also studied three brain-related traits, brain volume, education and cognitive performance, to assess causal effects of lipids on intermediate phenotypes. In the univariate analysis, we selected independent genetic instruments (p10), heterogeneity test (Cochranâ□□s Q) followed by radial analysis and visual inspection of the scatter plots. MR was conducted using R package â□□TwoSampleMRâ□□ with five methods: inverse-variance weighting (IVW), MR Egger, weighted median, weighted mode and simple mode. Three protective effects were identified including ApoA for AD (p=2e-9), HDL for education (p=7e-6), and triglycerides for general epilepsy (p=1e-6). Interestingly, our results revealed a protective effect of genetically predicted triglyceride level for epilepsy that is congruent with the ketogenic diet used to control seizures for epilepsy patients. Several suggestive (pHMGCR, *PCSK9* and *LDLR* to explore potential therapeutic effects on neurological traits. We found higher LDLR expression associated with reduced MS risk, but the signal appeared to be driven by a trans-eQTL at the *HLA* locus. MR analyses suggest causal effects of lipids in several neurological disease. Further examination is needed to confirm these findings and understand the underlying mechanisms.

PrgmNr 2733 - Investigating risk factors for perceived facial ageing: A Mendelian randomization study

View session detail

Author Block: **B. Scanlan**, L. Howe, S. Lewis, M. Lyon; Univ. of Bristol, Bristol, United Kingdom
Disclosure Block: **B. Scanlan:** None.

Biological age is one of the most important risk factors for a host of complex diseases because of age-related progressive tissue degeneration that disrupts vital organ architecture and function. At present, there is no gold standard for measuring biological age and existing quantitative techniques are invasive and costly. Perceived age, i.e. how others estimate your age based on your appearance, has been shown to be a reliable predictive biomarker of general cognitive and physical health. For example, looking older than your chronological age has been consistently linked to increased mortality and morbidity. Twin studies suggest a large proportion (approximately 40%) of variation in perceived age is driven by non-genetic factors. Understanding how various biological pathways influence tissue senescence and consequently disease risk and lifespan will identify how to best promote health and longevity in an aging population.

To improve our understanding of factors that influence biological ageing, we performed two-sample Mendelian randomization analyses using Genome-wide Association Study summary statistics to estimate effects of 17 exposures (including BMI, smoking status, alcohol consumption, water intake, educational attainment and age at menarche) on perceived facial ageing. Perceived facial ageing, was measured in UK Biobank (N = 423,999) using self-reported questionnaire data, participants selected whether they are generally told they look â younger than you areâ, â older than you areâ or â about your ageâ. We performed various sensitivity analyses to confirm the robustness of our findings including within-family analyses using sibling pairs.

Mendelian randomization analyses indicated that higher BMI ($P=2.14x10^{-22}$) and smoking heaviness ($P=2.69x10^{-5}$) may lead to being perceived as older than chronological age. Genetic variants associated with skin colour ($P=2.94x110^{-14}$), age at menarche ($P=1.32x10^{-8}$) and male balding patterns ($P=1.37x10^{-26}$, $1.22x10^{-3}$ and $4.78x10^{-16}$ for three balding types) were also associated with perceived facial ageing. Our results provide genetic evidence for effects of physically observable and substance-related phenotypes on perceived facial ageing.

In the frames of the Genetics of Anthropometric Traits - GIANT - consortium, we conducted a large-scale trans-ethnic meta-analysis for height including up to 4M individuals.

To identify traits and disease related outcomes that are affected by genetically determined height, we performed Phenome Wide Association Studies (PheWAS) analyses using a Polygenic Score (PGS) for increased height as the exposure and 1,421 phenotype codes or â□□phecodesâ□□ as the outcome. The phecodes were based on aggregated ICD-10 codes defining specific diseases or traits. The PGS consists of 6,772 conditionally independent variants derived from a trans-ancestry GWAS meta-analysis for adult height, using 50,000 unrelated and randomly sampled European participants of the UK Biobank as LD reference. We examined health-related outcomes from Hospital Episode Statistics (HES) data in the UK Biobank (N= 311,195) and the Million Veteran Project (MVP) (N=217,225). We meta-analysed the PheWAS results obtained from the two cohorts, using a Bonferroni adjusted significance threshold of pThe meta-analysis yielded 161 significant phecodes (pThe identified signals are being further interrogated through Mendelian Randomisation and mediation analyses. The trans-ethnic analysis described here will be also expanded to ancestry-specific groups.

PrgmNr 2735 - Large-scale genome-wide meta-analyses provide insights for the development of new disease modifying targets for osteoarthritis

Disclosure Block: **K. Hatzikotoulas:** None.
Osteoarthritis is one of the leading causes of disability and pain worldwide, with over 300 million people affected. Currently no curative treatments are available. A detailed understanding of disease aetiopathology and novel drug targets are therefore urgently needed. Here, we conducted the largest genome-wide association study (GWAS) meta-analysis for osteoarthritis to date, across 13 international cohorts stemming from 9 populations, in up to 826,690 individuals (177,517 osteoarthritis patients) of European and East Asian descent. We defined 11 phenotypes encompassing all major sites for osteoarthritis at both weight-bearing and non weight-bearing joints. We also performed a sex specific GWAS meta-analysis for each of the 11 osteoarthritis phenotypes separately and carried out a meta-analysis of early osteoarthritis, defined as age at onset younger than 45 years of age. To identify putative effector genes and causal pathways that represent high-value targets for therapeutics, we integrated supportive information from statistical fine-mapping, expression quantitative trait loci (QTL) colocalization, phenome-wide analyses, animal model data, human musculoskeletal and neuronal phenotype data, plasma protein QTL causal inference analysis and examination of quantitative proteomics and RNA sequencing data for all genes within 1Mb of the osteoarthritis-associated variants in primary patient tissues. We identify 100 unique and independently associated risk variants, 52 of which have not been associated with osteoarthritis before. We report the first thumb, spine, female-specific and early age-at-onset osteoarthritis risk single nucleotide variants (SNVs). We identify 637 genes with at least one line of evidence pointing to a putative effector gene. Gene-set enrichment analyses of these genes, identified bone-, cartilage- and nerve- developmental pathways to be significantly associated (FDRPPARD, *NR3C1*, *VDR*, *MAPK14*, *IGF1R*, *CHST3*). The remaining genes, have market authorisation or are in clinical development for other indications, which represent attractive targets for drug repositioning. In this study, we enhance our understanding of the genetic aetiology of osteoarthritis, shed novel biological insights, and provide a stepping stone for translating genetic associations into osteoarthritis drug development.

PrgmNr 2736 - Linkage analyses confirm chromosome 5q35 as a risk locus in African Ancestry population

View session detail

Genetic studies of African Ancestry (AA) with late-onset Alzheimer disease (AD) have been limited, despite evidence suggesting an increased risk for AD in AA populations. In this study, we performed whole-genome sequencing (WGS) in multi-generational AA AD families from the Research in African American Alzheimer Disease Initiative (REAAADI) and Late-Onset Alzheimer's Disease Family Study (LOAD) to identify rare causal variants influencing AD through linkage and segregation-based approaches. As part of REAAADI and LOAD, data were generated for 51 families (160 affected and 318 unaffected). We performed a multipoint linkage scan using MERLIN software and genotype data to identify the genetic loci likely to carry risk variants. Following the linkage analysis, WGS data were used to prioritize variants in the consensus regions (HLOD > 3) based on segregation with disease among affected individuals, rarity (MAF 5). The multipoint affected only dominant model identified a suggestive significant signal on Chromosome 5q35 (HLOD 3.20, eight families contributing > 0.58). 1-LOD region is flanking with the locus that was previously reported as a suggestive significant locus in two AA AD genome-wide association studies (Reitz et al. 2013 (p-value=6.9 Ã 10-8) and Kunkle et al. 2020 (p-value=2.6 Ã 10-6)). By conducting the segregation analysis using WGS data, we identified 6 rare variants (MAF 5 that segregated with disease in all affected individuals of the family NC94222 that contributed to the linkage peak with the highest LOD score. Remarkably, a rare variant (rs564891878) in the *DOCK2* gene segregates with the disease in a family with 7 AD individuals (family-specific LOD = 1.72). The variant is intronic, with rare allele frequency in the 1kGP reference data set (MAF = 0.0013) and a moderate CADD score (7.3). In this study, multiplex family linkage analysis confirmed the chromosome 5q35 risk locus previously identified in two AA genome-wide association studies. Our AA population-specific finding shows the importance of diversifying population-level genetic data to better understand the genetic determinants of AD on a global scale. Moreover, identified putative damaging rare variants in multiplex families indicates the critical role of rare variation in AD etiology.

PrgmNr 2737 - Sex-specific genetic modifiers of hemolysis in blood donors

Sex differences have been widely observed for many human traits and common diseases. Despite the increasing effort to account for sex in research design and data analysis, the underlying genetic mechanisms leading to such sex differences remains poorly understood. We investigated the sex differences in red blood cell (RBC) predisposition to spontaneous (cold storage) or stress (osmotic fragility, oxidative) hemolysis using data from the NHLBI Recipient Epidemiology Donor Evaluation Study (REDS)-III RBC-Omics cohort of 13,403 multi-racial American blood donors. RBCs undergo increasing hemolysis as they age and when stored after donation. Elevated RBC hemolysis is associated with many adverse outcomes of transfusion. Sex has been known to be related to differences in RBC metabolism and hemolysis in cold storage. These observations have motivated us to identify sex-specific genetic modifiers of hemolysis in blood donors.

We first conducted sex-stratified genome-wide association studies (GWAS) for osmotic hemolysis, which is a measurement of RBC membrane integrity shown in our previous analyses to be modulated by ion channels such as *PIEZO1*, and *ANK1*. Two variants in *SLC4A1* (rs1476512 and rs13306780) reached genome-wide significance (PSLC4A1 encodes for Anion Exchanger-1 (AE1 or band 3) protein, which is the most common protein in the RBC cell membrane. Mutations in *SLC4A1* are associated with hereditary spherocytosis, acidosis, and changes in the Diego blood group. Using the gene expression data from the Genotype-Tissue Expression (GTEx) project, we also identified a significantly higher expression of *SLC4A1* in female whole blood cells (T-test, P=0.039). Male-specific GWAS hits for oxidative hemolysis were found on chromosome 7 surrounds *IMPDH1*, the gene that encodes for the metabolic enzyme inosine monophosphate dehydrogenase. Additionally, we conducted genome-by-sex interaction analysis by incorporating an SNP-by-sex interaction term in GWAS. Several SNPs (rs7739752, rs6922548) surrounding *DEF6* and *PPARD* genes were identified with opposing effects on osmotic hemolysis (i.e., the same SNPs are associated with decreased hemolysis in males and increased hemolysis in females). These findings have led us to the conclusion that sex, as a biological variable, modulates the hemolytic response to genetic mutations that regulate RBC function. Such sex-specific genetic regulation of RBC biology and pathology may further advance the fields of precision transfusion medicine and genetic studies of hemolytic diseases.

PrgmNr 2738 - Unbiased metabolomics by Mendelian randomisation links serum isoleucine to risk of amyotrophic lateral sclerosis

Amyotrophic lateral sclerosis (ALS) is an incurable and rapidly neurodegenerative disease which affects 1/350 individuals. The cause of ALS is unknown but the majority of cases are thought to result from a complex gene-environment interaction. Two sample Mendelian randomisation (MR) enables causal inference between environmental exposures, such as serum metabolite concentrations, and disease risk. We obtained summary statistics from genome-wide association study (GWAS) of serum concentrations of 974 metabolites which were population matched with a GWAS study of ALS. For each metabolite we performed two sample MR using a liberal instrument (p15) instruments as this is likely to lead to false positive results due to instrument pleiotropy. After filtering p-value statistics were not significantly inflated (Î»GC=1.1). After Bonferroni multiple testing correction three metabolites were significantly related to ALS risk: Estrone-3-sulfate (p=6.58e-05, beta=-0.03, se=0.008) and bradykinin (p=8.07e-05, beta=-0.05, se=0.01) were protective which is consistent with literature describing a male preponderance of ALS and the protective effect of medications known to increase serum bradykinin. Serum isoleucine was positively associated with ALS risk (p=1.29e-04, beta=0.05, se=0.01). For each of these three metabolites MR results remained significant using robust measures and the association was confirmed in a distinct ALS GWAS, moreover there was no evidence of genetic pleiotropy or instrument heterogeneity. Isoleucine is metabolised via methylmalonyl-CoA mutase (MCM) in a reaction which consumes vitamin B12. Vitamin B12 insufficiency has been previously associated with ALS risk and our MR analysis revealed that serum vitamin B12 is protective against ALS (p=0.005, beta=-0.17, se=0.06). Multivariate MR revealed that the toxic effect of isoleucine is dependent on vitamin B12 (p>0.05 after correcting for serum vitamin B12). Leucine is a structural isomer of isoleucine but it is not metabolised via MCM; interestingly our MR analysis revealed no relationship between serum leucine and ALS risk. It is notable that a clinical trial of administration of branch chain amino acids, including isoleucine, was previously terminated because of excessive deterioration in the treatment group; this would be consistent with our conclusion that isoleucine exacerbates neuronal damage in ALS via depletion of vitamin B12. We suggest screening of ALS patients for high serum isoleucine levels and supplementation with vitamin B12.

Disclosure Block: **K. Su:** None.

Background: Genomic structural variations (SVs), defined as large scale (>50 bp) structural differences/genomic rearrangements, have been shown to have a substantial amount of heritability and are highly polymorphic in the human genome. These SVs contribute to biological speciation and diversification, and also may represent critical sources of phenotypic variability for a variety of complex human diseases. Osteoporosis, a heritable metabolic bone disorder mainly characterized by low bone mineral density (BMD), has previously been shown to be influenced by small scale copy number variations. However, the contribution of large-scale SVs to osteoporosis susceptibility has not yet been explored. In this study, we aimed to characterize the diverse patterns of SVs and investigate the association between SVs and osteoporosis in the human genome.
Methods: Whole genome sequencing (average depth ~22X) analyses were carried out in 5001 subjects from the Louisiana Osteoporosis Study (LOS). BreakDancer was used to detect SVs for genomic sequencing deletions and a gene-based burden test was applied to test the association between the presence of SVs within a given gene and hip BMD. A false discovery rate procedure was applied to correct for multiple comparisons.
Results:We identified 2,959 genes that contain at least one large deletion, including 155 genes that are commonly (in â¥ 50% of samples) affected by at least 50 bp genomic deletions, 1,915 genes affected in more than one but Conclusion: In summary, this study provided a population-based examination of genomic SVs and presented a novel layer of biological factors which may have an important impact on human bone biology. We also highlighted some potential risk genes that may provide new insights into the pathophysiology of osteoporosis.

PrgmNr 2740 - White matter integrity and nicotine dependence in smokers: evaluating vertical and horizontal pleiotropy

View session detail

Author Block: **Z. Ye**; Maryland Psychiatric Res. Ctr., Dept. of Psychiatry, Sch. of Med., Univ. of Maryland, Baltimore, MD
Disclosure Block: **Z. Ye:** None.

Tobacco smoking is an addictive behavior that supports nicotine dependence and an independent risk factor for cancer and other illnesses. Its neurogenetic mechanisms are not fully understood but may act through alterations in cerebral white matter that shows changes consistent with positive and negative cognitive reinforcement mechanisms. We hypothesized that the vertical pleiotropic pathways, where genetic variants influence a trait which in turn influences another trait, link genetic factors, integrity of cerebral white matter (WM) and nicotine addiction. We tested this hypothesis using individual genetic factors, WM integrity measured by fractional anisotropy (FA), and smoking/nicotine dependence in a large epidemiological sample (N=23,624 participants that have genetic, brain imaging and smoking status data available; N=8,830 participants that have genetic, brain imaging and cigarettes per day (CPD) data available) collected by UK Biobank. We performed genome-wide association study (GWAS) to identify previously reported loci associated with smoking and nicotine dependence. We then evaluated two competing vertical pathways: Genes -> WM integrity -> smoking severity versus Genes -> smoking severity -> WM integrity and a horizontal pleiotropy pathway where genetic factors independently affect both smoking severity and WM integrity. The identified variants were located in important susceptibility genes for smoking-induced diseases such as IREB2. Post-hoc analyses showed the genetic predisposition to smoking may act through vertical pleiotropy pathways that maintain nicotine addiction through changes in cerebral white matter.

PrgmNr 2741 - Amplification of CCND1/IGH@ Fusion in Plasma Cell Myeloma - A Case Report and Review of Literatures

View session detail

Author Block: **J. Liu**, J. Gong, J. Rodriguez, G. Uppal, D. Foster, S. Peiper; Thomas Jefferson Univ., Philadelphia, PA
Disclosure Block: **J. Liu:** None.
The t(11;14)(q13;q32) resulting in *CCND1/IGH* fusion is a frequent cytogenetics abnormality in plasma cell myeloma. Overexpression of cyclin D1 dysregulates the normal cell cycle, inhibits differentiation, promotes uncontrolled cellular proliferation and carcinogenic phenotypes.
We describe a 77- year-old female with a diagnosis of plasma cell myeloma and amplification of the *CCND1/IGH* fusion gene. This patient presented with back pain. She had a history of stage II, triple positive breast cancer, osteoporosis, worsening neurological deficits and a right MCA infarct. Innumerable small lucencies throughout chest, abdomen and pelvis along with thoracic and lumbar compression fractures were observed by imaging. Laboratory study showed worsening of known microcytic anemia, low albumin, normal calcium and creatinine. SPEP showed a 1.5g/dl M protein IgA Lambda. Fluorescence in situ hybridization (FISH) panel performed on non-enriched cultured cells demonstrated multiple positive findings suggestive of hyperdiploidy with complex chromosomal abnormalities, including tetrasomy 11, rearrangement of *IGH*, translocation of CCND1/IGH with or without amplification of the fusion product, and deletions of *RB1* and *TP53*. Conventional cytogenetic analysis showed a normal female karyogram most likely due to failed growth of the myeloma cells in culture. Concurrent bone marrow exam showed plasma cell myeloma with 88% bone marrow involvement. Flow cytometric analysis revealed a differential of 23% lymphocytes, 3% monocytes, 65% granulocytes, 24% plasma cells, and Four reports of *CCND1/IGH* fusion amplification have been reported in the literature, to the best of our knowledge, this is the fifth case of *IGH/CCND1* fusion amplification, the third in a patient with plasma cell myeloma. Although difficulty remains to determine the prognostic significance of *CCND1/IGH* fusion amplification due to its rarity, its association with karyotypic complexity and unfavorable outcomes in the published cases suggests a poor prognosis and need of aggressive treatments. Deciphering the underlining molecular pathogenic pathways was attempted. Clinical courses, genetics and laboratory findings and prognostic outcomes were also reviewed and discussed for the five known cases.

PrgmNr 2742 - Cancer Risk C, a functional genomics test, is a sensitive, specific, and rapid diagnostic for Lynch syndrome

Disclosure Block: **I. Alim:** None.

Heritable mutations in the DNA mismatch repair (MMR) pathway cause Lynch syndrome (LS), a condition that significantly increases risk of colorectal and other cancers. LS mutations are commonly found in the *MLH1*, *MSH2*, *MSH6*, *PMS2* and *EPCAM* genes. Diagnosis of LS is reliant on gene panel sequencing. However, at least half have a variant of uncertain significance (VUS) that cannot be classified for pathogenicity or have no result that informs their diagnosis. Many LS patients are identified only after microsatellite instability testing of tumors is found to be high (MSI-H). We developed a diagnostic test, Cancer Risk C (CR-C), using flow-cytometry based functional variant assays (FVAs) to aid in the diagnosis of LS. Using patient-derived lymphoblastoid cell lines (LCLs) from the Colon Cancer Family Registry (CCFR) an initial cohort was established with either known pathogenic (n=20) or benign variants (n=20). FVAs were tested to identify the effects of pathogenic variants in MMR genes on the nuclear translocation of the MLH1 and MSH2 proteins and the nuclear phosphorylation of the ATM and ATR proteins in response to treatment with the alkylating agent, methylnitronitrosoguanidine. To differentiate pathogenic and benign variants, a risk classification score was developed based on a combination of MLH1, MSH2 and ATR assays. CR-C was 98% sensitive and 95% specific and could be completed within 48 hours. A second cohort of CCFR patient-derived cells with either pathogenic (n=40) or benign variants (n=40) was tested with CR-C and observed to have similar sensitivity and specificity, thus creating a new diagnostic for LS. Amongst those with VUS and MSI-H tumors (n=60), 72% were identified as having LS. This finding contrasted to the previously observed rate of 16% MMR pathogenic gene variants amongst patients with MSI-H tumors. Edited cells with pathogenic variants in MMR genes were rescued from pathogenic to benign when transfected with an expression plasmid containing wild-type cDNA and tested with CR-C. Direct comparison of matched whole blood samples and LCLs yielded comparable results with CR-C (r^2>0.9). Compared to cancer gene panel sequencing, CR-C is more accurate and rapid for diagnosing LS and can be performed on whole blood. When combined with gene rescue experiments in edited cells or LCLs, CR-C can be used to classify VUS as pathogenic or likely pathogenic.

PrgmNr 2743 - Clinically relevant germline variants in a cohort of Mexican young women with breast cancer: analysis from whole-exome sequencing

Disclosure Block: **L. GÃ³mez Flores Ramos:** None.

Young women with breast cancer represent 15% of cancer cases in Latin America. Genomic studies have found that early-onset breast-cancer cases exhibit a higher genetic susceptibility and a specific genomic signature as compared to their older counterparts. The aim of this study was to describe clinically relevant germline variants in a cohort of young women with breast cancer. To achieve this, we analyzed hereditary-cancer genes from whole-exome sequencing (WES) data in 108 unrelated women with an extreme phenotype of breast cancer (â□¤40 years of age), diagnosed and treated at the National Cancer Institute of Mexico (NCIMx). We obtained approval from the Research Ethics Committee of the NCIMx (CEI/1123/16) and provided patients with genetic counseling and written consent. Exome capture and sequencing were conducted at the Laboratory of Translational Genomics, at the NCI, Maryland, USA. The GRCh37 assembly was used as the genome reference. Variants that failed to pass our pipeline quality control metric (CScorefilter), had a read depth â□□0.8 were excluded from the analysis. Variants were filtered using popmaxfreq BRCA2 represented half of the pathogenic variants found in this group and accounted for 6% of hereditary-cancer cases. *BRCA*1 represented 23% of mutations, followed by *PALB2* (15%)*; TP53* and *RAD51C* (8% each). We describe for the first time, in a patient with breast cancer, a pathogenic duplication in *RAD51C* (c.519dupT). The median age at diagnosis was 35 years overall; however, it was six years younger in patients with pathogenic variants. Age at diagnosis (OR=0.82, CI 95% 0.71-0.94; P= 0.008) and first-degree family history of cancer (OR=8.26, CI95% 1.35-50; P= 0.022) were the only epidemiological variables associated with mutational status. We found no differences in DFS (p=0.403) or OS (p=0.735) among mutational status subgroups. Genetic ancestry and tumor subtype were not associated with mutational status.

PrgmNr 2745 - Facilitators and barriers to implementing non-indication based genetic testing within corporate wellness programs

View session detail

Author Block: **J. M. Goehringer**[1], Z. Salvati[1], P. Deverka[2], M. S. Williams[1]; [1]Geisinger, Danville, PA, [2]Deverka Consulting, Raleigh-Durham-Chapel Hill, NC
Disclosure Block: **J.M. Goehringer:** None.
In the era of precision medicine, population health screening for inherited disease risks has gained momentum. Institutions and genetic testing vendors are increasingly promoting preventative practices and risk mitigation strategies, and employers have begun offering genetic testing as an employee health benefit. Stakeholders Assessing Genetics with Employers (SAGE) was funded by NHGRI to evaluate the broad experience of offering non-indication based genetic testing (NIBGT) through employer-sponsored health benefits. NIBGT is defined as voluntary, health-related genetic testing for individuals with or without a personal or family history of genetic disease.
Company leaders of self-insured employers, genetic testing vendors, and researchers who evaluate wellness programs were approached for participation in a qualitative research study. Nine individuals were enrolled and interviewed using a semi-structured interview guide. Episodic summaries, memos, and transcripts were analyzed with thematic coding, guided by the Framework Method. Here we focus on the facilitators and barriers to NIBGT implementation.

Barriers

Implementation of genetic testing in the wellness setting is more challenging than traditional wellness offerings and the evidence to support use as a screening tool is weak. Companies want to avoid being early adopters of genetic testing within the workplace as the return on investment is not yet demonstrated. This would require pooling large amounts data across employers to study outcomes which is hindered by companies avoiding collaboration with competitors. Further, the timeline for observing favorable health outcomes in genetic disease requires extensive longitudinal follow-up. There are perceptions that human resources and insurance carriers add complexity to the implementation process. Provider education is another barrier due to the complexity of genetics and provider concerns regarding managing employee genetic test results. Last, privacy concerns regarding the use of genetic information is prevalent. There is a lack of understanding about genetic information-related legal protections (mainly GINA) among both employers and employees, leading to reluctance to adopting NIBGT.

Facilitators

Approaching the right individuals within a company drives successful implementation of NIBGT within wellness programs. Implementation is often initiated when C-suite executives champion genetic testing and lead decision-making processes. Program implementation can be facilitated with the help of knowledgeable experts from inside the company including geneticists, other physicians, and genetic counselors.

PrgmNr 2746 - Genetic testing in patients with colorectal cancer; a real-world analysis of utilization and results

Background

Colorectal cancer (CRC) affects approximately 104,000 patients (pts) annually in the United States (U.S.), and up to one-third of cases are estimated to be genetic and/or familial. In 2020, a large U.S. insurer established Medical Policy allowing for and reimbursing germline genetic testing (GGT) for all CRC pts. This study reports overall uptake of GGT in CRC pts under this coverage policy with actionable findings and management implications for pts tested. **Methods** Two independent de-identified datasets were reviewed, including administrative claims data of commercially insured (COM) and Medicare Advantage (MA) enrollees from a large national health plan in the U.S., which included pts aged 18+ with CRC (â¥1 claim with ICD10 C18, C19 or C20) who were continuously enrolled (CE) in the health plan from 1/2019-12/2020. GGT was based on CPT codes during 2020. A second dataset of CRC pts whose GGT was performed by a large genetic testing laboratory and was billed to the insurer under the Medical Policy in 2020, was also reviewed. Patient demographics, clinical information and GGT results were descriptively analyzed. **Results** Of the >14 million CE enrollees, 39,382 were newly diagnosed CRC pts in 2020; 16,539 were COM and 22,843 were MA pts. Overall, 5.6% (2,196) of the cohort received GGT (8.1% of COM pts compared to 3.8% of MA pts). Those that received GGT were younger than the overall cohort of CRC pts, with a higher proportion in the COM population. From the GGT dataset, 787 pts had test results available for review. 142 (18%) pts had 152 pathogenic/likely pathogenic (P/LP) variants in 30 genes, including: *MSH2*, *MLH1*, *PMS2*, *MSH6*, *CHEK2*, *APC, BRCA2, ATM, MUTYH* (biallelic). Overall, 130 of the 142 (92%) had P/LP variants in genes with precision therapy, clinical trial and/or published management guidelines. In a subset of pts (n=674) with ethnicity data, Asian, Black/African-American and Hispanic pts showed lower uptake of germline testing relative to Caucasians. **Conclusions** Despite Medical Policy allowing for GGT for all pts with CRC,

PrgmNr 2747 - Prevalence of pathogenic mutations and variants of uncertain significance in Cambridge, MA

View session detail

Author Block: **C. JANI**[1], O. Al omari[1], H. Singh[2], K. Stafford[1], L. Agarwal[1], A. Rupal[1], A. Dar[1], M. Lotz[1], A. Dangelo[1], P. Lam[1]; [1]Mount Auburn Hosp., Cambridge, MA, [2]Med. Coll. of Wisconsin, milwaukee, WI
Disclosure Block: **C. Jani:** None.
Objective Genetic testing allows for enhanced prognostication and early intervention in patients with a high risk of developing cancer. The most common inheritable cancer syndromes include Hereditary Breast and Ovarian Cancer (HBOC) and Lynch Syndrome (LS). Genetic testing often reveals variants of uncertain significance (VUS), for which association with disease risk is unclear. The ambiguity of this finding creates a dilemma for everyone. In this retrospective observational study, we seek to determine the prevalence of pathogenic mutations and VUS identified in patients undergoing genetic testing in a community hospital in Cambridge, MA. **Methods** We included patients undergoing genetic testing at our hospital between July 2018 and October 2020. Medical charts were abstracted to identify patient demographics, clinical characteristics, family cancer history, indication for genetic testing, mutations and VUS identified, and subsequent management. As our study period spanned during the COVID-19 pandemic, we also assessed its impact on care accessibility. **Results** We reviewed data for 663 patients. The population had a mean age of 50 years (S.D 15). 597(90%) were females, 63 (9.5%) were males and 2 were transgender. There was a high proportion of Ashkenazi Jewish descent (14.3%). First-degree family had cancer history in 530 (79.9%) patients whereas 552 (83.3%) had positive cancer history in the second-degree family. 265 (39.9%) had a personal history of cancer, most commonly breast (214). The most common indication for genetic testing was HBOC (558, 84.2%). Out of 76 (11.4%) deleterious mutations, the most common were BRCA mutations (23, 30%) followed by MUTYH (10,13.1%), and Lynch mutations (5, 6.5%). Out of 200 (30.1%) VUS, the most common were APC (23). We found no significant trend in genetic counseling consultations over our 11 months (12/2021-10/2020) of COVID-19 part of our study period despite the pandemic (R^2 = 0.006). **Conclusions:** In our study, prevalence rates of pathogenic mutations and VUS were 11.4% and 30.1% respectively. Despite advances in identifying genetic risk for colon and gynecological cancers, the majority of patients presented for breast cancer-related screening. Due to the high prevalence of VUS, and the challenges faced in addressing these findings, future work needs to explore evidence-based approaches to communication and interpretation of these findings. Lastly, we noted high efficacy in our conversion of in-person genetics consultations to telemedicine during the COVID-19 pandemic, suggesting its robust format.

PrgmNr 2748 - Tumor genomic profiling (TGP) - identified mutations in moderate risk breast and ovarian cancer genes: worthy targets for germline confirmatory testing

View session detail

Author Block: **H. Llorin**[1], M. Graf[2], N. Chun[2], J. Ford[2]; [1]Mass Gen. Brigham, Boston, MA, [2]Stanford Univ., Stanford, CA
Disclosure Block: **H. Llorin:** None.
Tumor genomic profiling (TGP) has become more widespread and clinically actionable through advancements in sequencing technology and molecular oncology. Recent changes in oncology practice guidelines indicate that mutations in cancer susceptibility genes identified on TGP should prompt confirmatory germline testing; however, there are no established best practices for identifying which somatic mutations are most appropriate for germline confirmation. Our study aimed to determine the proportion of patients with TGP-identified mutations in moderate risk breast and ovarian cancer genes (ATM, BRIP1, CHEK2, PALB2, RAD51C, and RAD51D) who previously would not have been considered for germline testing based on previous clinical and family history. We retrospectively analyzed adult Stanford Health Care patients with any type of advanced cancer who had undergone solid tumor genomic profiling. From 7468 tumor genomic profiling reports, we identified 166 patients with TGP-identified mutations in moderate risk breast and ovarian cancer susceptibility. Retrospective chart reviews were performed on 160 patients on whom we had adequate information to determine demographic characteristics, cancer history, eligibility for germline testing, and germline testing results. Nearly half (45.3% [73/160]) of patients would not have been eligible for germline testing if not for a somatic mutation in the gene of interest. Of the 64 cases that underwent multigene panel germline testing that included our genes of interest, about half (51.5% [33/64]) had results that confirmed germline origin of the somatic finding. High rates of germline confirmation were found in PALB2 (100% [5/5]), ATM (40% [14/35]), CHEK2 (61.5% [8/13]), and BRIP1 (57.1% [4/7]). Furthermore, 13.7% (n=22) of cases had a founder mutation on TGP. This data shows that recent guideline changes increase eligibility for germline testing among patients with somatic mutations in moderate risk breast and ovarian cancer susceptibility genes. Traditional germline testing guidelines based on personal and family history do not adequately capture hereditary cancer syndromes among a cohort of advanced cancer patients. Rates of germline confirmation are ~40% or higher in patients with TGP-identified mutations in ATM, CHEK2, and PALB2. In the context of limited healthcare resources, more study is needed to determine which TGP-identified mutations should be prioritized for referral to cancer genetics to maximize hereditary cancer syndrome diagnoses.

PrgmNr 2749 - Disease risk prediction with two-phase study data

View session detail

Author Block: **D. Soave**[1], J. Lawless[2], N. Cheng[3], P. Awadalla[4]; [1]Wilfrid Laurier Univ., Waterloo, ON, Canada, [2]Univ. of Waterloo, Waterloo, ON, Canada, [3]Ontario Inst. for Cancer Res., Toronto, ON, Canada, [4]Ontario Inst Cancer Res., Toronto, ON, Canada
Disclosure Block: **D. Soave:** None.
The prognosis of many cancers is significantly improved when detected at early stages. Through retrospective selection of two-phase (2P) study samples, researchers can leverage the prospective nature of population health cohorts to investigate the relationships between expensive molecular information and rare diseases, such as cancer, prior to traditional clinical diagnosis. When carefully selected, 2P studies provide an efficient and cost-effective alternative to designs requiring the complete cohort. Outcome and covariate dependent sampling designs are needed for a 2P study, and proper specification of design weights is critical for aspects of both the building and assessment risk models. Often, however, the sampling mechanisms are misspecified or altogether ignored when analyzing the data. Here, we investigate techniques and tools for assessment of risk prediction model using 2P data. Unbiased assessment of model performance at the population level is estimated through pseudo (weighted) metrics of discrimination and calibration. We present the theoretical and numerical properties of weight-adjusted estimates of concordance, Kullback-Leibler score, Brier score, and time-dependent receiver operating characteristic curves. We further investigate the specification of design weights and baseline hazard estimation and the use of weight-adjusted criteria in the context of resampling based strategies for model selection. With the goal of detecting cancer prior to the onset of symptoms (and prior to diagnosis through clinical screening), we profiled cfDNA methylation in blood samples from pre-cancer (collected up to 7 years prior to the detection of breast or prostate cancer) and matched control participants (no cancer on follow-up under study) retrospectively selected from the Canadian Partnership for Tomorrowâ□□s Health (CanPaTH) study. Using a novel implementation of weighted regularized regression for two-phase failure time data, we develop and assess cancer risk prediction models using cfDNA methylation markers to predict who will and will not develop cancer up to 7 years prior to clinical detection.

PrgmNr 2750 - Evidence of divergent genetic associations across breast cancer molecular subtypes via distal mediator-enriched Transcriptome-Wide Association Study

View session detail

Author Block: **A. Patel**[1], M. Troester[1], M. Love[2], A. Bhattacharya[3]; [1]Univ. of North Carolina - Chapel Hill, Chapel Hill, NC, [2]UNC-Chapel Hill, Chapel Hill, NC, [3]Univ. of California at Los Angeles, Carrboro, NC
Disclosure Block: **A. Patel:** None.
Background: Breast cancer (BC) molecular subtype (Luminal A-like, Luminal B-like, HER2, Basal-like) is a central prognostic factor for BC mortality. Of the 210 genetic variants associated with risk for BC, many show differential associations across subtype. These variants are predominantly in non-coding regions, and genes and cellular contexts giving rise to the risk from these variants remain largely unknown. Approaches such as Transcriptome-Wide Association Study (TWAS), which offer gene-level assessment of association of variants, can bridge this gap and allow discovery of genetic mechanisms for known and novel loci. **Objective**: We aimed to identify genes whose germline-regulated expression is associated with risk of BC subtypes across healthy breast, adipose, fibroblast, and immune tissue. **Methods**: Using GTEx V8, we constructed predictive models of gene expression from germline variation in European ancestry individuals. Importantly, predictive models leveraged MOSTWAS and were enriched for distal regulatory variants in addition to local (1 Mb surrounding gene) variation. Genes with nominally significant h^2 (p R^2 for predicted and observed expression > 0.01 with p p = 3.4 x 10^{-7} (0.05/146,608 gene-tissue-subtype pairs) and we followed-up on significant genes with a permutation test on predictive model weights (FDR-adjusted p Results: At TWAS-significance and permutation threshold, we identified 353, 229, 184, and 203 genes associated with Luminal A-like, Luminal B-like, HER2, and Basal-like BC, respectively, across etiologically relevant tissue. For healthy breast tissue, 92, 49, 41, and 46 genes, respectively, were identified. Many identified genes were at loci not uncovered in GWAS. Across etiologically relevant tissues, only two genes (*CBX8*, *STK19*) were associated across all subtypes. For healthy breast tissue, only *CBX8*, a known oncogene, was associated across all subtypes, and associations were consistent in direction but differing in magnitude. **Conclusion**: Our findings suggest marked differences in the germline genetic basis of BC subtypes, which may be relevant for developing subtype-specific risk prediction models. Findings also suggest a high level of tissue-specificity for putative genes underlying etiologic heterogeneity for BC.

PrgmNr 2751 - Genetic susceptibility to smoking and alcohol use behaviors identifies differential risk in oropharyngeal and oral cavity cancer patients based on HPV status

Background: A recent meta-GWAS conducted by the GWAS & Sequencing Consortium of Alcohol and Nicotine use (GSCAN) has identified several loci associated with tobacco and alcohol use behaviors. We investigated how these findings translate in head and neck cancer (HNC). **Aim**: To investigate the association of genetic susceptibility to tobacco and alcohol use with risk of HNC within the context of Human Papillomavirus (HPV) infection. **Methods**: *Study population*: European ancestry individuals participating in the VOYAGER consortium, an international multi-site study focusing on the impact of HPV serology, germline, and tumor genomics on risk and outcome of HNC: 3580 cases of oral cavity (OC)/oropharyngeal cancer (OPC), 3240 healthy controls. *Classification:* HPV serology and p16 tumor status were used to classify cases based on HPV status: 1143 HPV-positive OPC, 2437 HPV-negative HNC [JL1] (HPV-negative OPC/OC). *Genotype data* were obtained from the VOYAGER consortium using the OncoArray chip. *Imputation* was performed on TOPMed Imputation Server using the TOPMed r2 panel. *Polygenic Risk scores* (PRS) were computed using LDpred2 and GSCAN summary statistics for smoking status, age of smoking initiation, cigarettes per day, smoking cessation, and number of drinks per week. *Analysis*: Firstly, measured behaviors were regressed using mixed effects models on their respective PRS with following covariates: age, sex, age-sex interaction, first 7 genetic principal components, and a random intercept for study site. Next, the outcome (HPV-positive OPC, HPV-negative HNC, control) was regressed, via a mixed effects logistic model, on each PRS, with the same covariates and random intercept as the first analysis. Finally, mediation analyses tested the proportion of effect of each PRS on both cancer groups, mediated through measured behavior. **Results**: Measured behaviors were significantly associated with their corresponding PRS across all populations (HPV-positive OPC, HPV-negative HNC, controls). Only PRS of smoking behaviors were associated with risk of HPV-positive OPC, while PRS of both smoking and alcohol behaviors were associated with risk of HPV-negative HNC. These associations were partly mediated through their measured behavior. Mediated effects were significantly larger for HPV-negative HNC than HPV-positive OPC. **Conclusions**: Genetic susceptibility to tobacco use is associated with risk of HPV-positive OPC. In contrast, the genetic susceptibility to both tobacco and alcohol use is associated with risk of HPV-negative HNC. These associations are partly mediated through measured behavior and to a larger extent for HPV-negative HNC than HPV-positive OPC.

PrgmNr 2752 - High prevalence of subclinical micro-FAFs in facial skin in Tuberous Sclerosis Complex

View session detail

Author Block: **K. Klonowska**[1], J. Grevelink[2], K. Giannikou[1], B. Ogorek[1], D. J. Kwiatkowski[1]; [1]Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, [2]Boston Dermatology and Laser Ctr., Massachusetts Gen. Hosp., Boston, MA

Disclosure Block: **K. Klonowska:** None.

Introduction: Tuberous Sclerosis Complex (TSC) is anautosomal dominant syndrome due to loss-of-function *TSC1*/*TSC2*mutations, characterized by the presence of distinctive hamartomatous tumors inmultiple tissues and organs, including brain, heart, kidney, lungs and skin. TSCtumors develop through a two-hit mechanism, and we had previously shown that UV-inducedmutation was the cause of second hits in TSC facial angiofibromas (FAFs).**Methods:** Recently, we developed a novel MPS method, MultiplexHigh-sensitivity PCR Assay (MHPA), that has a sensitivity of 0.01-0.05% variantallele frequency (VAF) in the most commonly mutated regions of *TSC2*.**Results:** MHPA analysis of 24 FAFs, including 19 from TSC patients with low level systemicmosaicism and 5 with heterozygous germline *TSC2* mutations, led tothe identification of 99 low VAF(0.01-8.02%, median:0.08%,) somatic *TSC2* indels/point mutations. Remarkably,two or more somatic *TSC2* mutations were identified in 19 of 24(79%) FAFs,suggesting that these small (2mm diameter) FAF biopsies contained at least twoangiofibroma clones. 34 of 99(34%)mutations were CC:GG>TT:AA dinucleotide variants (DNVs), indicativeof UV radiation causation, affecting 30 of 522(6%) CC:GG sites in the region sequenced. We alsodeveloped an MHPA assay for *TP53*, and identified an average of 8.1 *TP53* mutations per FAF biopsy (likely occurring in keratinocytes inthese biopsies). The nonsynonymous to synonymous mutation ratio [*TSC2*:10.4(83/8); *TP53*: 29.5(177/6)] in these samples indicatesthat mutations in both genes were likely conferring a selective growthadvantage. Single nucleotide variants (SNVs)/DNVs in *TSC2*/*TP53*were predominantly C:G>T:Aand CC:GG>TT:AA, with more C/CC than G/GG mutated, reflectingtranscription-coupled nucleotide excision repair occurring for UV mutations (untranscribedstrand bias, p=0.0007 and p=0.009, respectively). Our MHPA analysis also led tothe identification of a novel UV-related indel mutation signature, includingcomplex indel-SNV/DNV pattern, in 18 instances.**Conclusions:** Considering the number of mutations, themosaic VAF in FAFs, andthe size of the total facial skin, we estimate that 100-200,000 polyclonalfibroblast proliferations due to second hit mutations in *TSC2* (subclinicalâ□□micro-FAFsâ□□) occur in the skin of TSC patients, a small proportion of whichdevelop into observable FAF lesions. These observations highlight theimportance of sunblock and other measures to limit facial UV exposure for TSCindividuals of all ages to prevent FAF development. *The study was funded by FY2020 Tuberous SclerosisAlliance Postdoctoral Fellowship Award (KK) and Engles Family Fund*

The PhenX (**Phen**otypes and e**x**posures) Toolkit (https://www.phenxtoolkit.org/) is a web-based catalog of recommended measurement protocols and associated bioinformatics tools to assist with study design and facilitate cross-study data integration and analyses. PhenX protocols are recommended by domain experts using a consensus-based process which includes community input. The PhenX Toolkit currently includes more than 800 measurement protocols from 29 research domains (e.g., Demographics and Diabetes) and six collections that add depth to the Toolkit (e.g., Social Determinants of Health) and has over 3,800 registered users. The Toolkit has recently expanded with collections and tools for COVID-19 research. With input from crowdsourcing, 20 COVID-19 protocols were organized into six COVID-19 collections: Behaviors and Risks; Ethnicity, Race and Demographics; History, Treatment, and Outcomes; Information Resources; Psychosocial and Mental Health; and Socioeconomic. Because health disparities were identified as the number one concern for COVID-19 research, PhenX recommends use of the Social Determinants of Health: Core collection. The PhenX COVID-19 Library aggregates COVID-19 protocols in use and includes keyword search to filter protocols. To date, there are 118 collection tools and 517 modules that are annotated with sub-topics such as mental health and avoidant behaviors and main topics that conceptually link modules to the NIH Public Health Emergency and Disaster Research Response (DR2) site. A variable compare tool allows researchers to choose between COVID questionnaires from the COVID-19 collections and COVID-19 Library. This tool includes keyword search at the variable level, side by side comparisons of questionnaires and visual representation of the number of similarities between protocols. PhenX has also added a new domain of protocols for Cancer Outcomes and Survivorship research to complement the existing Cancer domain's focus on risk factors. It includes 15 protocols that are relevant for research focusing on cancer survivors and caregivers. Protocols address a wide range of topics including emotional, physical, and social impact and burden of cancer along with experiences with cancer related care. Also, a working group of experts completed the consensus process and recommended 15 measurement protocols for the new Genomic Medicine Implementation domain. The measurement protocols addressed the following scope elements: knowledge and education (both patients and providers), implementation science, changes in management and treatment, return of results, patient outcomes, and ELSI (ethical, legal, and social issues).

PrgmNr 2754 - Prevalence of autoimmune diseases in Li-Fraumeni Syndrome

View session detail

Author Block: **I. Obregon**, K. de Andrade, P. P. Khincha, R. Bremer, S. A. Savage; Clinical Genetics Branch, Div. of Cancer Epidemiology and Genetics, Natl. Cancer Inst., NIH, Rockville, MD
Disclosure Block: **I. Obregon:** None.
Li-Fraumeni syndrome (LFS) is an inherited cancer predisposition syndrome with extremely high cancer risks throughout the lifespan, caused primarily by germline pathogenic *TP53* variants. The effect of germline *TP53* variation on immune function or on immune surveillance in LFS-associated carcinogenesis is not known. In this pilot study, we evaluated the prevalence of autoimmune diseases in individuals with LFS compared to controls. Participants enrolled in the National Cancer Instituteâ□□s longitudinal LFS study (NCT01443468) completed questionnaires inquiring about 24 autoimmune disease diagnoses, age at diagnosis, and need for treatment. Individuals with confirmed LFS-associated *TP53* variants were compared to their non-carrier relatives (controls). Studentâ□□s T-test was used to compare ages between groups. Chi-Square test of independence was performed to assess the relationship between *TP53* variant status and the prevalence of autoimmune diseases. Of the 185 respondents, 113 were carriers of germline *TP53* variants and 72 were controls. There were 82 (72%) female carriers and 44 (61%) female controls. Variant carriers were younger than controls (median age 44 years *vs* 59 years respectively, pvs 46 years respectively, pTP53 variant status and occurrence of autoimmune disease. The predilection of female diagnoses and younger age at onset in the variant carriers may be due to reporting bias, or a true reflection of disease prevalence in this cohort. Further studies of larger cohorts and of *TP53* immunobiology are necessary to validate these results and to understand the role(s) of immune surveillance in cancer in LFS.

PrgmNr 2755 - Prostate cancer susceptibility variants and their interplay with lifestyle factors on the risk of lethal disease

View session detail

Author Block: **A. Plym**[1,2,3], Y. Zhang[2], K. Stopsack[2,4], B. Delcoigne[3], F. Wiklund[3], C. A. Haiman[5], A. S. Kibel[1], E. Giovannucci[2], K. Penney[1,2], L. A. Mucci[2]; [1]Brigham and Women's Hosp., Boston, MA, [2]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [3]Karolinska Inst.t, Stockholm, Sweden, [4]Mem. Sloan Kettering Cancer Ctr., New York, NY, [5]Univ. of Southern California, Los Angeles, CA
Disclosure Block: **A. Plym:** None.
Background While over 260 germline prostate cancer susceptibility variants have been identified to date, few variants have been specifically associated with advanced prostate cancer. We sought to identify variants associated with lethal prostate cancer and their possible interplay with lifestyle factors.
Methods We included 12,411 genotyped men in the Health Professionals Follow-up Study (HPFS) and the Physiciansâ Health Study (PHS) who have been prospectively followed for incident prostate cancer and lethal disease (metastases/cancer-specific death) between 1993 and 2019 (HPFS) and between 1983 and 2010 (PHS). Using Cox regression, we examined the association between 246 previously identified common (0.02 P **Results** 435 men in the cohorts developed lethal prostate cancer. Of the 246 prostate cancer risk variants, 10 were associated with lethal prostate cancer at *P* P = 4.11e-06) for one risk allele increase. The other risk loci included rs4901313 on 14q22 (HR, 1.50; 95% CI, 1.23-1.83; *P* = 5.59e-05), rs150184171 on 6q23 (HR, 1.3; 95% CI, 1.15-1.52; *P* = 1.04e-04), and rs7679673 on 4q24 (HR, 1.33; 95% CI, 1.14-1.55; *P* = 2.19e-04). For two of the variants, rs10090154 and rs7679673, we observed effect modification by lifestyle factors, with the highest risk among men with an unhealthy lifestyle.
Conclusion Our study demonstrates strong associations between previously identified prostate cancer susceptibility variants and lethal disease. We observed a possible interplay with lifestyle factors, which if replicated can help understand the etiology of aggressive prostate cancer.

PrgmNr 2756 - Quantification of cancer risk, patterns, and genotype-phenotype associations in Li-Fraumeni syndrome

View session detail

Author Block: **K. De Andrade**[1], P. Khincha[1], J. Hatton[1], M. Frone[1], T. Wegman-Ostrosky[2], K. Jones[3], K. Teshome[3], P. L. Mai[4], A. Best[5], S. A. Savage[1]; [1]Clinical Genetics Branch, Div. of Cancer Epidemiology and Genetics, Natl. Cancer Inst., NIH, Rockville, MD, [2]Basic Res. Subdirection, Inst. Program, Div. of Cancer Treatment and Diagnosis, Natl. Cancer Inst., NIH, Rockville, MD

Disclosure Block: **K. De Andrade:** None.

Li-Fraumeni syndrome (LFS) is a highly penetrant cancer predisposition syndrome caused by germline pathogenic *TP53* variants associated with very high risks of cancer starting in early childhood throughout the entire lifespan. There are limited data on the risk of cancer in LFS compared with the general population, on genotype-phenotype correlations, or on potential genetic modifiers of *TP53* function. This study included 480 carriers of pathogenic/likely pathogenic (P/LP) germline *TP53* variants participating in an IRB-approved study (NCT01443468). Median age at last follow-up was 36.7 years for females and 34.3 years for males. Variants were categorized based on loss-of-function (LOF) and dominant-negative effect (DNE) properties. LFS-associated cancer incidences were compared with the general population using the Surveillance, Epidemiology, and End Results (SEER) 1975-2017 registry. Cancer incidences were evaluated using family-clustered Cox-regression models. Eight polymorphisms in *TP53, MDM4,* and *MDM2* were evaluated as possible first-cancer incidence modifiers. Three hundred five (63.5%) participants were diagnosed with at least one cancer. The standardized incidence of any cancer in individuals with LFS compared with age and sex-matched SEER data peaks from childhood to age 30 (> 60-fold higher), remaining nearly 10-fold higher after age 50. Breast cancer accounted for 56.9% of all female first-primary cancers with a lifetime cumulative first-cancer incidence of approximately 56%. Median age at first cancer in women substantially increased by censoring breast cancer cases (59.4 *versus* 33.7 years). Regardless of DNE status, variants with LOF properties were associated with significantly earlier ages at first-cancer diagnoses. Individuals whose first cancers were diagnosed before 17 years of age develop a second cancer after a longer time interval than those with first cancers diagnosed at later ages. Multiple cancers were diagnosed within a short time frame in some individuals with LFS suggesting a â□□trigger effectâ□□ phenomenon. The polymorphism rs17878362-A2 showed the highest first-cancer risk (hazard ratio=3.06, pTP53 variant functional groups and common polymorphisms appear to modify median ages at first-cancer diagnoses in LFS. Risk-reducing mastectomy in females with LFS could improve their cancer incidence to parallel that of males with LFS. This study provides important data to develop cancer risk stratification strategies for individuals with LFS.

PrgmNr 2757 - *USP8* gene may contribute to the development of bilateral adrenal hyperplasia and ACTH-independent Cushing syndrome

View session detail

Author Block: **N. SETTAS**[1], E. Kassi[2], A. Angelousi[2], F. R. Faucz[3], C. A. Stratakis[4]; [1]NIH (NIH), BETHESDA, MD, [2]Natl. and Kapodistrian Univ. of Athens, Athens, Greece, [3]NIH / NICHD, Rockville, MD, [4]NICHD, NIH, Bethesda, MD

Disclosure Block: **N. Settas:** None.

Bilateral adrenocortical hyperplasias (BAHs), including primary pigmented nodular adrenocortical disease (PPNAD), isolated micronodular adrenocortical disease (iMAD) and primary macronodular adrenocortical hyperplasia (PMAH), are rare causes of ACTH-independent Cushing syndrome (CS). PPNAD and iMAD usually present in children or adolescents as multiple small (USP8 gene variants. *USP8* is mainly known for being mutated in Cushing disease but as a deubiquitinase it may be involved into other pathways such as Wnt/b-catenin and/or PKA.The first patient was diagnosed with BAH on prenatal ultrasound and subsequently required bilateral adrenalectomy for CS as she had virilization, hirsutism, hypertension and cardiac hypertrophy 9 weeks old. Adrenalectomy revealed that she had iMAD. She also presented with hemihypertrophy of the right leg, labia and mild newborn hypoglycemia, however she was negative for Beckwith-Wiedemann mutation. Gene analysis of *PRKAR1A* did not reveal any mutations. After whole exome sequencing (WES), we found a novel heterozygous *USP8* variant (c.1387_1393delinsT, p.A463_I465delinsF) at germline level and loss of heterozygosity (LOH) at tumor level. Immunohistochemistry showed significantly lower expression of USP8 protein in both of her adrenals compared to a control tissue. Immunofluorescence showed higher expression of PRKACA and PRKACB proteins compared to control tissue. The second case is a 59-year old female with osteoporosis who failed to suppress cortisol levels after low dose dexamethasone administration. MRI revealed an adenoma on the right adrenal (2.6cm). She underwent right adrenalectomy and was found to have PMAH. We performed WES in germline level and we detected a novel heterozygous missense *USP8* variant (c.287A>G, p.K96R) that is present also at tumor level. Immunohistochemistry showed significantly lower expression of USP8 protein in her adrenal tumor compared to the control tissue. Immunofluorescence showed higher expression of PRKACA and PRKACB proteins compared to control tissue. No LOH was identified. These preliminary findings support *UPS8* involvement in the development of adrenocortical disease. We are currently performing further in vitro studies to evaluate the effect of these two *USP8* variants into the canonical Wnt pathway and PKA pathway which are commonly involved in adrenocortical disorders.

PrgmNr 2758 - Cancer Risk B is a rapid and accurate test of peripheral blood mononuclear cells for prediction of breast cancer risk

View session detail

Author Block: **J. Loke**[1], H. Ostrer[1], S. D. Klugman[2], D. Gruber[3], D. H. Tegay[4], I. Alim[5], K. Onel[6], A. La Bella[7], S. Yam[8], L. C. Xia[1]; [1]Albert Einstein Coll. of Med., Bronx, NY, [2]Montefiore Med. Identifying women at high risk for developing breast cancer can trigger a personal program of surveillance for early detection, prophylactic surgery, or chemoprevention to reduce risk. Cancer gene panel sequencing yields risk-modifying results in only 15-20% of cases, suggesting the need for a new approach. Cancer Risk B (CR-B) is a rapid test (2 days) that uses flow variant analysis to assess the effects of variants in the DNA double strand break (DSB) repair pathway on the phosphorylation of p53 and nuclear localization of BRCA1 and BRCA2. CR-B was compared in matched peripheral blood mononuclear cells (PBMCs) and lymphoblastoid cells (LCLs; N=20), then applied to two groups of subjects who received coincidental gene panel sequencing to assess sensitivity, specificity and accuracy, and utility for annotating variants of uncertain significance (N=159). When comparing matched LCLs and PBMCs and inter-day tests, CR-B yielded highly reproducible results (r^2>0.9). The CR-B phenotype demonstrated a bimodal distribution: CR-B+, indicative of DSB repair defects, and CR-B-, indicative of wild-type repair**.** When applied to subjects with known pathogenic variants (positive controls) or negative relatives of known pathogenic variant carriers (negative controls), the sensitivity of the test was 91% and the specificity was 96%. The CR-B+ phenotype was rescued by gene transfer using wild-type cDNA expression plasmid transduction into LCLs or CRISPR-edited cells. As a functional genomics test with strong evidence, the CR-B- phenotype predicted VUS as benign or likely benign. CR-B could represent a rapid and accurate alternative to panel sequencing for identifying women at high-risk for cancer and is a useful functional genomics test for predicting VUS as benign.

PrgmNr 2759 - Casting a Wide Net: Finding actionable results in non-breast cancer genes on multi-gene panel testing in a breast cancer cohort

View session detail

Author Block: **M. Rohanizadegan**[1], L. Kipnis[1], S. Stokes[1], B. L. Bychkovsky[1], R. G. Scheib[1], H. Q. Rana[2], J. E. Garber[3]; [1]Dana Farber Cancer Inst., Boston, MA, [2]Dana-Farber Cancer Inst., Boston, MA, [3]Dana Farber Cancer Inst, Boston, MA

Disclosure Block: **M. Rohanizadegan:** None.

Background: Multi-gene panel testing (MGPT) for hereditary cancer syndromes allows for concurrent analysis of genes associated with various cancer types. This may lead to the identification of unexpected pathogenic/likely pathogenic variants (P/LPVs) in high penetrance cancer genes with no link to the original cancer. In this study we examined the landscape of P/LPVs in a breast cancer (BC) cohort who underwent MGPT and assessed clinical and family history features consistent with identified P/LPVs.

Methods: We retrospective reviewed patients seen at a single institution who underwent MGPT from 1/1/15- 5/24/21. MGPT was defined as additional gene testing beyond the 9 genes associated with BC (*ATM, BRCA1, BRCA2, CDH1, CHEK2, PALB2, PTEN, STK11, TP53*). Subjects with P/LPVs in moderate-penetrance BC genes for which cancer risk is not established yet, heterozygous P/LPVs in genes with a recessive inheritance pattern and those with *APC* I307K and *FH* p.Lys477dup were excluded. Deidentified pedigrees were analyzed to determine whether there was clinical suspicion of a P/LPV in any of the non-BC high-penetrance genes considering national testing guidelines or clinical diagnostic criteria. **Results**: Among 7086 patients, 888 (12%) were found to have at least one P/LPV in a cancer susceptibility gene. We identified 159 P/LPVs in genes not typically associated with risk for BC in 157 (2%) patients; among these, there was clinical suspicion for the identified P/LPV in only 51 patients (32%, including 45 with Lynch syndrome, 33 with ovarian cancer related genes i.e *BRIP1, RAD51C* and *RAD51D*, 18 with SDHx, and 17 with melanoma related genes such as *CDKN2A, BAP1* and *MITF*). Medical or surgical management would be affected by the MGPT result in 93% of subjects. Only 42% of subjects with Lynch syndrome had a clinical suspicion based on personal or family history, 11% with SDHx related hereditary cancer syndrome and 18% of subjects with genetic risk for ovarian cancer. **Conclusion**: Of 7086 BC patients who underwent MGPT, 2% were found to have a P/LPV in a high-penetrance non-BC gene that would have been missed by a smaller BC gene panel. In all cases, cascade testing was offered to at-risk family members, allowing for cancer and reproductive risk stratification and management. This study estimates the prevalence of P/LPVs from MGPT in a referral center, which may address some concerns about the chance of unanticipated findings with comprehensive testing in the breast cancer population.

PrgmNr 2760 - Cellular diversity of human breast tissue evaluated in Pre-templated Instant Partitions for single-cell RNA sequencing (PIPseq)

View session detail

Author Block: **J. Zhang**[1], K. Phong[2], Z. Gartner[2], R. Meltzer[1], K. Fontanez[1]; [1]Fluent BioSci., Watertown, MA, [2]Univ. of California, San Francisco, San Francisco, CA
Disclosure Block: **J. Zhang:** Salary/Employment; Fluent BioSciences.
Single-cell RNA sequencing (scRNA-seq) has made profound impacts in the study of cellular and molecular diversity in complex tissues. Breast tissue comprises a diverse mixture of epithelial, lymphatic, vascular, and immune cell populations, and the structure and composition of breast tissue remodels continuously throughout a womanâ□□s lifetime. Previous scRNA-seq analysis of banked reduction mammoplasty tissue has revealed changes in cell type abundances in response to physiological events such as childbirth and the menstrual cycle. Performing this analysis on a larger patient cohort will strengthen these correlations and identify further links between physiological factors and breast tissue cellular composition. However, current scRNA-seq platforms make it difficult and cost-prohibitive to process a large cohort of asynchronously obtained patient samples. Fluent BioSciences has developed Pre-templated Instant Partitions (PIPs) to simultaneously segregate complex cell mixtures into partitions with barcoded template particles that can be easily processed for scRNA-seq (PIPseq) without the need for complex instrumentation or microfluidic consumables, allowing PIPseq to be performed in any moderately equipped laboratory at a lower cost per cell than other commercially available scRNA-seq platforms. As an initial validation of PIPseq for the study of breast tissue, approximately 1000 primary human mammary epithelial cells were processed by PIPseq. Clustering analysis indicates 2 primary cell clusters, and marker gene analysis of Keratin 14 and 19 clearly segregates these populations to myoepithelial and luminal cell populations. This is in agreement with cell populations previously characterized with other scRNA-seq methods. PIPseq has the required biological sensitivity to identify cell populations in primary breast tissue samples. Future efforts will correlate cell populations in primary resected breast tissue with patient-matched estrogen and progesterone levels.

PrgmNr 2761 - Improving predictions of variant functional effects using deep mutational scanning data

View session detail

Author Block: **T. Yu**[1], J. Fife[1], R. Sherwood[2], C. Cassa[3]; [1]Brigham and Women's Hosp., Cambridge, MA, [2]Brigham and Women's Hosp., Harvard Med Sch., Boston, MA, [3]Harvard Med. Sch., CAMBRIDGE, MA

Disclosure Block: **T. Yu:** None.

Predicting the functional impact of coding variants remains a substantial challenge, with applications in population genetics, molecular biology, and clinical genetics. Computational predictive tools often rely on features related to structure, conservation, or population data. To complement these predictions, deep mutational scanning (DMS) methods are used to measure the functional effects of allelic variants. These *in vitro* screens are collectively informative, but may be individually noisy per variant.

We aggregate DMS data to identify regions of proteins likely to be functionally impactful versus regions more tolerant to mutation. We do this by pooling variant functional effect scores in a moving window. Importantly, we restrict our moving averages to a) amino acid substitutions that could possibly occur, and b) to the 80 amino acid substitutions that are most likely to be informative, by excluding substitutions that are often damaging or rarely damaging.

We then train a 2-state Hidden Markov Model (HMM) using this moving average, the phyloP 100-way score, and a positional score which represents the predicted functional effect from DMS data. The predicted states of the HMM then provide a regional â□□scaffoldâ□□ of functional impact for a mutation in the region. Importantly, no clinical diagnostic data was used to develop this scaffold.

Finally, we make a context-sensitive functional score for any SNV based on its HMM assignment and the specific amino-acid substitution. We generate the amino acid substitution matrix using DMS data from 11 genes other than *BRCA1*. Using lab-classified pathogenic and benign mutations in *BRCA1* from ClinVar, we can significantly separate these variants as pathogenic or benign based on the contextual score (p-6). In contrast, the normalized BLOSUM62 substitution matrix can only achieve pThis project provides two important contributions: 1) we are able to aggregate signal from DMS data to identify regions of higher or lower functional impact, and 2) by restricting to 80 amino acid substitutions, we are able to provide highly significant functional scores with substantially fewer DMS assays. Future work will integrate these functional scores with existing predictive features.

PrgmNr 2762 - Large-scale functional assessment of *RAD51C* missense variants with PARP inhibitor screens

View session detail

Author Block: **G. Montalban**[1], L. Milano[1], A. Rodrigue[1], Y. Coulombe[1], S. Desjardins[1], M. Dumont[1], C. Joly-Beauparlant[1], P. Soucy[1], K. Matreyek[2], J-Y. Masson[1], J. Simard[1]; [1]CHU de QuÃ©bec-UniversitÃ© Laval Res. Ctr., Quebec city, QC, Canada, [2]Case Western Reserve Univ. Sch. of Med., Cleveland, OH
Disclosure Block: **G. Montalban:** None.
Germline pathogenic variants in homologous recombination repair (HRR) genes are associated with increased risks of developing breast/ovarian cancer. RAD51C participates in HRR by interacting with other RAD51 paralogues to promote the stabilization of the RAD51 nucleoprotein filament in the homologous DNA strand. Large case-control studies have confirmed that *RAD51C* loss-of-function variants confer moderate risks of developing breast/ovarian cancer (Dorling L et al., NEJM 2021; Hu C et al., NEJM 2021). However, the increased identification of variants of unknown clinical significance (VUS) hampers genetic counseling of breast/ovarian patients and families. Here we present a massively parallel functional approach to study the molecular impact of all missense substitutions in the *RAD51C* gene using PARP inhibitor sensitivity as a readout. A *RAD51C* mutagenesis library was designed to cover all possible missense substitutions (~7,500 variants; 98% coverage). The library was barcoded and cloned into an inducible, recombinase-site containing vector. Landing pad cell lines were generated to allow the systematic integration of the library and to ensure the recombination of one variant per cell, keeping the genotype-phenotype link. Briefly, endogenous RAD51C expression was silenced using siRNAs targeting the 3â□□UTR region of the gene and cells were exposed to different PARP inhibitors. Genomic DNA from untreated and treated pools was extracted and sequenced in a NovaSeq instrument. To date, several â□□mini-screensâ□□ have been performed covering different regions of the gene. All variants were detected in the pre-treated pools at a similar abundance, confirming their optimal integration and expression. Variant read counts were reduced for known deleterious variants (positive controls) after treatment, confirming the synthetic lethal effect of PARPi when RAD51C is not functional. Whole screens with the barcoded library are ongoing, as well as the application of specific computational tools for the calculation and calibration of variant fitness scores (Enrich2 and DimSum; Rubin et al., 2027; Faure AJ et al., 2020, respectively). We have developed a large-scale functional approach to measure the impact of all missense variants in the *RAD51C* by screening for PARPi sensitivity. Future work will focus on validating our functional scores with published works, clinical databases and complementary functional assays. The final goal is to improve the interpretation of *RAD51C* VUS and accelerate their clinical translation.

PrgmNr 2763 - Measuring (almost) all possible*STK11/LKB1* missense variants in monogenic disease and cancer

View session detail

Author Block: **D. Zimmerman**, A. Cote, N. Kishore, M. Gebbia, W. Loggerenberg, J. Weile, F. Roth; Univ. of Toronto, Toronto, ON, Canada
Disclosure Block: **D. Zimmerman:** None.
Measuring the Functional Impact of (Almost) All Possible *STK11/LKB1* Missense Variants in Monogenic Disease and Cancer Germline missense variants in Serine/Threonine Kinase 11 (*STK11*, aka *LKB1*) cause Peutz-Jeghers Syndrome (PJS), a rare disease that increases lifetime cancer risk. Somatic *STK11* variants also contribute to multiple cancers (including ~30% of lung cancers). Early genetic diagnosis of PJS helps establish life-long disease management, in part by identifying patients for pre-emptive surgeries. *STK11*-deficient lung cancers are resistant to widely used immune checkpoint inhibitors and proactive detection would limit prescription of an ineffective therapy. Unfortunately, nearly 90% of clinically interpreted *STK11* missense variants are classified as Variants of Uncertain Significance (VUS). Resources for variant interpretation are sorely needed, the American College of Medical Genetics has listed *STK11* as one of their 59 clinically actionable genes. Since functional assays provide strong evidence for clinical variant interpretation, we aim to test all possible *STK11* missense variants. To this end, we have employed two scalable assays for *STK11* variant function: 1) complementation of a S. cerevisiae strain lacking the yeast orthologues *SAK1*, *TOS3*, and *ELM1*; and 2) toxicity of *STK11* expression in the human HeLa cell line. We describe assay validation, mutagenized library construction, and other progress towards a *STK11* missense variant effect map, potentially improving diagnosis and therapy for PJS and *STK11*-related cancers.

PrgmNr 2764 - Pathological variant c.8143C&gtT in *ATM* gene in a patient with non-Hodgkin lymphoma

View session detail

Author Block: **I. Cuero-Quezada**[1], L. Bobadilla-Morales[1], M. Orozco-Vela[1], S. A. BRUKMAN[2], A. Corona-Rivera[1]; [1]Univ. of Guadalajarada, Guadalajara, Mexico, [2]UNIVERSIDAD DE GUADALAJARA, GUADALAJARA, Mexico
Disclosure Block: **I. Cuero-Quezada:** None.
Introduction. Lymphomas belong to the group of lymphoid neoplasms, the prognosis depends on the histological type, clinical factors and molecular characteristics. Non-Hodgkin's lymphoma is a malignant neoplasm of B, T or NK cells, it can infiltrate lymphoid and hematopoietic tissues, the main symptoms are night sweats, fever and weight loss, the diagnosis is established through a tissue biopsy. Hodgkin's lymphoma is a B-cell lymph node neoplasm, the neoplastic cells are known as Reed-Sternberg cells. **Objective.** Present a case with an initial diagnosis of non-Hodgkin's lymphoma and relapsed Hodgkin's lymphoma presenting the c.8143C>T germinal variant in the ATM gene. **Clinical report.** 18-year-old female, normodevelopmental pregnancy, without alterations and adequate prenatal control, normal psychomotor development. Family history of CNS tumors. It begins with symptoms at 14 years of age with upper respiratory symptoms presenting fever of 39Â°C and cough, presence of pain in the left jaw, tooth extraction is performed, it is diagnosed as a histiocytoma with partial improvement, at 15 years of age it presents adynamia, weight loss, larger cervical nodes, a biopsy is taken obtaining the diagnosis of non-Hodgkin lymphoma of T cells with markers CD20(-), CD3(+), CD30(+), CD15(+), PML-1(-), Langerginas(-), MUM-1(-). The evolution was stable and remained in maintenance until the age of 17 when she presented dyspnea, B symptoms and generalized paleness, a relapse was confirmed by CT of the chest and abdomen, a mediastinal mass biopsy was taken with a result of CD20 mixed cellularity Hodgkin lymphoma (+) in 80% of Reed-Sternberg cells.Material and method. Conventional karyotype of the bone marrow had a normal result, with a family history of cancer and the presence of two primary tumors a search for mutations in familial cancer genes was performed using the CentoCancerÂ® panel. **Results.** Through sequencing, the variant c.8143C>T in the ATM gene (Leu2715Phe) was detected, classified as a variant of uncertain significance.Discussion. Mutations in ATM have been related to the risk of developing cancer, especially lymphoid neoplasms, it is suggested that ATM act as a tumor suppressor. The variant is classified as of uncertain significance, however, due to the antecedents, we consider it to be a pathological variant. Pathogenic variants have been reported in tumor cells and germ cells in various types of leukemia and lymphoma. The search for variants in ATM are important to help the risk stratification of patients who present them. **Conclusions.** This work makes it possible to add the ATM gene variant c.8143C>T as a pathogenic classification.

PrgmNr 2765 - Uncovering the functional variants and target genes of the 7q32 pancreatic cancer risk locus

View session detail

Author Block: **A. O'Brien**[1,2], J. Hoskins[1], D. Eiser[1], K. E. Connelly[1], J. Zhong[1], I. Collins[1], Pancreatic Cancer Case-Control Consortium, Pancreatic Cancer Cohort Consortium, S. J. Chanock[1], A. P. Klein[3], H. E. Arda[1], L. T. Amundadottir[1]; [1]NIH, Bethesda, MD, [2]Queen's Univ. Belfast, Belfast, United Kingdom, [3]Johns Hopkins Univ. Sch. of Med., Baltimore, MD
Disclosure Block: **A. O'Brien:** None.
Pancreatic ductal adenocarcinoma (PDAC) is set to become second leading cause of cancer mortality over the next decade. PDAC has a 5-year survival rate of only ~9%, necessitating a better understanding of its etiology. PDAC risk factors are both environmental and genetic, with heritability estimated at around 20%. However, highly penetrant coding variants are rare in the population and account for as little as 1% of the phenotypic variance for PDAC.

To identify common PDAC susceptibility alleles, genome-wide association studies (GWAS) in people of European ancestry have identified 17 loci at which germline variants associate with PDAC risk. Mostly non-coding, many of these variants are expected to confer risk through allele-specific changes in transcription factor binding, leading to altered target gene expression over a lifetime. The identification of functional variants from GWAS is complicated by the correlation of alleles through linkage disequilibrium (LD).

Here, we leveraged Bayesian fine mapping to identify a credible set (CS) of seven single nucleotide polymorphisms (SNPs) in high LD at the 7q32.3 risk locus. CS variants were annotated with epigenomic datasets we previously generated from a range of pancreatic cell lines, organoids and primary patient samples, encompassing histone modification marks (ChIP-seq), open chromatin (ATAC-seq) and chromatin conformation capture (Capture-HiC, HiChIP). Two variants from the CS (rs6971499 and rs6970779) were found to consistently lie within regions annotated as super-enhancers and marked by open chromatin. Electrophoretic mobility shift assays (EMSA) illustrate allele-specific protein binding for rs6971499-T and rs6970779-G in PANC-1 and MIA PaCa-2 cell lines, while luciferase reporter assays in the same cell lines demonstrate that both alleles drive significant changes in transcriptional activity.

Both SNPs exhibit chromatin looping to the promoters of *LINC-PINT* and *MIR29a*, representing two plausible target genes. *MIR29* family members are implicated in both suppression and progression of many cancers and are key regulators of PDACâ□□s characteristic stromal presentation. *LINC-PINT*, a p53-induced long non-coding RNA is associated with epigenetic silencing via recruitment of the PRC2 polycomb repressive complex.

Ongoing proteomic experiments aim to identify the transcription factors differentially bound to these alleles, while CRISPR is being used to validate enhancer variants in their native chromatin context. Future experiments may further characterize these transcription factors and their target genes with an eye toward better understanding their roles in PDAC carcinogenesis.

PrgmNr 2766 - 3D confirmation analysis of the *FGFR2* kinase domain with disease-associated mutations reveals novel features that correlate with clinical presentation

View session detail

Author Block: **Y. Lian**[1], D. Bodian[2], A. Shehu[1]; [1]George Mason Univ., Fairfax, VA, [2]Inova Translational Med. Inst., Falls Church, VA
Disclosure Block: **Y. Lian:** None.
Receptor tyrosine kinases (RTKs) play an essential role in the regulation of many cell signaling processes including cell proliferation, angiogenesis, and survival. Most members of the RTK family are transmembrane proteins that assume different conformations to perform their cellular functions. These conformational dynamics are physiologically regulated by binding ligands to the extracellular domain and post-translational modifications such as receptor activation by autophosphorylation of the intracellular kinase domain and are also affected by pathogenic mutations. Activation is tightly regulated, with dysregulation by germline or somatic mutation leading to activation in the absence of ligand binding and causing various cancers and developmental disorders.
Fibroblast growth factor receptor 2 (*FGFR2*) kinase has been a model for studying the mechanism by which gain of function mutations in the tyrosine kinase domain cause activation in the absence of ligand binding. Germline mutations in the kinase domain of *FGFR2* lead to skeletal disorders, primarily dwarfism, and craniofacial malformation syndromes. *FGFR2* has also been implicated in cancers including breast and gastric cancer. Many X-ray and NMR structures of inactive and activated forms, and of isoforms with activating or inhibiting mutations, are now available. Analysis of these structures has led to the proposal of a molecular brake preventing the ATP-binding A-loop from adopting the activated conformation. Activating mutations can relieve the brake, affecting a long-range allosteric process that causes a change in equilibrium between the active and inactive states. However, this fundamentally dynamic process is not well captured by the static structures and so remains not well characterized.
In this study, we employ all the available structures of *FGFR2* kinase from the Protein Data Bank (PDB) to capture and characterize the conformational dynamics of the *FGFR2* kinase domain and correlate these dynamics with known functional regions and disease type. We use machine learning methodologies to elucidate the relationship between conformational changes and the kinaseâ□□s activation region that occurs upon phosphorylation. We show that linear and nonlinear representation learning techniques agree on the characterized dynamics. Organizing structures by the revealed intrinsic motions and activated region and disease type shows good co-localization, linking mutations to dynamics and clinical presentation. Our work demonstrates the value of including machine-learned representations of conformational dynamics in identifying RTK regulatory functions and associated disease types.

PrgmNr 2767 - A genome-first approach characterizing the prevalence and cancer phenotype of pathogenic germline *DICER1* variants in two large, unselected cohorts

View session detail

Author Block: **J. Kim**[1], J. Haley[2], H. Rao[2], U. T. Mirshahi[2], Geisinger-Regeneron DiscovEHR Collaboration, K. Schultz[3], D. J. Carey[2], D. Stewart[4]; [1]Natl. Cancer Inst., Rockville, MD, [2]Geisinger Clinic, Danville, PA, [3]Intl. Pleuropulmonary Blastoma/DICER1 Registry, Minneapolis, MN, [4]Natl. Cancer Inst, Rockville, MD

Disclosure Block: **J. Kim:** None.

DICER1 is an RNaseIII endonuclease crucial for processing pre-microRNA into mature, active microRNA (miRNA). Loss-of-function germline variants in *DICER1* underlie an autosomal dominant disorder with an increased risk of numerous neoplasms, macrocephaly, and thyroid-related disease. The availability of large-scale, exome-sequenced cohorts with linked electronic health records (EHR) from the DiscovEHR study and UK Biobank cohort permits genome-first exploration of phenotype in individuals with a pathogenic germline *DICER1* variant. We previously observed *DICER1* pathogenic germline variants in 1 out of 4600 exomes and an increased risk of thyroidectomy and thyroid cancer in the DiscovEHR study of ~92K individuals. In this study, we described the prevalence of pathogenic germline *DICER1* variants in exomes of 175K individuals from the DiscovEHR study and 200K individuals from the UK Biobank cohort.*DICER1* variants were classified as pathogenic if it was a RNaseIIIb mutation hotspot, nonsense, frameshift, or a cryptic splice-site, and not located in last exon. For the UK Biobank cohort, we queried for cancer diagnoses and procedures using self-reported questionnaire, cancer and death registry, and EHR. For the DiscovEHR study, we queried the Geisinger Cancer Registry and EHR for similar diagnoses and procedures. We identified 21 individuals (1:8355) and 25 individuals (1:9234) with a *DICER1* pathogenic variant in the DiscovEHR study and the UK Biobank cohort, respectively. In the DiscovEHR study, we identified five people with malignancies, including two lung cancers (54 yrs, 62 yrs), meningioma (41 yrs), thyroid cancer (37 yrs), and breast cancer (57 yrs). Furthermore, of the 21 people, 12 had an ICD10 code for thyroid-related diseases (hypothyroidism, thyrotoxicosis, and/or nontoxic goiter). Age of first diagnosis for thyroid disease ranged from 20-71 yrs (female mean: 39 yrs, male mean: 52 yrs). In UK Biobank, we found three people with malignancies, including pineoblastoma (15 yrs) and two breast cancers (62 yrs and 50 yrs). The two people with breast cancer did not harbor exonic variants in known breast cancer susceptibility genes. In addition, we observed six cases of thyroid diseases (two thyroidectomy, two hypothyroidisms, thyrotoxicosis, non-toxic goiter), ranging from 14-68 yrs (female mean: 51 yrs, male: 14 yrs). In the UK Biobank, there was no ICD code (other than those for thyroid disease) excess in subjects with a *DICER1* pathogenic variant. Here we provide updated prevalence and thyroid penetrance for pathogenic *DICER1* variants in two large cohorts. The observation of breast cancer in the *DICER1* heterozygotes merits additional investigation.

PrgmNr 2768 - An analysis of automated cell-type labelling algorithms for tumour micro-environment single-cell RNA sequencing data

View session detail

Disclosure Block: **E. Christensen:** None.
Single cell RNA sequencing (scRNA-seq) allows researchers to precisely define complex cell populations through the examination of gene expression in individual cells from a sample. This is particularly useful in cancer research, as the tumour microenvironment (TME) can be incredibly heterogeneous, containing malignant cells, cells of the tissue of origin, immune cells, fibroblasts, and more. This heterogeneity often affects how cancer progresses and responds to treatment, making it important to accurately identify all cells within the TME. Most current scRNA-seq pipelines involve clustering the cells by differentially expressed genes and assigning cell type labels to each cluster based on gene sets. This labelling step is typically a manual task, which can rely on subjective decisions and may yield inconsistent results. Several automated methods for identifying cell types exist, and have been tested on healthy scRNA-seq samples, but their performance on more complex TME data is unknown.

Here we evaluate 26 methods to automate the process of assigning labels to TME cells - 19 supervised cell-based methods and 7 semi-supervised cluster-based methods. Our study shows that cell-based algorithms outperform cluster-based algorithms overall. This could be because the cell-based algorithms are fully supervised, learning from each individual cell in the training set instead of only examining select genes within a group of cells. Overall scPred, CaSTLe, scVI, and SVM are the top-performing algorithms. Of these algorithms, SVM is the fastest running. Among cluster-based methods, GSVA ranked highest. We also tested the ability of cell-based algorithms to train a classifier on one group of patients and predict the cells in another group and found that algorithms performing well with random training and testing sets also perform well on separate patients, suggesting they would be applicable in a clinical setting.

Cluster-based methods are often unable to identify malignant cells within a dataset due to lack of appropriate gene signatures. Cell-based algorithms, however, tended to perform better on the malignant cell categories - an interesting result as the algorithms learn from the data they are provided and most methods are not tailored to TME data specifically. This may be due to a higher proportion of malignant cells present in the data providing a better source for the algorithms to learn a malignant cell profile. In summary, our analysis presents a set of guidelines for researchers to understand the various cell type identification methods and select the best one for their work, allowing them to create new and improved treatments which ultimately improve patient care.

PrgmNr 2769 - Evaluating Immune Repertoire Patterns During Prostate Cancer Tumor Progression

View session detail

Author Block: **H. Arora**[1], A. Vedenko[1], R. Reddy[1], D. Van Booven[2]; [1]Dept of Urology, Univ. of Miami, Miami, FL, [2]Univ Miami Miller Sch Med, Miami, FL
Disclosure Block: **H. Arora:** None.
Introduction: Prostate cancer (PCa) progression from benign androgen (AR) dependent stage to AR independent castration resistant and then a neuroendocrine stage is often accompanied by resistance to therapy.. This resistance calls for ways that can help in understanding the etiology of progression in order to improve outcome.. Similarly, Immune checkpoint inhibition (ICI) has revolutionized treatment of many tumor types, including prostate cancer. Such therapies focus on restoring antibody diversity to eliminate tumor cells that evaded immune detection, but is effective only in a subset of patients.. This limited efficacy be in part from tumor heterogeneity and the unique ability of PCa to evolve. Therefore, this study focuses on evaluating the immunomodulatory patterns that are correlated to stages of PCa progression. **Methods**: The analysis contains 3 parts: PCa subclassification, mutation analysis, and Ig expression. First, we obtained all RNAseq from the PRAD project contained in the TCGA (n=500). A general PCA was performed, and then patients were stratified into subclasses by using gene signatures obtained from the Disease/Gene Database (disgene.net). The results were then classified using basic clustering to refine these genes, and finalize the subclasses. Second, mutations were downloaded for the same PRAD TCGA dataset. Mutation types as well as number of mutations were classified per patient in order to come up with a mutational profile per patient. These profiles were then used to scan for mutations across severity by Gleason score (GS). Thirdly, Ig profiles were evaluated using the software packages TRUST and MiXCR. Total CDR3 sequences as well as AA length was analyzed and compared with mutation rates as well as switching events. Finally, all stratifications were compared to known tumor severity by GS. **Results**: We observed patterns of Immunoglobulin (Ig) expression that are co-relatable to a) PCa subclasses such as Prostate Adenocarcinoma, Recurrent PCa, and Invasive PCa, b) mutation landscape (with focus on mutation types SNPs, SVs, and fusions), and c) Ig expression. Also, there are immunomodulatory patterns in IGHG1 and IGHG2 that are correlated with tumor severity and stages of PCa progression. Also, diversity variations exist in Shannon entropy with lower diversity in low grade tumor severity suggesting a significant change in the immune landscape. **Conclusions**: The results suggest there are immune modulatory patterns are correlated with stages of PCa, and their correlation with components such as mutations, GS, subclasses of PCa can help in better understanding PCa progression and design therapeutic strategy more effectively.

PrgmNr 2770 - Identification of the transcriptome signature of Beckwith-Wiedemann Syndrome hepatoblastoma predisposition

View session detail

Author Block: **N. Sobel Naveh**[1], E. M. Traxler[1], K. A. Duffy[1], J. Kalish[1,2]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Perelman Sch. of Med. at the Univ. of Pennsylvania, Philadelphia,, PA
Disclosure Block: **N. Sobel Naveh:** None.
Beckwith-Wiedemann Syndrome (BWS, OMIM 130650) is one of the most common epigenetic cancer predisposition syndromes. BWS is caused by alterations to human chromosome 11p15, which contains two independent domains subject to genomic imprinting. Imprinting Center 1 (IC1) encompasses *Insulin-like Growth Factor 2 (IGF2)* and the non-coding growth suppressor *H19*; Imprinting Center 2 (IC2) encompasses the *potassium voltage-gated channel subfamily Q member 1 (KCNQ1),* its antisense transcript *KCNQ1OT1*, and cell-cycle regulator *Cyclin Dependent Kinase 1C (CDKN1C)*. Patients with BWS caused by isolated loss of methylation (LOM) at IC2 or loss-of-heterozygosity due to paternal uniparental isodisomy (pUPD11) encompassing both domains are more likely to develop hepatoblastoma (HB) and patients with BWS have at an estimated 2,200 times greater risk of HB tumorigenesis. While 11p15 epigenetic changes are components of this pre-cancer genome, their downstream molecular effect and the mechanism by which they cause oncogenesis has not been previously investigated. Using clinical data and patient samples from the International BWS Registry and Biorepository, we performed RNA sequencing (RNA-Seq) on BWS HB tumors from patients with IC2 LOM or pUPD11. We identified 610 differentially expressed genes between the HB and non-tumor samples. We identified an additional 139 differentially expressed genes that comprise a BWS HB predisposition signature; these genes are over- or under-expressed in both BWS tumor and BWS matched normal samples compared to control livers. These genes largely represent members of cell cycle, chromatin organization, and response to insulin regulation, as well as the following signaling pathways: WNT, MAPK, AKT, and HIPPO. To better understand the potential relationship between these genes, we visualized their protein-protein interaction (PPI) network. Distinguishing this profile from non-syndromic tumors, proto-oncogenes such as *HRAS, SHC1,* and *WNT1* are under-expressed. In contrast, over-expressed hub genes *HDAC1, MAPK8, IL2*, and *TGFBR2* may represent future targets for BWS-associated HB therapeutic development. The central hub gene MYC has been observed to be regulated by *IGF2* and *KCNQ1OT1* levels in other cell types; as such we present a model wherein these 11p15 genes modulate *MYC* in BWS liver cells to initiate overgrowth and HB predisposition which then dysregulates the aforementioned pathways.

PrgmNr 2771 - Inferring cancer evolution from single tumour biopsies using synthetic supervised learning

View session detail

Author Block: **T. Ouellette**[1,2], P. Awadalla[1,2]; [1]Ontario Inst. for Cancer Res., Toronto, ON, Canada, [2]Univ. of Toronto, Toronto, ON, Canada
Disclosure Block: **T. Ouellette:** None.
A significant hurdle in understanding cancer evolution *in vivo* are the constraints surrounding serial sequencing, through space or time. For this reason, tumour biopsies are primarily sequenced in bulk from a single site and at a single time point. Although multi-region and single-cell data are becoming increasingly utilized, single time point, bulk sequenced biopsies still represent the major data source for studying cancer genomics and evolution in individual patients. Given this limitation, a reasonable strategy for inferring evolution in single tumour biopsies has been to utilize theoretical population genetics to capture signatures of selection from the variant allele frequency (VAF) distribution. The premise being that fitness-altering mutations will deterministically change in frequency over time, leading to characteristic and quantifiable deviations in the VAF distribution relative to some neutral evolutionary scenario. VAF-based methods have been employed to differentiate between positive selection and neutral evolution, to examine growth patterns, to quantify subclonal fitness and time subclonal emergence, and to build population genetics informed mixture models that account for neutral dynamics, that shape, to some extent, all tumour populations. With that said, existing VAF-based methods, although mechanistic and useful in many cases, have apparent limitations. For example, single statistics are compressive and cannot infer complex information, approximate Bayesian computation methods suffer from the curse of dimensionality and can be prohibitively slow due to a rate-limiting simulation step required for each sample, and mixture models, used to identify subclonal populations, are subject to incorrect clustering in the presence of excess dispersion or sparsity. **Here, we develop a synthetic supervised deep learning approach to infer cancer evolution in bulk sequenced single tumour biopsies using only VAF information.** By generating synthetic VAFs, as a proxy for ground truth, from plausible simulations of tumour evolution, we can train deep learning models to classify and quantify evolutionary parameters in real patient tumours. Overall, a synthetic supervised learning approach allows us to avoid information loss that comes with compressing data into a single statistic prior, to separate simulation and training from prediction which ultimately makes inferences faster, and to learn concise representations of the underlying data leading to more accurate predictions relative to existing methods. We apply our synthetic supervised learning approach to over 150 whole-genome sequenced (WGS) single tumour biopsies.

PrgmNr 2772 - Long-read sequencing reveals alternative splicing of transposable elements in breast cancer

View session detail

Author Block: **A. Nesta**[1,2], D. Veiga[2], O. Anczukow[2,1,3], J. Banchereau[2], C. R. Beck[4,2,3]; [1]Genetics and Genome Sci., Dept. of Genetics and Genome Sci., Univ. of Connecticut Hlth.Ctr., Farmington, CT, [2]The Jackson Lab. for Genomic Med., Farmington, CT, [3]Inst. for Systems Genomics, Univ. of Connecticut Hlth.Ctr., Farmington, CT, [4]Dept. of Genetics and Genome Sci., Univ. of Connecticut Hlth.Ctr., Farmington, CT
Disclosure Block: **A. Nesta:** None.
Transposable Elements (TEs) comprise more than half of our DNA and play an increasingly important role in gene expression. On the transcriptome level, transposons contain promoters, splice donors, splice acceptors, and polyadenylation signals which can alter splicing and expression of nearby genes. Many cancers exhibit genome-wide hypomethylation and widespread transcriptome alterations, which may promote the usage of TEs in novel transcripts that are not typically observed in normal tissues. Traditional short-read RNA-Seq methods have identified alternatively spliced TEs in cancer associated genes, but are unable to capture complete isoforms. Short reads may also miss events due to mapping limitations and the repetitive nature of transposons. To comprehensively examine the effects of TEs on cancer transcriptomes, we sequenced 30 breast tissue samples using long-read RNA-Seq (Iso-Seq) and identified >142,000 quality-controlled transcripts containing >84,000 novel alternatively spliced isoforms. We quantified alternative splicing of our Iso-Seq transcriptome using >1000 breast cancer RNA-Seq samples from The Cancer Genome Atlas (TCGA) and the Genome Tissue Expression Project (GTEx) and identified ~3500 tumor-specific splice events (Veiga and Nesta *et al.* BioRxiv 2020). Alternatively spliced TEs were identified by intersecting our data with RepeatMasker. We found that >70,000 (~49%) of our quality-controlled transcripts overlap with TEs and 275 (192 novel) splice events are more prevalent in human breast tumors than in adjacent normal samples or GTEx. Furthermore, 88 of our 275 splice events reside in breast cancer associated genes and may be functionally important. *Alu* transposons in the 3â□□ UTR of transcripts are subject to adenosine to inosine (A -> I) modifications via an RNA editing mechanism shown to promote breast cancer progression. We found 208 previously unannotated 3â□□ UTRs which exhibit A -> I editing in our Iso-Seq transcriptome. Polymorphic retrotransposition events can also impact gene expression. We queried the unmapped segments of our Iso-Seq reads and identified transposon insertions that may impact expression of breast cancer associated genes. Our computational findings have identified putatively disease relevant transcripts; we are currently validating these findings with in vitro assays to establish novel cancer biomarkers and to investigate the potential pro-oncogenic function of our novel TE-containing isoforms. Our research provides a comprehensive window into how TEs affect cancer transcriptomes, and the myriad ways they can influence gene expression.

PrgmNr 2773 - Multiple germline events lead to cancer development in patients with Li-Fraumeni syndrome

Li-Fraumeni syndrome (LFS) is an autosomal dominant cancer-predisposition syndrome associated with pathogenic germline variants in the *TP53* tumour suppressor gene, in approximately 70% of cases. The early identification of genetic susceptibility is especially important in these patients, as they are at markedly increased risk of developing a spectrum of early-onset malignancies. The impact of early identification of germline cancer-causing aberrations in these patients is substantial, as it informs the prospective management of patients and their families. As such, it is imperative to identify cancer-causing aberrations in the remaining ~30% of patients that fit the clinical definition of LFS, but lack a pathogenic germline variant in *TP53*. In addition, even among LFS patients that harbour a pathogenic germline *TP53* variant, the cumulative lifetime risk of developing cancer is approximately 68% in males and 93% in females. The incomplete/variable penetrance, suggests the presence of additional genetic and epigenetic driver events that contribute to increased or decreased cancer risk in certain individuals. Candidate gene approaches have been considered to evaluate other risk factors; however, few studies have utilized unbiased genome-wide DNA sequencing and epigenomic assays to explain this variability in cancer occurrence.

In this work, we leveraged family-based whole-genome sequencing and methylation of DNA procured from peripheral blood leukocytes to evaluate the germline genetic and/or epigenetic genomes of a large cohort of LFS patients (n=396) who harbour either pathogenic variant (n=374) or wildtype *TP53* (n=22). In patients lacking a pathogenic germline variant in *TP53*, we pinpointed the role of alternative cancer-causing genetic aberrations in 8/14 patients that developed cancer. Among *TP53* variant carriers, 19/49 individuals who developed cancer harboured an additional pathogenic variant in another cancer gene, while variants in the WNT signalling pathway were associated with decreased cancer incidence. In addition, we leveraged the non-coding genome and methylome to identify inherited epimutations that confer increased cancer risk. Overall, our study highlights the immense benefits of expanding genetic and epigenetic testing of LFS patients beyond *TP53*, as *TP53* status alone does not indicate whether an individual will develop cancer.

PrgmNr 2774 - Optical genome mapping reveals novel structural variants in pediatric brain tumors

View session detail

Author Block: **M. Bornhorst**, S. Bhattacharya, Y. Fu, A. Eze, D. Morinigo, J. Nazarian, E. J. Vilain, H. Barseghyan; Children's Natl. Hosp., Washington, DC
Disclosure Block: **M. Bornhorst:** None.
Background: Brain tumors are a leading cause of cancer-related mortality in children. Research shows that structural variants (SVs) play an important role in tumorigenesis and growth. However, most genetic studies have relied on short-read based exome/genome sequencing (SRS) that have limited ability to detect SVs. Optical genome mapping (OGM) utilizes ultra-long DNA molecules to construct and evaluate much longer genomic fragments, making it effective in identifying large SVs. In this study, we utilized OGM for the detection of novel clinically relevant SVs in pediatric brain tumors. Methods: Ultra-high molecular weight DNA was extracted from a cohort of pediatric brain tumors and matched normal samples (n=50). OGM was performed using nanochannel chip arrays on a Saphyr instrument and SVs (large insertions/deletions, inversions, translocations) were identified. We then used *nanotatoR* to subclassify SVs into functional pathways and determined which genes impact specific cell developmental functions. Tumor-associated, low population frequency SVs were identified in all samples. Results: The most common SV events were deletions and translocations. Nearly all samples had an SV that overlapped with a gene known to have clinical significance. *CDKN2A/B* deletions were most common in high grade tumors. OGM also detected clinically relevant, previously unknown fusions (i.e. *NTRK2-KANK1*, *C11orf95-NCOA1* fusion) and deletions (*NF1, ATRX*) that may have affected therapeutic management. We also discovered novel SVs overlapping genes and miRNAs that could impact tumorigenesis. Conclusion: OGM effectively identifies clinically relevant SVs in pediatric brain tumor samples, including SVs that were not discovered by other testing methods. This is a promising technology that allows mapping of the full SV spectrum of pediatric brain tumors. Future clinical studies in larger cohorts will help to determine the effect of SVs on response to treatment/prognosis.

PrgmNr 2775 - The putative tumor suppressor gene*USP13*in familial papillary thyroid carcinoma

View session detail

Author Block: **F. R. Faucz**[1], B. A. Barth[2], A. G. Maria[1], N. Settas[1], R. B. de Alexandre[2], C. A. Stratakis[1], F. (CCBS), Pontificia Univ.e CatÃ³lica do ParanÃi (PUCPR), Curitiba, Brazil
Disclosure Block: **F.R. Faucz:** None.
Papillary thyroid carcinoma (PTC) is a differentiated type of thyroid malignancy with a high incidence and prevalence. Advances in understanding the genetic basis for this disease revealed the potential involvement of several genes in the formation of thyroid tumors. Recent studies have shown that *USP13*, ubiquitin specific peptidase 13, serves as an important regulator of tumorigenesis and could also work as a tumor suppressor by regulating the PTEN/AKT signaling pathway in some cell types. The aim of this study was to identify genetic variants associated with the development of familial PTC in several members of a non-consagenious Brazilian family, through whole exome sequencing (WES), with *in vitro* characterization. WES analysis was performed in 13 members, including 5 with PTC. Sanger sequencing was used to confirm the main variants identified. A heterozygous missense variant in *USP13* (NM_003940.3) c.1483G>A (p.V495M) fully segregated with the disease. The variant was located in the USP domain of the USP13 protein and highly conserved. Moreover, *USP13* siRNA analysis was performed in MDA-T32 Papillary Thyroid Carcinoma Cells to access the significance of this gene in PTC. MDA-T32 cells treated with *USP13* siRNA showed a decrease of PTEN expression. This analysis suggests that *USP13* may be involved in the pathogenesis of PTC. However, further functional studies are needed to establish the putative role of the *USP13* gene in familial PTC predisposition.

PrgmNr 2776 - Treatment-specific gene regulatory pathways in colorectal cancer patients: CALGB/SWOG 80405 (Alliance)

Cetuximab or bevacizumab combined with chemotherapy are approved regimens for first-line metastatic colorectal cancer. However, hitherto underlying biological pathways can be responsible for the large variation observed in their efficacy and therapeutic responses. To elucidate these mechanisms, we investigated causal gene regulatory pathways related to overall survival (OS) using tumor RNA sequencing and germline SNP data from 1,039 patients with metastatic colorectal cancer treated with cetuximab or bevacizumab through a randomized phase III trial (CALGB/SWOG 80405). In this retrospective study, all analyses have been adjusted for BRAF V600E, all RAS mutations, age, gender, and treatment arm.

We identified 3,161 unique cis-eQTL for tumor gene expression (FDR C7, *CHST14*, *TECPR1*) acting as causal mediators for the impact of germline SNPs on OS. To better understand the regulation of these egenes, we built a transcriptomic-causal network and integrated the results of eQTL and MR analyses into the network. As a result, 7 gene regulatory pathways are identified (FDR Support: U10CA180821, U10CA180882, U24CA196171, https://acknowledgments.alliancefound.org; UG1CA180830, U10CA180888 (SWOG); Lilly, Genentech, and Pfizer; ClinicalTrials.gov Identifier: NCT00265850

PrgmNr 2777 - Trichostatin A sensitivity signature across hematological cell lines

View session detail

Author Block: **B. Przychodzen**; Vanda Pharmaceuticals, DC, DC
Disclosure Block: **B. Przychodzen:** None.
Histone deacetylase inhibitors (HDACi) are small molecules that increase acetylation of lysine residues by blocking histone deactylases. These anticancer agents affect epigenetic and non-epigenetic gene expression resulting in cell cycle arrest of cancer cells. Furthermore HDACi can enhance its anti-tumor effects via the pharmacologic modulation of macrophage (Li et al., 2020). Some HDACiâ□□s such as Trichostatin A (TSA) can also affected the tumor immune microenvironment by suppressing the activity of infiltrating macrophages and inhibiting myeloid-derived suppressor cell recruitment (Li et al.,). We conducted a high throughput screen comparing gene expression profiles in known hematological cell lines to identify transcriptional signatures associated with TSA sensitivity. We selected genes that showed at least 2 fold expression difference and were statistically significant (p

PrgmNr 2778 - A meta-genetic risk score across cardiometabolic risk factors for cardiovascular mortality: a prospective cohort study of UK Biobank

View session detail

Informatics, Univ. of Pennsylvania, Philadelphia, PA
Disclosure Block: **S. Jung:** None.
Background Cardiovascular disease (CVD) is one of the leading causes of mortality worldwide. Thus, early detection of individuals at high risk of CVD is important to lower their risk for cardiovascular (CV) mortality. CV mortality is a complex outcome driven by genetic and environmental factors. Recent studies showed that genetic risk score (GRS) in addition to clinical risk factors has shown the potential for early detect individuals of CVD risk groups. However, the utility of CVD GRS in CV mortality risk group stratification is uncertain. In this study, we generated metaGRS across cardiometabolic (CM) risk factors for CV mortality and evaluated its risk group stratification.
Methods We used data from the UK Biobank with 377,909 European descent participants. We randomly divided the whole dataset into 20% for derivation set and 80% for validation set. The metaGRS generation steps are as follows: i) We obtained GWAS summary statistics for seven well-known CV-related outcomes (stroke, coronary artery disease, chronic kidney disease, heart failure, hypercholesterolemia, hypertension, and type 2 diabetes) and 12 CM-related phenotypes (eGFR, BMI, height, lipid profiles, systolic & diastolic blood pressures, fasting glucose, HbA1c, and smoking status). ii) We generated GRSs for each phenotype and constructed metaGRS using cox proportional hazard model with 10-fold cross validation in the derivation set. The per-GRS hazard ratios (HRs) were applied as the weights in the final model.
Results We categorized participants into four risk subgroups of metaGRS: low (0-19th percentile), intermediate (20-79th percentile), high (80-98th percentile), and very high (99-100th percentile). In the validation set, the best single predictor for CV mortality was CAD GRS which was significantly associated with CV mortality risk (low vs. very high-risk groups; HR=2.96, 95% CI=2.22-3.94). The metaGRS was significantly associated with the highest risk of CV mortality (HR=3.50, 95% CI=2.67-4.60).
Conclusions In summary, metaGRS well stratified risk groups and improved prediction performance of CV mortality risk by combining individual GRSs, suggesting that genetic risk of each CM factor may be partly independent and complementary.

IMPORTANCE: Rheumatic heart disease (RHD), a sequela of rheumatic fever characterized by permanent heart valve damage, is the leading cause of cardiac surgery in Africa. However, its pathophysiologic characteristics and genetics are poorly understood. Understanding genetic susceptibility may aid in prevention, control, and interventions to eliminate RHD. OBJECTIVE: To identify common genetic loci associated with RHD susceptibility in Black African individuals. DESIGN, SETTING, AND PARTICIPANTS: This multicenter case-control genome-wide association study (GWAS), the Genetics of Rheumatic Heart Disease, examined more than 7 million genotyped and imputed single-nucleotide variations. The 4809 GWAS participants and 116 independent trio families were enrolled from 8 African countries between December 31, 2012 and March 31, 2018. All GWAS participants and trio probands were screened by use of echocardiography. Data analyses took place from May 15, 2017, until March 14, 2021. MAIN OUTCOMES AND MEASURES: Genetic associations with RHD. RESULTS: This study included 4809 African participants (2548 RHD cases and 2261 controls; 3301 women [69%]; mean [SD] age, 36.5 [16.3] years). The GWAS identified a single RHD risk locus, 11q24.1 (rs1219406 [odds ratio, 1.65; 95%CI, 1.48-1.82; P = 4.36 Ã~ 10â8]), which reached genome-wide significance in Black African individuals. Our meta-analysis of Black (n = 3179) and admixed (n = 1055) African individuals revealed several suggestive loci. The study also replicated a previously reported association in Pacific Islander individuals (rs11846409) at the immunoglobulin heavy chain locus, in the meta-analysis of Black and admixed African individuals (odds ratio, 1.16; 95%CI, 1.06-1.27; P = 1.19 Ã~ 10â3). The HLA (rs9272622) associations reported in Aboriginal Australian individuals could not be replicated. In support of the known polygenic architecture for RHD, over-transmission of a polygenic risk score from unaffected parents to affected probands was observed (polygenic transmission disequilibrium testing mean [SE], 0.27 [0.16] SDs; P = .04996), and

the chip-based heritability was estimated to be high at 0.49 (SE = 0.12; P = 3.28 Ã~ 10â□□5) in Black African individuals. CONCLUSIONS AND RELEVANCE: This study revealed a novel candidate susceptibility locus exclusive to Black African individuals and an important heritable component to RHD susceptibility in African individuals.

PrgmNr 2780 - Cardiac enhancer variants at the *MTSS1* locus are associated with smaller, more contractile hearts

View session detail

Author Block: **M. BURKE**[1], M. Morley[1], Y. Yang[1], T. Drivas[2], D. Choe[1], S. Day[1], K. Musunuru[1], M. Li[3], M. D. Ritchie[4], T. P. Cappola[1]; [1]Univ of PA, Philadelphia, PA, [2]Children's Hosp. of Philadelphia, Philadelphia, PA, [3]Univ Pennsylvania, Philadelphia, PA, [4]Univ. of Pennsylvania, Philadelphia, PA

Disclosure Block: **M. Burke:** None.

Introduction: Common variants at the *MTSS1* locus influence cardiac structure, function, and failure in multiple genome wide association studies (GWAS), yet the genetic mechanisms responsible remain unclear. We previously identified common variants residing in a cardiac specific enhancer in *cis* to *MTSS1* that influence MTSS1 transcript abundance in the human left ventricle (LV). Here we used bioinformatic approaches to determine if these enhancer variants explain the association between common *MTSS1* variation and multiple cardiac traits. We hypothesized that enhancer alleles that reduce *MTSS1* expression would be associated with smaller, more contractile hearts.

Methods: To confirm a shared causal variant between MTSS1 expression in the LV and cardiac traits, we combined human expression quantitative trait locus data from GTEx with GWAS data from the UK Biobank (UKBB) using co-localization. GTEx consists of 386 samples with RNAseq expression data from the LV. The UKBB is a prospective cohort of over 500,000 patients ages 40-69 recruited between 2006 and 2010 across the United Kingdom with extensive available phenotype data. In addition to baseline questionnaire and health assessment, electronic health record, and biomarker data, genotyping has been undertaken for the entire cohort. We utilized quantified cardiac MRI data from returned dataset 2383, which provides 82 cardiac phenotypes in 26,892 individuals. We obtained the relevant UKBB data as part of approved protocol 65965. Genome association tests were performed at the *MTSS1* locus (chr8:124550790 - 124728429) using Plink v.2.0; co-localization analysis was performed using Coloc.

Results: Co-localization analysis of 26,892 patients enrolled in the UKBB who underwent cardiac MRI imaging revealed three overlapping variants rs12541595, rs35006907, and rs34866937 in the *MTSS1* enhancer region significantly associated with LV expression of *MTSS1* as well as with multiple cardiac MRI traits. Notably, these traits included LV ejection fraction (LVEF) ($p = 1.3 \times 10^{-10}$), LV end-systolic volume ($p = 1.2 \times 10^{-8}$), and global circumferential strain ($p = 1.1 \times 10^{-7}$). Variants in this enhancer region that decrease *MTSS1* expression are associated with decreased volumes, increased LVEF, and improved global circumferential strain, all of which are consistent with a cardioprotective phenotypic effect.

Conclusions: In this study, we utilize a bioinformatics approach to clarify the genetic mechanisms by which a previously identified locus modulates cardiac traits. These results clearly support a cardioprotective phenotype associated with reduction in *MTSS1* gene expression in the LV.

PrgmNr 2781 - Cell-type-specific gene expression and transcriptional networks reveal *Adamts2* as a robust regulator of cardiac homeostasis during heart failure

Heart failure (HF) is a highly heterogeneous disorder characterized by the interactions of multiple genetic and environmental factors as well as the interaction of different cell types in the heart. Although reductionistic approaches have successfully identified many genes involved in HF, heritability studies show many more candidate genes than can be studied individually. By utilizing cell-type-specific gene expression paired with additional transcriptomic data from a large cohort of mice, we sought to identify important drivers of HF using a systems genetics approach. Mice from 93 unique inbred lines of the Hybrid Mouse Diversity Panel were given 30 ug/g/day of isoproterenol for three weeks via osmotic minipump to induce heart failure. Transcriptomes were generated from these mice and the weighted Maximal Information Component Analysis (wMICA) algorithm was applied to generate transcriptomic gene networks. Cardiomyocytes and Fibroblasts were isolated from both control and isoproterenol-treated adult C57BL/6J hearts using a Langendorff apparatus (n=3 per sex/treatment) and transcriptomes were generated. Significantly differentially expressed genes were identified using DESEQ2 and used to query the wMICA-derived network, identifying the gene *Adamts2* as a potential regulator of cardiac hypertrophy. Follow-up *in vitro* and *in vivo* work has demonstrated that *Adamts2* knockdown significantly blunts the hypertrophic effect of isoproterenol on cardiomyocytes while simultaneously reducing fibroblast proliferation and increasing apoptosis as measured by TUNEL staining. Careful examination of the gene network reveals evidence of paracrine signaling between cardiomyocytes and fibroblasts and suggests a key trans-cell-type role of *Adamts2* in the regulation of HF after catecholamine stimulation. In conclusion, Co-expression network algorithms combined with cell-type-specific transcriptomics identified *Adamts2* as a driver of HF. *Adamts2* plays an important role via paracrine signaling in the proliferative response of fibroblasts and hypertrophic response of cardiomyocytes to catecholamines. Further mechanistic analysis of *Adamts2* will further reveal its role in the progression of heart failure.

PrgmNr 2782 - Dissecting 90 percent of lipoprotein(a) heritability in 487,571 UK Biobank participants

Sch., Boston, MA, [2]Charlemont, MA, [3]Massachusetts Inst. of Technology, Marblehead, MA, [4]Harvard Med. Sch., Boston, MA, [5]Brigham and Women's Hosp. / Harvard Med. Sch., Boston, MA
Disclosure Block: **R.E. Mukamel:** None.
Lipoprotein(a) concentration [Lp(a)] is a highly heritable (h^2>90%), monogenic cardiovascular risk factor whose primary genetic determinant is the size of the *LPA* kringle IV-2 (KIV-2) repeat, which explains ~60% of Lp(a) heritability. However, the full spectrum of other functional sequence variants in *LPA* and the way in which they shape Lp(a) variation has been unclear due to the difficulty of genotyping KIV-2 variation from high-throughput genomic assays. We developed methods to accurately estimate haplotype-resolved KIV-2 allele lengths in N=49,959 exome-sequenced UK Biobank (UKB) participants (RMSE ~1 repeat unit), and to impute KIV-2 lengths into SNP haplotypes for the remaining N=437,612 UKB participants (imputation R^2=0.9).
To systematically identify and measure the effects of additional Lp(a)-altering variants, we isolated the contributions of individual *LPA* haplotypes by analyzing heterozygous carriers of two coding variants known to create nonfunctional alleles (rs41272114 and rs41259144, combined MAF=0.05). This approach created an effective haploid model for Lp(a). Stepwise conditional analyses controlling for KIV-2 length pointed to a series of 20 additional protein-altering and 5â UTR variants that appeared to further shape Lp(a). Together with KIV-2 length, these variants explained 90% of heritable Lp(a) variance in European-ancestry participants in a model that accounted for nonlinear and cis-epistatic effects. These variants also largely explained the ~4-fold variation in median Lp(a) across populations: the higher Lp(a) commonly observed in African populations appeared to result from a relative paucity of alleles carrying a large-effect Lp(a)-reducing coding or splice-altering SNP in LPA (affecting 13% vs. 43% for African vs. European alleles) and the high frequency of the Lp(a)-increasing 5â UTR variant rs1800769 (46% vs. 17% for African vs. European alleles).
The accuracy of genetically predicted Lp(a) also enabled insights into epidemiological associations with Lp(a). The myocardial infarction risk-increasing effect of higher Lp(a) extended to extreme Lp(a) levels in UKB (OR=3.1, 95% CI=1.9-5.2 for individuals with predicted Lp(a)>400 nmol/L). In contrast, lower genetically predicted Lp(a) did not associate with increased type-2 diabetes (T2D) risk, suggesting that the 17% (s.e. 1%) lower levels of measured Lp(a) observed in T2D patients represents reverse causation resulting from T2D itself, T2D-related liver comorbidities, or T2D medication.
These results demonstrate that complex genetics can underlie even monogenic traits and inform genetic approaches to cardiovascular risk stratification.

PrgmNr 2783 - Genetic association analysis of dilated cardiomyopathy in the VA Million Veteran Program

Disclosure Block: **J.E. Huffman:** None.

Background/Aims: Dilated cardiomyopathy (DCM) is a major cause of heart failure and the leading global cause of heart transplantation. Rare, Mendelian drivers of DCM are well-established, but the potential contribution of common genetic variation to DCM risk has only recently begun to emerge. To date, common variant association studies (CVAS) of DCM have relied predominantly on prospectively recruited cases of DCM. We sought to conduct a CVAS of DCM in a large biobank. **Methods:** We established an electronic health record-based phenotypic definition of DCM in the Million Veteran Program (MVP), using an ICD-10 code of I42.0 to define cases, and excluding heart failure cases and other cardiomyopathies from the controls. We performed ancestry-specific CVAS then trans-ethnic meta-analysis in MVP participants of European and African genetic ancestry. We pursued replication of genomic findings in the UK Biobank. We also assessed the association of sentinel DCM SNPs with hypertrophic cardiomyopathy (HCM) in MVP, and subclinical cardiac magnetic resonance imaging (MRI) measures of left ventricular (LV) structure and function in UK Biobank. **Results:** Among 459,937 MVP study participants, mean age was 61.5, 43,971 (9.6%) were female, and 5,597 met phenotypic criteria for DCM (N=3,786 European ancestry, N=1,811 African ancestry). In the trans-ethnic meta-analysis, we identified eight genomic regions associated with DCM at genome-wide significance (P -8). These included three of four known DCM associations near *HSPB7*, *LSM3*, and *BAG3*; and five novel genomic regions near *SLC39A8*, *CDKN1A*, *CD36*, *NEDD4L*, and *MAP3K7CL*. Of the five novel genomic regions, three (*CDKN1A*, *NEDD4L*, and *MAP3K7CL*) were replicated in the UK Biobank (all p-4; N=899 DCM cases, 449,574 controls). While only four of the significant DCM loci achieved nominal significance with HCM (N=1,533 HCM cases, 465,877 controls), we observed a previously-reported trend that the direction of effect for sentinel SNPs was opposite between these two cardiomyopathies. SNPs associated with increased DCM risk also associated with greater LV size and reduced LV function - the defining traits of DCM - even in UK Biobank participants without clinical heart failure or cardiomyopathy (N > 31,614). **Conclusions:** We identified 5 novel, common genetic loci associated with DCM and replicated three of these in an external DCM cohort, and provided plausible supporting evidence through association with DCM-relevant subclinical MRI traits. Our findings highlight the potential to leverage large, multi-ethnic biobank populations to enhance common variant discovery for DCM.

PrgmNr 2784 - Genetic variation in/near *LIPC*, *MGAT1*, and *APOA1* is associated with longitudinal change in serum lipid levels in Samoan adults

Samoan adults have a high incidence of cardiovascular disease which is significantly associated with abnormal lipid levels. Here we studied the relationship between longitudinal changes in fasting serum lipid levels (high-density lipoprotein cholesterol (HDL), low density lipoprotein cholesterol (LDL), triglycerides (TG) and total cholesterol (TC)) and eight SNPs that were associated with cross-sectional lipid levels in previous genome-wide association scans in Samoan adults. We focused on 519 adult participants who completed assessments in both 2010 and 2017-2019. We constructed rate-of-change models for 32 trait-marker pairs to evaluate the relationship between longitudinal changes in lipid levels and each SNP using linear regression adjusting for age, ageÂ², sex, and other baseline covariates selected by LASSO which was performed in 2,304 Samoans from the 2010 study that do not overlap with the 519 participants studied here. Selected covariates varied by trait, but often included census region, smoking status, diabetes status, waist-hip ratio, and arm circumference. We found that the A allele of rs10438284 near *LIPC* is associated with lower rate-of-change in HDL (Î² = â□□0.179 mg/dL per year, p = 0.010). The T allele of rs1038143 near *MGAT1* was associated with higher rate-of-change in LDL (Î² = 0.470 mg/dL per year, p = 0.048). Residential census region was also associated with rate-of-change in LDL with more rural areas having higher rates-of-change compared to the Apia Urban Area (Î² = 1.079 mg/dL per year for peri-urban Northwest Upolu, p = 0.008; Î² = 1.103 mg/dL per year for rural Rest of Upolu, p = 0.009). We also observed a positive association between the C allele of rs964184 near *APOA1* and rate-of-change in triglycerides (Î² = 1.17 mg/dL per year, p = 0.026). Our study showed that genetic variation in/near *LIPC*, *MGAT1,* and *APOA1* as well as demographic factors have an impact on longitudinal changes in serum lipid levels. A better understanding of these factors might inform who is at greatest risk of achieving unhealthy serum lipid levels, lead to future interventions, and help reduce the burden of cardiovascular disease in Samoans.

PrgmNr 2785 - Genome-wide association study of coronary heart disease in chronic kidney disease: the Chronic Renal Insufficiency Cohort (CRIC) study

View session detail

Author Block: **J. Wen**[1], B. Lin[2], G. Li[3], Q. Sun[1], Y. Li[4], N. Franceschini[5]; [1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Univ. of North Carolina, Chapel Hill, NC, [3]Univ. of North Carolina at Chapel Hill, BELLEVUE, WA, [4]Univ North Carolina, Chapel Hill, NC, [5]Univ North Carolina at Chapel Hill, Chapel Hill, NC

Disclosure Block: **J. Wen:** None.

Chronic kidney disease (CKD) is associated with premature and widespread atherosclerosis, and atherosclerotic cardiovascular disease is a main cause of death in CKD patients. The underlying genetic factors for increased cardiovascular disease susceptibility in CKD are unknown. To identify loci associated with coronary heart disease in CKD, we performed a genome-wide association study (GWAS) of incident myocardium infarction in the CRIC study, a multi-center cohort of CKD participants recruited from seven U.S. clinical centers. Genotypes were imputed to TOPMed whole genome sequencing multi-ethnic reference panel (freeze 5b). We performed time to event analysis using additive models adjusted for age, sex, site of recruitment, baseline estimated glomerular filtration rate (eGFR) and genotype principal components. Among 2,793 participants without coronary heart disease at baseline (mean age 56.4 years, 55% men, 42% African Americans, 58% whites, mean eGFR 45.3 ml/min/1.73 m^2), 214 developed a clinical event at an average of 9.1 years of follow-up. GWAS (with genomic control Î»=1.003) identified two loci at the genome-wide significance threshold (PMYO6) and an intronic variant on chromosome 9 (*TRPM6*). Both of these are novel loci comparing to the GWAS catalog loci for coronary heart disease in non-CKD general population. Further checking gene expression in different tissues from GTEx v8, we find *MYO6* is highly expressed in kidney and brain; *TRPM6* expressed in brain. We also replicated, accounting from multiple testing, 36 known coronary heart disease loci including the *APOB*, *LPL*, *FGF5*, *EDNRA* and *CDKN2B* loci. These findings suggest that both shared and CKD-specific genetic factors contribute to clinical coronary heart disease in individuals with CKD.

Identifying the genetic determinants of variation in lipid species (lipidome) may provide deeper mechanistic insight in CVD risk beyond traditional lipids. Previous studies have been largely population based and thus only powered to discover common genetic variants. Founder populations represent a powerful resource to accelerate discovery of novel biology associated with rare population alleles that have risen to higher frequency by genetic drift. We performed a GWAS of 355 lipid species in 650 individuals from the Amish founder population. The population-based Genetics of Lipid Lowering Drugs and Diet Network (GOLDN) study was used for replication and fine mapping along with publicly available functional annotations. We report for the first time the lipid species associated with two rare-population but Amish-enriched lipid variants: the cardioprotective *APOC3*_rs76353203 (MAF=0.02 vs 0.0008 in the general European population) was associated with lower levels of 3 phosphatidylethanolamines (PE(36:2), (38:6), (34:2)) (p =6.3E-13 to 1.3E-10), and the familial hypercholesterolemia variant *APOB*_rs5742904 (MAF=0.06 vs 0.0004) was associated with increased levels of several cholesterol esters, sphingolipids and phospholipids (p =7.9E-25 to 3.1E-10). We also identified novel associations for 3 rare-population Amish-enriched loci: The first is a missense variant (rs536055318, A263T) (MAF=0.07 vs 0.001) in an active transcription start site in the promoter of the *GLTPD2* gene associated with lower sphingomyelins (SM(d40:0)) (p =1.1E-12). *GLTPD2* is mainly expressed in liver and kidney and plays a role in the intermembrane transfer of glycolipids. The second is a potentially disease-causing splice donor missense variant (rs771033566, Val344Leu) (MAF=0.04 vs 0.01) in the *CERS5* gene, associated with lower SM(32:2) (p =2.2E-14). *CERS5* is one of the six members of the ceramide synthase gene family which plays a major role in the sphingolipid metabolic salvage pathway. The third is an intronic variant (rs531892793) (MAF=0.04 vs 0.0001) in the *AKNA* gene associated with lower levels of 5 glucosylceramide species (GlcCer(d38:1), (d40:1), (d41:1), (d42:1), (d42:2)) (p =4.0E-17 to 1.9E-12). rs531892793 is located in the promoter flanking region and has the top ENCODE DNase score of 1000 indicating very strong evidence of being a DNase hypersensitivity site, an eigenPC score of 3.5 indicating a strong functional prediction based on conservation and allele frequency, and predicted to affect transcriptional factor. Our results show the power of founder populations to discover novel biology associated with rare population variants through allele enrichment.

Disclosure Block: **W.P. Bone:** None.

Atherosclerosis, which is the narrowing of the arterial walls via accumulation of cholesterol-rich arterial plaques, is the leading cause of vascular disease worldwide, including myocardial infarction and ischemic stroke. Although atherosclerosis affects arteries throughout the body, previous genome-wide association studies (GWAS) have been performed on specific atherosclerotic phenotypes such as coronary artery disease (CAD) and peripheral artery disease (PAD). There is substantial evidence to suggest that these more specific atherosclerosis phenotypes share a common genetic etiology. We performed a series of multi-trait GWAS using combinations of two atherosclerosis traits and seven atherosclerosis risk factor traits and detected 31 novel pleiotropic loci. We performed these multi-trait GWAS using the N-GWAMA multi-trait GWAS method and summary statistics for CAD (van der Harst et al. 2018), PAD (Klarin et al. 2019), body mass index (Pulit et al. 2019), type II diabetes (Vujkovic et al. 2020), smoking initiation (Wootton et al. 2020), and lipid traits (Klarin et al. 2019). We identified candidate causal genes for 14 of these loci through colocalization analysis with GTEx expression quantitative trait locus (eQTL) data. *VDAC2* and *PCSK6* are two candidate causal genes that our results and previous literature suggest are potential therapeutic targets. *VDAC2* eQTLs in aorta and tibial artery colocalized with a multi-trait GWAS signal detected in the CAD PAD multi-trait GWAS. Previous work has shown that *VDAC2* regulates apoptosis, and our results suggest increased *VDAC2* expression in smooth muscle cells could increase smooth muscle cell accumulation in atherosclerotic plaques. A sQTL (splicing QTL) for *PCSK6* in liver colocalized with a multi-trait GWAS signal between PAD and LDL. Further analysis of the sQTL signal suggested that the effect allele correlates with a more active isoform of *PCSK6*, which could increase lipid fractions and risk of atherosclerosis. These results show that joint analysis of atherosclerotic disease traits and their risk factors allows for identification of unified biology that may offer the opportunity for therapeutic manipulation.

The Global Lipids Genetics Consortium trans-ancestry genome-wide association study (GWAS) of 1.65 million individuals has identified 2,399 index variants associated with any of 5 lipid phenotypes (LDL-C, HDL-C, total-cholesterol, triglyceride, and nonHDL-C). A limitation of GWAS is that the causal gene for associated variants is not readily discernible. We aimed to identify the likely functional genes for our lipid associated index variants by employing four locus-dependent approaches: 1) the closest gene to the index variant, 2) genes with associated protein coding variants, 3) expression QTLs (eQTLs) colocalized genes, and 4) genes prioritized by transcript-wide association studies (TWAS), and two genome-wide dependent approaches: 1) gene-level Polygenic Priority Score (PoPS), and 2) co-regulation of gene expression and reconstituted gene sets (DEPICT). We further quantified how often the same gene was prioritized by multiple methods for each index variant and determined scores that ranged from 1-6, based on the number of methods that prioritized the gene. To evaluate the performance of each prioritization method and the credibility of the scores, we used 23 genes known to cause Mendelian dyslipidemias (gold standard set) and 747 mouse knockout genes causing lipid phenotypes (silver standard set). As validation, we estimated the proportion of genes in the gold and silver standard sets that were correctly prioritized based on our selection of approaches. Within the gold standard set, the proportion of genes correctly prioritized were: 79.6% by TWAS, 78.6% by PoPS, 60.2% by DEPICT, 57.3% by protein coding variants, and 42.7% by the closest gene. A similar rank order for the silver standard genes was observed. However, since TWAS had prioritized 3,511 genes which was greater than other methods (~1000), it had a much smaller proportion of correctly prioritized genes out of the total number of genes prioritized by those methods. Based on the above, we assigned candidate causal genes for each index variant with an *ad hoc* confidence level: high, medium high, medium low and low. In addition to the 23 gold-standard genes, we prioritized a further 94 genes with high confidence. Text mining of PubMed titles and abstracts suggests that 43.6% of the 94 high confidence genes have minimal (

PrgmNr 2789 - Proteomic analysis of 92 circulating proteins and their effects in cardio-metabolic diseases

Introduction Human plasma contains many circulating proteins derived from multiple organs and that participate in a wide range of biological processes. Circulating proteins play an important clinical role as biomarkers (eg, NT-proBNP) and also as drug targets (eg, PCSK9). Recent advances in high throughput quantification have allowed for the scale up of investigating association of genetic variants with circulating protein levels.
Methods We conducted genome-wide association studies of autosomal chromosomes in 12 cohorts involving up to 22,997 European ancestry individuals to identify protein quantitative trait loci (pQTLs) for 92 plasma proteins on the â□□metabolismâ□□ panel using OLINKâ□□s proximity extension assay. Meta-analysis was conducted with a random effects model using GWAMA and independent associations identified with PLINK and GCTA-COJO. Heritability and pairwise genetic correlations were calculated using LD score regression. Additionally, we performed a sex-stratified meta-analysis on up to 10,870 men and 12,127 women. Two sample Mendelian randomization (MR) was conducted using TwoSampleMR package on R.
Results We identified 503 significant conditionally independent pQTLs (337 cis and 166 trans) in 77 proteins at P 0.25, >0.5, and >0.75. A sex stratified analysis revealed a total of 552 pQTLs in women and 258 pQTLs in men (p **Conclusion** Large-scale genome wide meta analyses across circulating plasma proteins provides insight into causal mechanisms of disease and potential drug therapeutic targets. Sex stratified analysis suggests similar genetic underpinnings of circulating plasma proteins, however a few sex-specific pQTLs may point to some differences.

PrgmNr 2790 - Rare variant carrier status on risk of coronary artery disease among individuals with high polygenic risk

View session detail

Author Block: **M. Shivakumar**[1], S-H. JUNG[2], J-S. Yun[3], M. D. Ritchie[2,4], D. Kim[2]; [1]Dept. of Biostatistics, Epidemiology and Informatics, Univ. of Pennsylvania, Philadelphia, PA, USA, Philadelphia, PA, [2]Univ. of Pennsylvania, Philadelphia, PA, [3]The Catholic Univ. of Korea, Bryn Mawr, PA, [4]Inst. for BioMed. Informatics, Univ. of Pennsylvania, Philadelphia, PA
Disclosure Block: **M. Shivakumar:** None.

Polygenic risk scores (PRS) derived from large GWAS studies have been able to capture a large portion of genetic risk for coronary artery disease (CAD) risk. Previous studies have shown that the PRS for CAD (PRS_{CAD}) can be used to identify the subgroup from the population that is at greater than three-fold increased risk for CAD. However, in general, rare variants are known to have larger impacts than common variants, and complex diseases like CAD are influenced by both common and rare genetic variants. In this study, we examined the changes in the risk conferred by carriers of rare variants in known genes associated with CAD.

Among 154,799 unrelated individuals of European ancestry, we identified 2,553 CAD cases with both genotype and exome sequencing data available in UK Biobank (UKBB). PRS_{CAD} for all samples were calculated using genotype data using LDpred and summary statistics from the CARDIoGRAMplusC4D GWAS study. The rare variants were obtained from the exome sequencing data and were filtered to keep only predicted loss of function (LOF) variants, variants predicated with high impact by Variant Effect Predictor, and missense variants with REVEL score > 0.5. We split samples into 10 groups based on 5 PRS_{CAD} quantiles and rare variant carrier status. We calculated the risk of CAD between the first and last quantile combined with rare variant carrier status.

Of the 47 known replicated genes for CAD, we found 22 genes where the carriers of rare variants showed higher odds of CAD risk than non-carriers, and in the other 25 genes, the carriers of rare variants showed lower odds of CAD risk than the non-carriers in the high risk PRS group. The samples with LOF rare variants in genes such as *MIA3* (Lowest vs. highest PRS with non-carrier OR: 2.00, carrier OR: 4.13) and *TCF21* (non-carrier OR: 2.00, carrier OR: 3.09) showed higher OR. The high expression of MIA3 is expected to promote atheroprotective vascular smooth muscle cells and higher expression *TCF21* is known to inhibit risk for coronary artery disease. On the contrary, genes like *SMAD3* (non-carrier OR: 2.02, carrier OR: 1.25E-05) and HHIPL1 (non-carrier OR: 2.01, carrier OR: 1.29E-05) showed lower odds, and their expression is known to increase CAD progression.

We showed that the LOF rare variant carriers in the high risk PRS groups may increase or decrease the odds of CAD risk. This study also shows the need to take rare variants into consideration for risk stratification. Robust methods for integration of rare variants with PRS are greatly needed to further improve risk prediction for CAD and allow for the development of improved preventive measures and also novel therapeutic opportunities for CAD.

Disclosure Block: **G. Iannello:** None.

Introduction: Lowe syndrome (LS) is a rare, genetic disorder caused by mutations in the X-linked gene *OCRL*. The cardinal clinical features are congenital cataracts, intellectual and developmental disability, and renal tubular dysfunction. *OCRL* codes for inositol polyphosphate 5-phosphatase, a protein that regulates several cellular processes including cell proliferation, cytoskeletal function, and membrane trafficking. *OCRL* has also been shown to localize in the primary cilium, and may be involved in cilia assembly through RhoGTPase signaling. We identified a boy with a frameshift mutation in *OCRL* without the renal and eye features of LS. This study aims to identify if the different phenotype could be explained by differential isoform expression across tissues. Materials and Methods: Whole exome sequencing of the trio was performed on Illumina platform with a mean coverage of ~100X (> 90% targets 20x). The Infinium Global Screening Array BeadChip 24v1.0 and WES data were used for calling copy number variants. The workflow in Seqr software was used for data analysis. To assess the transcript expression of *OCRL*, we used WT-fibroblast, renal cortex and neuroprecursor cells. RNA extraction was performed following the manufacturerâ□□s instructions, and qRT-PCR was conducted on Applied Biosystems QuantStudio Flex 7. Protein expression was assessed in the fibroblasts from the proband, WT control and LS patients by Western Blot (WB).

Results: We identified a novel hemizygous X-linked frameshift variant (c.2136_2139del+1insCT, p. L713Rfs*28) in *OCRL* in a 5-year old boy with extreme obesity (BMI 27 kg/m2, Z +5) and short stature (Z -2.2). The proband also had bilateral webbed toes, central hypoventilation, neurobehavioral dysfunction, and ganglioneuroblastoma. The variant segregates in the carrier mother, maternal aunt and maternal grandmother, and is absent in the unaffected father and maternal grand uncle. It is located in exon 18a (NM_000276), a 24bp region that is only present in the longer transcript of the *OCRL* gene (transcript a). Tissue expression profiling shows the presence of exon 18a in the neural precursor cells, but not in fibroblasts or renal cells. WB showed normal protein expression in the proband and WT, and absent in LS fibroblasts.

Conclusion: In this study, we report a new frameshift variant in *OCRL* in a proband with severe obesity, short stature and neurobehavioral phenotype, but no eye or renal disease. The differential isoform expression of OCRL in the brain and the peripheral tissues (fibroblasts and kidney) may explain the differences in phenotype. The unique location of the variant in this patient may help elucidate the role of *OCRL* in the brain.

PrgmNr 2792 - Adiponectin and cardiometabolic outcomes in sub-Saharan Africans: A Mendelian randomization study

View session detail

Author Block: **K. Meeks**, A. R. Bentley, A. Doumatey, A. A. Adeyemo, C. N. Rotimi; Ctr. for Res. on Genomics and Global Hlth., Natl. Human Genome Res. Inst., Bethesda, MD
Disclosure Block: **K. Meeks:** None.
Background: High adiponectin levels have been favorably associated with cardiometabolic outcomes in observational studies across populations. Mendelian randomization (MR) studies assessing the causality of these associations have generated contradictory results and MR studies in African ancestry populations are scarce. We performed MR analysis to assess the presence of a causal relationship between adiponectin and cardiometabolic outcomes in sub-Saharan Africans. In addition, we assessed whether this relationship differed for normal weight versus overweight/obese individuals.
Methods: We constructed a polygenic risk score (PRS) for circulating adiponectin levels using 3,393 unrelated Nigerian, Ghanaian, and Kenyan individuals from the Africa America Diabetes Mellitus (AADM) study. Summary statistics from the largest meta-analysis for genome-wide association studies on adiponectin to date were used as base data. The PRS was used as the instrumental variable in an MR analysis implemented using the two-stage least-squares method to assess its association with insulin resistance, high-density lipoprotein cholesterol (HDL), low-density lipoprotein cholesterol (LDL), total cholesterol, triglycerides, systolic blood pressure, diastolic blood pressure, Type 2 Diabetes (T2D), and hypertension. Models were adjusted for age, sex, population stratification, Body Mass Index (BMI), alcohol intake, and smoking status. Analyses were conducted for the total sample and separately for normal weight (BMI 2) and overweight/obese (BMI â¥ 25 kg/m^2) individuals.
Results: Serum adiponectin levels were associated with all cardiometabolic outcomes. The constructed PRS contained 222 SNPs and had an F-statistic of 116.7, confirming that it is a strong instrumental variable. In MR analyses, the adiponectin PRS was associated with only LDL of the cardiometabolic traits considered (Î² = 25.2, 95%CI = 2.2 - 48.2, P = 0.032). The PRS was also associated with LDL in overweight individuals (Î² = 25.8, 95%CI = 0.1 - 51.4, P = 0.049). In normal weight individuals, the PRS was associated with T2D (OR 0.17, 95%CI = 0.03 - 0.96, P = 0.045). Epidemiological and causal estimates were directionally concordant.
Conclusions: The findings of this first MR study for adiponectin in sub-Saharan Africans support an influence on LDL in overweight individuals and T2D in normal weight individuals. Neither of the two previous MR studies that included other populations of African ancestry found evidence for a causal association with LDL, and one of the two found a causal role in T2D. Both genetic and environmental factors could be driving differences in association between populations.

PrgmNr 2793 - Analyzing human knockouts to validate *GPR151* as a therapeutic target for reduction of body mass index

Finding novel drug targets for sustained reduction in body mass index (BMI) may help curb obesity, which has become a global health risk that will affect half of the world population by 2030. Here, we show that GPR151 antagonism is not a compelling therapeutic approach for BMI reduction. To follow up on a previously published genetic association with BMI, we use the worldâ□□s largest biobank of human knockouts, the Pakistan Genome Resource (PGR), which has identified >14,000 knockouts for >5,000 genes through whole-exome sequencing. Previous studies from other cohorts have shown that heterozygous putative loss-of-function (pLoF) in *GPR151*, which encodes a G protein-coupled receptor, is associated with reduced BMI and reduced odds ratio of type 2 diabetes (T2D). To date, however, no homozygous pLoF carriers (human knockouts) have been characterized. Here, we test (i) if complete knockout of *GPR151* is compatible for survival in humans, and (ii) if *GPR151* pLoF is associated with a therapeutically meaningful (>5%) reduction in BMI. We investigate gene-dosage effect in *GPR151* pLoF heterozygotes and complete knockouts by analyzing BMI measurements (N = 27,329) and T2D status (6,561 cases, 33,162 controls). We identify 10 pLoF variants in *GPR151* with a cumulative allele frequency of 2.2%, comprising 38 knockouts and 1,141 heterozygous pLoF carriers. In vitro, GPR151 pLoF variant proteins are unstable and not expressed. In human knockouts, we do not identify any clinically meaningful reduction in BMI (26.3Â±4.4 kg/m^2 in knockouts versus 26.7Â±3.3 kg/m^2 in non-carriers). We observe a modest, nominally significant increase in T2D odds ratio in pLoF heterozygous carriers (odds ratio=1.2 [1.0 - 1.4], P=0.03). In a mouse model, *GPR151*$^{-/-}$ body weight is indistinguishable from wild-type on a standard chow diet. On a high fat diet, body weight of male *GPR151*$^{-/-}$ mice is elevated compared to wild-type. In total, complete loss of *GPR151* does not lead to BMI reduction in humans or in a preclinical mouse model.

PrgmNr 2794 - Circulating metabolite biomarkers for osteoporosis: Evidence from Mendelian randomization and direct metabolite measurement

View session detail

Author Block: **Y. Chen**[1,2], S. Zhou[1,2], V. Forgetta[3], A. Cerani[1], C. Langenberg[4,5], J. Richards[1,1,2]; [1]McGill Univ., Montreal, QC, Canada, [2]Lady Davis Inst., Jewish Gen. Hosp., Montreal, QC, Canada, [3]Lady Davis Inst., Montreal, QC, Canada, [4]Univ Cambridge, Cambridge, Cambridgeshire, United Kingdom, [5]CharitÃ© Univ. Med., Berlin, Germany
Disclosure Block: **Y. Chen:** None.
Objective: Circulating metabolites that causally influence bone density could be used as biomarkers or drug targets for osteoporosis. **Methods**: Here we undertook Mendelian Randomization (MR) studies to screen over 300 metabolites for their effects on estimated bone mineral density (eBMD) using data from three metabolite GWASs (up to N = 9,736) and one eBMD GWAS (N = 426,824). We then confirmed metabolites that were significantly associated with eBMD using sensitivity and colocalization analyses. Next, we tested the effects of these metabolites on DXA-measured BMD (up to N = 53,236) via additional MR studies. Last, we measured the prioritized metabolites and tested their association with hip total BMD using up to N = 7,109 plasma samples from the Canadian Longitudinal Study on Aging (CLSA) cohort. **Result**: MR results identified 40 metabolites estimated to influence eBMD (FDR 0.8) or had their genetic variants positionally close (within 1 Mb region) to a gene that encodes the enzyme or transporter for the metabolites. 4 of these metabolites (i.e., proline, pro-hydroxyproline, epiandrosterone sulfate, and 3-methyl catechol sulfate) were further replicated in the MR of DXA-measured BMD and the direct association test with total hip BMD in CLSA. Notably, using the different set of genetic variants selected from three metabolite GWASs, proline showed a consistent improving effect on eBMD and DXA-measured BMD. Evidence on the direct association of metabolites and hip total BMD using CLSA data also highlighted the effect of the proline pathway on bone density in humans.**Conclusion**: By integrating evidence from large-scale genetic data and direct metabolite measurements, we identified circulating metabolites and pathways that influence bone density in humans.

PrgmNr 2795 - Constructing Metabolic Syndrome-related polygenic scores in the multiethnic GENNID family study

View session detail

Author Block: **J. Y. Wan**, L. Simon, D. Robinson, A. R. Freedland, T. Norden-Krichmar, K. L. Edwards, American Diabetes GENNID Study Group; Dept. of Epidemiology and Biostatistics, Program in Publ. Hlth., Univ. of California, Irvine, CA
Disclosure Block: **J.Y. Wan:** None.
Objective: There is great interest in utilizing polygenic scores (PGS) to predict risk of common chronic conditions. PGS are often based on meta-analysis comprised of multiple genome-wide association analyses (GWAS) that emphasize common variants. It is not clear how well PGS based on GWAS from European ancestry (EA) populations will predict disease in non-EA populations. We use a multi-ethnic sample of families to: (1) evaluate the association between a common-variant genetic burden PGS and metabolic syndrome (MetS)-related traits; (2) to compare / contrast the prediction of MetS traits from PGS based under different scenarios.
Methods: The GENNID study consists of 1502 subjects in 259 families from European-American (EA), Mexican-American (MA), African-American (AA), and Japanese-American (JA) families. We used PLINK and R for data quality-control of the GENNID dataset, base GWAS summaries, and PGS analyses. Clumping and Thresholding (C + T) method was used to construct PGS based on single ancestry-specific GWAS meta-analysis summaries, summaries based on EA samples only, and from a meta-analysis consisting of multiple populations. We evaluated the association of PGS constructed under these different scenarios with BMI using a linear mixed effects model (with fixed covariate effects and random family effects). P-values were approximated using a normal distribution. For each ethnic group, ROC curves and AUC values (using bootstrapping methods) were used to compare the ability of PGS to predict obesity (BMI>30) and MetS traits.
Results: PGS based on a GWAS meta-analysis of multiple populations predicted better (i.e., had higher AUC) than PGS based on either ancestry-specific or EA GWAS. The AUC values ranged from 53% to 71% and explained less than 6% of the variance in obesity.
Conclusions: In general, the proportion of variance explained was low but is consistent with the literature for other common, complex conditions. Future analyses will evaluate whether including additional genomic variants identified through family-based methods will boost the predictive ability of a PGS.

PrgmNr 2796 - Enrichment of Motilin Receptor LOF variants in Gastroparesis

View session detail

Author Block: **J. Carlin**, S. Smieszek, M. Fisher, M. Bagger, D. Madonick, C. Kupersmith, M. Lopez-Lascurain, G. Birznieks, M. Polymeropoulos; Vanda Pharmaceuticals Inc., Washington, DC
Disclosure Block: **J. Carlin:** Salary/Employment; Vanda Pharmaceuticals Inc..
Gastroparesis is a serious chronic disorder characterized by delayed gastric emptying and upper gastrointestinal symptoms of nausea, vomiting, bloating, fullness after meals, abdominal discomfort and pain. To ascertain the genetic risk factors for gastroparesis, we conducted a large whole genome sequencing (WGS) study of idiopathic and diabetic gastroparesis subjects in a phase 3 study cohort. We previously reported an enrichment of Motilin Receptor (MLNR) gene LOF variants in WGS study of gastroparesis (phase 2 study VP-VLY-686-2301). Here we replicate this enrichment in an independent cohort of gastroparesis samples obtained from a phase 3 study VP-VLY-686-3301. We investigated the frequency and effect of rare loss-of-function (LOF) variants in adult subjects (n=320) with idiopathic or diabetic gastroparesis, evidence of delayed gastric emptying, and moderate to severe nausea. Patients were excluded with another active disorder or treatment which could contribute to gastroparesis symptoms including but not limited to gastric malignancy or neurological disorder or patients needing gastric or parental feeding.
In this dataset we report an increased frequency of a frameshift mutation within MLNR gene, variant rs562138828 in gastroparesis subjects compared to controls. Motilin is a 22 amino acid peptide hormone expressed throughout the gastrointestinal (GI) tract. The protein encoded by this gene is a motilin receptor which is a member of the G-protein coupled receptor 1 family. We have shown previously increased frequency of a frameshift mutation with MAF 0.01 as compared 0.0009 AF in GNOMAD (p-value=0.01). We reported 4/119 gastroparesis patients carry the variant of interest that results in p.Leu202ArgfsTer105. In the current data, the effect persists and we report 13 out of 894 versus controls 13 out of 1912 (MAF: cases 0.007; MAF: controls 0.003) and OR: 2.15. The variant has increased allelic frequency in African American population per GNOMAD controls, we inspected the frequencies in this group alone: MAF AA cases: 0.024 and MAF AA controls 0.01, OR: 2.36 (Relative risk: 1.71, p-value 0.02). The carriers were equally split among idiopathic and diabetic, so this possible gastroparesis risk factor appears to be agnostic as to diabetes status.
The identified LOF variants within the region can serve as a risk factor for disease as well as inform treatments, especially given accumulating evidence supporting different responses to treatment. The finding may be of direct relevance to individuals with the identified mutation as they may respond differently to gastroparesis treatments; especially those targeting MLNR.

PrgmNr 2797 - Exome-wide association analyses of MRI imaging-derived traits in up to 32k participants of the UK Biobank identify genes and variants involved in the regulation of body composition

View session detail

Author Block: **H. Kim**[1], J. Linge[2,3], O. Dahlqvist-Leinhard[2,3], J. Goodman[4], E. J. Keliher[4], C. L. Hyde[5], E. B. Fauman[1], M. R. Miller[1]; [1]Internal Med. Res. Unit, Pfizer, Cambridge, MA, [2]AMRA Med., LinkÃ¶ping, Sweden, [3]LinkÃ¶ping Univ., LinkÃ¶ping, Sweden, [4]Early Clinical Dev., Digital Med. and Imaging, Pfizer, Cambridge, MA, [5]Early Clinical Dev., Biostatistics, Pfizer, Groton, CT
Disclosure Block: **H. Kim:** Salary/Employment; Pfizer.
The combined analyses of imaging and genetic data offer an opportunity to study the genetic underpinnings of body composition traits such as adipose tissue volumes and ectopic fat deposits, which are important risk factors for cardiometabolic outcomes. In this study, we performed exome-wide association analyses (ExWAS) for 5 whole-body MRI imaging-derived traits in up to 32k individuals of European ancestry, combining currently available imaging data from 40k individuals and exome sequences from 450k individuals in the UK Biobank. From the MRI images, visceral adipose tissue (VAT), abdominal subcutaneous adipose tissue (ASAT), and thigh muscle volumes as well as liver and intramuscular fat percentages were quantified. Traits were adjusted for carefully selected sets of covariates and inverse normal transformed. We tested associations both at the individual variant level using BOLT-LMM and at the gene level, aggregating protein-altering variants into four variant sets and applying burden and SKAT tests. The analyses identified a total of 56 significant associations (P-value threshold adjusted for the number of variants or variant sets and for genomic inflation factor per trait) across 4 traits (no significant association for thigh muscle volume), including 47 associations of individual protein-altering (pLOF, missense, or inframe indel) variants and 9 associations of gene-level variant sets. All but one association overlapped with GWAS loci (defined by +/-500kb of significant variants) of the corresponding trait, including protein-altering variants in well-characterized genes such as *PNPLA3*, *TM6SF2*, *APOE*, *GCKR*, *GPAM*, *MTARC1*, *MTTP*, and *PPARG*. There was at least one significant ExWAS association in 28 GWAS loci, which can help inform potential causal genes for the GWAS signals. There was one association outside of GWAS loci: the burden association of the *APOB* pLOF variant set with liver fat (P-value = 6.1e-14, beta = 1.3 SD unit, aggregate MAF = 0.6%), which is consistent with the known function of *APOB* in VLDL secretion from the liver. Notably, in the *APOB* region, no individual variants from exome or imputed data had associations reaching exome- or genome-wide significance (minimum P-value in the region = 9.4e-5). This study shows that ExWAS of imaging-derived traits has the potential to identify new genes and variants not captured by GWAS and help prioritize causal genes and variants in the GWAS loci. We expect that the statistical power of ExWAS for imaging traits will increase further as the number of individuals with both imaging and exome data reaches the projected goal of 100k individuals.

PrgmNr 2798 - G6PD deficiency associated genetic variants and the diagnostic utility of HbA1c: the Africans in America Study

View session detail

Author Block: **K. Ekoru**[1], A. A. Adeyemo[1], A. R. Bentley[1], C. W. DuBose[2], A. C. Patterson[2], A. Wentzel[2], C. N. Rotimi[1], A. E. Sumner[2,3]; [1]Ctr. for Res. on Genomics and Global Hlth., Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [2]Section on Ethnicity and Hlth., Natl. Inst. of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, [3]Natl. Inst. of Minority Hlth.and Hlth.Disparities, Bethesda, MD

Disclosure Block: **K. Ekoru:** None.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked red cell enzymopathy associated with increased risk of hemolysis. Genetic variants in G6PD have been reported to be associated with non-glycemic lowering of HbA1c with potential impact on diagnosis and monitoring of diabetes and related phenotypes. Within the context of the Africans in America Study, we evaluated the diagnostic utility of glycated hemoglobin A1c (HbA1c) for detecting abnormal glucose tolerance (AGT) [2-hour postprandial glucose â¥7.8 mmol/L] in 350 African-born blacks living in the United States [65% male, mean age 40 (SD 10) years, mean body mass index (BMI) 27.9 (SD 4.4) kg/m2] with and without the G6PD A- (202A/376G) deficiency haplotype. (African region of origin: West 50%, Central 17%, East 33%). Forty percent [40% (141/350)] of the participants had AGT [8% diabetes and 32% prediabetes] by the oral glucose tolerance test (OGTT), and 16% (56/350) carried the G6PD A- (202A/376G) haplotype. In logistic regression models adjusted for age, sex and BMI, the 202A/376G haplotype was strongly associated with AGT as defined by HbA1c [OR = 0.045 (95% CI 0.010-0.211), p= 8.056 X 10^{-5}]. On the other hand, a similar model for AGT defined by the OGTT showed a much weaker though still significant association [OR = 0.483 (95% CI 0.248-0.942), p=0.033]. Among individuals carrying the 202A/376G haplotype, the model-based Receiver Operating Characteristic (ROC) curve for the ability of HbA1c to detect AGT-OGTT was below the reference line, indicating a diagnostic accuracy worse than random classification. In contrast, the ROC curve was above the reference line among individuals carrying the wild-type genotype [AUC = 0.62 (95% CI 0.55 - 0.69)]. These findings show that the G6PD A- (202A/376G) deficiency haplotype is strongly associated with AGT, with a bigger effect on AGT defined by HbA1c versus AGT defined by OGTT. Notably, HbA1c has poor utility for diagnosing both prediabetes and diabetes in the presence of the G6PD A- (202A/376G) deficiency haplotype. These findings add to the list of factors that affect the utility of HbA1c for the diagnosis and monitoring of glycemic status and highlights the need to develop additional glycemic biomarkers or combine HbA1c with other markers such as glycated albumin or fasting glucose.

PrgmNr 2799 - Genome-wide assessments of obesity and 138 inflammatory markers to characterize obesity-induced inflammation

Chronic inflammation induced in obesity plays an etiological role in the development of obesity-related diseases such as coronary heart disease (CHD), stroke, type 2 diabetes (T2D), and colorectal cancer (CRC). **However**, specific inflammatory molecular/cellular profiles induced by obesity and their genetic basis are largely unknown, hindering the identification of therapeutic targets that ameliorate obesity-related diseases. **We aimed to** identify biomarkers for obesity-induced inflammation and investigate the shared genetic architecture between obesity and such an inflammatory profile. **Pooling multiple databases**, we curated the largest genome-wide association summary statistics for 138 markers including 126 inflammatory proteins (C-reactive protein [CRP] N>450k, other proteins N~4k-45k) and 12 blood immune cell types (N>450k) and subsets (N~2.5k); and for body mass index (BMI) and waist-hip ratio (WHR, with/without adjusting for BMI; N~695k-807k), CHD, stroke, T2D, and CRC (N~522k-898k). **In Mendelian randomization analyses**, both BMI and WHR showed significant causal effects for 6 inflammatory markers (*FDR*PFDRFDRGenome-wide cross-trait meta-analyses identified 2329 independent genetic loci significantly coregulating obesity (BMI and/or WHR) and at least one marker of obesity-induced inflammation (e.g., *ACAD10* coregulated BMI and 8 markers, *P*enriched expressions in blood vessels and brain tissues, while loci coregulating WHR and WHR-induced inflammation harbored genes highly expressed in adipose tissue, blood, and blood vessels (*FDR*Finally, we identified markers of obesity-induced inflammation showing significant causal effects for obesity-related diseases (e.g., IL6 for CHD, stroke, and T2D; *FDR*In conclusion, we identified a comprehensive profile of molecular/cellular markers for obesity-induced inflammation and characterized genetic architecture between obesity and such a profile. Our data indicate shared and distinct inflammatory pathways induced by obesity and central obesity, and suggest specific pathways contributing to obesity-related diseases.

PrgmNr 2800 - Identifying novel high-impact rare disease-causing mutations, genes and pathways in exomes of Ashkenazi Jewish inflammatory bowel disease patients

Disclosure Block: **Y. Itan:** None.

Inflammatory bowel disease (IBD) is a group of chronic digestive tract inflammatory conditions whose genetic etiology is still poorly understood. The incidence of IBD is particularly high among the Ashkenazi Jews (AJ). Here, we identified 7 novel and plausible IBD-causing genes from the exomes of 4,974 genetically identified AJ IBD cases (1,905) and controls (3,069). Various biological pathway analyses were then performed, along with bulk and single-cell RNA sequencing, to demonstrate the likely physiological relatedness of the novel genes to IBD. Importantly, we demonstrated that the rare and high impact genetic architecture of AJ adult IBD displays a significant overlap with very early onset IBD genetics. Moreover, by performing phenome-wide analyses in major biobanks, we found that IBD genes have pleotropic effects that involve other immune responses. Finally, we showed that polygenic risk score analyses based on genome-wide high impact variants have high power to predict IBD susceptibility.

PrgmNr 2801 - Integrating genetics and plasma proteomics to predict risk of type 2 diabetes in adults and children: A two-sample Mendelian randomization study

View session detail

Author Block: **F. Ghanbari**[1], N. Yazdanpanah[1], M. Yazdanpanah[1], D. Manousaki[2]; [1]Univ. de Montreal, montreal, QC, Canada, [2]Sainte Justine Hosp., Montreal, QC, Canada
Disclosure Block: **F. Ghanbari:** None.
Type 2 diabetes (T2D) is a global pandemic in adults, and its prevalence has increased substantially in children in the past two decades, despite stabilization of the obesity rates. In both adults and children, primary prevention of T2D through lifestyle modification is key, and identification of biomarkers enabling early disease prediction is important for selecting candidates for these interventions. Proteins are key factors that transfer information from genome to phenome, can be measured in the blood using high-throughput proteomic platforms, and represent promising drug targets. Therefore, identification of circulating protein biomarkers that are causal in T2D in adults and children can be used to enhance prediction and understanding of the mechanism underlying this disease. Here, we applied a large scale two-sample Mendelian randomization (MR) study, using *cis* genetic determinants of n=1,089 circulating proteins for adult T2D and n=174 proteins for youth-onset T2D from five large genome-wide association studies (GWAS). We screened these proteins for causal associations with adult T2D risk in 74,124 T2D cases and 824,006 controls of European ancestry, and with youth-onset T2D risk in 664 T2D cases and 1,976 controls of European ancestry from the largest available GWAS on these traits. Our MR analysis identified 20 candidate proteins for adult T2D, among which 6 proteins (MANS domain containing 4 [MANSC4], Histo-blood group ABO system transferase [ABO], Haptoglobin [HP], Sodium/potassium-transporting ATPase subunit beta-2 [ATP1B2], Spermatogenesis-associated protein 20 [SPATA20], C-type mannose receptor 2 [MRC2]) shared a common causal variant with adult T2D in colocalization analyses. Moreover, we identified 11 proteins with evidence of causal association with youth-onset T2D. In summary, using an unbiased MR approach, our study leveraged large-scale proteomic and T2D GWAS data to identify circulating proteins as candidate biomarkers and drug targets for adult and youth-onset T2D.

PrgmNr 2802 - Integrative multiomics analyses reveals link between obesity and insulin resistance-associated plasma metabolites and adipose tissue transcripts in African Americans

View session detail

Author Block: **S. K. Das**[1], N. D. Palmer[1], M. E. Comeau[1], N. K. Sharma[1], C. Zhang[2], A. Mardinoglu[2], D. W. Bowden[1], L. E. Wagenknecht[1], M. C. Ng[3], C. D. Langefeld[1]; [1]Wake Forest Sch. of Med., Winston-Salem, NC, [2]KTH-Royal Inst. of Technology, Stockholm, Sweden, [3]Vanderbilt Univ. Sch. of Med., Nashville, TN

Disclosure Block: **S.K. Das:** None.

Metabolic changes initiated by obesity and insulin resistance (IR) are risk factors for type 2 diabetes (T2D), a disease diagnosed by increased plasma glucose levels. Analyses of plasma metabolite levels has facilitated the understanding of biochemical mechanisms of obesity and IR, but such studies in non-European ancestry cohorts remain limited. Derangement of gene expression in tissues involved in glucose homeostasis are likely to be mechanistically linked with altered plasma metabolite levels in obesity and IR, but remain understudied.To address these issues, we integrated measures of insulin sensitivity (Matsuda index from OGTT, and S_I from FSIGT) and obesity (BMI), fasting plasma metabolite profiles (liquid chromatography-mass spectrometry, Metabolon), and adipose and muscle tissue gene expression (Illumina HT12-v4) data in 253 non-diabetic African Americans (AA) from AAGMEx cohort.Among the 1124 plasma metabolites evaluated in AAGMEx participants, 166, 153 and 60 were significantly associated (FDR-PI, respectively. Lipid metabolites 1-oleoyl-GPC and cortolone glucuronide and amino acids hypotaurine and glycine were among the top ranked BMI and IR-associated metabolites in AAGMEx. Analyses were similarly undertaken in AAs from the IRASFS cohort (N~565) which replicated directionally consistent significant association of 100 and 36 metabolites for BMI and S_I, respectively. Glycine was positively associated, while palmitoyl-linoleoyl-glycerol (a Diacylglycerol) was inversely associated with S_I in both cohorts. Hierarchical clustering of BMI and IR-associated metabolites defined the clusters of correlated metabolites. GWAS of metabolites selected from these clusters, identified SNPs in genetic loci putatively regulating plasma levels of a subset of these metabolites in AAGMEx. Reporter metabolite analyses by integrating genome-scale metabolic model for human, and adipose tissue transcript-trait association statistics in AAGMEx predicted significant correlations of 60, 48, 51 metabolites with BMI, Matsuda index and S_I, respectively. Empirically measured plasma metabolite data in AAGMEx validated 12 metabolites. Plasma mannose levels were inversely correlated with Matsuda index (b= -1.4, FDR-P = 7.37E-7), and in adipose, expression of genes involved in mannose metabolism (*GMPPA*, *GMPPB*, and *GMDS*) were also inversely correlated with Matsuda index. In summary, this study delineates the architecture of obesity and IR-associated metabolites in African Americans, and also suggests a role for altered adipose tissue gene-expression in determining at least a subset of these metabolites.

Disclosure Block: **N.D. Palmer:** None.

Obesity is a complex disease characterized by extensive metabolic dysregulation. Metabolomic profiles are highly informative capturing the interaction of cellular processes and environmental exposures to promote disease. Therefore, metabolomics has the potential to improve mechanistic understanding and identify clinically relevant targets. However, use of this technology can be limited by cost and sample availability. To facilitate metabolite investigations into complex disease, data from the Insulin Resistance Atherosclerosis Family Study (IRASFS, n=943 Mexican Americans) with empiric metabolomics data (Metabolon HD4) and genome-wide genotype data were used. 950 metabolites were significantly heritable (P2 up to 0.87). Ridge and LASSO regression revealed cross validated correlation between predicted and observed measures >0.1 for 448 metabolites. In an independent set of 192 Mexican Americans, the LASSO regression (enforcing sparsity by selecting a small proportion of variants) yielded better estimation performance than the ridge penalty (full polygenic architecture) suggesting that the genetic architecture of metabolites in this sample was sparse. Most metabolites had multiple independent loci (1-22, median=21) contributing to the estimation. Estimation was extended to the six Mexican American cohorts in the GUARDIAN Consortium to assess their association with measures of adiposity. Multiple significant (FDR P2=0.47) and was negatively associated with BMI, WC and WHR (FDR P=0.014-8.5E-6). In addition, three uncharacterized metabolites also exhibited high heritably (h^2>0.56) and significant association with measures of adiposity (FDR P=0.014-3.1E-6) suggesting this approach could contribute to metabolite characterization. In conclusion, we have developed genetic algorithms for estimating 448 metabolites with good performance in independent datasets and found strong evidence of a sparse genetic architecture. This estimation model was used to assess association with adiposity phenotypes highlighting known and novel associations, further demonstrating utility. Future work will expand genetic coverage to include rare variants and phenotypic associations to further characterize metabolic dysregulation.

PrgmNr 2804 - Mapping genomic regulation of kidney diseases and traits at a cell type and variant level of specificity

View session detail

Author Block: **C. J. Benway**, S. Han, M. T. McNulty, A. Greenberg, D. Lee, Nephrotic Syndrome Study Network (NEPTUNE), M. Sampson; Boston Children's Hosp., Boston, MA
Disclosure Block: **C.J. Benway:** None.
Although numerous genetically associated loci for kidney function and disease have been identified by genome-wide association studies (GWAS), determining the causal genes and functional variants remains a major challenge. Since the majority of trait-associated variants map to intergenic and non-coding genomic regions, integration of GWAS results with other data types (such as expression quantitative trait loci [eQTL]) can help identify causal and functional variants in a tissue- or cell-type specific manner. Further, analysis of disease tissue (rather than healthy tissue) may uncover context-specific associations that may otherwise not be detectable. To more precisely resolve the regulatory landscape of kidney diseases and traits, explain heritability, and identify potential mechanisms, we integrated eQTL data from micro-dissected glomerular (n = 240) and tubulointerstitial (n = 311) RNA-seq transcriptomes from individuals with nephrotic syndrome (NS) and summary statistics from two large trans-ethnic GWAS meta-analyses for estimated glomerular filtration rate (eGFR) and urinary albumin-to-creatinine ratio (UACR).
Utilizing a Bayesian statistical framework for eQTL discovery and multi-SNP fine-mapping (TORUS/DAP), we identified 5,526 glomerular eQTLs and 9,742 tubulointerstitial eQTLs at 50%) for eGFR. This result includes replication of gene expression associations for *UMOD* and *FGF5*, as well as novel associations to *LARP4B* and *RRAGD* which can be attributed to colocalization at a single variant for each locus. We identified 7 tubulointerstitial and 16 glomerular co-localization signals (RCP > 50%) for UACR. In addition to replicating co-localization signals at *PRKCI* and *TGFB1* in glomerular tissue, we refined the co-localization signal at *PTH1R* to a single variant, rs6787229, which also co-localized with expression of *MYL3*.

Disclosure Block: **V. Buchanan:** None.

Elevated central adiposity is a risk factor for cardiometabolic disease (CMD), and its prevalence has increased in the US over the past three decades, with stark disparities among minorities. While the genetic impact on central adiposity is well-established, metabolomic dysregulation in the pathogenesis of central obesity, which may point to dysregulated genomic pathways that underlie disease manifestation, remains understudied. We thus aim to identify metabolites associated with waist circumference (WC) and downstream CMD in a large ancestrally diverse cohort of Hispanic Americans.

HCHS/SOL is a community-based prospective cohort of Hispanic/Latino adults from randomly selected households at 4 US field centers. Interviews and clinical assessment were conducted at in-person visits from 2008-2011 (Visit 1). A total of 3972 participants were randomly selected for metabolomic profiling (using Visit 1 fasting blood draws) using an untargeted platform. We investigated cross-sectional associations between metabolites and WC adjusted for BMI, age, study center, background group, and sample weights from Visit 1 using linear regression models, first stratified by sex and then meta-analyzed.

Data for 687 known metabolites and WC were available for 3806 participants (mean age: 45.8 years, 57% female). We identified Bonferroni-corrected significant associations (pThis work will help in better understanding the pathways leading from genes to central obesity in a diverse, highly admixed population. Identification of central obesity-related metabolites may provide novel insights concerning the metabolic and physiologic mechanisms underlying central obesity.

PrgmNr 2806 - Methylation profiles at birth linked to early childhood obesity

View session detail

Author Block: **S. J. Craig**[1], D. Lariviere[1], I. M. Paul[2], M. E. Marini[1], F. Chiaromonte[1], K. D. Makova[1], M. L. Reimherr[1]; [1]Penn State Univ., University Park, PA, [2]Penn State Coll. of Med., Hershey, PA
Disclosure Block: **S.J. Craig:** None.
Obesity affects 18.5% of children and adolescents in the United States. Previous studies have suggested an overlap of the underlying mechanisms of obesity across the lifecourse. It has also been shown that obesity is linked to a widespread change in the methylation profile in peripheral blood. Based on this, we aimed to measure how changes in methylation profile in mothers and newborns at birth are correlated to the childâ□□s growth during the first three years after birth and to the probability of a child to be overweight. We used the data from a subset of the SIBSight (Effects of Birth Order and Genetics on Infant Parenting and Obesity Risk) birth cohort that followed approximately 117 second born children from birth to age 3 years. In addition to genetic profiles, the study tracked the childâ□□s growth and environmental factors such as nutrition quality and familial environment. The analysis presented here focused on 48 children whose methylation profiles were measured at birth using Illumina Infinium MethylationEpic chips. The methylation profiles were evaluated by sampling placenta tissue and cord blood. We performed regression analyses to identify genes with differential methylation patterns associated with children's growth from birth to age 2 years. We show that the two types of tissue studied have different methylation patterns and highlight different sets of genes linked to childrenâ□□s growth index. The majority of the genes identified here were linked to weight-related traits in previous studies through GWAS and variant analyses. For instance, they were linked to body mass index (BMI), hip-to-waist ratio, or nutrient assimilation. Our results suggest a link between the methylation profile during pregnancy and the prevalence of obesity in early childhood.

PrgmNr 2807 - Multi-ethnic genome-wide meta-analysis in type 1 diabetes

View session detail

Author Block: **D. A. Michalek**[1], C. C. Robertson[1], W-M. Chen[1,2], B. M. Delelegn[1], T1DGC, S. Onengut-Gumuscu[1,2], S. S. Rich[1,2]; [1]Ctr. for Publ. Hlth.Genomics, Univ. of Virginia, Charlottesville, VA, [2]Dept. of Publ. Hlth.Sci., Univ. of Virginia, Charlottesville, VA
Disclosure Block: **D.A. Michalek:** None.
Background: Type 1 diabetes (T1D) is an autoimmune disorder caused by destruction of pancreatic Î²-cells. The original GWAS meta-analysis (2009) and fine mapping have identified over 50 loci associated with risk of T1D, yet limited GWAS have been completed over the last decade. **Objective:** Discover new T1D loci utilizing a multi-ethnic GWAS approach. **Methods:** A total of 3,222 families (11,476 individuals, majority of European ancestry), 891 African ancestry (AFR, 409 T1D cases, 482 controls), and 308 Admixed individuals (AMR, 153 T1D cases, 155 controls) were genotyped on the Illumina CoreExome BeadChip. A total of 430,930 SNPs passed quality control metrics with additional SNPs and insertion/deletion (indel) polymorphisms obtained from imputation (TOPMed). Family data was analyzed with the Generalized Disequilibrium Test (GDT), and case-control data employed logistic regression (PLINK). Meta-analysis (METAL) identified SNPs and indels associated with T1D with P -8. **Results:** Following imputation, 8,711,967 variants (MAF > 0.01) were used in meta-analysis. Eight loci were associated with T1D, including the MHC (rs9273364, P = 2.94 x 10^{-501} in *HLA-DQB1*), *INS* (rs3842753, P = 1.35 x 10^{-49}, in complete LD with known *INS* rs689), *PTPN22* (rs2476601, P = 3.45 x 10^{-26}), *SH2B3* (rs3184504, P = 1.05 x 10^{-18}), *ERBB3* (rs705708, P = 1.60 x 10^{-14}), *RNLS* (rs3781197, P = 4.01 x 10^{-12}) and *CTLA4* (rs3087243, P = 1.82 x 10^{-9}). A new locus, *NRP1* (rs2666237, P = 3.61 x 10^{-8}) on 10p11.22 was identified. Two regions (*FAM43A*, 3q29, novel; *IL2RA*, 10p15.1, known) had suggestive (P -7) evidence of association with T1D. Neuropilin-1, encoded by the *NRP1* gene, is a marker for murine CD4+FoxP3+ regulatory T (Treg) cells. *NRP1* also positively regulates T cell proliferation. *FAM43A* is expressed in NK cells, naÃ¯ve B cells, monocytes and in certain subgroups of CD4+ T cells (DICE project) yet little is known about its function and relationship with T1D. **Conclusions:** These findings suggest that inclusion of subjects with diverse genetic ancestry can identify new and refine known regions of the genome contributing to risk of T1D, and the results can aid in understanding the biology underlying type 1 diabetes.

PrgmNr 2808 - Novel Genetic Loci Associated with Age-of-onset of Type 1 Diabetes

Hlth.Ctr., Montreal, QC, Canada

Disclosure Block: **H. Qu:** None.

Type 1 diabetes (T1D) has been traditionally recognized as an autoimmune disease, and numerous autoimmune genes have been identified for underlying the genetic susceptibility of T1D. A minor proportion (~5-10%) of Caucasian patients diagnosed as T1D have non-autoimmune pathogenesis, i.e. T1bD(Leslie, Atkinson et al. 1999). For most patients with T1D, the pancreatic destruction is irreversible once T1D is diagnosed. Prediction of T1D onset and early intervention have been warranted for research efforts. Sharp et al. developed a specific genetic risk scoring (GRS) system for T1D, (T1D-GRS2), using 67 single nucleotide polymorphisms (SNPs) from known autoimmune loci(Sharp, Rich et al. 2019), which demonstrated excellent performance for the prediction of T1D genetic susceptibility. As shown in the Type 1 Diabetes Genetics Consortium (T1DGC) GWAS cohort, the GRS2 scores are also correlated with the T1D age-of-onset (r=-0.102, *P*= 8.35E-11). By a large collection of European T1D cases and controls, we defined high GRS2 vs low GRS2 at GRS2=8.43 with the sensitivity of 0.855 and the specificity of 0.719 for T1D prediction. In further, our genetic association study showed distinct genetic architecture between cases with high GRS2 and those with low GRS2, suggesting the phenotypic heterogeneity of T1D (Qu, Hui-Qi et al. 2021). Based on this GRS definition, 3510 (86.9%) of 4037 T1DGC cases had high GRS, and 527 (13.1%) had low GRS. GRS2 scores in both GRS groups are correlated with the T1D age-of-onset (high GRS2 group r= -0.064, *P*=1.54E-04; low GRS2 group r= -0.093, *P*=0.033). In our study based on the imputation by the TOPMed (Version R2 on GRC38) Reference Panel, we searched for genetic association with T1D age-of-onset in the two GRS groups separately, corrected for GRS2 scores and population structure. In the high GRS group, four independent association signals with T1D age-of-onset were identified at the *HLA DR/DQ* region, i.e. rs602457 (*P*=1.98E-13), rs9273371 (*P*=5.42E-09), rs4713573 (*P*=5.58E-09), and rs35353422 (*P*=8.76E-09); and one independent signal at the *HLA* class I region was associated with T1D age-of-onset, i.e. rs116020851 (*P*=1.93E-08). In contrast, in the low GRS group, the only one association signal with genome-wide significance was not from the *HLA* region, but from the *SLC22A31* gene region at Chr16, tagged by rs4785604 (*P*=2.83E-08). *SLC22A31* has biased expression in lung and pancreas. The SNP rs4785604 is associated with the expression level of *SLC22A31* in brain, testis, and spleen (https://www.gtexportal.org). In addition to the potential of T1D onset prediction, these novel loci highlight the heterogeneous pathogenesis of high GRS T1D and low GRS T1D.

PrgmNr 2809 - Pleiotropic Loci Influencing Cystic Fibrosis-Related Diabetes and Neonoatal Intestinal Obstruction

Disclosure Block: **M. Atalar Aksit:** None.

Introduction: Cystic fibrosis (CF), a life-limiting autosomal recessive disorder, has a range of phenotypes that vary considerably amongst individuals, including CF-related diabetes (CFRD) and neonatal intestinal obstruction (meconium ileus; MI). Though MI and CFRD are not correlated, several loci are â□□pleiotropicâ□□, i.e., associate with both traits. Here, we investigate the degree of genetic overlap between MI and CFRD using data from the CF Genome Project (CFGP). **Methods:** Whole genome sequencing was performed on enrollees with CF from 5 studies (CF Twin and Sibling Study, CFRD Study, Genetic Modifier Study [GMS], GMS of Severe CF Liver Disease Study, and Early Pseudomonas Infection Control Observational Study). 4,473 individuals with exocrine pancreatic insufficient CF (905 with MI; 1,410 with CFRD) were studied. MI was modeled as a binary variable via mixed-effects logistic regression, adjusted for site, birth cohort, residual CFTR function (zero vs. nonzero), 4 principal components, and genetic relatedness. CFRD was modeled as a mixed-effects linear regression for Martingale residuals for age of onset, with the same covariates as MI plus sex, as it associated with CFRD. Variants with MAF>0.5% were analyzed. **Results:** Common variants at *SLC26A9*, *CEBPB* and *PRSS1* were significantly associated with both MI and CFRD: the direction of effect was shared at *SLC26A9* and *CEBPB* (the risk allele increases risk of CFRD and MI), but was discordant at *PRSS1*. The *PRSS1* variants, which increase risk for MI and are protective for CFRD, are also protective for pancreatitis in non-CF individuals (Derikx, et al. 2015.). High-risk variants for *CEBPB* also increase risk for type 2 diabetes in non-CF individuals (Klupa, et al. 2000). A less common (MAF 1%) missense variant in *SLC26A9 (V172M)* associated with MI and not CFRD. Variants associated with MI but not CFRD at *CLPS/SLC26A8*, *EMSY* and *SLC6A14* while variants at *TCF7L2* and 16p12.1 associated with CFRD but not MI. **Conclusions:** Both MI and CFRD are influenced by multiple genetic variants, some of which associate with only one of the two traits, some which influence both traits in the same direction, and one of which associates in opposite directions. *Supported by CFF grants CUTTIN18XX1, BAMSHA18XX0, and KNOWLE18XX0 and submitted on behalf of the CF Genome Project.*

PrgmNr 2810 - Polygenic susceptibility to obesity modifies the impact of salivary amylase gene (*AMY1*) copy number on BMI

View session detail

Author Block: **L. Stalbow**[1,2,3], R. A. J. Smit[1,2,3,4], M. H. Preuss[1,2,3], A. Moscati[1], N. Patel[5,3], P. Garg[5,3], A. J. Sharp[5,3], R. J. F. Background: As GWASs get larger and are able to explain more of the genetic variation in body mass index (BMI), polygenic risk scores (PRS) can better identify individuals with a genetic susceptibility for high BMI. These scores are based on GWAS summary statistics and cannot capture more complex genetic architecture, such as copy number (CN) variations, and are therefore missing some of the genetic structure of BMI. For example, low CN of the salivary amylase gene (*AMY1*) has been associated with an increase in BMI in many, but not all studies. This inconsistency may be ascribed to the overall polygenic environment, influencing the impact of *AMY1* CN on BMI. Here we examine how high BMI polygenic susceptibility exacerbates the effect of *AMY1* CN on BMI.
Methods: Through exome sequencing of 6,653 individuals of European ancestry (EA) of the Mount Sinai Bio*Me* biobank, we determined *AMY1* CN using CNVnator on a subset of Bio*Me* with whole genome sequencing, and extrapolating the results to the exome sequencing files. We generated a BMI PRS using recent GWAS summary statistics from ~700,000 EA participants. We estimated the association between *AMY1* CN and the PRS (both standardized) with BMI using linear regression analyses. We then divided the PRS into a high group (top third of the PRS) and low group (lower two thirds of the PRS) and examined the interaction between *AMY1* CN and the PRS groups. Analyses were adjusted for age, sex and the first ten principal components.
Results: A 1-standard deviation (SD) increase in PRS was associated with a 1.4 kg/m^2 (SE 0.07, P AMY1 CN was not significantly associated with BMI (-0.087 kg/m^2 (SE 0.065, P=0.18)). There was some evidence that the PRS affects the association between *AMY1* CN and BMI ($P_{interaction}$ = 0.21), which was most pronounced at the highest PRS-level ($P_{interaction}$ = 0.002), i.e., the effect of *AMY1* CN on BMI was different between individuals in the high vs low PRS groups. Specifically, in the high PRS group, a 1-SD increase in *AMY1* CN was significantly associated with a -0.37 kg/m^2 (SE 0.13, P=0.005) decrease in BMI (or 1.1 kg in body weight for a 1.7m tall person), whereas in the low PRS group, a 1-SD increase *AMY1* CN was not associated with BMI (0.06 kg/m^2 (SE 0.074, P=0.4)), and the direction of effect was reversed.
Conclusion: We show that in the presence of a high polygenic susceptibility for increased BMI, low AMY1 CN contributes to an increase in BMI. Interestingly, this effect was not observed in individuals with a low PRS. These findings contribute to the discussion as to the effect of AMY1 CN on BMI, and highlights the interplay between CN and polygenic susceptibility.

PrgmNr 2811 - Role of diet and submaximal cardiorespiratory fitness as mediators of genetic susceptibility to obesity: results from the Quebec Family Study

View session detail

Author Block: **L. PÃ©russe**[1], R. Jacob[1], C. Bertrand[1], C. H. Llewellyn[2], A. Tremblay[1], C. Bouchard[3], M-Ã. LabontÃ©[1], V. Drapeau[1]; [1]Laval Univ., Quebec, QC, Canada, [2]Univ. Coll. London, LONDON, United Kingdom, [3]Pennington BioMed. Res Ctr, Baton Rouge, LA

Background : Genome-wide association studies (GWAS) have identified a large number of genetic variants associated with body mass index (BMI). The mechanisms by which these genetic variants contribute to the increased risk of obesity can be investigated using mediation analysis, an approach used to assess the extent to which the effect of an exposure (e.g. genetic susceptibility) on an outcome (e.g. obesity) is explained by a given set of hypothesized mediators (also called intermediate variables). **Objective:** This study aimed to assess the role of diet and submaximal cardiorespiratory fitness (CRF) as potential mediators of the relationship between genetic susceptibility to obesity (assessed using a polygenic risk score or PRS) and BMI and waist circumference (WC). **Methods:** This cross-sectional study included 750 adult participants from the Quebec Family Study. A PRS of obesity based on >500,000 BMI genetic variants was calculated using the LDpred2 software. Dietary intakes were assessed with a 3-day food record from which intakes of various food groups and a diet quality score (i.e., Nutrient Rich Food Index 6.3) were derived. CRF was determined by an incremental submaximal exercise test performed on ergocycle. The mediating effect ($Î²_{indirect}$) of diet and CRF on the association between the PRS of obesity and BMI and WC was assessed using a regression-based and bootstrapping approach after adjustment for age, sex, menopause, smoking and dieting and misreporting (for dietary data). **Results :** The PRS explained 25.7% and 19.8% of the variance in BMI and WC, respectively. The association between PRS and BMI was partly mediated by a low CRF ($Î²$=0.74Â±0.21, p=0.0008), high intakes of sodium ($Î²$=0.74Â±0.22, p=0.0002), fat and high-fat foods ($Î²$=0.46Â±0.16, p=0.002) and sugar-sweetened beverages ($Î²$=0.25Â±0.14, p=0.03), low intake of fruits ($Î²$=0.37Â±0.12, p=0.006) and poor diet quality ($Î²$=0.33Â±0.12, p=0.009). Similar results were observed for WC. **Conclusion:** The results show that genetic susceptibility to obesity is partly mediated by a poor diet quality, undesirable intake of specific food groups and a low CRF, suggesting that improvements in diet quality and exercise capacity may reduce obesity risk among individuals with high genetic susceptibility.

PrgmNr 2812 - Therapeutic validation of *FATP5*/*SLC27A5* using loss-of-function variation in humans

FATP5 (SLC27A5) is a fatty acid transporter, expressed almost exclusively in the liver, which facilitates uptake of long-chain fatty acids in hepatic cells and is required for recycling of bile acids. Deletion of FATP5 in mice has shown to lower triglyceride levels in the liver and protect against obesity, through a reduction in food intake. Importantly, knocking out FATP5 in mice with diet induced NASH, has also shown to reverse the NASH phenotype and improve glucose homeostasis. Given the increasing disease burden of NASH and obesity worldwide, pharmacological inhibition of FATP5 could be an attractive therapeutic target. Here, we used human genetics approach utilizing Pakistan Genetic Resource (PGR) and other publicly available biobanks (UK Biobank and Biobank Japan) to assess therapeutic validity of FATP5, and associated benefits/risks for metabolic syndromes. We meta-analyzed FATP5 common variants for hepatic, cardiovascular, glycemic, and inflammatory serum biomarkers (n=21) along with anthropometric traits (BMI and waist circumference). Total 15 biomarkers/traits were observed associated with an FDR

GWAS meta-analyses of individuals of diverse ancestry incorporating allelic effect heterogeneity across populations can identify new loci. We compared results from fixed-effect and mixed-effect models used to perform trans-ancestry meta-analyses for waist-to-hip ratio adjusted for body mass index (WHRadjBMI). Our combined sample size was >1.1 million individuals, including 947K, 136K, 41K, 33K, and 28K individuals of European, East Asian, South Asian, Hispanic/Latino, and African populations, respectively, from 201 studies that contributed GWAS results to the GIANT consortium. We performed a fixed-effects trans-ancestry meta-analysis including 92M variants (5M indels) using RAREMETAL and a mixed-effects trans-ancestry meta-analysis using MR-MEGA with three axes of variation as covariates for allelic effects to better account for allelic heterogeneity across populations. In addition, to evaluate potential inflation due to population stratification, we calculated lambda-GC values with three MAF thresholds (>0%, 0.5%, and 5%) and estimated linkage disequilibrium score regression (LDSR) intercepts and attenuation ratios using ~3M common variants. For comparison between methods, we identified distinct loci (P -9) based on distance (+/- 500 kb) from index/lead variants. Also, we compared these counts to a previous WHRadjBMI GWAS meta-analysis of 694K individuals of European ancestry that identified 346 loci (Pulit, 2019). The lambda-GC values from RAREMETAL and MR-MEGA ranged between 1.09-1.26 and 1.07-1.29, respectively. In general, lambda-GC values were lower for MR-MEGA than RAREMETAL, consistent with MR-MEGAâ□□s ability to account for heterogeneity between populations. However, based on LDSR among the ~80% European-ancestry individuals, only ~1.4% of the inflation in test statistics could be attributed to stratification, suggesting that GC values are inflated due to polygenicity. Trans-ancestry analyses using RAREMETAL without correction identified 611 loci, while using MR-MEGA identified 500 loci. Compared to the 118 loci identified only by RAREMETAL (8 index variants with MAF = 0.01) showed greater allelic heterogeneity across populations (mean chi-square het 20.8+/- 5.5 vs 2.4+/-1.8 for RAREMETAL). While the MR-MEGA analysis identified fewer loci overall, it detected some loci missed under an assumption of homogeneous effects. Using either model, our trans-ancestry meta-analysis had a 71% larger sample size than the previous European-focused WHRadjBMI meta-analysis and identified over 150 new loci.

PrgmNr 2814 - *IL10RB* as a key regulator of COVID-19 host susceptibility and severity

Background/Aims: Recent efforts have identified genetic loci that are associated with coronavirus disease 2019 (COVID-19) infection rates and disease outcome severity. Translating these genetic findings into druggable genes and readily available compounds that reduce COVID-19 host susceptibility is a critical next step. **Methods:** We integrate COVID-19 genetic susceptibility variants, multi-tissue genetically regulated gene expression (GReX) and perturbargen signatures to identify candidate genes and compounds that reverse the predicted gene expression dysregulation associated with COVID-19 susceptibility. The top candidate gene is validated by testing both its GReX and observed blood transcriptome association with COVID-19 severity, as well as by in vitro perturbation to quantify effects on viral load and molecular pathway dysregulation. We validate the *in silico* drug repositioning analysis by examining whether the top candidate compounds decrease COVID-19 incidence based on epidemiological evidence. **Results:** We identify *IL10RB* as the top key regulator of COVID-19 host susceptibility. Predicted GReX up-regulation of *IL10RB* and higher *IL10RB* expression in COVID-19 patient blood is associated with worse COVID-19 outcomes. In vitro *IL10RB* overexpression is associated with increased viral load and activation of immune-related molecular pathways. Azathioprine and retinol are prioritized as candidate compounds to reduce the likelihood of testing positive for COVID-19. **Conclusions:** We establish an integrative data-driven approach for gene target prioritization. We identify and validate *IL10RB* as a suitable molecular target for modulation of COVID-19 host susceptibility. Finally, we provide evidence for a few readily available medications that would warrant further investigation as drug repositioning candidates.

PrgmNr 2815 - A genome-wide association study identifies two novel loci for respiratory infection with *Pseudomonas aeruginosa* in cystic fibrosis

View session detail

Author Block: **B. Lin**[1], J. Gong[2], N. Panjwani[3], K. Keenan[3], C. Wang[4], L. Sun[1], L. J. Strug[5]; [1]Univ. of Toronto, Toronto, ON, Canada, [2]the Hosp. for Sick Children, Toronto, ON, Canada, [3]The Hosp. for Sick Children, Toronto, ON, Canada, [4]Toronto, Canada, [5]Hosp for Sick Children, Toronto, ON, Canada
Disclosure Block: **B. Lin:** None.
Pseudomonas aeruginosa (*Pa*) is a common pathogen that contributes to progressive Cystic Fibrosis (CF) lung disease. Genetic factors contribute approximately 50% to 85% of the variation in age of chronic *Pa* infection in CF individuals but remain unknown. We conducted a genome-wide association study of genetic modifiers for the age of first and chronic *Pa* infection in Canadian individuals with CF. Our primary analysis on 1,037 individuals identified two novel genome-wide significant loci, *rs62369766* (near *FGF10* on Chromosome 5; *P* value=1.78E-8) and *rs927553* (*SPATA13* on Chromosome 13; *P* value=1.72E-8), for chronic *Pa* infection age. Through a phenome-wide association study of *rs62369766* and *rs927553* in population-based databases, we observed their association with lung function and immunological phenotypes, respectively in non-CF cohorts. We further investigated the genetic overlap between chronic *Pa* infection age and lung function in CF through a polygenic risk score (PRS), defined in the largest GWAS of CF lung disease to date (n=6,365). CF lung function has a moderate phenotypic correlation with chronic *Pa* infection age (Pearson correlation coefficient=0.12, *P* value=2E-4). The PRS constructed from ~8,000 SNPs associated with CF lung function is significantly associated with chronic *Pa* infections age (*P* value = 0.006), supporting the presumption that targeting some genetic factors associated with lung function will delay the onset of chronic infections. Our study identifies novel loci potentially modifying the age of chronic *Pa* infections in CF, and provides new insights into the genetic basis of *Pseudomonas aeruginosa* infections.

PrgmNr 2816 - Aberrant levels of CXCL16 in severe COVID19 patients

View session detail

Author Block: **S. Smieszek**; Vanda Pharmaceuticals, DC, DC
Disclosure Block: **S. Smieszek:** None.
Genome-wide association studies have recently identified 3p21.31, encompassing the *CXCR6* gene, as one of the strongest thus far reported susceptibility loci for hospitalized COVID-19 (rs73064425, OR=2.14, discovery p=4.77 Ã 10^{-30} Pairo-Castineira et al., 2020). Nakanishi et al., reported that risk allele carriers experienced an increased risk of COVID-19 related mortality/ complications: severe respiratory failure (odds ratio [OR] 2.0, 95%CI 1.6-2.6), venous thromboembolism (OR 1.7, 95% CI 1.2-2.4). CXCL16 is synthesized as a transmembrane molecule that is expressed as a cell surface-bound molecule, and as a soluble chemokine. CXCL16 interacts with CXCR6 promoting chemotaxis or cell adhesion. CXCL16 has been previously implicated in the pathogenesis of lung injury and functions as a chemoattractant for CXCR6+ T cells. The CXCR6/CXCL16 axis mediates homing of T cells to the lungs in disease and hyper-expression is associated with localized cellular injury. To characterize the CXCR6/CXCL16 axis in the pathogenesis of severe COVID-19, plasma concentrations of CXCL16 from 114 hospitalized COVID-19 patients participating in ODYSSEY COVID-19 clinical trial (and 37 controls) were assessed. CXCL16 levels in plasma were determined with ELISA kit (Themofisher). We also obtained samples for WGS analysis as well as for viral genome sequencing. We report a significant difference in plasma CXCL16 between COVID-19 hospitalized cases and controls (p-valueCXCR6 and *CXCL16* was observed in severe COVID-19 compared to mild disease and significant functional polymorphisms in *CXCR6* were linked to viral control. Our current study further supports crucial role of the CXCR6/CXCL16 axis in the immunopathogenesis of severe COVID-19.

PrgmNr 2817 - Adding polygenic risk scores drastically improves the diagnostic accuracy of conventional lab tests for systemic lupus erythematosus

View session detail

Author Block: **C. Khunsriraksakul**[1], Q. Li[2], M. Patrick[3], R. Sauteraud[4], D. J. McGuire[5], B. Li[6], L. C. Tsoi[7], D. J. Liu[8]; [1]Penn State Coll. of Med., Hershey, PA, [2]Univ. of Michigan, Ann Arbor, MI, [3]Univ. of Michigan, Ann Arbor, [4]Penn State Univ., Hershey, PA, [5]Penn State Coll. of Med., Hummelstown, PA, [6]Vanderbilt Univ, Nashville, TN, [7]Univ MICHIGAN, Ann Arbor, MI, [8]Penn State Univ., hershey, PA
Disclosure Block: **C. Khunsriraksakul:** None.
Systemic lupus erythematosus (SLE) is a systemic, remitting, and relapsing autoimmune disease that predominantly affects young women of childbearing age. The treatment option for SLE is rather limited. The diagnosis of SLE is heavily relied on the clinical classification criteria, and traditional lab tests used for SLE lack either sensitivity or specificity. It remains challenging for accurate diagnosis. Importantly, a late diagnosis of SLE is often associated with a worse prognosis (and even fatality), and therefore, accurate early diagnosis and effective intervention are critical for the patients. Here, we explore the benefits of incorporating polygenic risk score (PRS) in conjunction with other clinical features for SLE diagnosis. To create PRS models, we directly utilized the most recent summary statistic from SLE genome-wide association study (GWAS) of 4,943 cases and 8,483 controls (Julia et al., 2018) and further created another joint summary statistic by applying multi-trait analysis of GWAS (MTAG) to summary statistics of SLE and a few other related syndromes (e.g. rheumatoid arthritis, systemic sclerosis). We, then, derived a total of twelve candidate PRS models using six different PRS methods, including SBLUP, LDpred-inf, LDpred-funct, LASSOSUM, PRS-CS-auto, and SBayesR. We tested the validity of each PRS model in Vanderbilt University Biobank (BioVU; N = 49,707 and SLE prevalence = 0.35%). PRS-CS-auto with MTAG joint summary statistics achieve the best area under the curve (0.79) for the receiver operating characteristic curve. We found that individuals with PRS above the 98th percentile confer at least >5x increased risk for SLE compared to the general population. We further investigated the added benefits of PRS, when used in conjunction with routine clinical lab tests for SLE diagnosis (e.g. anti-nuclear antibody (ANA) and anti-dsDNA). Our result indicated that PRS can improve the stratification of patients with certain classical SLE lab results. For individuals that are ANA-positive or anti-dsDNA-negative, PRS further distinguished cases from controls, and thus improved the accuracy of conventional lab tests. Specifically, ANA-positive and anti-dsDNA-negative individuals with PRS above 95th percentile and 90th percentile were 20 and 12 times more likely to have SLE than that with low PRS. Finally, we validated our PRS models in Michigan Genomics Initiative and the results were consistent across all scenarios. We anticipate that genomics-informed precision medicine will facilitate physicians to give a more accurate, confident, and earlier diagnosis of this convoluted and hard-to-diagnose disease lupus.

PrgmNr 2818 - Application of a novel instrument-free and microfluidics-free single-cell analysis technology (PIPseq) that is well suited for viral applications in resource constrained laboratories

View session detail

Author Block: **R. Meltzer**[1], J. Turcinovic[2], J. Connor[2], A. May-Zhang[1], A. Osman[1], S. Kiani[1], K. Fontanez[1]; [1]Fluent BioSci., Watertown, MA, [2]Boston Univ., Boston, MA
Disclosure Block: **R. Meltzer:** Salary/Employment; Fluent BioSciences.
Single cell RNA sequencing (scRNA-seq) has made profound impacts in the study of cellular and molecular diversity in complex tissues. In the study of virology, this resolution of single-cell transcriptional changes in response to viral infection provides valuable insight into the mechanisms of infection and host response. Current scRNA-seq methods are not easily adopted in the virology lab as they are expensive, require complex instrumentation and consumables, and hence can be challenging to implement in a laboratory with limited resources and accessibility. Fluent BioSciences has developed a novel scRNA-seq approach with Pre-templated Instant partitions (PIPseq) that enables the analysis of thousands of cells without requiring complex instrumentation and consumables. The small format and convenient workflow, with the lack of instrumentation, allows PIPseq to be easily implemented in high-containment laboratories. Using a GFP-expressing control virus, we have demonstrated simultaneous capture and barcoding of viral and cellular transcriptomes, identified cellular gene expression shifts in response to viral infection, and identified gene expression responses in non-infected cells from low MOI infected samples compared to mock controls. Furthermore, we have demonstrated that the PIPseq protocol is effective at inactivating residual virus in sequencing library samples, thus enabling convenient sample post-processing outside of the high containment virology laboratory. Overall, we demonstrate that PIPseq is an effective method to study viral-host interactions at a single-cell resolution. The ongoing COVID-19 pandemic exemplifies the need for new tools and methods to elucidate the mechanisms of viral infection, pathogen-host responses, and diversity in cellular responses to infection.

PrgmNr 2819 - Assessing the potential correlation of polymorphisms in the *IL6R* gene with relative IL-6 elevation in severely ill COVID-19 patients

View session detail

Author Block: **A. Kaden**, J. L. Brzezynski, J. A. Shinn, M. M. Gibson, C. Xiao, S. P. Smieszek, C. Polymeropoulos, V. Polymeropoulos, G. Birznieks, M. H. Polymeropoulos; Vanda Pharmaceuticals Inc., Washington, DC
Disclosure Block: **A. Kaden:** Salary/Employment; Vanda Pharmaceuticals Inc..

Elevated levels of interleukin-6 (IL-6) may play an important role in the pathophysiology of COVID-19, yet attenuated responses are not seen across all severe patients. We aimed to determine the effect of baseline IL-6 levels, as well as other clinical variables, on outcomes (including mortality) in hospitalized COVID-19 patients. Additionally, we aimed to explore the genetic variants associated with attenuated IL-6 responses. Blood samples for baseline IL-6 levels and whole genome sequencing (WGS) analyses were collected from hospitalized patients enrolled in ongoing Vanda COVID-19 clinical studies.

We report significantly elevated levels of IL-6 in COVID-19 infected hospitalized patients (n = 100; p In prior literature, several variants including IL6-174 G/C (rs1800795 A), a variant in the promoter of the *IL-6* gene, have been reported to affect IL-6 serum levels. Interestingly, in our study the minor allele seemed to correlate with mortality (n = 150). We also inspected WGS data from our COVID-19 patients for the presence of loss-of-function *IL-6* variants, and we did not report any in this study cohort. Additionally, we tested the association between variants in the *IL-6* IL6R region and IL-6 plasma levels. Linear regression corrected for principal components and covariates identified a strong significant signal driven by the known exonic variant rs2228145 C, previously shown to affect IL-6 serum levels; the minor allele of this variant is associated with higher serum IL-6 levels.

While it is unlikely that a â□□cytokine stormâ□□, where the immune system produces an overabundance of cytokines, is seen in the majority of patients with severe COVID-19, baseline elevations of IL-6 greater than 150 pg/mL may be associated with the worst clinical outcomes and may warrant specialized treatment considerations. So far, no clinical studies have used IL-6 baseline assessments to stratify patient populations. We believe that careful examination and interpretation of IL-6 levels and genetic variants can help determine the patient population with the most likely robust clinical response to IL-6 inhibition.

PrgmNr 2820 - Comparative genetic architecture of the inflammatory bowel disease across East Asian and European populations

View session detail

Author Block: **R. Liu**[1,2], H. Gao[3], M. Li[4], H. Huang[2,1], Z. Liu[3]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA, [3]Ctr. for IBD Res., Dept. of Gastroenterology, Shanghai Tenth Peopleâ□□s Hosp. of Tongji Univ., Shanghai, China, [4]Dept. of Gastroenterology, Third Affiliated Hosp. of Guangzhou Med. Univ., Guangzhou, China

Disclosure Block: **R. Liu:** None.

The inflammatory bowel diseases (IBD) are a group of chronic autoimmune disorders including two major subtypes: Crohnâ□□s disease and ulcerative colitis. The prevalence and incidence of IBD are increasing worldwide, especially in East Asia and other developing countries. Genome-wide association studies have identified over 240 of risk loci for IBD. However, the majority of IBD genetic studies were conducted using subjects of European descent (EUR), limiting the discovery and application of IBD genetics to the rest of the world populations. To address this issue, we conducted a large-scale IBD genetic study in the East Asian populations (EAS) using subjects from China, Japan and Korea, for a total sample size close to 18,000 (CD: 4,323, UC: 3,648, and Control: 10,014). All subjects were genotyped on the Illumina Immunochip or the Asia Screening Array, and have undergone stringent quality controls and imputation. Using this cohort, we found 33 genetic loci associated with IBD beyond genome-wide significance, among which 17 had never been reported in IBD genetic studies in EAS. Two of these new IBD-associated loci in EAS are implicated by coding variants in *RUNX3* (P=2.9e-8) and *ADAP1* (P=2.8e-8). *RUNX3* is a transcription factor playing an important role during the development of T cells and regulating TGFÎ² signaling. Runx3 knockout mice spontaneously develop IBD. *ADAP1* is involved in the BCR Signaling Pathway. We also found a pleiotropic variant (P=1.1e-8), located in the intron of *GTF21*, associated with both IBD and systemic lupus erythematosus. Across the genome, we found common variants underlying IBD genetic risk have similar genetic effects between EAS and EUR ancestries, with a genetic correlation of 0.95. We also found the odds ratios of IBD putative causal variants highly consistent across ancestries (slope: 0.9). Despite the overall consistency and in line with previous reports, we found a few loci showing clearly different genetic effects in EAS vs EUR, including *TNFSF15* and *IL23R*, suggesting gene-environment interactions modifying the genetic risks across populations. Encouraged by the overall consistency of genetic effects across populations, we performed a fixed-effect meta-analysis with the latest European IBD GWAS and identified over 50 new loci associated with IBD. In summary, we have demonstrated the value of including diverse ancestries in IBD genetics research through building and leveraging the largest IBD genetics cohort of non-European ancestry. Through joint and comparative analyses with European IBD GWAS, we have identified over 50 new IBD genetic loci and revealed important insights into the genetic IBD epidemiology across populations.

PrgmNr 2821 - COVID-19 Dynamic pQTLs: Genetic Determinants of Proteins that are Unique to SARS-CoV-2 Infection

View session detail

Author Block: **S. Zhou**[1], T. Nakanishi[1], E. Brunet-Ratnasingham[2], G. Butler-Laporte[3], D. Morrison[1], L. Laurent[1], V. Forgetta[1], V. Mooser[4], D. E. Kaufmann[2], B. Richards[1]; [1]Lady Davis Inst., Jewish Gen. Hosp., McGill Univ., Montreal, QC, Canada, [2]Res. Ctr. of the Ctr. Hosp.ier de lâ□□UniversitÃ© de MontrÃ©al, Montreal, QC, Canada, [3]Lady Davis Inst., Jewish Gen. Hosp., McGill Univ., MontrÃ©al, QC, Canada, [4]McGill Genome Ctr., Montreal, QC, Canada

Disclosure Block: **S. Zhou:** None.

SARS-CoV-2 leads to profound changes in protein abundances. These changes vary widely between samples, suggesting that there are drivers of protein levels that are activated during infection, and these changes may be influenced by the host genome. Identifying these critical control points for changes in levels of these protein targets could lead to new targets for drug development. We therefore performed proteomic GWASs of 4,701 protein targets measured on the SomaLogic platform in two cohorts: 190 COVID-19 European ancestry patients during acute infection stage; and 160 European ancestry individuals who were post-COVID-19 infection or were SARS-CoV-2 PCR negative. We identified pQTLs (p-11) associated with levels during acute COVID-19 infection for 718 proteins, of which 66 were cis-pQTLs. All 66 cis-pQTLs were identified in healthy cohorts. A total of 590 proteins with trans-pQTLs were found only in COVID-19 patients during infection, while absent from proteomic GWAS of SARS-CoV-2 PCR negative individuals or large population cohorts. Among these acute infection de-novo trans-pQTLs, 45 proteins showed differential expression in patients between acute infection and post-infection phases. Some of these proteins, such as IRF9, PLK1 and TMPRSS11A have important roles in immune response. In conclusion, we identified a set of proteins whose genetic determinants might change during acute SARS-CoV-2 infection. Such proteins are likely important control points for the host response to COVID-19.

PrgmNr 2822 - Data-driven analysis exploring age and sex effects on gene expression for dengue hemorrhagic fever

View session detail

Author Block: **L. Rogers**; Univ. of the Virgin Islands, St Thomas, Virgin Islands, U.S.
Disclosure Block: **L. Rogers:** None.
Background: Dengue fever (DF) is a mosquito-borne disease caused by the dengue virus (DENV). DENV is prevalent in tropical/subtropical regions and has four known serotypes. It is also the most pervasive infection transmitted by *Aedes* mosquitoes. Dengue hemorrhagic fever (DHF) is a fatal complication of DENV infection, with hemorrhaging and vascular leakage symptoms. In addition, DHF often occurs because of secondary DENV infections. Our study analyzes pre-existing DF expression data and defines and explores how expression profiles may be affected by sex, age, and DF disease severity.
Methods: We are analyzing pre-existing protein array data from Brazil (12 subjects: 6 severe acute DF; 6 mild acute DF) and corresponding expression data after DF recovery. We use a linear mixed-effects model to investigate multiple study factors, identify differentially expressed genes, and assess disease severity, age, and sex effects on DF. We are also conducting a meta-analysis to determine expression profile differences between dengue-infected and healthy subjects. We are using publicly available gene expression datasets that we are curating from Array Express, Immune Space, and Gene Expression Omnibus (GEO). Our analysis focuses on datasets where the donor's disease state, age, and gender are reported. We are pre-processing the data by performing background correction, data normalization, and batch effect correction. We will also use a linear model to identify differentially expressed genes and explore the effects of our study factors (age, sex, disease state) on DF gene expression profiles.
Results: Our approach will highlight significant gene signatures and pathways associated with DF. Furthermore, we will identify potential gene targets for improving current treatments and exploring genes expressed equally across ages and sex when considering vaccinations for DENV.
Conclusion: Finally, analyzing host systemic responses can help characterize and differentiate between gene expression profiles for non-severe and severe DF.

PrgmNr 2823 - Downregulation of exhausted cytotoxic T cells in gene expression networks of multisystem inflammatory syndrome in children

View session detail

Author Block: **N. Beckmann**[1], P. Comella[1], E. Cheng[1], L. Lepow[1], A. G. Beckmann[1], S. Tyler[1], M. Konstantinos[1], N. Simons[1], G. E. Hoffman[1], N. Disclosure Block: **N. Beckmann:** None.
Multisystem inflammatory syndrome in children (MIS-C) presents with fever, inflammation and pathology of multiple organs in individuals under 21 years of age in the weeks following severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection. Although an autoimmune pathogenesis has been proposed, the genes, pathways and cell types causal to this new disease remain unknown. Here we perform RNA sequencing of blood from patients with MIS-C and controls to find disease-associated genes clustered in a co-expression module annotated to $CD56^{dim}CD57^{+}$ natural killer (NK) cells and exhausted $CD8^{+}$ T cells. A similar transcriptome signature is replicated in an independent cohort of Kawasaki disease (KD), the related condition after which MIS-C was initially named. Probing a probabilistic causal network previously constructed from over 1,000 blood transcriptomes both validates the structure of this module and reveals nine key regulators, including TBX21, a central coordinator of exhausted $CD8^{+}$ T cell differentiation. Together, this unbiased, transcriptome-wide survey implicates downregulation of NK cells and cytotoxic T cell exhaustion in the pathogenesis of MIS-C.

PrgmNr 2824 - Fine-mapping of multiple sclerosis susceptibility loci in a multi-ethnic population

View session detail

Author Block: **A. H. Beecham**[1], L. Gomez[1], S. Caillier[2], C. P. Manrique[1], P. Calabresi[3], K. Fitzgerald[3], N. A. Patsopoulos[4], D. Woo[5], S. Delgado[6], A. Chinea[7], L. Amezcua[8], J. Oksenberg[2], J. L. McCauley[1]; [1]John P. Hussman Inst. for Human Genomics, Univ. of Miami, Miami, FL, [2]Dept. of Neurology, Univ. of California at San Francisco, San Francisco, CA, [3]Dept. of Neurology, Johns Hopkins Univ., Baltimore, MD, [4]Brigham & Women's Hosp, Boston, MA, [5]Dept. of Neurology and Rehabilitation Med., Univ. of Cincinnati Coll. of Med., Cincinnati, OH, [6]Multiple Sclerosis Div., Dept. of Neurology, Univ. of Miami, Miami, FL, [7]San Juan MS Ctr., Guaynabo, PR, [8]Dept. of Neurology, Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA

Disclosure Block: **A.H. Beecham:** None.

Although 200 autosomal genetic variants outside of the Major Histocompatibility Complex (MHC) have been identified for association with multiple sclerosis (MS) risk; minimal work has been done to fine-map surrounding regions and pinpoint causal variants which may have a direct effect on disease pathology. While the discovery effort which identified the 200 MS risk variants included only populations of European ancestry, recent studies have shown substantial replication of risk variants in Hispanics and African Americans. Fine-mapping in genetically diverse populations is advantageous given the lower levels and distinct patterns of linkage disequilibrium (LD). Our goal was to fine-map MS risk loci in populations of African Americans (1676 MS cases, 1511 controls) and Hispanics (2399 MS cases, 2622 controls) who were genotyped on a genome-wide array (Illumina Infinium Multi-Ethnic Global + ImmunoArray-24 v2 BeadChip) with additional customized content for targeted fine-mapping. Preliminary analyses have focused on African Americans. We found statistical replication (one-sided p CD58 on chromosome 1, *CD86* on chromosome 3, and an intergenic region on 16q24.1. In all three regions, the most likely causal configuration included two variants (rs12025416 and rs9651076 for *CD58*, rs73179936 and rs73192176 for *CD86*, and rs79034022 and rs8052618 for 16q24.1), with all but one demonstrating posterior inclusion probabilities (PIP) for causality > 0.98 (rs9651076 PIP = 0.83). The two fine-mapped variants for *CD58* were in LD (R2 > 0.2) with the previously identified risk variant (rs1335532) in both Europeans and Africans; however, the fine-mapped variants for the other two loci were not in LD with previously identified variants. This may be because the fine-mapped variants identified for *CD86* were both rare with minor allele frequency

PrgmNr 2825 - Genetic and expression changes associated with recurrence in the perioperative ileal resection period

View session detail

Author Block: **K. Gettler**; Icahn Sch. of Med. at Mount Sinai, NEW YORK, NY
Disclosure Block: **K. Gettler:** None.
Background: Bulk and single cell RNASeq provide complementary mechanistic insight from direct ex-vivo gut sampling in high priority clinical scenarios. Sampling in the perioperative ileal resection period may provide insight into early pathogenic and protective cells, the impact of steroid and anti-TNF use, and allow for integration with genetics in this severe Crohnâ□□s disease cohort. **Methods:** Ribo-depleted bulk RNASeq was performed using paired-end 150 bp reads of 57-90 (mean 70) million reads from 241 terminal ileum pinch biopsy samples. Reads were mapped using STAR, then tested for differential expression between non-recurrence (Rutgeerts scores 0-1, 159 samples) vs. recurrence (Rutgeertâ□□s scores > 2, 82 samples) and those with or without anti-TNF at the time of post-op colonoscopy using DESeq2. DESeq2 normalized expression values of genes corresponding to 84 genes found in an anti-TNF non-response module defined by single cell RNASeq of resected tissues (Martin et al., Cell 2019) were also used to calculate combined Z-scores for samples showing recurrence vs. non-recurrence. Bulk RNASeq differentially expressed genes onto scRNASeq clusters was performed. **Results:** Z-scores were significantly higher among individuals with Rutgeerts recurrence when comparing expression scores of the anti-TNF nonresponse gene module. DESeq2 identified 7,791 genes differentially expressed between recurrence and non-recurrence, with 4,214 genes more highly expressed with recurrence; in contrast, results comparing anti-TNF use were less significant. Upstream regulators of genes upregulated with recurrence included both pro-inflammatory markers such as lipopolysaccharide (p-value = 2.34E-84) and TNF (p-value = 2.89E-69) as well as the anti-inflammatory steroid dexamethasone (p-value = 1.79E-63), while upstream regulators of downregulated genes included HNF4A (p-value = 2.44E-28) and HNF1A (p-value = 1.60E-10). Projecting up-regulated genes onto scRNASeq clusters shows broad gene induction in inflammatory macrophages and activated fibroblasts. **Conclusions:** We correlate a reported anti-TNF non-response gene module with disease recurrence, despite very few differentially expressed genes based on anti-TNF use. We will present developing results from integration of genetic data, including TWAS and eQTL analyses, further refining cellular and molecular mechanisms.

PrgmNr 2826 - Genome-wide analysis of schizophrenia and multiple sclerosis reveals shared genetic loci outside the major histocompatibility complex

View session detail

Author Block: **M. Ahangari**[1], E. Everest[2], T-H. Nguyen[1], E. Turanli[3], B. P. Riley[4]; [1]Virginia Commonwealth Univ., Richmond, VA, [2]Istanbul Technical Univ., Istanbul, Turkey, [3]NIH, Bethesda, MD, [4]Virginia Commonwealth Univ, Richmond, VA

Disclosure Block: **M. Ahangari:** None.

Epidemiological and clinical studies of schizophrenia suggest immune abnormalities in patients with schizophrenia, and genome-wide association studies (GWAS) show enrichment of schizophrenia signals at enhancers that are active in tissues with important immune functions. In this study, we analyzed the largest available GWAS data of schizophrenia (N= 306,011) and multiple sclerosis (MS) (N=41,505), an autoimmune, neurodegenerative disease of the central nervous system, using causal mixture model (MiXeR), and pleiotropy informed false discovery rate (pleioFDR) framework 1) to evaluate the polygenic overlap between schizophrenia and MS, and 2) to improve statistical power for genetic discovery between these disorders, outside the major histocompatibility complex (MHC). We observed polygenic overlap between schizophrenia and MS, and a substantial genetic enrichment in schizophrenia conditional on association with MS and vice versa. By leveraging this cross-trait enrichment, we identified 25 novel schizophrenia risk loci and 21 novel MS loci at conditional FDR

PrgmNr 2827 - Genome-wide association study of juvenile idiopathic arthritis identifies novel risk loci

View session detail

Author Block: **J. Li**[1], Y. Li[1], J. Glessner[1], M. March[1], H-Q. Qu[1], X. Chang[1], M. Khan[1], P. M. Sleiman[2], H. Hakonarson[1], JIA- CHOP consortium; [1]the Children's Hosp. of Philadelphia, Philadelphia, PA, [2]CHOP, Philadelphia, PA

Disclosure Block: **J. Li:** None.

Juvenile Idiopathic Arthritis (JIA) is the most common type of chronic immune-mediated joint disease among children, which can lead to severe complications. JIA is considered to be a highly heterogeneous group of autoimmune conditions, including seven subtypes based on based on clinical presentations. However, overlap in phenotypic presentations and genetic risk loci, as well as altered gene expression common to JIA subtypes, suggest potential shared molecular mechanism underlying JIA subtypes. Therefore, to identify novel genetic risk loci of JIA, we combined the JIA cases of seven subtypes in our study cohort and did a genome-wide association study (GWAS) including 1245 JIA cases and 9250 age, race and sex matched controls. We further performed meta-analysis with a similar combined JIA cohort in GWAS catalog (LÃ³pez-Isac E., Ann Rheum Dis. 2020), which is composed of 3305 patients and 9196 healthy controls. In the meta-analysis, we identified four genome-wide significant novel loci. Functional annotation indicates that these loci overlap with chromatin modification marks, enhancer, promoter regions in immune cell types. The candidate target genes at these loci function in immune regulation. Experimental studies are underway to examine the transcriptional regulation of candidate genes by the noncoding GWAS variants at these loci.

PrgmNr 2828 - Genomic surveillance of SARS-CoV-2 variants for the center of disease control using full viral genome sequencing in 12,000 confirmed patient saliva specimens

Disclosure Block: **S. Nahas:** None.
Introduction: To date in the U.S., >30 million COVID-19 cases (~600K deaths) have been confirmed. Genetic variations are known to increase transmission and pathogenicity. The CDC contracted with diagnostic labs to sequence samples across the U.S. The purpose is to perform routine analysis of genetic sequence data to enable the CDC and its public health partners to identify and characterize variant viruses, either new ones identified or those already identified abroad, to investigate how variants impact disease severity and the effectiveness of vaccines and treatment. Infinity Biologix LLC (IBX), was awarded one of these contracts. We sought to highlight the results, from viral genomic sequencing of the first ~12,000 previously confirmed positive COVID-19 patients collected from saliva and interrogate correlations of cycle thresholds (Ct) with genomic sequencing success rates. Methods: Positive RNA patient samples, confirmed with the IBX TaqPath SARS-CoV-2 Assay (EUA200090), were selected for sequencing usingâ¯an N Gene CT value cutoff ofâ¯

PrgmNr 2829 - Identification of miR-eQTLs from small RNA Seq in Children with Asthma

Author Block: **A. Tiwari**[1], J. Hecker[1], J. Li[2], A. Kho[3,4], J. CeledÃ³n[5], S. T. Weiss[6], K. G. Tantisira[6,7], M. J. McGeachie[6]; [1]Brigham and Women's Hosp. and Harvard Med. Sch., Boston, Massachusetts, BROOKLINE, MA, [2]Res. Ctr., The Seventh Affiliated Hosp. of Sun Yat-Sen Univ., Shenzhen 518107, China, Shenzen, China, [3]Brigham and Women's Hosp. and Harvard Med. Sch. ,Boston, Massachusetts, BROOKLINE, MA, [4]Computational Hlth.Informatics Program, Boston Children's Hosp., Brookline, MA, [5]Div. of Pediatric Pulmonary Med., UPMC Childrenâ□□s Hosp. of Pittsburgh, Univ. of Pittsburgh, Pittsburgh, PA, USA, Pittsburgh, PA, [6]Brigham & Women's Hosp, Boston, MA, [7]Div. of Pediatric Respiratory Med., Univ. of California San Diego, San Diego, CA, USA, San Diego, CA
Disclosure Block: **A. Tiwari:** None.
Introduction: MiRNAs are increasingly identified as mediators in biological pathways related to asthma and other inflammatory diseases. Identifying genotypes associated with miRNA expression (miR-eQTLs) can assist in understanding the role of microRNA as a mediator in the development of complex traits by providing insights into transcriptional regulation of the microRNAs themselves. **Objective:** The purpose of this study was to identify microRNA expression quantitative trait loci (miR-eQTL) and their association with asthma. **Methods:** We performed small RNA sequencing on 1159 serum samples from the Genetics of Asthma in Costa Rica Study (GACRS), a cross-sectional study of children from of Costa Rica with physician-diagnosed asthma. Small RNA-seq libraries were prepared using the Norgen Biotek Small RNA Lib Prep Kit and sequenced with Illumina NextSeq 500. The exceRpt pipeline was employed for QC, alignment, and annotation of the small RNA-seq data. Whole-genome sequence (WGS) data was available through the TOPMed program. Variant calls were obtained from TOPMed data freeze 8 variant call format files aligned to the GRCh38 genome reference. In our analyses, we included only biallelic SNPs with a minimal depth of coverage of 10 reads that were marked as PASS in the VCF FILTER column. The Matrix eQTL package was used to conduct both cis- and trans- association analysis for each genetic variant passing quality control with each robustly expressed miRNA. Cis- and trans- associations with an FDR **Results:** 1054 GACRS samples passed QC for both miRNA sequencing and WGS. Serum-derived miRNA expression levels of 318 mature miRNAs and 5,734,792 genetic variants passed quality control metrics. We found 25 unique genome variants acting as cis-eQTLs to 36 miRs with p-values ranging from 1.81E-51 to7.19E-06 and 3 miRs with significant trans-eQTLs (p-values 2.79E-13 to 3.15E-11). Among the significant cis-eQTL-miR pairs was rs10175383 located within the primary sequence of hsa-miR-3679, providing a potential mechanism of effect. One miR, hsa-miR-4433b-5p, was previously associated with asthma exacerbations (p-value 0.002), while five cis-eQTL variants were associated with asthma-related phenotypes in the GACRS (p **Conclusion:** We identified a substantial number of miRNAs that are controlled by cis genetic regulatory elements. Our genome-wide miR-eQTL mapping study provides new insights into the genetic regulation of miRNA transcription and the roles of miRNAs using sequencing data, showing that cis-eQTLs may be biologically active variants in asthma.

PrgmNr 2830 - The Genetics of The Antibody Response to Human Adenovirus infection in Healthy Individuals

Disclosure Block: **C. Valencia:** None.
Mastadenovirus is a viral genus that infect mammals and includes the human adenovirus (HAdv) species that encompasses 7 subgroups with more than 67 serotypes. HAdvs can cause epidemic outbreaks in children, elderly and immunocompromised individuals, however, currently there is no vaccine for these group of individuals. HAdvs can infect different cell types and cause lytic, latent and oncogenic infections. Genetically modified HAdv are also use as vectors for gene therapy, however, pre-existing immunity in patients can limit their use. There is variability in the Immunoglobulin G (IgG) reactivity to the HAdvs capsid proteins, however the genetic contribution to the serum IgG response of HAdv infection remains unknown. Previous studies identified genetic variants in the Human Leukocyte Antigen (HLA) locus associated with IgG levels against Epstein Barr virus, Rubella, and Human polyomavirus. We evaluated the genetics of the antibody response against 52 prevalent HAdvs peptides in a group of 478 European and 147 African ancestry healthy individuals included in the NIH Vaccine Research Center (VRC) study. The mean age was 34 years, and 56% were female. Phage Immunoprecipitaition Sequencing â□□PhIP-seqâ□□ was performed, scaled and dichotomized to classify the samples as positive or negative for reactivity to each peptide. We interrogated 7,331,696 imputed variants across the genome with each of the 52 HAdvs peptides using the penalized quasi-likelihood (PQL) approximation to the GLMM implemented in the R package Genesis. Integrating epitope level antibody reactivity with genetic variation we identified genetic association in the HLA Class II genes with 4 peptides. These peptides are from the minor capsid protein VIII and the core-associated proteins V and VII. The two VIII peptides (amino acids 1-56) represented the same B cell epitope and are from HAdv 48 and HAdv B serotype 3. The other two peptides are from HAdv 55 and correspond to protein V (amino acids 168 - 224) and protein VII (amino acids 141 - 192). HLA fine-mapping identified that the alleles *HLA-DQB1*06:02* (OR=3.79, p=1.85e-8) and *HLA-DRB1*15:01* (OR=3.28, p=7.54e-8) were associated with the antibody reactivity against the minor capsid protein VIII. Conditional analysis for this epitope found an additional association with *HLA-DRB1*11*. In summary, to our knowledge this is the first study that supports the evidence of genetic association of the HLA class-II locus with the IgG antibody response to HAdv infection.

PrgmNr 2831 - Comprehensive genetic screening for variants associated with spermatogenic failure

Disclosure Block: **J. Hardy:** None.

Despite significant progress in male infertility research in mouse, no standard clinical genetic assay exists for comprehensively evaluating idiopathic spermatogenic failure (SPGF) in humans. In an effort to establish a clinical test for the routine identification of pathogenic mutations, we assessed genomic variants found in severe forms of SPGF: azoospermia (absence of sperm in the ejaculate) and severe oligozoospermia (TEX11 or novel hemizygous/homozygous losses (e.g. exons 2-8 of *STK11*). Additionally, 20 nonsynonymous, potentially pathogenic SNVs were identified through both sporadic and familial WES studies (n=60). Importantly, a significant proportion of these gene candidates are known to play a role in meiosis (e.g. *BRDT, MEI1, MEIOB, SYCP2,* and *TEX15*). Notably, we were able to detect mosaic chromosomal aneuploidies (e.g. XXY) missed by traditional karyotyping. Our data clearly demonstrates the utility of comprehensive genomic analysis in clinical genetic testing, elucidating molecular etiologies of SPGF at a significantly higher detection rate than existing clinical practice (i.e. aneuploidy and Y chromosome microdeletions). We are currently in process of evaluating the efficiency of an experimentally derived test of more than 150 genes responsible for non-obstructive male infertility with the aim of establishing a single comprehensive clinical genomic screening assay.

PrgmNr 2833 - Glucocorticoid Regulated KCNA5 Mediates Cell Cycle in Fetal Membranes

View session detail

Author Block: **S. J. Cunningham**, T. Allen, L. Feng, T. E. Reddy; Duke Univ., Durham, NC
Disclosure Block: **S.J. Cunningham:** None.
Preterm Premature Rupture of Membranes (PPROM) is a pregnancy complication in which the chorion and amnion weaken and rupture in prior to 37 weeks of pregnancy and before contractions have begun. PPROM results in 30-40% of preterm birth cases and is closely linked to maternal psychological stress. To study the response to glucocorticoid signaling in primary amnion cells, cells from 10 patients were treated with a glucocorticoid receptor agonist and a subset of cells we challenged with Tumor Necrosis Factor Î± in addition. This was repeated with glucocorticoid receptor knocked down and a control siRNA treatment. From this analysis, KCNA5 emerged as a potential GR up-regulated gene with evidence from the literature of having an effect on cell turnover. KCNA5 was directly knocked down in primary amnion epithelial cells from 12 additional patients. KCNA5 knock down and control cells were compared in assays of proliferation and apoptosis. KCNA5 knockdown significantly increased proliferation but seemingly has no effect on apoptosis. To understand to role of increases in KCNA5 expression, KCNA5 was over-expressed in HEK293T cells using a lentiviral system. Over the course of pregnancy, elevated glucocorticoid signaling could increase expression of KCNA5, decreasing proliferation in the amnion epithelium which could lead to membrane weakening and ultimately PPROM.

PrgmNr 2834 - Reprograming human fibroblasts into Sertoli cells: a tool for personalized medicine

View session detail

Disclosure Block: **A. Parivesh:** None.
Disorders/Differences of Sex Development (DSD) are congenital conditions in which development of chromosomal, gonadal, or anatomical sex is atypical. These achieve poor clinical or research diagnostic outcomes using biochemical assays or *in vitro* cellular/animal model validation of pathogenic variants discovered through DNA sequencing/mapping. The current DSD diagnostic regimen can be augmented by investigating transcriptome/proteome *in vivo*, but it is marred by unavailability of affected gonadal tissue at the disease relevant developmental stage. We try to mitigate this limitation by reprogramming readily available skin tissue derived dermal fibroblasts into Sertoli cells (SC), which could then be deployed for different diagnostic strategies. SCs form the target cell type of choice because they act like organizing center of embryonic gonadal development and many DSD arise when these developmental processes go awry.We employed a computational predictive algorithm for cell conversions called Mogrify to predict the transcription factors (TFs) required for direct reprogramming of human dermal fibroblasts into SCs. We established trans-differentiation culture conditions where stable transgenic expression of these TFs was achieved in 46, XY adult dermal fibroblasts using lentiviral vectors. The resulting Sertoli like cells (SLCs) were validated for SC phenotype using several approaches. These cells exhibited Sertoli like morphological and biophysical properties distinct from fibroblasts as revealed by morphometry and xCelligence assays. They also showed Sertoli-specific expression of molecular markers such as SOX9, PTGDS, BMP4, or DMRT1 as revealed by IF imaging, RNAseq and qPCR. The SLC transcriptome shared ~69% of its differentially expressed genes (DEGs) with a human adult SC transcriptome when compared with fibroblast transcriptome. These cells additionally lacked expression of markers of other gonadal cell types such as Leydig, germ, peritubular myoid or granulosa cells.The trans-differentiation method was applied to a variety of commercially available 46, XY fibroblasts derived from patients with DSD and to normal 46,XX. The resulting cells displayed varying levels of trans-differentiation in comparison to normal 46, XY derived SLCs as estimated by morphological and molecular phenotypes as well as affected molecular pathways, thus showcasing the robustness of this new trans-differentiation model

PrgmNr 2835 - The identification of disease complication risk via disease-disease network: an application to obstetric disorders in the UK Biobank

View session detail

Author Block: **V. Sriram**[1], Y. Nam[2], S. Lee[3], A. Verma[2], D. Kim[2]; [1]The Univ. of Pennsylvania, Philadelphia, PA, [2]Univ. of Pennsylvania, Philadelphia, PA, [3]Seoul Natl. Univ. Coll. of Med., Seoul, Korea, Republic of

Disclosure Block: **V. Sriram:** None.

Recent studies have shown that women with pregnancy-related disorders are at risk for a variety of long-term complications. However, the underlying pathophysiology of these associations remains undetermined, and it is unclear how much of a role is played by genetics. Thus, the interactions between obstetric diseases and subsequent phenotypes suggest that a network-based view that incorporates knowledge of other diseases and genetic associations will enable us to uncover the exact basis of pregnancy-related disease complications. A disease-disease network (DDN), where nodes represent diseases and edges represent commonalities between diseases such as shared SNPs, can be used to evaluate genetic correlations between phenotypes. By applying graph-based semi-supervised learning (GSSL), an approach for topology-based label propagation, potential shared genetic associations between obstetric disorders and their disease complications can be identified. We constructed a SNP-based DDN from UK Biobank (UKBB) PheWAS summary data, which included 232 phenotypes for 27,193 imputed variants. To select the most appropriate obstetric phenotypes for GSSL analysis, we applied case count and weighted degree thresholds. A minimum case count of 500 was used to ensure sufficient statistical power for the PheWAS summary results. Then, phenotypes were sorted according to normalized weighted degree in order to select those that shared the highest number of SNPs with other phenotypes. The final obstetric disorders we considered included hemorrhage during pregnancy, early labor, placenta previa, antepartum hemorrhage, and hemorrhage in early pregnancy. For each obstetric phenotype under consideration, we assigned a â□□+1â□□ label to the disease and performed GSSL label propagation. The results of our complication risk prediction for placenta previa and subsequent phenotypes yield AUCs ranging from 0.604 to 0.678 when compared to clinical co-occurrences derived from UKBB electronic health records, suggesting that genetic associations play varying roles in disease complications. This current result suggests that our methodology holds promise as a clinical tool for the identification of possible genetic drivers for the development of disease complications.

PrgmNr 2836 - Genome-wide association study and gene-based analysis of participants with hemophilia A and inhibitors in the My Life Our Future study

View session detail

Author Block: **S. Lessard**[1], C. He[2], D. Rajpal[1], K. Klinger[1], C. Loh[3,4], T. Harris[4,5], J. Dumont[6];

Disclosure Block: **S. Lessard:** Major Stockholder/Ownership Interest; Sanofi. Salary/Employment; Sanofi.
Up to 30% of people with hemophilia A (PwHA) develop factor VIII (FVIII) inhibitors, the most serious complication of hemophilia A treatment, as factor replacement is made ineffective. The mechanism of inhibitor development is poorly understood. The My Life Our Future (MLOF) repository gathered *F8* and *F9* gene mutation information, phenotypic data, and biological material from >11,000 PwHA and hemophilia B enrolled at US hemophilia treatment centers from 2012 to 2018, including >5000 whole-genome sequences (WGS). Identifying inhibitor-associated genes may contribute to understanding why patients develop inhibitors.
We performed a genome-wide association study of inhibitor and gene-based analyses to identify inhibitor-associated genes in male PwHA from the MLOF repository. Those of reported active inhibitors and prescribed bypassing agents or immune tolerance induction or with a history of inhibitors were included (>5 Bethesda units at peak were considered high-titer inhibitors). Non-inhibitor PwHA were defined as controls (no history of inhibitors or evidence of active inhibitors). Those of unknown inhibitor status were excluded. We performed discovery association analyses (single variant and gene-based) in participants of European ancestry and attempted to replicate significant findings in those of African and Hispanic ancestry.
We identified a genome-wide significant association with 6:32438468_CA/C (P=4Ã□10^{-8}), located near *HLA-DRA* in the human leukocyte antigen (HLA) locus, in PwHA with *F8* intronic inversions. Low resolution WGS-based HLA typing showed independent associations with HLA alleles HLA DRB1*15:01 and DQB1*03:03 post Bonferroni correction. Variant aggregation tests identified low-frequency coding variants (minor allele frequency GRID2IP, encoding the GRID2-interacting protein, that were significantly associated with high-titer inhibitors in participants of European ancestry (P=7Ã□10^{-7}). We replicated this finding in participants of African ancestry (P=0.008).
Our study confirms association of DRB1*15:01 with FVIII inhibitors and reveals a novel association with HLA-DQB1*03:03 in PwHA with intronic inversions of *F8*. The results also implicate *GRID2IP* with the presence of inhibitors, suggesting a new role of this gene in autoimmunity.

Disclosure Block: **D. Brown:** None.

Myelofibrosis (MF) is a rare myeloproliferative neoplasm (MPN) characterized by bone marrow fibrosis, progressive bone marrow failure, and increased risk of acute myeloid leukemia. While myelofibrosis arises from somatic driver mutations in *JAK2*, *MPL*, and *CALR*, previous work on MPNs suggests a heritable component. To comprehensively examine the genetic etiology of MF, we performed the first integrative analysis of SNP array genotyping (using Infinium Global Screening Array), and telomere length (TL, using qPCR assay). Somatic mosaic chromosomal alterations (mCAs) were called with MoChA using raw genotyping intensity data to detect allelic imbalances. The study included 937 patients who received hematopoietic cell transplant for MF between 2000 and 2016 and who had an available pre-HCT blood sample at the Center for International Blood and Marrow Transplant Research Repository. GWAS of 827 European MF cases and 4,135 genetically-matched controls identified six independent loci at genome-wide significance (P-8); four of which replicate prior MPN susceptibility loci [9p24.1(*JAK2*), 5p15.33(*TERT*), 3q25.33(*IFT80*), and 4q24(*TET2*)] and two novel MF loci [6p21.35(*HLA-DQB1-AS1*) and 17p13.1(*TP53*)]. A transcriptome-wide association study using whole blood GTEx data highlighted the 9p24.1 locus with increased *JAK2* expression associated with elevated risk of MF (P= 2.18Ã□10^{-19}). A strong statistical colocalization further indicated shared genetic etiology between eQTL and this *JAK2* locus (HyPrColoc Posterior Probability= 0.6). Utilizing available clinical mutation data on a subset of 185 patients, MF cases carrying the risk haplotype of the 9p24.1(*JAK2*) susceptibility locus were observed to more frequently have the $JAK2^{V617F}$ mutation (P= 0.02). Detectable autosomal mCAs were abundant in MF cases with 67.4% having at least one mCA (compared to ~3% in the general population) and 27.6% having an mCA spanning *JAK2* (mostly copy number neutral loss of heterozygosity (CNLOH)). In addition, a *cis* relationship was identified at 9p24.1 in which the MF risk haplotype was predominantly duplicated by CNLOH (binomial P=1.36Ã□10^{-9}). Finally, we observed an inverse association between autosomal mCAs and telomere length (OR= 0.22, 95% CI= 0.07-0.65, P= 6.40Ã□10^{-3}). Our results suggest a molecular framework for the genetic etiology of MF in which germline variation at *JAK2* predisposes to the acquisition of a somatic $JAK2^{V617F}$ mutation and subsequent duplication of $JAK2^{V617F}$ by mCAs (usually CNLOH). This process leads to aberrant *JAK2* activity and increased clonal proliferation, exhausting telomere length and increasing genomic instability in MF patients.

Introduction: Chronic traumatic encephalopathy (CTE) is a neurodegenerative tauopathy associated with repetitive head impact (RHI) exposure. Variation in the *MAPT* gene, which encodes the tau protein, is associated with other tauopathies, but its role in CTE remains unclear. The 17q21 region, including *MAPT,* contains a megabase-long inversion polymorphism (H1/H2, unique to European ancestry) and many copy number variations, including Î±, Î² and Î³ segments, which determine various structural subhaplotypes. *Boettger et al.* previously showed that these structural subhaplotypes can be imputed with SNPs from a genome-wide array and a reference haplotype panel. Here, we imputed 17q21 structural haplotypes and tested their associations with CTE neuropathological endophenotypes. **Methods:** 144 men with European ancestry and RHI exposure (117 neuropathologically-confirmed CTE cases and 27 controls) were genotyped on 4,739 SNPs across the *MAPT* region. Using the *Boettger et al.* reference haplotype panel, SHAPEIT and IMPUTE2, 12 biallelic surrogate markers for H1/H2, Î±/Î²/Î³ segments and 5 common subhaplotypes (H1Î²1Î³1, H1Î²1Î³2, H1Î²1Î³3, and H2Î±2Î³2) were imputed. We tested associations between these haplotypes and CTE endophenotypes [CTE status, CTE stage (0-4) and semi-quantitative measures of tau burden (0-3) in eleven brain regions affected in CTE] in logistic and linear regression models adjusted for age and principal components of population substructure. **Results:** The 12 surrogate markers were well-imputed (imputation quality R^2: 0.57-0.74). The H1 haplotype (freq = 0.85) was not associated with CTE status or stage, but was significantly associated with tau burden in the amygdala in the full sample ($\hat{I}^2$ = 0.32; P = 0.049) and among CTE cases ($\hat{I}^2$ = 0.58; P = 0.002). The H1Î²1Î³1 subhaplotype (freq = 0.37) was significantly associated with tau burden in the amygdala ($\hat{I}^2$ = 0.25; P = 0.049) among the CTE cases. The H1Î²1Î³1 subhaplotype was also significantly associated with CTE stage in the full sample ($\hat{I}^2$ = 0.33; P = 0.03) and among CTE cases ($\hat{I}^2$ = 0.27; P = 0.03). Additionally, among H1 homozygotes, the numbers of Î³ segments, which is physically located at the upstream of the gene KANSL1, had a significant protective effect on CTE stage ($\hat{I}^2$ = -0.41; P = 0.01). **Conclusion:** Imputation of structural haplotypes with the SNP/haplotype reference panel allowed for new insights into the relationship between structural variants in the *MAPT* region and CTE, including a significant association between the H1 haplotype and amygdala tau burden and the H1Î²1Î³1 subhaplotype, CTE stage and amygdala tau burden.

PrgmNr 2839 - Autism spectrum disorder phenotype subset in attention deficit hyperactivity disorder: An analysis of first-tier test results and phenotype spectrum and severity

View session detail

Author Block: **J. J. Kapalanga**[1,2], R. Kamran[2], T. M. Parikh[1]; [1]Western Univ.GBHS, London, ON, Canada, [2]McMaster Univ., Hamilton, ON, Canada
Disclosure Block: **J.J. Kapalanga:** None.
The autism spectrum disorder (ASD) phenotype is frequently identified in a subset of individuals diagnosed with attention deficit hyperactivity disorder (ADHD). Both ASD and ADHD are highly heritable and share a phenotype distributed across five domains including adaptive malfunctioning, social competence deficits, intellectual deficit/developmental delay, emotional dysregulation, and a history of medical disorders. Individuals with ASD or ADHD can present with a combination of hyperactivity, impulsivity, anxiety, mood issues, developmental delay/cognitive deficits, social dysfunction, gastroesophageal reflux, feeding difficulties during infancy and hypermobility syndrome. **Objectives:** To analyze first tier genetic test results and phenotype spectrum and severity in a cohort of children with an initial diagnosis of ADHD or suspected ASD, aged 6 to 17 years who have been followed for at least 3 years. To compare first tier test results, phenotype spectrum and severity between ADHD and a subset of individuals diagnosed with ASD. **Methods:** 967 children with suspected ADHD and or ASD were referred from the community through primary care providers between January 2010 to December 2020. Children with at least one phenotypic feature from each of five phenotype domains were identified. The eligible children were assessed with instruments used for assessing ASD and/or ADHD. Based on these assessments children were diagnosed as ASD and ADHD. Symptoms were quantified as 1 (mild), 2 (moderate) and 3(severe). Following diagnosis, first tier genetic testing were performed. Multinomial logistic regression models were used to explore the association of phenotype spectrum and phenotype severity, and ASD and ADHD. Multivariate analysis was used to compare phenotype severity and first-tier test results between ASD and ADHD. **Results:** Of the 967 children 397 children fulfilled inclusion criteria. Among the 397, 250 (63%) were male and 147 (37%) were female. Median age at diagnosis for males was 5.8 years and for females, 7 years. Among the 397 children 64 (16%) were diagnosed with ASD and 333 (84%) with ADHD. The overall phenotype severity was .78 (95% CI, 0.81-0.89) for ADHD and .92 (95% CI, 0.82-0.88) for ASD. In the ADHD group 47 (14 %) and in the ASD group 10 (16.2 %) had abnormal first tier test results. **Conclusion**: The findings suggest that ASD and ADHD share a phenotype spectrum, but phenotype severity is significantly greater in ASD. The results of first tier test results were similar for ASD and ADHD with no obvious disorder specific abnormal test result, consistent with findings in previous studies.

PrgmNr 2840 - Brain trans-pQTL analysis of GWAS loci reveals novel link between psychiatric disorders and neurodegenerative diseases

View session detail

Author Block: **T. S. Wingo**[1], S. M. Vattathil[1], E. S. Gerasimov[1], Y. Liu[1], D. A. Bennett[2], N. T. Seyfried[1], A. I. Levey[1], A. P. Wingo[1]; [1]Emory Univ. Sch. of Med., Atlanta, GA, [2]Rush Univ., Chicago, IL
Disclosure Block: **T.S. Wingo:** None.
Background: Many psychiatric disorders and neurodegenerative diseases have shared symptomatology and genetic basis. GWAS of each of these brain illnesses identified multiple genetic loci associated with each illness; however, how these loci confer disease risk remains unclear. Here, we hypothesize that some genetic risk is explained by influences on brain protein expression. To test this hypothesis, we examined whether GWAS loci were associated with either proximally or distally encoded proteins in the human brain. Identified proteins were then tested for evidence of causality, and finally, results were combined to identify shared proteins linking psychiatric disorders and neurodegenerative diseases.
Methods: The following brain illnesses were considered: Alzheimer's disease (AD), frontotemporal dementia, amyotrophic lateral sclerosis, Parkinson's disease (PD), insomnia, depression, schizophrenia, anxiety disorders, bipolar disorder, post-traumatic stress disorder, problematic alcohol use, and neuroticism. Independent GWAS signals from these conditions were identified and tested for association with brain proteins in a discovery dataset (N=503) of human brain proteomes. Significant results from the discovery analysis were followed-up in an independent replication dataset (N=135) of human brain proteomes. Next, proteins with consistent associations were further examined using summary data-based Mendelian randomization and HEIDI to test for evidence of causality/pleiotropy and exclude associations likely due to linkage disequilibrium, respectively. Results were combined across all conditions to examine for evidence of shared proteins or convergence of physical protein-protein interaction using direct interaction data from BioGRID database.
Results: Among the GWAS significant loci, we identified 19 pairs of trans-pQTLs and the distal protein it regulates in AD, PD, schizophrenia, alcohol problematic use, neuroticism, and depression. Fifteen pairs showed evidence that the protein mediates the association between the GWAS SNP and disease after Mendelian randomization and HEIDI. We found that these 15 proteins had evidence of substantial protein-protein interactions. We also found evidence linking AD, neuroticism, and depression by syntaxins, syntaxin-binding proteins and secretory membrane proteins.
Conclusion: These networks of interacting proteins reveal novel links and biological insights between psychiatric and neurodegenerative diseases.

Disclosure Block: **A. Tucci:** None.
Background: Estimation of heritability of Alzheimerâ□□s Disease (AD) ranges from 49-79%, but the conventional single nucleotide variants (SNVs) identified to date account for Method: To accelerate the discovery of genetic traits of AD, the Alzheimerâ□□s Disease Sequencing Project (ADSP) sequenced whole genomes of AD cases and cognitively normal controls from multiple ethnic groups. Leveraging this large-scale Whole Genome Sequence (WGS) collection, we conducted AD genetic association analyses across a full spectrum of CNVs (small or large, common or rare, and coding or non-coding in genomic regions). We developed a bioinformatics pipeline consisting of four steps. First, we applied three CNV calling algorithms, CNVnator, JAX-CNV, and Smoove, on each sample. Results from each tool were then merged by Svimmer. Second, we employed GraphTyper for genotyping. GraphTyper is a graph-pangenome-based method that may mitigate bias of human references. Third, we resolved issues of multiple CNVs overlapping in a region with bedtools, which is a requirement for working with most association study tools. Finally, with the CNV callsets, we performed genome-wide association analyses on common and rare CNVs to identify CNV regions that contribute to AD. For common CNVs, we defined CNV regions (CNVRs) using a density-threshold trimming procedure (as defined in CNVRuler) and conducted CNVR-based analysis. For rare CNVs, we preformed chromosome-wide CNV collapsing tests. In all association analyses, we adjusted for age, sex, APOE e4 dose and race-ethnicity status.
Result: The ADSP dataset consists of 1,737 AD cases and 2,063 cognitively normal controls. For each sample, we identified an average of 7,959 CNVs by three algorithms. After merging CNVs of all samples, we obtained 56,316 deletions and 16,390 duplications for GraphTyper joint genotyping. For common association analysis, there were ~30 CNVRs significantly associated with AD at genome-wide significance level. Rare CNV collapsing tests revealed a significant signal on 17p13, and rare CNV burden tests showed signals on chromosomes 1 and 5. Further validations of those CNVs are under process.
Conclusion: We developed a scalable CNV detection pipeline and applied it to 3,800 ADSP WGS samples. The preliminary results of the association study validate some known AD, dementia, and dystonia genes. To the best of our knowledge, this is the first large-scale CNV investigation of AD using WGS data.

Background: AD is the most frequent neurodegenerative disease with a strong genetic component. GWAS studies have identified numerous associated loci, but have been focused only on the autosomes. We aimed to identify functional rare variants on X-Chromosome (Chr), which contribute to the AD risk using the whole exome sequencing (WES) of a multi-ethnic AD sample. **Methods:** We analyzed X-Chr data from the WES Release 2 dataset in the ADSP, which were jointly-called across 9 multiethnic datasets of 11,460 non-Hispanic White (NHW), 4,108 African American, and 2,159 Hispanic samples. Variants on X-Chr of 8,789 AD cases and 9,613 controls were quality-controlled (QC) within each source of dataset (i.e. subset) and capture kit and were functionally annotated using Variant Effect Predictor (VEP). After QC, 494 nonsynonymous variants with severe pathogenicity prediction and presence in more than two subsets were selected and further analyzed within each sex and ethnic group. A study-wide significance threshold was assigned at $1.01x10^{-4}$ (= 0.05 / 494). We performed AD association tests using logistic regression, accounting for age, relationship matrix, principal components for population substructure, and subsets. Phenomic impact in carriers of selected variants was examined using Geno2MP database. **Results:** In the 6,908 NHW women (3,684 cases / 3,224 controls), we identified one study-wide significant association with AD at rs73227155 (minor allele counts = 84, OR = 2.61, P = $8.3x10^{-5}$), which was present across all subsets. Rs73227155 is a rare, missense variant located in MTMR8 (allele frequency in non-Finish Europeans from gnomAD = 0.006) and predicted to be deleterious by SIFT in VEP. However, rs73227155 was not associated with AD in the 4,552 NHW men (2,580 cases / 1,972 controls; OR = 1.25, P = 0.27) and other ethnic samples (P > 0.05). No other significant variant was found across other ethnicities in sex-specific manner. From the meta-analysis across sexes and ethnic groups, we did not identify other significant associations. From Geno2MP, we found 80 carriers of the minor allele of rs73227155 or their relatives, and 30 subjects out of 80 expressed phenotypic abnormalities in nervous system including intellectual disability, cerebellar hypoplasia, and autism. **Conclusion:** We identified one highly functional rare missense variant, rs73227155, in *MTMR8*, on X-Chr among the NHW women. MTMR8 functions in autophagy in neuronal cells for removing lipids and amyloids. Replication studies will use independent subjects from an AD GWAS sample after TOPMed-imputation in AD Genetics Consortium (ADGC) and Whole Genome Sequencing of ~17,000 multiethnic sample in ADSP.

PrgmNr 2843 - Genetic Variant, rs2304672, in 5â UTR region in *hPER2* gene and its association to Parasomnias and other sleep disorders in Puerto Rico

View session detail

Author Block: **G. Pagan**; Univ. de Puerto Rico, Recinto de Mayaguez, Mayaguez, PR
Disclosure Block: **G. Pagan:** None.
Sleeping is one of the main physiological processes of cellular and physiological restoration. Inadequate sleep patterns can impede adequate systemic restoration and can lead to the development of chronic health conditions. In 2014, both World Health Organization and the Central Disease Control in the United States categorized inadequate sleep patterns as a public health crisis. Both entities majorly agree that, approximately 40 percent of the general population suffers from sleep disorders, with 60 percent of these opt for medication to induce sleep. Researchers from Epidemiologist suggest that a series of external factors, have been theorized to contribute to lack in sleep quality. Including high levels of stress, sounds, and light quality. Alternatively, there has been a limitation regarding studying internal factors affecting sleep quality and sleep behavior. Parasomnia is an abnormal sleep behavior in any of the five sleep stages characterized by sleep walking, sleep talking, bedwetting, nightmare disorders, and sleep paralysis principally. To date, little is known about this sleep abnormality and its origins. In this study, we referenced data from the 1000 Genome Project to study the genetic variant, rs2304672, of the *hPER2* gene in Puerto Rico, whose general population houses the highest percentage of the variant in all the Americaâs. Provided data suggests that this genetic variant is linked to poor sleep quality and parasomnias. In Puerto Rico, modern demographics evidence that the population is comprised of three main ethnic groups. We theorize that a bottleneck effect is an influential factor in the distribution and prevalence of said genetic variant in the island. Our results found that the genetic variant is common in the southwestern and southeastern coastal regions of Puerto Rico. Additionally, we found that the genetic variant frequency in the entire island is of approximately 4 percent in the general population of Puerto Rico.

Objective: Stroke is the second leading cause of death worldwide. Our previous study (Li, J 2021 Neurology Genetics) identified pathway-specific polygenic risk scores (PRS)s associated with ischemic stroke (IS). The goal of this study is to determine whether these disease-related PRSs are also associated with overall survival post-IS and to develop PRS-based mortality prediction models. Methods: 1756 patients with acute IS and European ancestry were identified by leveraging Electronic Health Records and chart review confirmation. The cohort was split into discovery (n=1226) and replication (n=530) with up to 3-year post-IS observation. PRS derived from previously identified gene sets of Gene Ontology (GO) Biological Process was used to stratify the cohort. Univariate Cox proportional hazards (Coxph) regression analysis was used for primary screening of prognostic PRSs. Only the significantly associated PRSs were used to construct a multivariate Coxph model. PRS selection was conducted by LASSO penalized cox regression model from the training cohort. The selected PRSs and their coefficients were applied to the testing cohort. Results: Using all common or low-frequency variants (0.01

PrgmNr 2845 - Replicating genetic associations in Alzheimer's Disease using data from Eisai's BAN2401 ABBA 201 clinical trial

View session detail

Author Block: **F. Tao**, C. Zhang, A. A. Mitchell, M. Nagle, J. E. Hutz; Eisai Ctr. for Genetics Guided Dementia Discovery, Cambridge, MA
Disclosure Block: **F. Tao:** Salary/Employment; Eisai Inc..
Introduction: Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by memory loss and cognitive impairment. ABBA 201 is a randomized, controlled clinical trial to determine whether BAN2401, an anti-amyloid Î² antibody, can slow the progression of early AD. Over 800 amyloid positive subjects with mild cognitive impairment or early AD (Mini-Mental State Exam MMSE >= 22) participated in the clinical trial, and 665 subjects consented to participate in exploratory genetic research. The aim of the genetic study is to replicate or further characterize known genetic associations in AD phenotypes. **Methods:** DNA samples from 665 participants (335 males, 330 females) were genotyped using Illumina Infinium Multi-Ethnic Global-8 v1.0 BeadChip. The clean dataset after standard quality control includes 47 million genotyped and imputed variants in 641 European-ancestry individuals. Variants in about 90 genes previously reported in AD were selected for analysis. Phenotypes data include age at onset (AAO) of AD, baseline cognitive scores and laboratory tests. Genetic association analysis was performed in PLINK v1.9, adjusting for age, sex, and top five principal components. *APOE* E4 carrier status, a known AD risk variant, was intended to serve as a positive control to confirm its effect through genome-wide analysis, and therefore was not included as a covariate. Other relevant factors such as disease duration were included as covariates in the analysis as appropriate. **Results:** The genetic analyses validated two previously known AD-associated loci: (1) *APOE* was confirmed as the strongest locus in association with AAO of AD (beta = -2.4 years, P = 5.5E-7 for APOE E4 allele, which consists of rs429358-C and rs7412-C). Rs429358 is associated with AAO with beta = -2.5 years and P = 3.2E-7. Rs7412 is not associated with AAO (P=0.29). (2) We found a suggestive association signal in the *FCER1G* gene on chromosome 1 with AD Composite Score (ADCOMS) (beta = -0.06, P = 7.2E-6 for top SNP rs1136207 T allele). The top SNP rs1136207 was also associated with Clinical Dementia Rating - sum of boxes (CDR-SB) (beta = -0.47, P = 1.8E-5). Genetic association in the *ADAMTS4*/*FCER1G* locus was previously reported in the AD GWAS by Jansen *et al.* (PMID 30617256). In addition to *FCER1G*, other candidate genes in this region include *NDUFS2*, *ADAMTS4*, *TOMM40L*, and *APOA*. **Conclusions:** This study confirms that *APOE* E4 is associated with earlier AAO of AD. We also replicated the association of the *ADAMTS4*/*FCER1G* locus previously reported in AD GWAS. Further study will expand the scope to genome-wide association analysis to identify potential novel genetic associations in AD phenotypes.

PrgmNr 2846 - Severity of dementia ratings in Hispanic Latinos as a function of country of origin and APOE

View session detail

Author Block: **P. Mena**[1], A. Zaman[1], M. Prough[1], S. Tejada[1], M. Contreras[1], L. D. Adams[2], C. Silva[3], M. Illanes-Manrique[4], M. R. Cornejo-Olivas[5], B. Feliciano[6], J. M. Vance[1], M. A. Pericak-Vance[7], M. L. Cuccaro[8]; [1]Univ. of Miami, Miami, FL, [2]Univ Miami, Miami, FL, [3]Univ. Central del Caribe, Bayamon, Puerto Rico, [4]Neurogenetics Res. Ctr., Inst. Natl. de Ciencias NeurolÃ³gicas, Lima, Peru, [5]Inst. Natl. de Ciencias Neurologicas, Lima, Lima, Peru, [6]PRADI, UCC, SJB Sch. of Med., Caguas, PR, [7]Miami, FL, [8]Univ Miami Sch Med, Miami, FL

Disclosure Block: **P. Mena:** None.

Background: Hispanic Latinos are underrepresented in Alzheimer disease (AD) research. As a group, Hispanic Latinos are culturally and genetically diverse. A source of diversity is country of origin which confers differences in symptoms as well as sociocultural and genetic backgrounds. While differences in symptoms may arise from genetic background, sociocultural differences may affect reporting of symptoms in different countries. For this study we investigated the relationship of country of origin and *APOE* genotype to dementia severity ratings in a multi-country of origin dataset. We hypothesize that there will be differences in severity related to country of origin. **Methods:** Participants (N=353) whose countries of origin were Puerto Rico (N=242), Cuba (N=29), and Peru (N=83) were drawn from genetic studies of AD in Hispanic Latino populations. Participants underwent standard clinical assessments that included the Clinical Dementia Rating scale (CDR). We restricted participants to those with CDR scores of $\geq$0.5. The CDR box score sum (CDR-sb; 0-18) was used as an outcome measure; sex, *APOE* (*e*4 present/*e*4 absent), age at onset (AAO), age at exam (AAE), and country of origin were predictors. We tested the association of these predictors to CDR-sb using linear regression. **Results:** Our sample was 67% female with a mean AAE of 77.8 (sd=9.4) years and mean AAO was 72.6 (sd=9.6); 42% had an *e*4 allele. The mean CDR-sb was 9.4 (sd=6.0). Our linear regression showed that compared to Puerto Ricans, Cubans had lower CDR-sb scores (B= -3.65, p B=1.82, p = 0.008). We also found that AAE was positively associated with CDR-sb (B=0.51, pB=-0.33, p B=0.04, p=0.95) or APOE (B=0.89, p = 0.12) were significant predictors of CDR-sb scores. **Discussion:** Our results showed that country of origin was a significant predictor of dementia severity ratings with Peruvians having the highest score and Cubans the lowest. Not surprisingly lower age at onset and greater age at exam were significant contributors to ratings of dementia severity. However, the presence of *APOE e*4 did not contribute significantly to dementia severity ratings. Given that ratings of dementia severity are used to classify participants for genetic studies of AD/dementia it is critical to understand the role of sociocultural influences on these ratings in studies that enroll participants from different countries. Future studies should investigate population specific sociocultural and genetic contributions to dementia severity ratings and harmonize measures such as the CDR across populations.

PrgmNr 2847 - SnRNA-seq probing of the differential vulnerability of motor neurons in ALS

View session detail

Author Block: **P. Alipour**[1,2], J. Ross[1,2], D. Rochefort[1,2], P. Dion[1,2], G. A. Rouleau[1,2,3]; [1]Montreal Neurological Inst., and Hosp., McGill Univ., Montreal, QC, Canada, [2]Dept. of Human Genetics, McGill Univ., Montreal, QC, Canada, [3]Dept. of Neurology and Neurosurgery, McGill Univ., Montreal, QC, Canada

Disclosure Block: **P. Alipour:** None.

Background: selective vulnerability of some neuronal subpopulations is a common feature of neurodegenerative disorders. While upper and lower MNs degenerate in Amyotrophic Lateral sclerosis (ALS) ocular motor neurons including oculomotor nucleus (CNIII) seem to be largely spared. Diverse CNS cell types may contribute differently to neurodegeneration and are differentially vulnerable. Utilizing a single-nucleus RNA sequencing (snRNA-seq) method we aim to compare transcriptomic profile of differentially vulnerable regions to identify intrinsic properties of oculomotor nucleus that would be absent in medulla in ALS. Methods: Post-mortem CNS tissues from 5 ALS cases and 4 normal controls were obtained from the Douglas-Bell Canada Brain Bank, McGill university. Nuclei isolation was performed according to the Nagy et al. Following nuclei isolation, library preparations, sequencing, and Cellranger analyses were performed as per established protocol by 10X Genomics. Following the reception of the expression matrix, nuclei were analyzed in the single-cell analysis R package, Seurat. After quality control and clustering, the differentially gene expression was performed to compare oculomotor nucleus vs medulla in ALS patients. Results: clustering of 92K nuclei revealed 23 cell types. Endothelial cell and astrocytes are the only major cell types under-represented in the ALS samples. The majority of DEGs in oculomotor nucleus attribute to astrocytes and oligodendrocytes precursor cells (OPCs), while in the medulla the majority of DEGs attribute to neurons, astrocytes and OPCs. Glial cells show divergent signature in medulla vs oculomotor; while in oculomotor OPCs are involved in pathway indicating activation of the proteasome and phagosome system in response to proteinopathy in medulla OPCs are mostly enriched in antigen processing and presentation including major histocompatibility complex class I (MHC-I); microglia subpopulation signature in medulla represents Disease Associated Microglia (DAM) which is associated with reactive microglia. Conclusion: Based on the observation we made thus far, it appears that glial cells are active in the two ALS regions examined here but top DEGs identified in oculomotor do not reveal neurotoxic pathways but are rather associated with the maintenance of cell homeostasis. Given the neuronal dysregulation observed in oculomotor nucleus from ALS cases is minimum, by comparison to what is seen in medulla region, it is presumed that glial cells might be more supportive in this region and better deal with cellular stress of the disease.

PrgmNr 2848 - The influence of *APOE e*4 and global ancestry on self-reported anxiety and depression in Hispanic, Non-Hispanic Whites, and African Americans

View session detail

Author Block: **A. Zaman**[1], F. Rajabli[1], P. Mena[1], L. D. Adams[1], M. Contreras[1], F. Lacroix[1], S. Tejada[1], C. Silva-Vergara[2], M. Illanes-Manrique[3], J. Welch[1], M. R. Central del Caribe, Bayamon, PR, [3]Inst. Natl. de Ciencias Neurologicas, Lima, Peru, [4]Maya Angelou Ctr. for Hlth.Equity, Winston-Salem, NC, [5]Case Western Reserve Univ., Cleveland, OH
Disclosure Block: **A. Zaman:** None.
Background: Anxiety (Ax) and Depression (Dp) co-occur with Alzheimer disease (AD) and are associated with a worse prognosis. There are limited data regarding the relationship between ancestry and race/ethnicity differences in Ax and Dp in AD. For this study we compared the prevalence of Ax and Dp and their association with global ancestry, self-reported race/ethnicity, *APOE e*4 presence, and phenotype [cognitively normal (CN), mild cognitive impairment (MCI), and AD]. Based on prior work we hypothesize that regardless of phenotype, Hispanics (HI), will have the highest prevalence of Ax and Dp followed by African Americans (AA) and Non-Hispanic Whites (NHW). Given that NHWs are predominantly of European (EU) ancestry we predict that EU ancestry will be negatively associated with Ax and Dp.
Methods: We identified 3597 older adults (mean age=74.2 Â± 9.0) from a study of AD genetics. Race/ethnicity were self-reported (HI=790; AA=481, NHW=2326). To estimate admixture proportion for each individual, we performed model-based clustering using ADMIXTURE software. *APOE* genotyping was performed as in Saunders (1996). Ax and Dp status (yes/no) were based on participant/family member report. Participants were classified as AD (n = 955), MCI (n = 514), or CN (n = 2128) by consensus diagnosis. A logistic regression examined Ax and Dp prevalence across race/ethnic groups (HI, AA, NHW), global ancestry [EU, African (AF), American Indian (AI)], *APOE e*4 presence, sex, age, and phenotype (AD, MCI, CN).
Results: Compared to NHW, HI had an increased prevalence of both Ax (p p 1) compared to EU ancestry, AF ancestry was associated with a lower prevalence of Ax (p = 0.001) and Dp (p = 0.015), while AI ancestry was only associated a lower prevalence of Ax (p 2) age was negatively associated with the prevalence of Ax (p p 3) compared to CN individuals, those with AD and MCI had a higher prevalence of Ax and Dp and females had a higher prevalence of Ax and Dp. *APOE e*4 was not associated with Ax or Dp.
Conclusion: The prevalence of Ax and Dp was greater in AA and HI compared to NHW while, at the same time, higher proportions of EU ancestry were associated with a greater prevalence of Ax and Dp. These novel results highlight the different contributions of self-reported race/ethnicity (e.g., sociocultural influences) and ancestry (e.g., genetic background) to neuropsychiatric phenotypes in AD. Moving forward, we need to explore how these contributions can inform the evaluation and treatment of Ax and Dp in underrepresented populations with AD to reduce the burden of these disorders.

PrgmNr 2849 - Two Genetic Variants Explain the Association of European Ancestry with Multiple Sclerosis Risk in African-Americans

Disclosure Block: **N.J. Nakatsuka:** None.

Epidemiological studies have suggested differences in the rate of multiple sclerosis (MS) in individuals of European ancestry compared to African ancestry, motivating genetic scans to identify genetic factors that could contribute to such patterns. In a whole-genome scan in 899 African-American cases and 1,155 African-American controls, we confirm that African-Americans who inherit segments of the genome of European ancestry at a chromosome 1 locus are at increased risk for MS [logarithm of odds (LOD) = 9.8], although the signal weakens when adding an additional 406 cases, reflecting heterogeneity in the two sets of cases [logarithm of odds (LOD) = 2.7]. The association in the 899 individuals can be fully explained by two variants previously associated with MS in European ancestry individuals. These variants tag a MS susceptibility haplotype associated with decreased *CD58* gene expression (odds ratio of 1.37; frequency of 84% in Europeans and 22% in West Africans for the tagging variant) as well as another haplotype near the *FCRL3* gene (odds ratio of 1.07; frequency of 49% in Europeans and 8% in West Africans). Controlling for all other genetic and environmental factors, the two variants predict a 1.44-fold higher rate of MS in European-Americans compared to African-Americans.@font-face {font-family:'Cambria Math'; panose-1:2 4 5 3 5 4 6 3 2 4; mso-font-charset:0; mso-generic-font-family:roman; mso-font-pitch:variable; mso-font-signature:-536870145 1107305727 0 0 415 0;}p.MsoNormal, li.MsoNormal, div.MsoNormal {mso-style-unhide:no; mso-style-qformat:yes; mso-style-parent:''; margin:0in; margin-bottom:.0001pt; mso-pagination:widow-orphan; font-size:12.0pt; font-family:'Times New Roman',serif; mso-fareast-font-family:'Times New Roman';}.MsoChpDefault {mso-style-type:export-only; mso-default-props:yes; font-family:'Cambria',serif; mso-ascii-font-family:Cambria; mso-ascii-theme-font:minor-latin; mso-fareast-font-family:'MS Mincho'; mso-fareast-theme-font:minor-fareast; mso-hansi-font-family:Cambria; mso-hansi-theme-font:minor-latin; mso-bidi-font-family:'Times New Roman'; mso-bidi-theme-font:minor-bidi;}div.WordSection1 {page:WordSection1;}

PrgmNr 2850 - Two-trait integrative analysis of de novo mutations in autism spectrum disorder and developmental disorders identifies shared CNS processes and epigenomic functions

View session detail

Author Block: **M. Kealhofer**[1], B. P. Riley[2], T-H. Nguyen[3]; [1]Virginia Commonwealth Univ. Sch. of Med., Richmond, VA, [2]Virginia Commonwealth Univ, Richmond, VA, [3]Virginia Commonwealth Univ., Richmond, VA

Disclosure Block: **M. Kealhofer:** None.

Exome studies of autism spectrum disorder (ASD) and other developmental disorders (DD) have implicated *de novo* mutations (DNMs) in overlapping genes and pathways. ASD and DD also share comorbidities, including intellectual disability and childhood onset seizures. In this analysis, we aim to use a two-trait analytic approach to increase statistical power for gene discovery based on the shared genetic etiology of ASD and DD. We jointly analyzed exome variants identified from 6,430 ASD trios and 31,058 trios with severe DD using a Bayesian integrative analysis method, mTADA (multi-trait transmission and de novo association test). We identified 164 ASD risk genes and 302 DD risk genes using a cutoff of 80% on their respective posterior probabilities. Among the ASD risk genes identified, 93 had not previously been implicated in single-trait analyses of this sample, although some were implicated in other ASD studies. Similarly, among the DD risk genes identified, 79 had not been identified in previous single-trait analyses. Among these genes, 153 were identified as being risk genes for both ASD and DD using the same posterior probability threshold. KEGG pathway analysis of these shared risk genes identified 20 enriched pathways after multiple test correction, including overlapping pathways for dopaminergic (p

PrgmNr 2852 - Assortative mating drives pathogenicity of variably expressive CNVs

View session detail

Author Block: **C. Smolen**[1], M. C. Jensen[1], L. Pizzo[1], A. Tyryshkina[1], V. Pounraja[1], L. Dyer[2], J. S. Juusola[2], 16p12.1 Consortium, S. Giririjan[1]; [1]Pennsylvania State Univ., University Park, PA, [2]GeneDx, Gaithersburg, MD
Disclosure Block: **C. Smolen:** None.
Many disease-associated copy-number variants (CNVs) are variably expressive, conferring risk for a range of neurodevelopmental and psychiatric features. For example, the developmental delay-associated 16p12.1 deletion is inherited in >90% of cases from a parent with mild features. We previously found that affected children were more likely to carry rare variants elsewhere in the genome compared to parents with the deletion, suggesting that the phenotypic variability observed in deletion carriers is driven by combinatorial effects with variants in the genetic background. We performed detailed phenotyping and whole genome sequencing of 125 families with the deletion to identify factors contributing to variable expressivity. The burden of secondary variants in probands was strongly associated with family history of neuropsychiatric phenotypes, likely due to increased transmission from non-carrier parents. We hypothesized that this increase in genetic burden and phenotypic severity may be driven by assortative mating, a form of non-random mating among individuals with similar genotypes or phenotypes. We found that 41/59 carrier and 29/65 non-carrier parents manifested neuropsychiatric features, and identified significant correlations between specific traits in pairs of parents. For example, individuals with depression or anxiety were more likely to pair with other individuals with similar phenotypes (OR=11, FDR=0.041). To further examine the role of assortative mating in driving phenotypic heterogeneity, we assessed genetic similarity (kinship coefficients) of 16p12.1 parents, and compared the results to parents from the Simons Simplex Collection (SSC) and Searchlight cohorts. Parental pairs in 16p12.1 cohorts had significantly higher kinship coefficients than random pairs within the cohort, and the degree of assortative mating was about three times higher compared to the SSC cohort (16p12.1 AUC: 0.141, SSC AUC: 0.051). This increase in kinship was not seen in families with autism-associated 16p11.2 CNVs, which mostly occur de novo. We further assessed parental kinship values in a larger set of 367 affected individuals carrying 21 disease-associated CNVs, and found higher kinship values for families with variably-expressive CNVs, such as 1q21.1 and 16p13.11 CNVs, compared to syndromic CNVs such as Smith-Magenis syndrome (p=0.033). Kinship values were also higher for families with inherited CNVs than de novo CNVs (p=0.014). These results suggest that assortative mating contributes to interactions between variably-expressive CNVs and additional variants in the genetic background to modulate the ultimate phenotypic trajectories.

PrgmNr 2853 - Clinical value of adding copy number, tandem repeat and antipsychotics metabolizer status analysis to diagnostic sequencing of patients with psychotic disorders

View session detail

Disclosure Block: **A. Alkelai:** None.

Background: Schizophrenia has a multifactorial etiology, involving a polygenic architecture. The potential yield of whole genome sequencing (WGS) in schizophrenia and other psychotic disorders is not well studied. Moreover, the benefit of different types of genome analyses is not systematically investigated. **Methods:** We investigated the yield of WGS analysis of single nucleotide variants (SNVs) or small insertions or deletions (indels) in 251 families with a proband diagnosed with psychotic disorder, by systematically applying the American College of Medical Genetics and Genomics (ACMG) criteria for categorization of variants. In addition, we used WGS data to analyze copy number variants (CNVs) and tandem repeats and determined antipsychotic metabolizer status by *CYP2D6* genotype data according to recommendations from the clinical pharmacogenetics implementation consortium. **Results:** The total diagnostic rate was 6.4%. We found clinically significant single nucleotide variants or indels in 14 families (5.6%) and CNVs in 2 families (0.8%). We did not detect any significant tandem repeats in patients with psychotic disorders. In addition, we were able to provide *CYP2D6* genotypes for most participants and determine their antipsychotic metabolizer status. 21.9% of our probands were found to be ultrarapid, intermediate or poor metabolizers, thus could potentially benefit from *CYP2D6* genotyping. **Discussion:** Taken together, the benefit of performing copy number and tandem repeats analyses using WGS data of patients diagnosed with psychotic disorders is very low. However, patients can potentially benefit from *CYP2D6* genotyping analysis. Yet, in order to provide actionable recommendations based on this data, integration of clinical information is required.

PrgmNr 2854 - Contribution of copy number variants to schizophrenia in East Asian populations

View session detail

Huang[4]; [1]Stanley Ctr. for Psychiatric Res., Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Dept. of Psychiatry, Massachusetts Gen. Hosp., Harvard Med. Sch., Boston, Boston, MA, [3]The Ctr. for Applied Genomics, The Hosp. for Sick Children, Peter Gilgan Ctr. for Res. and Learning, Toronto, Toronto, ON, Canada, [4]Boston, MA, [5]UC San Diego, La Jolla, CA, [6]Harvard Med. Sch., Malden, MA

Disclosure Block: **Q. Feng:** None.

Schizophrenia is a chronic and severe mental disorder affecting approximately 1% of worldwide populations, with East Asians contributing the largest patient number. Recent studies have established an important role for copy number variants (CNVs) in the etiology of schizophrenia using individuals of European descent. However, to date, the extent to which CNVs contribute to schizophrenia in other continental ancestries is unclear. Here, we report findings from the largest CNV study outside of European ancestry, using subjects of East Asian ancestries from Japan, Korea, mainland China, Taiwan, Singapore and Indonesia. Stage 1 of this analyses included 12,056 schizophrenia cases and 12,978 controls. After extensive quality control harmonising datasets across various arrays, we observed a significant enrichment of genome-wide rare CNV burden (length >500kb, frequency

PrgmNr 2855 - Dissecting Biological Pathways of Psychopathology using Cognitive Genomics

Author Block: **M. Lam**[1], C-Y. Chen[2], R. Tian[3], H. Huang[4], H. Runz[5], T. Ge[6], T. Lencz[7]; [1]The Broad Inst., Cambridge, MA, [2]Biogen, Cambridge, MA, [3]Malden, MA, [4]Boston, MA, [5]Biogen Inc., Cambridge, MA, [6]Harvard Med. Sch., Malden, MA, [7]Zucker Hillside Hosp., Glen Oaks, NY
Disclosure Block: **M. Lam:** None.
Cognitive deficits are known to be related to most forms of psychopathology. Recent work in the psychiatric and cognitive genomics literature indicated that pleiotropic associations between cognitive dimensions and psychiatric traits could further illuminate putative underlying biological mechanisms. Here, we perform local genetic correlations as means of identifying independent segments of the genome that might show biologically interpretable pleiotropic associations between cognitive dimensions and psychopathology. We utilized GWAS summary statistics for two major cognitive dimensions: *General Cognitive Ability (GCA)* and *Non-Cognitive Skills (*NCS*)*; the former indexes â□□*g*â□□ while the latter is derived from Educational Attainment after removing variance related to â□□*g*â□□. Applying local genetic correlation analysis, we were able to identify collective segments of the genome, defined as â□□meta-loci,â□□ that showed differential pleiotropic patterns for GCA and NCS against psychopathological. These meta-loci offer higher resolution and greater interpretability of the shared genetic architecture between cognitive dimensions and psychopathology as compared to global genetic correlations. Functional annotation and gene set analyses revealed a broad distinction between meta-loci associating psychopathology to GCA as compared to NCS, extending our prior work in schizophrenia: neurodevelopmental pathways predominated in GCA-relevant meta-loci, while synaptic pathways were more involved in NCS-relevant meta-loci. Driver genes related to GCA were found to be expressed during the prenatal-early childhood phase whereas those implicated with NCS were expressed in later childhood, young adulthood and beyond. Most notably, we found that many genes whose protein products were identified as presently druggable for psychiatric and nootropic indications were found within NCS meta-loci. These genes were predominantly within the GABA-ergic receptor, glutamate, and cholinergic family of genes.

PrgmNr 2856 - Enrichment of the VNTR *PER3* variant in DSWPD patients: A large whole genome sequencing analysis

View session detail

Author Block: **J. Brzezynski**, A. R. Kaden, J. A. Shinn, J. Wang, C. Xiao, S. P. Smieszek, C. Polymeropoulos, G. Birznieks, M. H. Polymeropoulos; Vanda Pharmaceuticals Inc., Washington, DC
Disclosure Block: **J. Brzezynski:** Salary/Employment; Vanda Pharmaceuticals Inc..
We have conducted a rigorous observational research study in suspected delayed sleep-wake phase disorder (DSWPD) patients. The objective was to measure sleep-wake patterns and to conduct exploratory genetic analyses to delineate the genetic landscape of the DSWPD phenotype.
We measured the sleep-wake patterns (self-reported bed time, wake time, midpoint of sleep, and sleep latency) of participants by daily post-sleep diaries for 10 weeks. Participants completed questionnaires on demographics, medical and surgical history, sleep history, and concomitant medications. Altogether, 119 participants were consented and 76 participants provided samples for whole genome sequencing. Seventy-eight participants were females and the mean age was 44 years. Principal component analysis defined ancestry as 29.3% AFR, 17.3% AMR, and 53.4% EUR.
We observed a significant enrichment of the minisatellite 54bp (1: 7829913-7829966 (GRCh38)) variable number of tandem repeat (VNTR) *PER3* rs57875989 4 allele. We observed significantly higher frequencies of the 4/4 variant, 59.2% when compared to the super control population frequency of 42.2% (n = 315; recessive: OR 1.9, CI 1.07 to 3.65, p This variant is of particular interest as it is located in the coding region of VNTR (exon 18). Functionally, *PER3* is phosphorylated by casein kinase 1 (CK1) and translocates to the nucleus to inhibit CLOCK/BMAL1 in the presence of *PER1*. The VNTR motif contains clusters of potential phosphorylation sites for CK1. Given the VNTR *PER3* variant could change protein phosphorylation levels in addition to tertiary protein structure and also have interactions with binding partners, it is hypothesized that the VNTR would cause functional changes in *PER3*. The observed accumulation of the *PER3* VNTR 4/4 supports prior literature describing evening-types and DSWPD patients as having greater frequencies of $PER3^{4/4}$ homozygotes; this effect can be as high as 75% homozygotes in DSWPD.
These results demonstrate that, on average, DSWPD individuals are more likely to harbor variants within their core clock genes with particular enrichment of the VNTR variant, potentially leading to a pronounced delay in sleep period. This variant can further impact the response to treatment across carriers of the 4/4.

PrgmNr 2857 - Extracellular vesicles: A window into the etiology of major depressive disorder

Disclosure Block: **P. Ibrahim:** None.

Major Depressive Disorder (MDD) is one of the leading causes of disability worldwide, affecting 20% of the population. MDD also confers a 20-fold higher risk of suicide. Environmental factors are thought to play a role in disease development, resulting in biological changes mediated by epigenetic mechanisms. MicroRNAâ□□s (miRNA) are well known epigenetic regulators that are disrupted in the depressed brain, and they are packaged into extracellular vesicles (EVs). EVs have emerged as means of intercellular communication, a process that is also disrupted in MDD. They are thought to transfer miRNA, as well as other bioactive molecules such as proteins, between cells. This can alter gene expression in recipient cells. Different cell types in the brain have been shown to release EVs, so it is possible that EVs might play a role in the pathogenesis of central nervous system disorders, including MDD. Therefore, we hypothesize that EV cargo from the anterior cingulate cortex, a brain region highly implicated in MDD, will have a disease specific profile that could mediate disease development in MDD subjects compared to healthy controls (HC). Our objective is to isolate EVs from human post-mortem anterior cingulate cortex, profile the miRNA and protein cargo, and compare it between MDD subjects and HC. EVs were isolated from post-mortem human brain tissue from the anterior cingulate cortex of 43 MDD subjects and 43 HC using size exclusion chromatography. The quality was assessed by western blots and transmission electron microscopy (TEM). RNA was extracted and a small-RNA library was constructed and sequenced using the Illumina Platform. Proteins were also extracted and profiled using LC-MS/MS. Differential expression analysis was then performed. Western blots showed little to no contamination with cellular debris, along with enrichment of the exosomal marker CD9. TEM images showed the typical cup-shaped morphology with sizes mostly between 30 and 200 nm, and vesicles were labelled with the exosomal marker CD81. Preliminary differential analyses revealed sex-dependent dysregulation in miR-4485-3p, miR-142-5p, miR-33a-5p, miR-132-5p, and miR-92a-3p, as well as in proteomic profiles of the EVs in MDD. In conclusion, this will be the first study to profile brain-derived EV miRNA and protein in the context of depression. Future studies will be needed to determine the effect of the dysregulated EV cargo in MDD. This could provide novel mechanistic insights into the pathophysiology of MDD, which could serve as a starting point for the development of targeted therapeutic strategies as well as prevention measures.

PrgmNr 2858 - Genome-wide genetic susceptibility to pain and depression predicts suicidal thoughts and attempts inschool-agedchildren

View session detail

Author Block: **P. H. Lee**[1,2], A. E. Doyle[1,2], X. Li[1], M. D. Silberstein[1], J-Y. Jung[3], A. Nierenberg[1,2], R. Liu[1,2], R. Kessler[2], R. H. Perlis[1,2], M. Fava[1,2]; [1]Massachusetts Gen. Hosp., Boston, MA, [2]Harvard Med. Sch., Boston, MA, [3]Stanford Univ., Stanford, CA

Disclosure Block: **P.H. Lee:** None.

Background: Suicide is among the leading cause of death in children and adolescents. There are well-known risk factors of suicide, including abuse, family conflicts, social adversity, and psychopathology. While suicide risk is also known to be heritable, few studies have investigated genetic risk in younger individuals.

Methods: Using polygenic risk score (PRS) analysis, we examined whether genetic susceptibility to chronic pain and major depression, two clinical conditions that have been linked to increased suicide risk, is associated with suicidal thoughts and behaviors (STBs) among 11,878 children enrolled in the Adolescent Brain Cognitive Development study (ABCD). The ABCD study represents school-aged children of diverse demographic and socioeconomic backgrounds in the USA, for which a wide range of social, familial, physical, mental, and behavioral aspects have been collected longitudinally since 2016, along with genome-wide genotype data. STBs were assessed using the Kiddie Schedule for Affective Disorder and Schizophrenia (KSADS-5). After performing robust quality control of genotype data, unrelated individuals of European descent were included in analyses (N=4,405). The average age of the children used in the analyses was 9.91 (0.62) years old in the baseline (47.84% female).

Results: Depression PRSs were associated with lifetime suicide attempts reported by children (*OR*=1.49, 95% *CI*=1.11-2.00, *p*-value=$8.65x10^{-3}$), after adjusting for childrenâ□□s sociodemographic backgrounds, family history of suicide, and psychopathology measured using the Child Behavior Checklist (CBCL). The *OR* represents the odds of inclusion in the suicidal group with an increase of one standard deviation change in the PRS. In contrast, pain PRSs were associated with lifetime suicidal ideation (*OR*=1.29, 95% *CI*=1.10-1.51, *p*-value=$9.36x10^{-4}$), suggesting a distinct contribution of the genetic risk underlying pain and depression on suicidal behaviors of children. Association of pain susceptibility was particularly strong for active suicidal thoughts involving specific methods, which remain significant after accounting for childrenâ□□s somatic health complaints.

Conclusion: The largest genetic sample of suicidality data in US children suggests a significant genetic basis of suicidality related to pain and depression. Although the predictive utility of suicide risk factors, including pain and depression PRSs, is still modest, future efforts may benefit from utilizing genetic risk factors when developing proactive screening and early intervention strategies for mitigating suicide risk in children.

Major depressive disorder (MDD) is a serious psychiatric disorder and a leading cause of disability worldwide. Its etiopathophysiology is complex and not well understood. While MDD has a genetic component, it is likely highly polygenic. In order to better understand the complexities surrounding MDD, we carried out a polygenic risk score analysis of 1,171 MDD patients from the Individualized Medicine: Pharmacogenetic Assessment & Clinical Treatment (IMPACT) study. We performed K-means clustering with cluster number ranging from two to five using polygenic risk scores for MDD, bipolar disorder, educational attainment, insomnia, alcohol addiction, maltreatment, impulsivity, loneliness, and post-traumatic stress disorder (JMP v15). We found the two-cluster solution to have the highest Cubic Clustering Criterion. One cluster has higher average polygenic risk scores for impulsivity, alcohol addiction, and loneliness, and lower average scores for MDD, bipolar disorder, educational attainment, and insomnia than the other cluster (p

PrgmNr 2861 - Pathways Implicated in Risk for Suicide Attempts in the Million Veterans Program

View session detail

Author Block: **E. R. Hauser**[1,2], X. J. Qin[3], A. E. Ashley-Koch[4], M. A. Hauser[2], B. H. McMahon[5], J. H. Lindquist[1], R. Madduri[6], J. E. Huffman[7], N. A. Kimbrel[1,2], J. C. Beckham[1,2], and the MVP Suicide Exemplar Workgroup; [1]Durham VA Hlth.Care System, Durham, NC, [2]Duke Univ., Durham, NC, [3]Durham VA Hlth.Care System, Durham, NC, [4]Duke Univ Med Ctr, Durham, NC, [5]Los Alamos Natl. Lab., Los Alamos, NM, [6]Argonne Natl. Lab., Lemont, IL, [7]VA Boston Hlth.care System, Jamaica Plain, MA
Disclosure Block: **E.R. Hauser:** None.
We conducted a genome-wide association study (GWAS) of suicide attempts in the large, multi-ethnic Million Veterans Program (MVP), comparing U.S. veterans with a documented history of suicide attempts (N=14,089) to U.S. veterans with no documented history of suicidal thoughts or behaviors (N=395,359). Analyses were conducted within four populations (European, African American, Asian, and Hispanic) as well as a multi-ethnic meta-analysis. To identify specific biological pathways implicated in risk for suicide attempts, we applied Over-Representation Analysis (Boyle et al. 2004) in the Web-Gestalt package, defining pathways with the KEGG database. Within the multi-ethnic meta-analysis, multiple pathways converged on mood alteration and stress. Most significantly over-represented was oxytocin signaling (FDR $P=1.9x10^{-5}$), which plays a key role in social bonding and feelings of well-beingâ□□disruptions of this pathway could lead to feelings of despair and suicidal behavior. Multiple stress pathways were represented, including cortisol synthesis and secretion, as well as blood pressure regulating pathways (renin secretion, aldosterone synthesis and secretion, and vascular smooth multiple contraction). There is striking consistency across analyses of individual racial groups, with more than half of the 30 pathways implicated in the meta-analysis also significantly over-represented in both Caucasians and African Americans. Pathways significant in all 5 analyses include arrhythmogenic right ventricular cardiomyopathy (ARVC), and phospholipase D signaling. Among the most interesting pathways implicated in individuals with a history of suicide attempts were the circadian entrainment and circadian rhythm pathways. Disruptions of circadian rhythm profoundly affects mood, as CLOCK protein regulates dopaminergic transmission in the ventral tegmental areaâ□□the critical neurological reward circuits. Based on the over-representation of circadian rhythm pathways in the GWAS data, we examined the prevalence of sleep disorders within the MVP GWAS cohort, as defined by the VITAL (VITamins And Lifestyle) questionnaire. Individuals with a history of suicide attempts reported 3.5 (S.D.=2.2) sleep problems, compared with 2.2 (S.D. 2.0) in controls, strongly corroborating the pathway analysis. In summary, while ethnic-specific GWAS identified different genetic variants and loci, pathway analysis across all populations are in broad agreement on the biological factors underlying increased risk of suicide attempts.

Background/Aims: Serious mental illness, including schizophrenia, bipolar disorder, and major depression are heritable, highly multifactorial disorders and major causes of disability worldwide. Polygenic risk scores (PRS) aggregate variants identified from genome-wide association studies (GWAS) into individual-level estimates of liability to disease, and are a promising tool for risk stratification in clinical settings.

Methods: Leveraging the VAâ□□s extensive electronic health record (EHR) and an embedded cohort of 9,378 individuals with confirmed diagnoses of schizophrenia or bipolar I disorder, we validated automated case-control assignments based on ICD-9/10 codes, and benchmarked the performance of current PRS in 660,000 Million Veteran Program (MVP) participants. We explored broader relationships between PRS and 1,700 disease categories and 70 laboratory values via phenome-wide association studies (PheWAS). Given the substantial genetic overlap between neuropsychiatric disorders, we applied genomic structural equation modeling (gSEM) to derive novel PRS indexing common and disorder-specific latent genetic factors.

Results: Among 3,953 and 5,425 individuals with confirmed diagnoses of schizophrenia or bipolar disorder, 95% were correctly identified using ICD-9/10 codes (2 or more), with 25% also meeting criteria for the incorrect diagnosis. Encouragingly, PRS performed best in comparisons of confirmed cases, followed by individuals who had received inpatient treatment, individuals who received any treatment, and persons with spectrum diagnoses. Our PheWAS confirmed previous reports that individuals with higher neuropsychiatric PRS are at elevated risk for a range of psychiatric and physical health problems, and we demonstrate that many of these findings are generalizable to African Americans. In our novel LabWAS, we observed robust, positive associations between schizophrenia PRS and cholesterol levels, white blood cell count, and glomerular filtration rate, and significant negative associations with serum glucose and electrolyte levels.

Conclusions: Using current neuropsychiatric PRS, we have demonstrated the validity of EHR- based phenotyping approaches across diverse US populations. Our PheWAS uncovered novel associations and replicated previously reported relationships between schizophrenia, bipolar disorder, and major depression PRS and a range of clinical traits and outcomes, highlighting the potential of PRS for disentangling biological and mediated pleiotropy.

PrgmNr 2863 - Perspectives on the COVID-19 pandemic: Report from individuals with copy number variations and their caregivers

Background: The world has suffered immeasurably during COVID-19, with concomitant behavioral health problems. University of Pennsylvania (UPenn) investigators reported a 1SD increase in COVID-19 worries associated with a 2-fold increase in generalized anxiety, 67% increase in depression, and an escalation of postpartum depression. The G2MH Network sought to understand how stakeholders affected by copy number variations (CNVs), including 22q11.2, were coping during the pandemic. **Methods:** The UPenn abbreviated COVID-19 Distress Survey was circulated by 22 advocacy groups, including 22q11.2 organizations, in English and 11 other languages. **Results:** 663 people from 26 countries completed the survey. Most respondents were mothers of children with 22q11.2 CNVs. Top worries included: family members acquiring COVID, unknowingly transmitting/personally acquiring COVID, financial pandemic-related burdens, dying from COVID, and currently having COVID. Total COVID-19 distress was higher in individuals completing the survey towards the end of the study (later pandemic wave) and individuals living in urban environments. There were no differences by region, CNV type, respondent type, timing of the survey, sex or age. A significant minority of participants (37%, n=253) reported pandemic realted healthcare interruptions had significant negative effects on their health. A total of 46% (N=305) of participants receiving hospital-based primary care delayed appointments due to COVID-19 fears and over half of participants (n=341) worried about future treatment disruption if the pandemic continued. Medical care disruptions, fears, and avoidance were related to higher COVID-19 distress. **Conclusions:** Effects of the COVID-19 pandemic for rare CNVs were broadly consistent with research results from other patient populations. Long term effects of COVID-19 distress, interruptions to care, and hospital avoidance require further study.

PrgmNr 2864 - Suicide attempts among European ancestry veterans in the Million Veteran Program exhibits correlation with multiple psychiatric conditions

View session detail

Author Block: **X. Qin**; Durham VA Hlth.Care System, Durham, NC
Disclosure Block: **X. Qin:** None.
Background Nearly 800 000 people die due to suicide globally every year, and the rate of suicide among U.S. military veterans is now 1.5 times higher than the rate of suicide among their civilian counterparts. For each adult who died by suicide, there may have been more than 20 others who attempted suicide. There is growing evidence that familial and genetic factors contribute to the risk for suicidal behavior. Moreover, major psychiatric illnesses, including bipolar disorder, major depression, schizophrenia, alcoholism and substance abuse, as well as certain personality traits are associated with suicidal behavior. Calculation of the genetic correlation between suicide attempts (SA) and different phenotypes is an efficient way to understand the genetic pleiotropy that leads to the phenotypic correlations.
Methods: The MVP cohort included 9196 veterans who made a SA and 287577 controls, all of European ancestry (EA). GWAS of SA was conducted using plink, adjusting for age, gender and genetic principle components. Several GWASs in EA for psychiatric illnesses were publicly available in ldhub, Psychiatric Genomics Consortium, as well as NEALE LAB-UKbiobank. For the purpose of this analysis, we examined bipolar, major depressive disorder, PTSD, schizophrenia, insomnia, sleep disorder. The genetic correlation between SA GWAS and psychiatric illnesses GWAS was calculated using LD score regression (LDSC).
Results: Some phenotypes showed strong significant genetic correlation with SA. The genetic correlation with bipolar was 0.38 (p-value=4.5E-09), with MDD was 0.63 (p-value 1.9E-20), with PTSD was 0.57 (p=5.59E-15), with schizophrenia was 0.46 (p=9.23E-16), and with insomnia was 0.096(p=5.7E-03).
Conclusions /Discussion SA among veterans with European ancestry in the MVP cohort exhibits strong genetic correlation with several psychiatric phenotypes that are often comorbid with SA, including MDD, PTSD, schizophrenia and bipolar disease. There is also limited, but significant genetic correlation between SA and sleep disorders. These observations should guide future genetic studies to elucidate the underlying genetic etiology of SA.

PrgmNr 2865 - Whole exome sequencing meta-analysis of depression suggests subtle role for functional variants in known GWAS loci

Major depression (MD) is one of the most prominent causes of morbidity in the modern world and perhaps the single greatest source of years lived with disability, responsible for 7.8% of all disability in the Americas in 2018. In addition to the profound distress and impairment for the individual with MD, the aggregate public health impact is substantial, with the total annual economic burden of major depression in recent years estimated at over $200 billion in the United States. MD is a multifactorial disorder, with well-established risk factors including stressful life events, chronic sleep disturbance, and substance use. There are also genetic influences on MD, as shown by family studies using biometrical models. The availability of large genetic datasets with expansive clinical information has enabled successful analyses of genetic factors in association with MD, but most of these have been conducted on imputed genome-wide array data predominantly in European populations, which may miss lower-frequency and functional variants, or variants in other populations that could contribute to the disorder. We generated a composite phenotype across multiple depression measures in the UK Biobank (UKB) sample, informed by the work of Howard et al. 2019, and Glanville et al. 2021. We also created depression phenotypes with the published eMERGE algorithm in two hospital biobank cohorts, Geisinger Health Systemâ□□s DiscovEHR, and Mount Sinai Hospitalâ□□s Bio*Me* Biobank. We then used these phenotypes across the three datasets to conduct a genetic association analysis in individuals of all ancestral backgrounds on whole exome sequenced and genome-wide imputed data. We find 68 genome-wide significant loci, 25 of which are not previously reported to the authorsâ□□ knowledge, with 7 of these having non-synonymous or splice region variants in strong linkage disequilibrium (LD) with the index variants, including within the genes *TYR* and *TCF4*, and in 7 genes within the major histocompatibility complex (MHC) region; while 12 additional regions have variants that underlie expression quantitative trait loci (eQTL). Notably, as previously reported for other psychiatric disorders such as schizophrenia, we find a strong signal in the MHC region on chromosome 6, a region known for its complex, strong LD patterns. To discern which variants may be most responsible for these associations in the MHC and each other locus genome-wide, we use FINEMAP to prioritize credible sets of potentially casual variants. Our results suggest that functional and low-frequency variants may contribute to MD in addition to common variants of small effect in known genetic association loci.

PrgmNr 2866 - Whole-exome sequencing in the UK Biobank reveals risk gene *SLC2A1* and biological insights for major depressive disorder

Major depressive disorder (MDD) is a common and polygenic psychiatric disorder. Nearly two hundred depression risk loci have been identified by genome-wide association studies (GWAS). However, the impact of rare coding variants on depression remains poorly understood. Here, we present the largest to date exome analysis of depression based on 320,356 UK Biobank participants. We showed that the burden of rare protein-truncating coding variants and damaging missense variants in loss-of-function intolerant genes (pLI>0.9) conferred risk to a range of depression phenotypes as defined by different degrees of diagnostic stringency, with the most prominent effect in electronic health record (EHR)-defined depression (OR=1.17, 95% CI=1.13-1.21, *P*=3.57e-18). Among all depression definitions, we also found the strongest association between damaging missense variant burden and EHR-defined depression risk (OR=1.08, 95% CI=1.05-1.23, *P*=8.52e-6). We performed gene-based protein-truncating and damaging missense variant burden tests across the exome in the EHR-defined cohort (Ncase=10,449; Ncontrol=246,719), and identified *SLC2A1* (*P*=2.96e-07), which exceeded exome-wide significance, and a total of 30 risk genes with false discovery rate (FDR) SLC2A1 (*GLUT1*) encodes glucose transporter and facilitates transport of glucose into the brain cross brain-blood barrier. Mutations of *SLC2A1* impair energy supply for the brain and cause GLUT1 syndrome, characterized by developmental delay. Using human brain expression profiles and 10,271 gene sets (biological process, cellular component and molecular function) from MSigDB v7.2, we replicated known biological pathways of neuron projection development and muscle activities identified in depression GWAS. By jointly analyzing polygenic scores with exome data, we demonstrated additive contributions of common and rare coding variants to depression risk. Finally, we observed elevated genetic risk for depression in genes implicated by exome analyses of developmental disorder, autism and schizophrenia. Our study provides novel insights into the genetic architecture and biology of depression, and the genetic relationships across developmental and psychiatric disorders.

PrgmNr 2867 - A genetic epidemiologic study of myalgic encephalomyelitis (ME)/chronic fatigue syndrome (CFS) identifies links with autoimmune disease and cancer

View session detail

Author Block: **R. Moslehi**[1], A. Kumar[2], A. Dzutsev[3]; [1]Univ. at Albany, State Univ. of New York (SUNY), Albany, NY, [2]Univ. at Albany, SUNY, Albany, NY, [3]Natl. Cancer Inst. (NCI), NIH (NIH), Bethesda, MD
Disclosure Block: **R. Moslehi:** None.
Background: Myalgic encephalomyelitis (ME)/chronic fatigue syndrome (CFS) is a disabling multi-system complex disorder with prevalence of 875 per 100,000 (up to 3.4 million people) in the United States. There are no known etiologic or risk factors and no approved treatments for ME/CFS. We conducted a genetic epidemiologic study in order to test the hypothesis that ME/CFS may be an autoimmune disease (AID), and to explore the link between ME/CFS and cancer, specifically hematologic cancers. Methods: Our clinic-based study involved carefully selected cases with confirmed diagnosis of ME/CFS (n=59) and healthy controls (n=54) frequency matched to cases on age, gender, and ethnicity. During structured interviews, detailed multigeneration pedigrees and answers to an epidemiologic questionnaire were obtained on all subjects. Data analysis involved comparison of cases and controls with respect to the prevalence and cumulative incidence of AID and cancer among their first-degree relatives by calculating risk ratios, 95% confidence intervals (CI) and p values. Odd ratios (OR) were calculated for comparison of epidemiologic factors. Results: The prevalence of AID was significantly higher among first-degree relatives of cases compared to those of controls (OR=5.30; 95%CI: 1.83-15.38; p=0.001). The prevalence of AID among mothers was 14% for cases and 1.9% for controls (p=0.03). 11.2% of first-degree relatives of cases had an AID compared to 3.1% of relatives of controls (prevalence ratio=3.71; 95% CI: 1.74-7.88; p=0.0007); age-adjusted analysis was also significant (p=0.0025). Similar patterns of increased risk among the relatives of cases were found for cancer in general and hematologic cancers specifically. 20% of first-degree relatives of cases had any type of cancer compared to 15.4% of the relatives of controls (p=0.03). The cumulative incidence of hematologic cancers was significantly higher among the relatives of cases (p

PrgmNr 2868 - A multi-model data approach to improve statistics for Metabolite-Variant-Disease (MVD) relationship in SOL dataset

Independent GWAS and MWAS studies have been carried out to better understand the association between phenotype, genetics and metabolites on various sample population with obesity disease, is a complex and heterogeneous disease. We used a novel multi-model data approach via a knowledge graph (ObesityHub) to study the associations of metabolites (M), variants (V), and obesity disease (D), and improve the statistics by using a large ancestrally diverse cohort of Hispanic Americans. The Hispanic Community Health Study / Study of Latinos (HCHS/SOL) is a multi-center epidemiologic study in Hispanic/Latino populations that was conducted between 2008-2011 with study participants aged between 18-74 years. The meta-analysis from GWAS-associations with phenotypes, MWAS-associations with phenotypes, and GWAS-associations with metabolite was carried out and loaded into the existing knowledge graph (KG) in NEO4J, which also has multiple existing knowledge sources e.g., GTex, KEGG. Conducting GWAS or MWAS-associations with phenotypes alone reveals the associations between phenotypes and obesity disease, however, does not provide information about the underlying biological pathway mechanisms. Thus, by applying MWAS- and GWAS-associations with phenotypes and metabolites for the SOL cohort, we leverage the associations between the M, V and D for the same population via a KG. In addition, we were able to leverage the existing knowledge sources to find associations that drive variants and chemical interactions that affect obesity within the SOL population. We performed 3-way Cypher queries between a M, V, D, which we identified as â□□triangleså□□ of associations, based on a threshold of p-value

Epistasis is a mechanism by which the effect of a disease-causing gene mutation is dependent on mutations in one or more other genes, called modifiers. Finding modifier genes is a major challenge in humans as there is a lack of efficient strategies to reach this goal. To counteract this impediment, we developed a novel unbiased pedigree-based strategy to study large French-Canadian families affected by primary open-angle glaucoma (POAG), a highly prevalent and genetically complex disorder of the eye. Using genome-wide linkage studies and deep phenotyping in 156 heterozygotes for the autosomal dominant glaucoma myocilin K423E mutation (*MYOC*^{K423E}), we previously mapped a modiï¬er locus for variability of ages-at-onset (AAO) at chromosome 20q13. The locus is named, here, *MOG1* for *Modifier of Glaucoma 1*. Towards the characterization of the *MOG1* gene, we designed an algorithm that optimizes the identiï¬cation of reliable double-mutants who simultaneously carry the *MYOC*^{K423E} disease mutation and one (1) *MOG1* marker haplotype, or one (1) of its alleles, which is associated with extreme values for AAO. The method is named DIGGI for Double-mutants that participate In Gene-Gene Interactions. DIGGI is a two-stage algorithm that exploits datasets obtained with diverse types of markers that can be coded like microsatellites, VNTRs, SNPs and CNVs. The 1st stage is the identiï¬cation of *MOG1* alleles, or *MOG1* marker haplotypes, associated with the modiï¬er. The 2nd stage is the identiï¬cation of double-mutants who simultaneously carry the primary disease mutation and show higher contrasting ages at onset when compared to the AAO of individuals who are within their neighborhood (kinship coefficient defined as Î¦(X,Y) â¥ 0.0625 meaning that X and Y are people closer or equal to first degree cousins) and carry the K423E myocilin mutation. From our pool of *MYOC*^{K423E} heterozygotes, we will keep for further analysis as double-mutants (i.e., sequencing) only those who are double-mutants at the extremes of the extremes contrast distribution of the AAOs within their neighborhood. Conversely, we will keep as controls, *MYOC*^{K423E} carriers who do not harbour *MOG1* alleles, or *MOG1* marker haplotypes, at these opposite extremes for AAO. Combined with simulation and statistical studies, our data show that this algorithm is reliable as it selects unequivocal double-mutants that participate in gene-gene interactions. In conclusion, we developed and successfully applied to the case of glaucoma modiï¬er gene a powerful strategy to identify family members who share common modifier haplotypes, or modifier alleles, associated with speciï¬c endophenotypes for quantitative traits.

PrgmNr 2870 - Association of Clonal Hematopoiesis with Chronic Obstructive Pulmonary Disease

Background: Chronic obstructive pulmonary disease (COPD) is associated with age and smoking, but other determinants of the disease are incompletely understood. Clonal hematopoiesis of indeterminate potential (CHIP) is a common, age-related state in which somatic mutations in clonal blood populations induce aberrant inflammatory responses. Patients with CHIP have an elevated risk for cardiovascular disease, but the association with COPD remains unclear. **Methods:** We analyzed whole-genome and exome sequencing data to detect the presence of CHIP in 48,835 subjects, of whom 8,444 had moderate-to-very-severe COPD. Cases of CHIP were defined based on somatic mutations detected using the sequencing data that are in a pre-specified list of variants predicted or reported to be pathogenic and drivers of myeloid malignancies. The subjects were selected from four separate cohorts with COPD phenotyping and smoking history, including COPDGene, additional TOPMed cohorts, ICGN-EOCOPD study, and UK Biobank. We applied logistic regression and generalized linear mixed effect models to COPD status adjusting for age, gender, sequencing center, number of pack-years, smoking status, and genetic ancestry. Random-effects meta-analyses were conducted to combine the cohorts. As *TET2* was commonly mutated in hematopoietic cells, we measured emphysema in murine models in which *Tet2* was deleted in hematopoietic cells and performed single cell RNA-sequencing in lung tissues of the Tet2-wildtype and Te2-knockout mice. **Results:** In COPDGene, individuals with CHIP had a risk of moderate-to-severe and severe or very severe COPD 1.6 and 2.2 times greater than non-carriers, respectively (adjusted 95% confidence intervals [CI], 1.1 to 2.2 and 1.5 to 3.2). These findings were consistently observed in three additional cohorts and meta-analyses of all subjects. CHIP was also associated with decreased FEV_1% predicted in COPDGene (mean between group difference -5.7%; adjusted 95% CI, -8.8 to -2.6), a finding replicated in additional cohorts. Smoke exposure was associated with a small but significant increased risk of having CHIP (OR 1.03 per ten pack-years, 95% CI 1.01-1.05) in the meta-analysis of all subjects. In cigarette smoke exposure models, inactivation of *Tet2* in mouse hematopoietic cells enhanced pulmonary inflammation, increased interferon signaling, decreased TGF-Î² signaling, and increased emphysema development. **Conclusions:** Age-associated somatic mutations in blood cells are associated with the development and severity of COPD, independent of age and cumulative smoke exposure.

PrgmNr 2871 - Exome sequencing and primary care data from the UK Biobank reveal an opportunity for an RNAi therapeutic targeting XDH to treat gout

View session detail

Author Block: **A. Deaton**[1], M. M. Parker[2], L. D. Ward[2], A. Flynn-Carroll[1], R. Hoffing[1], G. Hinkle[1], K. Yucius[1], A. Borodovsky[1], P. Nioi[1]; [1]Alnylam Pharmaceuticals, Cambridge, MA, [2]Alnylam, Cambridge, MA
Disclosure Block: **A. Deaton:** Salary/Employment; Alnylam Pharmaceuticals.
Large biobanks offer the opportunity to identify tractable drug targets through genetic analyses and to examine the real-world efficacy of current therapeutics. We used gene-based collapsing tests to identify genes associated with urate levels in ~364,000 exome-sequenced participants in the UK Biobank. Aggregated predicted LOF (pLOF) and predicted damaging missense variants in XDH associated with lower urate levels (p-value = 3.4 x 10^{-10}, effect = 0.05 SD decrease) and protection from gout (p-value = 0.009, OR = 0.87). XDH encodes xanthine oxidase, an enzyme involved in the production of urate and the target of allopurinol, a drug commonly prescribed to treat gout. We examined allopurinol prescriptions and subsequent urate tests in primary care data from UK Biobank and found that 42% of individuals prescribed allopurinol did not reach target urate levels of 357Âµmol/L. This was highest for those prescribed lower doses of allopurinol, 56% for those with a 100mg prescription compared to 21% for those with a 300mg prescription (p-value= 1.34 x 10^{-80}). This observation is consistent with the known challenges of properly titrating allopurinol in clinical practice to achieve adequate urate control and highlights the need for a novel therapeutic. After confirming high expression of XDH in human liver, we developed ALN-XDH a hepatocyte-directed siRNA targeting XDH. Studies in non-human primates demonstrated durable reduction in XDH protein levels in liver by up to 91% following subcutaneous treatment with ALN-XDH. These results highlight the utility of combining analysis of rare variants with health records to identify drug development opportunities.

Disclosure Block: **Z.Y. Fang:** None.

Human milk oligosaccharides (HMOs) are carbohydrates secreted exclusively in human breast milk and absent from most infant formulas. HMOs are known to shape the development of the immune system in breastfeeding infants, which have lasting health effects. Earlier studies reported that inter-individual variations in HMO secretion are associated with both genetic and environmental factors. In this study, we determine the impact of interactions between maternal genetics and exposures on HMO composition. Breast milk samples from 980 mothers of the CHILD Cohort Study, collected between 3 to 4 months postpartum, were used to quantify the 19 most abundant HMOs by high-performance liquid chromatography. Genome-wide single nucleotide polymorphisms (SNPs) were genotyped in these mothers using the Illumina HumanCoreExome BeadChip. We applied a generalized linear model to assess the effects of interactions between maternal genetic variants and exposures (e.g., prenatal diet and vitamin intake) or health conditions (e.g., depression, atopy, gestational diabetes) on HMO concentrations. We determined that interactions between SNPs in chromosome 14 and maternal atopy were significantly associated with concentrations of Lacto-N-hexaose (e.g., rs79899738, P = 2.1 Ã□â□□$10^{â□□8}$). We also found that 2â□²-Fucosyllactose is significantly associated with interactions between loci in chromosome 16 and usage of analgesics during labor (e.g., rs12051213, P = 4.3 Ã□â□□$10^{â□□8}$). Finally, interactions between SNPs on chromosome 20 and prenatal fruit consumption significantly modulate 6Â´Sialyllactose concentrations (e.g., rs6036178, P = 2.9 Ã□â□□$10^{â□□9}$). Thus, our study reports interaction effects of maternal genetic and non-genetic factors such as diet, medication use and atopy on HMO composition. A better understanding of the determinants of breast milk composition such as HMOs will help facilitate more nuanced studies of the benefits of breastfeeding on infantsâ□□ health and the development of personalized interventions such as prebiotics.

PrgmNr 2873 - Generalizing Kernel Association Tests with a Protein Structure Based Kernel

View session detail

Author Block: **S. Sadhuka**; Harvard Univ., Cambridge, MA
Disclosure Block: **S. Sadhuka:** None.

Rare coding variants have the potential to identify genes involved in disease. However, few associations have been reported for complex traits, in part due to difficulties in aggregating variants within a gene. One reason is that kernel-based approaches (KATs) â the most widely used rare variant association tests â make strong assumptions about the correlation structure between different variants in a gene, such as independence among variantsâ effects or constant correlation across them. Violations of these assumptions may not only be widespread but predictable from variant properties such as their proximity in 3D protein space.

We hypothesize that (a) functional variants cluster in particular regions of proteins and (b) this clustering is stronger in 3D space than linear sequence space. We verify this hypothesis by showing two types of variant functional effect clustering: (a) variant cellular effects significantly cluster in 3D space (p Based on this hypothesis, we construct a âbiologically informedâ KAT where the correlation between variant effect sizes is inversely proportional to the distance between the variants in 3D space. We show that our test not only mathematically generalizes existing KATs that use non-biologically-informed correlation structures but also â in contrast to prior ad hoc methods â can model how 3D structure influences effects of variants on disease. Our generalization permits many possible variant correlation functions, including those that incorporate biological annotations beyond 3D location.

When used to analyze simulated data in which variant effects are localized to a spherical protein region, we show that our method increased sample sizes by 20-40% relative to existing methods. The increases are strongest when effects are localized to a sphere with radius ~15A, about 20% of an average protein domain. When used to conduct type 2 diabetes (T2D) association analysis within 45,231 exome sequences from the AMP-T2D-GENES consortium, seven of eight known T2D drug targets yielded lower p-values under our methods relative to existing KATs. For instance, for DPP4 our method leverages a cluster of variants to identify a significantly stronger association ($p = 0.006$) than existing KATs ($p = 0.36$).

These results demonstrate that both variant cellular and phenotypic effects exhibit clustering within 3D protein space and provide a foundation to build improved association tests to leverage this information.

Genome-wide association studies (GWAS) have identified thousands of genetic variants linked to the risk of human disease. However, GWAS have thus far remained largely underpowered to identify associations in the rare and low frequency allelic spectrum and have lacked the resolution to trace causal mechanisms to underlying genes. Here, we combined whole exome sequencing in 392,814 UK Biobank participants with imputed genotypes from 260,405 FinnGen participants (653,219 total individuals) to conduct association meta-analyses for 744 disease endpoints across the protein-coding allelic frequency spectrum, bridging the gap between common and rare variant studies. We identified 975 associations, with more than one-third of our findings not reported previously. Through multiple approaches including computational and functional characterization, we demonstrate population-level relevance for mutations previously ascribed to causing single-gene disorders, map GWAS associations to likely causal genes, explain disease mechanisms, and systematically relate disease associations to levels of 117 biomarkers and clinical-stage drug targets. Our approach benefits considerably from the Finnish genetic background where our theoretical and empirical simulation results suggest the increasing utility of enriched variants for identifying associations quantitatively towards lower allelic frequencies. We identify the most prominent relative power gain in the rarest variant frequency spectrum, highlighting a role for sequencing studies and integrating additional population cohorts with enriched variants for identifying novel disease associations at scale. Combining sequencing and genotyping in two population biobanks allowed us to benefit from increased power to detect and explain disease associations, validate findings through replication and propose medical actionability for rare genetic variants. Our study provides a compendium of protein-coding variant associations for future insights into disease biology and drug discovery.

PrgmNr 2875 - Genetically increased circulating FUT3 level is associated with reduced risk of Idiopathic Pulmonary Fibrosis: a Mendelian Randomization Study

Disclosure Block: **T. Nakanishi:** None.

Idiopathic pulmonary fibrosis (IPF) is a progressive, fatal fibrotic interstitial lung disease. Few circulating biomarkers have been identified to have causal effects on IPF.

To identify candidate IPF-influencing circulating proteins, we undertook an efficient screen of circulating proteins by applying a two-sample Mendelian randomization (MR) approach with existing publicly available data. For instruments we used genetic determinants of circulating proteins which reside cis to the encoded gene (cis-SNPs), identified by two genome-wide association studies (GWASs) in European individuals (3,301 and 3,200 subjects). We then applied MR methods to test if the levels of these circulating proteins influenced IPF susceptibility in the largest IPF GWAS (2,668 cases and 8,591 controls). We validated the MR results using colocalization analyses to ensure that both the circulating proteins and IPF shared a common genetic signal.

MR analyses of 834 proteins found that a one SD increase in circulating FUT3 and FUT5 was associated with a reduced risk of IPF (OR: 0.81, 95%CI: 0.74-0.88, $p=6.3x10^{-7}$, and OR: 0.76, 95%CI: 0.68-0.86, $p=1.1x10^{-5}$). Sensitivity analyses including multiple-cis SNPs provided similar estimates both for FUT3 (inverse variance weighted [IVW] OR: 0.84, 95%CI: 0.78-0.91, $p=9.8x10^{-6}$, MR-Egger OR: 0.69, 95%CI: 0.50 - 0.97, p=0.03) and FUT5 (IVW OR: 0.84, 95%CI: 0.77-0.92, $p=1.4x10^{-4}$, MR-Egger OR: 0.59, 95%CI: 0.38 - 0.90, p=0.01) FUT3 and FUT5 signals colocalized with IPF signals, with posterior probabilities of a shared genetic signal of 99.9% and 97.7%. Further transcriptomic investigations supported the protective effects of FUT3 for IPF.

An efficient MR scan of 834 circulating proteins provided evidence that genetically increased circulating FUT3 level is associated with reduced risk of IPF.

PrgmNr 2876 - Genetics of male pattern baldness in sub-Saharan Africa

View session detail

Author Block: **J. Lachance**[1], M. Harlemon[1], M. Kim[2], C. N. Simonti[1], R. Janivara[1], T. Rebbeck[3,4], MADCaP Network; [1]Georgia Inst. of Technology, Atlanta, GA, [2]Fred Hutchinson Cancer Res. Ctr., Seattle, [3]Dana-Farber Cancer Inst., Boston, MA, [4]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA
Disclosure Block: **J. Lachance:** None.
Male pattern baldness is a heritable trait, and the prevalence of baldness varies greatly across global populations. Unfortunately, much of what is known about the genetics of male pattern baldness comes from individuals of European descent, and it is unknown if the genetic architecture of this trait varies by ancestry. Here, we analyzed a novel dataset of 1,033 individuals from Ghana, Nigeria, Senegal, and South Africa who were genotyped using the MADCaP Array (a custom genotyping platform that is optimized for African populations). Applying polygenic risk scores for male-pattern baldness to African data, we find that genetic predictions generated from European GWAS perform poorly in sub-Saharan African populations, yielding AUC statistics that are slightly better than random chance. This lack of generalizability is due to multiple causes, including continental differences in allele frequencies, the presence of introgressed Neanderthal alleles in non-African populations, and genotype-by-environment interactions. We subsequently conducted the first African GWAS of androgenic alopecia, finding 24 independent loci that are associated with baldness at age 45 (p-value -5), including one locus that reached genome-wide significance (rs79284602, near *TRIM33* at 1p13.2). Notably, this polymorphism is restricted to African populations. Topologically associated domains near baldness GWAS hits were enriched for genes involved in lipoprotein assembly, remodeling, and clearance pathways. Although the majority of baldness associated loci are autosomal, X-linked variants contribute a relatively large fraction of the SNP-based heritability for this trait in African populations. Collectively, our results highlight the limited transferability of predictions across different ancestries as well as the need to conduct genetic studies in a wide range of populations.

PrgmNr 2877 - Genome-wide association and comparative gene set enrichment analysis identifies both similarities and differences between skeletal growth phenotypes

Hlth., UC San Diego, San Diego, CA

Disclosure Block: **E. Bartell:** None.

Background: Genome-wide association studies (GWAS) have identified thousands of common genetic variants associated with human height; however, less is known about the genetics of body proportion. Understanding the genetics of Sitting Height Ratio (SHR), leg length (Leg), and sitting height (SH), commonly-used measures of skeletal proportion, would further the study of skeletal growth.
Objective: To understand skeletal growth using genetic studies of SHR and height-related phenotypes.
Design/Methods: We use data from the UK Biobank (UKB) and China Kadoorie Biobank (CKB) to expand our genome-wide association study of SHR (Chan et al. 2015) from ~25,000 to >500,000 individuals from 2 ancestries, and analyze Leg and SH. We perform GWAS using BOLT-LMM in ~400,000 european and ~76,000 east asian individuals. MAGMA (de Leeuw 2015) was used to perform Gene Set Enrichment Analysis (GSEA) on individual traits and on heterogeneity summary statistics calculated using Cochranâ□□s Q (Cochran 1937).
Results: We identified between 900-1800 genome-wide significant SHR-, Height-, Leg-, and SH-associated lead variants (pConclusions: Using GWAS in two major ancestries, we identified >3100 novel associations with SHR, Leg, and SH. We performed conditional analysis and developed and implemented comparative-GSEA to provide insights into the genetic and biological differences between measures of body proportion and overall skeletal growth.

PrgmNr 2878 - Genome-wide inter-chromosomal epistatic associations identified across complex diseases in the ~300,000 participants from eMERGE and UK Biobank

Ritchie[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Philadelphia, MA, [3]Univ. of Pennsylvania, Philadelphia, PA, [4]411 Waupelani Drive A-341, Philadelphia, PA, [5]State College, PA, [6]Columbia Univ., New York, NY, [78]Mayo Clinic, Rochester, MN, [9]Marshfield Clinical Res Fndn, Marshfield, WI, [10]Univ. of Wisconsin, Madison, WA, [11]New York, NY, [12]Children's Hosp. of Philadelphia, Philadelphia, PA, [13]CHOP, Philadelphia, PA, [14]Children S Hosp. of Philadelphia, Philadelphia, PA

Disclosure Block: **S.S. Verma:** None.

Capitalizing on linkage disequilibrium (LD) patterns to determine population substructure allows the discovery of additive association signals in genome-wide association studies (GWAS). As standard GWAS analyses are well-powered to interrogate additive models, investigating other plausible modes of inheritance such as dominance and epistasis may often require new approaches. Epistasis - interaction between genes, play an essential role in elucidating complex genetic networks that impact the human genome's structure and evolution. Given that evidence from model organism studies indicates long-range high LD regions to be under evolutionary selection, we hypothesized that these regions might play a key role in regulating disease mechanisms across various complex traits. Thus, we selected 20 diverse complex traits (neurological, ocular, cardiometabolic, immune) and created case/control cohorts of individuals in the eMERGE and UKBB datasets. We calculated Ohtaâ□□s D statistic on genome-wide pairs of variants to identify pairs in long-range (> 0.25cM) LD due to epistatic selection. On these resulting 136,019 SNPs culminating in a total of 5,625,845 SNP-SNP models, we used a penalized regression framework to determine the association of SNP-SNP pairs with a disease. Across 12 of the 20 phenotypes, we found 290 models (majority inter-chromosomal) that replicated in UKBB and eMERGE after multiple hypothesis testing correction. Characterization of replicating models indicate the genes they map to are 1) highly conserved gene families with complex roles in multiple pathways, 2) essential genes, and/or 3) already associated in the literature with complex traits that have diverse phenotypic presentations. Together, these results demonstrate the highly pleiotropic nature of variants under epistatic selection in conserved regions, supporting the hypothesis that epistatic interactions regulate diverse clinical mechanisms and can produce a range of phenotypic outcomes. A key example is the WFS1 gene, coding for the calcium-regulating wolframin protein. Over 200 mutations in WFS1 have been associated with Wolframin Syndrome, characterized by different combinations of diabetes, optic atrophy, urinary tract dysfunction, loss of hearing, and neurological symptoms. Our results support the conclusion that epistatic interactions between *WFS1* and other genes, including *VRK2, NT5C2, INA, and DIP2C*, regulate this syndrome and produce the range of phenotypes seen. This study examines numerous such cases and sheds light on the pleiotropic interactions underlying disease etiologies providing a more unified view of epistasis and pleiotropy in complex traits.

PrgmNr 2880 - Human milk oligosaccharides alter the milk microbiota in lactating mothers and impact the gut microbiota of breastfed infants with asthma

Disclosure Block: **S.A. Stickley:** None.

Human milk consists of hundreds of complex glycans known as human milk oligosaccharides (HMOs), which are absent from most infant formulas and associated with changes in the milk microbiota of lactating mothers and the gut microbiota of breastfed infants. In addition, HMOs contribute to the development of the immune system in infants and have been associated with infant health outcomes. The aim of our study is to generate new hypotheses for the underlying mechanisms by which HMOs impact the milk and gut microbiota to influence lung health in breastfed infants. We quantified the 19 most abundant HMOs using high performance liquid chromatography from the human milk samples of 980 mothers of the CHILD cohort study, collected at 3 months postpartum. A subset of these human milk samples (N=721) were used to assess milk microbial composition using 16S rRNA sequencing. Gut microbial composition were determined by 16S rRNA sequencing of stool samples from breastfed infants at 3 months (N=323) and at 1 year (N=342). We performed differential abundance analyses to determine how HMO concentrations modify the mothers□□ milk microbiota and the infants□□ gut microbiota. Our results indicate that high concentrations of the HMO lacto-N-neotetraose is associated with elevated levels of *Lactobacillus iners* in the human milk (P = 7.23 x 10-47). In turn, breastfed children exposed to high *L. iners* in human milk had lower prevalence of recurrent wheeze (P = 1.11 x 10-26) and asthma (P = 1.25 x 10-6). Moreover, specific HMOs such as difucosyllactose (P = 1.20 x 10-30) and 3□²-sialyllactose (P = 1.96 x 10-30) were associated with lower abundance of *Bacteroides caccae* in the gut at 3 months. Children with lower *B. caccae* in the gut microbiota had lower prevalence of recurrent wheeze (P = 4.40 x 10-14) and asthma (P = 2.07 x 10-11). In conclusion, our study suggests that HMO composition among lactating mothers influences the milk and gut microbiotas, which in turn, impacts the risk of recurrent wheeze and asthma among breastfed infants.

PrgmNr 2881 - Identifying synthetic interactions between synonymous mutations in the UK Biobank WES data using REVEAL: Biobank

View session detail

Author Block: **Z. Pitluk**; Pardigm4, Inc., Waltham, MA
Disclosure Block: **Z. Pitluk:** None.

Historically, most research into discovering the impact of mutations on human health and disease has focused on algorithmically determined mutations of consequence. However, synonymous or silent mutations are known to have a dramatic impact on the rate of translation of proteins, and potentially on the stability of individual proteins and complexes of proteins. Multiple studies have linked synonymous mutations to changes in protein expression, and translation efficiency, among others. In this work, we evaluate the role of synonymous mutations across the 200K whole exome sequencing data made available through the UK Biobank (Application ID: 51518) by systematically looking for evidence of synthetic interactions between individual synonymous mutations in pairs of genes. To perform this large-scale study, we will be using Paradigm4â□□s software analytics platform, REVEAL™: Biobank, which is built upon an array-native computational engine called SciDB. We will employ fisherâ□□s exact test and check for co-occurrence and anti-occurrence of mutations to efficiently rank putative synthetic lethal and synthetic obligatory interactions. Additionally, we will utilize linkage disequilibrium and burden tests to measure correlation between variant pairs and their effect on phenotypes. Finally, we will use bioinformatics to develop testable hypotheses to understand prospective interactions.

PrgmNr 2882 - Incident disease associations with mosaic chromosomal alterations on autosomes, X and Y chromosomes: insights from a phenome-wide association study in the UK Biobank

View session detail

Author Block: **S-H. Lin**[1], D. W. Brown[1], B. E. Rose[2], F. R. Day[3], O. Lee[1], S. Khan[1], J. Hislop[1], S. J. Chanock[4], J. R. Perry[5], M. J. Machiela[1]; [1]Natl. Cancer Inst., Rockville, MD, [2]Univ. of Miami, Miami, FL, [3]Cambridge Univ, Cambridge, United Kingdom, [4]Natl. Cancer Inst, Rockville, MD, [5]Univ Cambridge, Cambridge, United Kingdom

Disclosure Block: **S. Lin:** None.

Mosaic chromosomal alterations (mCAs) can develop in hematopoietic cells and achieve a high clonal fraction of circulating cells: events can be classified as large chromosomal gains, losses and copy-neutral losses of heterozygosity (LOH). The clonal selection of mutated cells harboring mCAs relative to normal cells can alter gene dosage and expression, potentially having an impact on leukocyte function. While many individuals with mCAs have no apparent adverse impacts on health at the time of assay, the effect of such events can be explored in prospective studies, such as the UK Biobank. We performed a phenome-wide association study (PheWAS) using existing genotype and phenotype data from 482,396 UK Biobank participants to investigate potential associations between mCAs and incident disease. A total of 17,113 (3.5%) participants had at least one detectable autosomal event, 43,297 (19.6%) males had mosaic Y loss and 12,550 (4.8%) females had mosaic X loss. First occurrence of 1,764 ICD-10-coded diseases were derived from linkage to primary care, hospital admission, cancer registry, death register data as well as self-report disease history. PheWAS models included adjustment for age, age^2, sex, and a detailed 25-level smoking variable. Our adjusted analysis identified a total of 50 incident disease outcomes associated with mCAs at PheWAS significance levels (P-5). Overall autosomal mCA associations included lymphoid and myeloid malignancies, infectious disease risk and cancer related phenotypes. When a PheWAS was performed separately for each autosome, we observed outcomes associated with mCAs for nearly every chromosome (e.g., chronic lymphoid leukemia) whereas other associations were restricted to fewer chromosomes (e.g., myeloid leukemia). For sex chromosome analyses, we observed mCAs in chromosome X were associated with increased lymphoid leukemia risk and mCAs of chromosome Y were linked to potential reduced metabolic disease risk. Further exploratory analyses using prevalent disease as well as reported medication data further confirm reported mCA associations. Our findings detail a broad spectrum of associations between mCAs and incident diseases that varies by type of mCA and highlight the critical importance of careful covariate adjustment to minimize confounding.

PrgmNr 2883 - Integration of a *MUC5B* Promoter Variant and a Polygenic Risk Score for Idiopathic Pulmonary Fibrosis and Interstitial Lung Abnormalities

View session detail

Author Block: **M. Moll**[1], S. Chun[2], R. J. Allen[3], A. J. Ghosh[1], J. Ziniti[1], R. K. Putman[1], H. Hatabu[1], J. Hecker[4], B. D. Hobbs[5], E. K. Silverman[6], B. A. Raby[7], L. V. Wain[8], G. M. Hunninghake[6], M. H. Cho[9]; [1]Brigham and Women's Hosp., Boston, MA, [2]Boston Children's Hosp., Boston, MA, [3]Univ. of Leicester, Leicester, United Kingdom, [4]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, Germany, [5]Needham, MA, [6]Brigham & Women's Hosp, Boston, MA, [7]Newton Center, MA, [8]Univ Leicester, Leicester, United Kingdom, [9]Duxbury, MA

Disclosure Block: **M. Moll:** None.

Rationale: Idiopathic pulmonary fibrosis (IPF) is characterized by progressive lung scarring and death. Early disease detection is paramount. Chest computed tomographic imaging can detect interstitial lung abnormalities (ILA), which can progress to IPF. The *MUC5B* promoter variant rs35705950 is a common variant (MAF [Europeans]=0.11) of large effect size that confers risk for both IPF (OR 6-13, heterozygotes) and ILA (OR 2-3). The relative contributions of rs35705950 and other variants to IPF and ILA are not clear. We hypothesized that a polygenic risk score (PRS) excluding the *MUC5B* region would add complementary predictive value to the *MUC5B* variant for IPF and ILA. Methods: Using previously published European-ancestry genome-wide association summary statistics for IPF, we used lassosum to develop an IPF PRS excluding a 500 kb region around rs35705950 (PRS-NO-M5B). We trained a composite risk score of the PRS-NO-M5B and *MUC5B* rs35705950 (PRS+M5B) using 10-fold cross-validation (100 bootstraps) in IPF cases and controls from the external Lung Tissue Research Consortium (LTRC). We tested the associations of PRS-NO-M5B, rs35705950 alone, and PRS+M5B with IPF in LTRC and ILA in the Genetic Epidemiology of COPD (COPDGene) study. Multivariable logistic regressions were performed, adjusting for age, sex, smoking, and genetic ancestry. We assessed interaction by testing association of cross-product terms with each outcome. Area-under-the-curve (AUC) analyses were used to assess model predictive performances. We examined phenotypic variance explained by each risk factor using Nagelkerke R^2. Results: In LTRC (270 controls, 255 IPF cases), the PRS-NO-M5B (OR 4.5 [95% CI: 3.3 - 6.1], p=8.0e-22) and rs35705950 (OR 3.6 [95% CI: 2.4 - 5.2], p=6.4e-11) were both associated with IPF, and when considered in a single model, effect sizes were largely unchanged. PRS+M5B demonstrated a larger effect (OR 18 [95% CI: 10 - 30], p=5.0e-26) compared to either component risk factor. The PRS-NO-M5B X rs35705950 interaction term was not significant (p=0.7). There was a stepwise increase in predictive performances of models including rs35705950 (AUC 0.74), PRS-NO-M5B (AUC 0.83), and PRS+M5B (AUC 0.86). Phenotypic variability in IPF explained by PRS+M5B (R^2=0.41) was greater than PRS-NO-M5B (R^2=0.33) and rs35705950 alone (R^2=0.12). In COPDGene (6417 controls, 250 ILA), PRS+M5B (OR 1.5 [95% CI: 1.2-1.9],p=5.4e-4) and rs35705950 (OR 1.8 [95% CI: 1.4-2.4], p=2.7e-6), but not the PRS-NO-M5B (p=0.08), were significantly associated with ILA. Conclusions: The *MUC5B* rs35705950 variant and a PRS excluding the *MUC5B* region offered complementary predictive value for IPF, but not ILA.

PrgmNr 2884 - Investigating the transferability of European height associated loci in Africans

African populations have been underrepresented in genome-wide association studies (GWAS), limiting our understanding of the genetic architecture of complex traits. We studied standing height in a Sub-Saharan African cohort (N=2274) that was whole-genome sequenced as part of the TOPMed initiative. This cohort represents diverse ancestry groups in Sub-Saharan Africa, including Nilotic pastoralist and Central African hunter-gatherer populations, that exhibit phenotypic extremes in height. We performed GWAS and meta-analysis with GWAS of other African ancestry cohorts to examine the transferability of height loci across populations and evaluated polygenic score prediction for diverse African ancestries. For the GWAS we used a linear mixed model, controlling for population stratification with a genetic relatedness matrix. By permuting phenotypes within ethnic groups, we found this approach sufficiently controlled for inflation for common variants above 5% minor allele frequency in our heterogenous Sub-Saharan African dataset. To increase power, we meta-analyzed our GWAS with previously published GWAS of African cohorts (N=43,984). We observed at least 15 independent and significant loci, some of which replicate known height associated loci such as *HMGA2* and *LCORL.* To examine the transferability of European height associations in Africans, we looked at concordance in direction of effect from significant GWAS variants from a European cohort from the UK biobank (2097 SNPs) and observed 64.5% concordance (P = 1.59Î¾10-40). Stratifying by the top tenth percentile of most associated SNPs in the African ancestry meta-analysis, we observed 90.5% concordance (P = 3.08Î¾10-35). Given this general consistency in effects, we investigated how well these European height associated variants predict height in the Sub-Saharan African cohort using polygenic scores (PS). We observed a partial R^2 of 0.048 for the PS when controlling for age and sex, higher than what has been previously reported in other African cohorts. In a model controlling for genetic ancestry, the partial R^2 of the PS was 0.033, indicating the PS explained some of the variance in height across ancestry groups. When comparing variation in mean height across ethnic groups with mean polygenic scores, however, we found that European height alleles did not explain these population differences for those at the extremes of the distribution in Africa.

PrgmNr 2885 - Large-scale exome sequencing identifies 8 genes impacting adult cognitive function

View session detail

Author Block: **C-Y. Chen**[1], R. Tian[1], J. Z. Liu[2], M. Lam[3], Biogen Biobank Team, E. A. Tsai[1], H. Huang[3], T. Lencz[4], T. Ge[5], H. Runz[1]; [1]Biogen, Cambridge, MA, [2]GSK, Philadelphia, PA, [3]The Broad Inst., Cambridge, MA, [4]Zucker Hillside Hosp., Glen Oaks, NY, [5]Massachusetts Gen. Hosp., Boston, MA
Disclosure Block: **C. Chen:** Salary/Employment; Biogen.
Genome-wide association studies have identified over one thousand genetic loci of relevance to cognitive function in adults. However, the contribution of rare coding variants to cognitive function have largely remained unknown. Here, we present the first large-scale exome sequencing study investigating the impact of protein-coding variants on cognitive phenotypes in the adult general population. Leveraging whole-exome sequencing data from 454,787 UK Biobank (UKB) participants ascertained for educational attainment (EDU), reaction time (RT) and verbal-numerical reasoning (VNR), we discovered that exome-wide protein truncating variant (PTV) and missense burden have significant damaging effects on cognitive function. This was reflected in lower educational attainment, longer reaction time and lower verbal-numerical reasoning score in carriers of rare coding variants (exome-wide PTV burden: P=1.95x10^{-21} for EDU, 8.79x10^{-19} for RT and 6.99x10^{-22} for VNR; missense burden: P=5.95x10^{-24} for EDU, 5.95x10^{-4} for RT and 4.87x10^{-12} for VNR). Furthermore, the strongest signals were driven by PTVs and damaging missense variants (MPC>3 and 3â¥MPC>2) in loss of function intolerant genes (pLIâ¥0.9), indicating potential impact from both classes of variants on cognitive function. Through gene-based PTV burden tests, we identified 8 adult cognitive function genes (*ADGRB2*, *KDM5B*, *GIGYF1*, *ANKRD12*, *SLC8A1*, *RC3H2*, *CACNA1A* and *BCAS3*) at Bonferroni corrected exome-wide significance level, and 5 additional genes at FDR *Q*NDUFA6, *ARHGEF7*, *C11orf94*, *KIF26A*, and *MAP1A*). For established Mendelian disease genes, we showed that the heterozygous PTVs are associated with a milder form of cognitive impairment in adults, highlighting the spectrum of cognitive phenotypes and related disorders that could be influenced by PTVs. We further contrasted cognitive function genes with genes underlying developmental delay and autism spectrum disorder and discovered shared genetic mechanisms that influence cognitive function at different life stages. Gene sets identified through PTV-based burden analyses strengthened prior evidence that distinct biological processes including neurogenesis and synapse formation modulate cognitive function. Finally, we demonstrated additive contributions of rare coding variants and common variant-based polygenic risk on cognitive function in adults. Our findings uncovered a substantial contribution of rare protein-coding variants on cognitive function, identified novel cognitive genes, and provided new insights into the genetics of cognitive function in relation to neurodevelopmental disorders and developmental delay.

PrgmNr 2886 - Neuroimaging-guided functional variant multi-ancestry PheWAS using electronic health records from UK Biobank

View session detail

Author Block: **Y. Veturi**[1], C. Davatzikos[1], M. D. Ritchie[2]; [1]Univ. of Pennsylvania, State College, PA, [2]Univ. of Pennsylvania, Philadelphia, PA
Disclosure Block: **Y. Veturi:** None.
Several studies have identified genetic overlaps between neuroimaging data and complex human diseases (e.g. Alzheimerâ□□s disease, type II diabetes, stroke, etc.). A comprehensive investigation of functional associations connecting neuroimaging phenotypes to diseases in electronic health records (EHR) **across the phenome** can yield novel image-derived phenotype (IDP) biomarkers for complex diseases as well as provide pleiotropic gene targets for drug repurposing. We first conducted a phenome-wide imaging study (PheWIS) in UK Biobank to identify disease-IDP associations (*n*=40,201 samples) between 689 International Classification of Disease (ICD) codes and 870 structural and diffusion MRI IDPs. Next, we conducted a phenome-wide association study (PheWAS) across 689 ICD codes (*n*=452,595 samples) on 52,570 Bonferroni-significant genetic variants (p-valuers34404554/*TOMM40*: Alzheimerâ□□s disease and angina pectoris), we also found pleiotropic associations between IDPs and diseases across the phenome including respiratory (e.g. *ORMDL3*: asthma), digestive (e.g. *GBAP1*: diseases of stomach and duodenum), musculoskeletal (e.g. *PSMB9*: rheumatoid arthritis), eye and adnexa (e.g. *CDKN2B*: glaucoma), genitourinary (e.g. *SP1*: hydrocele and spermatocele) systems as well as neoplasms (e.g. *HLA-DQB1*: follicular non-Hodgkinâ□□s lymphoma). We will conduct statistical colocalization as well as obtain causal pathways between correlated IDP clusters and complex diseases in independent medical biobanks to robustly identify endophenotypes for future prevention and treatment strategies.

PrgmNr 2887 - Organelles and aging: a human genetics approach

View session detail

Author Block: **R. Gupta**[1,2], K. J. Karczewski[1], D. Howrigan[1], B. M. Neale[3,1], V. K. Mootha[3,1]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Harvard Med. Sch., Boston, MA, [3]Massachusetts Gen. Hosp., Boston, MA

Disclosure Block: **R. Gupta:** None.

Most age-related human diseases are accompanied by a decline in cellular organelle integrity, including impaired lysosomal proteostasis, elevated endoplasmic reticular stress, and defective mitochondrial oxidative phosphorylation. While classical inborn errors of metabolism tend to be mapped to â□□causalâ□□ organelles (e.g., lysosomal storage diseases), an open question is the degree to which inherited variation impacting each organelle contributes to common age-related disease pathogenesis.

Here, we evaluate if organelle-relevant loci confer greater-than-expected age-related disease risk. As mitochondrial dysfunction is a â□□hallmarkâ□□ of aging, we begin by comprehensively assessing loci relevant to mitochondria: nuclear DNA loci near genes producing mitochondria-localizing proteins, published nuclear DNA quantitative trait loci for biomarkers of mitochondrial dysfunction, and common mitochondrial DNA variants. To our surprise, we observe a lack of enrichment across 24 age-related traits using several distinct approaches. Within nine other organelles, we find no enrichment with one exception: the nucleus. Via further partitioning of the ~6300 genes annotated to contribute to the nuclear proteome, we find that this signal primarily emanates from nuclear transcription factors. By sub-dividing transcription factors across dimensions of DNA-binding domain, age, and breadth of gene expression across human tissues, we found signal predominantly among the non-KRAB domain-containing transcription factors. Further analyses of genetic loci associated with parental lifespan and healthspan continued to prioritize nuclear transcription factors over other organelles. In agreement with our results, we find that genes encoding several organelles tend to be â□□haplosufficient,â□□ while we observe strong purifying selection against protein-truncating variants impacting the nucleus.

Our work identifies common variation near nuclear transcription factors as having outsize influence on age-related trait risk, motivating future efforts to determine if and how this variation contributes to age-related organelle deterioration.

PrgmNr 2888 - Pakistan Genomic Resource: The worldâ□□s largest biobank of human knockouts

Individuals carrying 2 copies of plof (putative loss of function) variants, disrupting both copies of a gene (â□□human knock-outsâ□□) can provide valuable insights into gene function and help assess the therapeutic potential of pharmacological inhibition of a gene target. The chances of seeing homozygous plof carriers in consanguineous individuals, whose parents are cousins, are much higher compared to the general population. The Pakistan Genomic Resource (PGR) is an ongoing study that will sequence 1 million participants living in Pakistan, a region of the world with high levels of consanguinity. We have currently enrolled >150,000 participants, 40% of which report that their parents are second cousins or closer. After applying standard plof filtering on the initial 77,929 whole-exome / whole-genome sequenced samples, we identify 15,840 (20.3% of total population) homozygous carriers of rare plofs (alternate allele frequency SLC30A8 was associated with reduced risk of type 2 diabetes, at *GDF15* with absent growth differentiation factor 15 (GDF15) levels and homozygosity with MHCR1 was associated with an increase in obesity risk. Given projections based on our data and others, sequencing up to 1 million participants would allow us to observe up to 90% of all viable knock outs for genes in which no homozygous plof has been observed yet, resulting in a unique resource to help understand novel biology and inform drug discovery efforts.

PrgmNr 2890 - Polygenic gene-environment interactions: from genetic architecture to pharmacogenomics

View session detail

Author Block: **A. R. Marderstein**[1], L. Poyraz[2], S. Kulm[1], C. Peng[3], R. Tamimi[1], O. Elemento[1], A. G. Clark[2]; [1]Weill Cornell Med., New York, NY, [2]Cornell Univ., Ithaca, NY, [3]Brigham and Womenâ□□s Hosp., Boston, MA

Disclosure Block: **A.R. Marderstein:** None.

While genetic effects are often strongly modulated by the environment in model organisms, single-locus gene-environment (GxE) interactions have been a challenge to detect in humans. On the other hand, polygenic GxE interactions, which involve interactions with thousands of small-effect causal variants across the genome, may play an underappreciated role in the genetic architecture of many human phenotypes. To explore this, we analyzed body mass index levels (BMI) and breast cancer (BC) in UK Biobank (UKB).

For BMI: We find that the polygenic contribution is strongly modulated by lifestyle factors. While only the *FTO* locus contained single-SNP interactions reaching genome-wide significance (*P* -8), the three tested GxE interactions between a BMI polygenic score (PGS) and physical activity (PA), sedentary behavior, and alcohol intake are each highly significant (*P* -15). For PA, the effect size of the BMI PGS in low-PA individuals is nearly 34% greater than individuals with high-PA. In a stratified GWAS of only high-PA individuals, we found that individual SNP effects are reduced by 37% on average compared to SNP effects estimated in only low-PA individuals; generally, this aligns with the estimated difference in SNP-heritability between low- and high-PA individuals (35%) despite nearly identical genetic correlations (r_g=0.95). Importantly, individuals with a PGS in the highest risk decile (>90th percentile) and high-PA levels have the same mean BMI as those with an average PGS (40-60th percentile) but low-PA levels. Thus, we found widespread evidence of GxE polygenicity with important implications regarding BMI genetic architecture and prediction.

For BC: We used a PGS-based approach to explore whether widely-taken approved drugs (not targeting BC) modulate BC genetics in UKB women. Notably, we find that a BC PGS explains nearly three-times greater variation in disease risk within corticosteroid users compared to non-users. We show that the PGS can be used to discover the underlying SNP interactions, mapping 35 genes significantly interacting with corticosteroid use (*FDR* HR = 3.41 per-allele within users). In comparison, there are no differences in BC risk within the reference allele homozygotes.

Overall: The high prevalence of polygenic GxE has great potential, from improving risk prediction to analyzing off-target drug effects.

PrgmNr 2891 - Prioritizing Research Variants in the NIH Undiagnosed Diseases Program

View session detail

Author Block: **D. R. Adams**[1], B. N. Pusey[2], C. J. Tifft[3], C. Toro[4], M. Malicdan[4], T. C. Markello[5], W. A. Gahl[6], Undiagnosed Diseases Network; [1]NIH, Bethesda, MD, [2]Natl Human Genome Res. Inst., Bethesda, MD, [3]Office of the Clinical Director, Bethesda, MD, [4]NIH, Bethesda, MD, [5]NIH - NHGRI, Bethesda, MD, [6]NHGRI (NIH), Bethesda, MD

Disclosure Block: **D.R. Adams:** None.

A significant number of rare, high-penetrance, heritable diseases remain undiagnosed after standard of care clinical exome and genome analysis. Follow up research analysis occasionally yields unusual or hard to detect mutations affecting known disease genes. For remaining cases, undiagnosed disease research requires identification and prioritization of DNA variants in potential new disease genesâ□□'research variantsâ□□. The selection of research variants must balance an estimate of prior probability of success, research resources, bioinformatic assessments, gene function correlation with patient phenotypes and availability of expertise. Optimally, selection should be designed to minimize ascertainment bias based on reviewer expertise, quantity of available gene information and low-evidence prior assessments of disease-gene associations. The NIH Undiagnosed Diseases Program, a clinical site of the NIH Undiagnosed Diseases Network, was founded in 2008 to investigate and diagnose diseases that remain undiagnosed after extensive medical workup. Of 1500 evaluated individuals (including family members), there were 1032 *probands* who remained without a conclusive diagnosis at the time of our in-person clinical evaluation. For these individuals, diagnoses have been made or are under validation for approximately 281 (27%). Of the 751 undiagnosed individuals, 680 remain under active investigation. Of the 680 ongoing cases, 303 have been subject to exome or genome sequencing, with 185 (61%) having one or more identified research variants under study. Past UDP research variants have been converted to diagnoses via a variety of mechanisms including published assertion of a new disease by the UDP or UDN, recognition after external publication of a new disease assertion, application of new bioinformatics analyses, published phenotype expansions and other events. Conversely, research variants have been deprioritized based on laboratory research data, public database updates and other sources of new information. We present data summarizing and describing the patterns observed for past UDP research variants and describe our experience-based considerations for an optimized prioritization strategy.

Human diseases have tissue-specific etiologies and manifestations. In this context, determining how genes influence these complex phenotypes requires mechanistically understanding expression regulation across different cell types, which in turn should lead to improved treatments. Integrating functional and GWAS data has improved the identification of these transcriptional mechanisms which, when dysregulated, commonly result in tissue- and cell lineage-specific pathology. However, widespread gene pleiotropy and polygenic traits reveal the highly interconnected nature of transcriptional networks, which complicates the interpretation of genetic effects and hampers translational efforts. We have developed a polygenic approach that maps both gene-trait associations and drug-transcriptional responses into a common representation based on tissue-specific gene co-expression patterns.

We integrated thousands of gene-trait associations (using TWAS from PhenomeXcan) and transcriptional profiles of drugs (LINCS L1000) into a low-dimensional representation learned from public gene expression data on tens of thousands of RNA-seq samples (recount2). This low-dimensional space comprised features representing groups of genes (gene modules) with coordinated expression across different tissues and cell types. When mapping gene-trait associations to this reduced expression space, we observed that diseases were significantly associated with gene modules expressed in relevant cell types, such as hypothyroidism with T cells and thyroid, coronary artery disease with cardiomyocytes, hypertension and lipids with adipose tissue, and heart problems with heart ventricle and muscle cells. We replicated gene module associations with cardiovascular and autoimmune diseases in the Electronic Medical Records and Genomics (eMERGE) network. We also performed a CRISPR-screen to analyze lipid regulation in HepG2 cells and observed more consistent trait associations with modules than we observe with individual genes. Compared to a single-gene approach, our module-based method also better predicted FDA-approved drug-disease links by capturing tissue-specific pathophysiological mechanisms linked with the mechanisms of action of drugs (e.g. niacin with cardiovascular traits via a known immune mechanism). Exploring the phenotype-module space also revealed stable trait clusters across different resolutions, including a complex branch involving lipids with cardiovascular, autoimmune, and neuropsychiatric disorders. We offer a novel gene module approach to enhance the understanding of complex diseases and their therapeutic modalities.

PrgmNr 2893 - Quantifying factors that affect polygenic risk score performance in the eMERGE dataset

Polygenic risk scores (PRS) have poor portability across ancestries, and evidence suggests that for some traits e.g., those related to adiposity, this disparity is exacerbated by environmental or personal-level variables such as age. Efforts to quantify how performance of PRS is affected when the study individuals and genome-wide association study (GWAS) summary statistics are not of homogeneous ancestry and personal background will provide insight into factors that limit transferability of PRS across populations. PRS were calculated for body mass index (BMI) on individuals from the eMERGE cohort (N=77,473), which includes individuals of diverse ancestry and ages (17% non-European ancestry, 19% less than age 21). Stratified analyses were conducted in three ancestry groupings and four age categories (2 than the UKBB GWAS (.0156 vs .0107, $p=2.72x10^{-19}$) in African ancestry adults, when both analyses used their best performing LD panel. In European ancestry adults, the UKBB GWAS had 24% higher R^2 than the GIANT GWAS (.0590 vs .0474, $p=2.03x10^{-164}$) - in both analyses, the LD panel using all individuals in 1000 Genomes performed best. Model performance was similar between adults and teenagers - using the best performing summary statistics and LD panels for each run, we observed differences in R^2 of .0590 vs .0591 ($p=8.52x10^{-8}$), .0504 vs .0417 ($p=8.57x10^{-11}$), and .0156 vs .0324 ($p=9.62x10^{-42}$) for European, all, and African ancestry individuals, respectively. Performance greatly degraded in children (R^2s of 0.0293, 0.0180, 0.0102 in European, all, and African ancestry individuals, respectively). In conclusion, we observed that 1) even small amounts of non-European ancestry individuals in the GWAS where effect estimates are derived greatly improved prediction performance in African ancestry individuals; 2) all of 1000 Genomes LD reference panels outperformed solely European ancestry LD panels even when both summary statistics and test individuals were of European ancestry; and 3) model performance was similar between adults and teenagers but degraded greatly for children.

PrgmNr 2894 - Rare variant GWAS of African American and Hispanic patients using WGS data from the TOPMed program on the NHLBI BioData Catalyst

Disclosure Block: **S. Gilhool:** None.
Asthma is the most common chronic respiratory disease, affecting over 300 million people worldwide. In the United States alone, asthma creates a financial burden of over $50 billion annually. This burden is not distributed equally; asthma is more prevalent and severe among African Americans and Hispanics, as compared to Caucasians. Asthma is known to be caused by a combination of environmental and genetic factors, but our knowledge of the genetic causes of asthma is still incomplete.

A small number of common genetic variants have been identified through genome wide association studies (GWAS), but these explain only a small proportion of asthma heritability. Furthermore, many GWASs have focused on Caucasian cohorts, leaving variants specific to other populations largely unknown.

In this project, we explore new ground in the genetic landscape of asthma by 1) probing rare variants, which could have larger effect sizes and may be population-specific, and 2) analyzing a cohort of traditionally under-studied populations. We leverage WGS data from the Asthma Translational Genomic Collaborative (ATGC) in the NHLBI Tran-Omics for Precision Medicine (TOPMed) program. In total, we analyze over 15,000 African American and racially admixed Hispanic patients.

The analysis is performed on NHLBI BioData Catalyst powered by Terra. The NHLBI BioData Catalyst facilitates this research by allowing TOPMed data to be easily imported to a scalable, high-performance cloud workspace, and to be analyzed using custom and community-developed workflows.

Hail is used to perform quality control on variant calls and filter for rare variants at two different frequency thresholds (MAF Our approach is focused on identifying novel genes harboring rare variants which are associated with asthma in under-studied populations. We anticipate our results will improve our understanding of the genetics of asthma, contribute to efforts to precisely tailor treatments to each patient's unique genetic background, and ultimately help reduce healthcare disparities.

PrgmNr 2895 - Rare, functional variants amongst 180,256 exomes from the UK Biobank influence mitochondrial copy number

Med. and Pathology, Univ. of Minnesota Med. Sch., Minneapolis, MN

Disclosure Block: **V. Pillalamarri:** None.

Over 1.45 billion years since the endosymbiotic origin of mitochondria, mitochondrial function has evolved to become obligatory for eukaryotic cellular function and survival; mitochondria play vital roles in oxidative phosphorylation (oxphos), apoptosis and metabolism, and defects in human mitochondrial genomes (e.g. in genes encoding core subunits of oxphos) lead to disease. A portion of intercellular and interindividual variation in the number of mitochondrial genome copies (mtDNA-CN) reflects mitochondrial function and has recently been shown to be a heritable component under nuclear genetic control via common polygenic variation. We therefore hypothesized that nuclear genes would harbor an excess of rare, functional variants in aggregate that could influence variation in mtDNA-CN. Amongst 180,256 exomes from the UK Biobank cohort, we tested rare variants below one percent allele frequency, both at the level of single variants and through aggregate burden, SKAT and SMMAT analyses, for association with computed mtDNA-CN adjusted for cell counts and other relevant covariates. A survey across 16 variant sets composed of coding sequence and loss-of-function mutations at varying rare allele frequencies identified eight genes at Bonferroni significance and 21 genes at a false discovery rate TWNK ($p=1.03e^{-12}$) and mitochondrial transcription factor *TFAM* ($p=1.23e^{-5}$). Several novel gene associations included the essential iron transporter Mitoferrin-1 *SLC25A37* ($p=9.28e^{-7}$), *C20orf144* ($p=7.68e^{-7}$), and a single variant in the infertility gene *SPAG4* ($p=4.5e^{-15}$). The most significant association was with *SAMHD1* ($p=5.49e^{-30}$, q-value=$7.55e^{-25}$), a cytoplasmic host restriction factor involved with viral defense response and involved in the mitochondrial nucleotide salvage pathway. Using leave-one-out analyses, we pinpointed three functional variants driving the *SAMHD1* signal, the most explanatory being a single missense mutation at hg38:chr20:36,893,060.C>T ($p=1.4e^{-19}$, beta=+0.7, se=0.08 SD increase in mtDNA-CN) which falls within the critical region of Aicardi-GoutiÃ¨res syndrome 5 (AGS5) involved with childhood encephalopathy and chronic interferon-mediated inflammatory response. We hypothesize this missense variant within the AGS5 region disrupts the alternate role of SAMHD1 in resection of single-stranded DNA at stalled replication forks. This might lead to a buildup of cytosolic ssDNA, triggering an interferon-mediated inflammatory response via the cGAS-STING pathway and lead to an increase in mtDNA-CN.

PrgmNr 2896 - Relationship between autozygosity and complex traits in the Amish

View session detail

Author Block: **M. Lynch**[1], K. A. Maloney[2], H. Xu[3], A. R. Shuldiner[4], B. D. Mitchell[5]; [1]Univ. of Maryland Baltimore, Baltimore, MD, [2]Univ Maryland, Baltimore, MD, [3]Baltimore, MD, [4]Regeneron Genetics Ctr., Tarrytown, NY, [5]Univ Maryland, Baltimore, Baltimore, MD

Disclosure Block: **M. Lynch:** None.

Autozygosity, which measures portions of the genome that are homozygous by descent, has been associated with variation in traits of biomedical importance impacting evolutionary fitness in some populations. Estimates of autozygosity can be made from runs of homozygosity (ROHs) that arise when identical-by-descent (IBD) haplotypes are inherited from each parent. In population isolates with a small set of common founders and lack of mating with outside members, autozygosity measurements are elevated and members of such populations often have an increased burden of genetic disease due to increased homozygosity of rare, recessive variants. In this study, we examined the relationship between genome-wide autozygosity and complex traits in 7221 Old Order Amish individuals residing in Lancaster County, PA genotyped on a high-density genome wide array (Illumina Global Screening Array).

We obtained genome-wide estimates of individual autozygosity using the IBD tool implemented in Plink and calculated F_{ROH}, the proportion of the autosomal genome in runs of homozygosity above a specified length. The Amish are a relatively recent founder population, having immigrated from Europe to Lancaster 14-15 generations ago. In this population, the average length of an ROH segment was 5700 KB and the average number of segments per individual was 20, spanning ~3.7% of the genome. Measurements of F_{ROH} were then used as the primary predictor of various traits of interest in association analysis. We analyzed 72 traits including basic anthropometrics, blood pressure, fasting blood lipids, glucose, insulin, HbA1c, basic medical blood chemistry measurements, and medical histories. We did not identify any associations that withstood Bonferroni-correction, but the lead association ($p = 0.003$) with genome-wide F_{ROH} was with EKG QT interval. Although no traits were associated with autozygosity at the genome-wide level, we are currently estimating F_{ROH} regionally for incremental windows across the genome for use in autozygosity mapping to identify novel recessive trait associations.

PrgmNr 2897 - Single cell enrichment of expression and splicing QTL target genes mapped to GWAS loci identifies causal genes and pathogenic cell types for glaucoma and intraocular pressure

Disclosure Block: **A.R. Hamel:** None.

Primary open-angle glaucoma (POAG), characterized by progressive optic neuropathy, is a leading cause of blindness worldwide, for which there are no cures and the pathophysiology is not well understood. Elevated intraocular pressure (IOP) is a major risk factor. A recent multi-ethnic genome-wide association study (GWAS) meta-analysis of 34,179 POAG cases and 349,321 controls identified 127 loci associated with POAG risk, and an IOP GWAS meta-analysis of 139,555 individuals identified 133 associated variants. However, the implicated causal genes and cell types are not known, as the majority of variants lie in noncoding, multi-genic regions, and few measurements of regulatory effects at single cell resolution are available. We developed a novel method, ECLIPSER (Enrichment of Causal Loci and Identification of Pathogenic cells in Single Cell Expression and Regulation data) that tests whether the expression of genes mapped to GWAS loci based on expression quantitative trait loci (eQTLs) and splicing QTLs (sQTLs) for a given complex disease or trait, is enriched in specific cell types. We used colocalization analysis or linkage disequilibrium between e/sQTLs and GWAS loci to map genes to loci. For each trait, tissue, and cell type combination, ECLIPSER scores GWAS loci by the fraction of cell type-specific genes (fold-change>1.4, FDRcis-eQTLs or sQTLs from 49 tissues in GTEx v8 or peripheral retina (EyeGEx), found â¥1 e/sQTLs likely to share a causal effect with 58% of GWAS loci (Posterior Prob>0.5), with an average of 4 eGenes and 2 sGenes per locus. These genes were enriched in cell-cell adhesion, ribonucleotide metabolism, negative regulation of cytokine production, and neuron differentiation. We next applied ECLIPSER to these POAG and IOP GWAS locus sets, using single nucleus expression data from the anterior segment of the eye, retina, and optic nerve head. We found significant enrichment for POAG and IOP in specific cell types, including Beam cells of the trabecular meshwork (TM) and vascular endothelial cells in the outflow pathway, implicated in elevated IOP. Sixteen known and new genes in the TM Beam cells were proposed to contribute to POAG risk, e.g. an sQTL acting on *ANTXR1*. This work proposes cell type-specific causal regulatory mechanisms and genes, and pathogenic cell types for glaucoma that could help guide novel therapeutic design. Our new method can be applied to other complex diseases.

Current publicly available tools that allow rapid exploration of linkage disequilibrium (LD) between markers (e.g., HaploReg and LDlink) are based on low-coverage (2-6X) whole-genome sequence (WGS) data from 1,092 individuals in the 1000 Genomes Project. Here, we present Top-LD, an online tool to explore LD inferred using Trans Omics for Precision Medicine (TOPMed) high-coverage (~30X) WGS data from 15,578 individuals, which include 13,160 individuals of European ancestry, 1,335 individuals of African ancestry, 844 individuals of East Asian ancestry, and 239 individuals of South Asian ancestry. Individuals were selected as those having > 90% ancestry from one of these populations, as estimated from the TOPMed data using RFMix. Top-LD provides a significant upgrade compared to current LD tools as the TOPMed WGS data provide a much more comprehensive representation of genetic variation in these four populations compared to the 1000 Genomes Project. For example, Top-LD encompasses LD information on 134.4, 43.9, and 27.3 million variants with minor allele frequency S1PR3 that is in near perfect LD (Rsq=0.99) with a GWAS sentinel SNP (rs28450540) for circulating monocyte counts. We will present this and other examples of information from Top-LD that have aided fine-mapping of known loci. Top-LD is freely available at http://topld.genetics.unc.edu/topld.

PrgmNr 2899 - Trans-ethnic Transcriptome-wide Association Study and fine-mapping analysis in 3.4 million individuals shed lights on the genetic architecture of alcohol and smoking addiction

View session detail

Author Block: **F. Chen**[1], X. Wang[1], G. Saunders[2], the GWAS & Sequencing Consortium of Alcohol and Nicotine use, Trans-Omics for Precision Medicine (TOPMed) Program; [1]Penn State Coll. of Med., Hershey, PA, [2]Univ. of Minnesota, Minneapolis, MN
Disclosure Block: **F. Chen:** None.
Cigarette smoking is a well-established major heritable risk factor for human diseases. And alcohol consumption has been increasingly associated with the development of chronic diseases and other serious problems, such as heart disease, stroke, and cancer. The availability of large datasets in recent years enabled a breakthrough in the genetics of smoking and alcohol addiction, with more than 400 loci discovered to date (most are with smoking). The identified loci numbers keep growing thanks to the rapidly increasing sample size and involvement of ethnically diverse populations. But it remains challenging to map these non-coding variants to their target genes and translate their biological and clinical relevance. To address this gap, we developed a novel trans-ethnic TWAS approach, TESLA (trans-ethnic transcriptome-wide association study approach using an optimal linear combination of association statistics), that has provably optimal power to integrate trans-ethnic GWAS with eQTL data from a possibly unmatched ancestry. TESLA uses a mixed effect meta-regression model to model ancestry-specific effect across different studies in meta-analysis. We showed using simulation that TESLA substantially outperforms other strategies, including TWAS using fixed effect meta-analysis results and TWAS using only studies from matched ancestries. Using this approach, we aggregated trans-ethnic GWAS and whole-genome sequencing data from GSCAN2 (total N = 3.4 million) and GTEx v8 eQTL data in 49 tissues to further empower gene discovery for tobacco and alcohol use behaviors. We identified 2,652 genes; among them, 148 are novel genes that are outside 1 million basepair window of GWAS sentinel variants. These results provide us much more susceptibility genes for alcohol and smoking addiction than hitherto. For example, besides the well-studied *CHRNA3, CHRNA5, IREB2* and *PSMA4* genes, we also identified novel genes such as *HMGN3* and *LATS1* associated with CigDay (Cigarettes per Day) in multiple tissues. Consistent with previous studies, our results also showed a general lack of tissue specificity across all phenotypes where the most significant genes in each tissue are often ranked the top across many tissues. Further, we performed a fine-mapping analysis in these risk TWAS loci to prioritize putative causal genes. The 90%-credible set of 778 loci were narrowed down to a single gene. These results could help us develop a deeper understanding and broad vision of the genetic architecture of smoking and alcohol use behaviors.

PrgmNr 2900 - Whole exome sequencing analysis identified five novel genes associated with Osteoarthritis

View session detail

Author Block: **S. Werdyani**[1], Q. Li[2], M. Liu[1], A. Dohey[3], D. ORielly[3], P. Rahman[4], G. Zhai[1]; [1]Div. of BioMed. Sci. (Genetics), Faculty of Med., Mem. Univ. of Newfoundland, St. John's, NL, Canada
Disclosure Block: **S. Werdyani:** None.
Background: Osteoarthritis (OA) is the most common chronic progressive joint condition and one of the ten most disabling diseases worldwide. Pathogenesis of OA remains elusive but is thought to be caused by interaction of genetic and environmental factors. This study was to identify genes for knee and hip OA by whole exome sequencing (WES) analysis from the well-established Newfoundland Osteoarthritis Study (NFOAS).
Methods: Study participants were total knee or hip replacement patients due to primary OA who were recruited to the NFOAS before 2017 in St. Johnâ□□s, Canada. Patientsâ□□ blood DNA was extracted and sequenced by the IlluminaÂ® NovaSeq 6000 at the Translational Genomics Laboratory of Memorial University. GATK Best Practices pipeline was followed to align the WES raw paired end reads to the GRCh37 human reference genome, produce master binary alignment map (BAM) files, and create variants calling format (VCF) files. The resulted VCF files were used for the functional variant annotation using ANNOVAR software. Quality control (QC) filtering was set to exclude genetic variants with â□¤ 20X overall depth of coverage and â□¤ 5X for alternative allele. Further, variants having minor allele frequency (MAF) â□¤ 0.01 and â□¥ 0.1 in the general population based on the 1000 genomes project, ExAC, and gnomAD databases were excluded. Finally, only variants present in â□¥ 80% of OA patients were considered as potential OA associated genetic variants.
Results: A number of 144 knee and 56 hip OA patients from the NFOAS (mean age 62.83Â±7.61 years, and 51.5% of them were females) were included in the study. A total of 526,459 genetic variants were identified in the cohort, after the QC, 92 of them were identified to be associated with OA. These genetic variants presented in â□¥ 80% of the OA patients with a MAF of ~ 0.49, for both knee and hip OA. The MAFs of these variants in all public available databases were â□¤ 0.06. Ten exonic nonsynonymous SNV located in *IGSF3*, *ZNF717*, *PRSS1*, *AQP7*, and *ESRRA* genes were estimated to have significant damaging effects on the related proteinsâ□□ structure and function by > 4 functional and pathogenic prediction tools. These genes play a central role in metabolism of water-soluble vitamins and cofactors, aquaporin-mediated transport, glucagon signaling in metabolic regulation, regulation of lipolysis in adipocytes, and the extracellular matrix degradation, but have not been reported in previous OA GWAS studies.
Conclusion: Our data showed five novel genes to be associated with OA. While confirmation is required, the findings provided new insights into better understanding of knee and hip OA pathogenesis and hold promising as druggable targets for developing OA therapies.

PrgmNr 2901 - A comprehensive functional screen detects multiple polymorphic RET enhancers affecting Hirschsprung disease risk

View session detail

Author Block: **L. Fries**[1], K. M. Karasaki[2], A. Kapoor[3], S. Chatterjee[4]; [1]Ctr. for Human Genetics and Genomics, NYU Sch. of Med., New York, NY, [2]Dept. of Biology, Johns Hopkins Univ., Baltimore, MD, [3]UTHSC, Houston, TX, [4]NYU Sch. of Med., New York, NY
Disclosure Block: **L. Fries:** None.
Hirschsprung disease (HSCR), a congenital disorder characterized by enteric aganglionosis, arises from both rare coding and common enhancer variants in the receptor tyrosine kinase gene RET. Though both genome wide association studies (GWAS) and whole genome sequencing have demonstrated the association of multiple non-coding variants at the locus, there hasnâ□□t been a comprehensive functional screen to determine which of these variants disrupt cis-regulatory elements (CREs) and affect *RET* function.Our GWAS on 220 European ancestry trios has deciphered 38 common (minor allele frequency, MAF â□¥10%), non-coding HSCR associated single nucleotide polymorphisms (SNPs) at the RET locus. Functional screens on 8 of these SNPs led to the discovery of 3 independent SNPs, residing within enhancers, that disrupt binding of the transcription factors (TF) RARÎ², GATA2 and SOX10 and affect the transcription of RET and multiple genes of the RET gene regulatory network (GRN).Using the human neuroblastoma cell line SK-N-SH we have now tested the remaining 30 HSCR associated common variants to demonstrate that 22 lie within CREs and of which 7 have sequence variants with differential enhancer and RET gene expression activity in addition to the 3 identified before. We demonstrate that the risk of HSCR is significant for two haplotypes, GCAGGTTGGT (OR 12.2, 95% CI: 5.97-24.93, P=7.02x10-12) and CTGAGTTGGT (OR 7.2, 95% CI: 3.26-15.91, P=1.02x10-6). Two of the new CREs bind transcription factor PAX3, known to affect neural crest cell migration and ENS differentiation. Reducing PAX3 expression using siRNA decreases RET gene expression as well as that of SOX10, the major TF in the RET GRN. Deleting these SNP containing RET CREs using CRISPR/Cas9 genome editing reduces RET expression by only 20-30% but is insufficient to perturb gene expression for other GRN genes as those effects are evident only when RET gene expression falls below 50% of its wildtype level. Therefore, in HSCR, significant reductions of gene expression at RET and its GRN to affect ENS development only occurs in individuals with multiple CRE variants in combination with variants in other GRN genes.

PrgmNr 2902 - Association of DNA Methylation with Mixed Substance Use in an HIV-positive Cohort

View session detail

Author Block: **M. Lin**, A. Justice, K. Xu; Yale Univ., New Haven, CT
Disclosure Block: **M. Lin:** None.
Background Substance use is common in people with HIV and results in worsening HIV progression even under antiretroviral therapy. People may alternately use different substances at different period, referred as mixed substance use (MSU). Recent studies link epigenetic mechanisms with individual substance use such as tobacco smoking, alcohol, or cocaine. However, no study of DNA methylation and MSU has been reported. This study aimed to test an association of DNA methylation in circulating blood of HIV-positive patients who used different level of substances from a longitudinal cohort, Veteran Aging Cohort Study (VACS).
Methods This study included 561 male HIV-positive African Americans. Confirmatory factor analysis was conducted to extract a second-order factor of substance use, accounting for shared variance between tobacco, cannabis, alcohol, cocaine, and heroin use and across three follow-up timepoints. Severity of each substance used was assessed by self-reported frequency of use for each substance at each time point. DNA methylation was profiled with Illumina HumanMethylation EPIC Beadchip. The methylation profiles were filtered and functional normalized with *minfi* package. Singular value decomposition was conducted to remove noise from data. Differential methylation CpG position (DMP) and region (DMR) were analyzed and followed by Gene Ontology and pathway analysis.
Results Confirmatory factor analysis revealed three categories of MSU: Severe (N=166, age=47.83Â±5.94), Moderate (N=305, age=48.06Â±7.77) and Mild (N=90, age=49.81Â±9.45). In comparing Severe and Mild MSU groups, we identified 169 DMPs and 10 DMRs (False Discovery Rate, FDRAHRR, ELMSAN1, SEPT9, MATR3, SIL1, NSMCE1, PRR15, C17orf97, and two long non-coding genes *AC068134.5* and *AC108004.3*. Compared to mild MSU group, individuals with severe MSU showed 69 hypermethylated CpG sites and 100 hypomethylated CpG sites. The genes harboring 169 CpG sites were enriched on inflammatory bowel disease pathway in KEGG pathway database (P BMERB1 gene (FDR = 0.041). No differentially methylated CpG site was identified in comparing Severe to Moderate groups.
Conclusion Our results indicate that mixed substance use is associated with altered DNA methylation. The enrichment of MSU-associated DNA methylation on biological pathways may enhance our understanding of the underlying mechanisms of HIV and its comorbidity.

PrgmNr 2903 - Cis-regulatory hubs constitute a powerful model to understand the impact of 3d organization in schizophrenia

View session detail

Author Block: **L. Mangnier**[1], C. Joly-Beauparlant[2], A. Droit[2], S. Bilodeau[3], A. Bureau[4]; [1]Laval Univ., Medecine Faculty, Quebec, QC, Canada, [2]Ctr. de Recherche du CHU de QuÃ©bec - UniversitÃ© Laval, Quebec, QC, Canada, [3]Ctr. de recherche du CHU de QuÃ©bec â UniversitÃ© Laval, Axe Oncologie, Quebec, QC, Canada, [4]Univ Laval, QuÃ©bec, QC, Canada

The cis-regulatory modules (CRMs) are noncoding regulatory regions, playing a crucial role in the regulation of transcription and the emergence of complex phenotypes. Recent single-cell multi-way analyses show that several CRMs and genes locally co-interact through 3D contacts, building hubs. Despite the importance of CRM hubs in gene regulation, their precise implication in complex diseases such as schizophrenia remains unclear. In the present study, we model cis-regulatory hubs (CRHs), using available Hi-C data in neurons derived from induced pluripotent stem cells and the activity-by-contact model linking active enhancers to promoters. Comparing CRHs to either equivalent tissue-specific or non-tissue-specific structures, we showed that they constitute a relevant organization for schizophrenia. Firstly, we defined CRHs as active structures, associated with gene activity. Then, we assessed the relevance of CRHs in schizophrenia using H-Magma. Considering the noncoding SNPs in 3D contact with genes, we found an enrichment in schizophrenia-associated genes within CRHs compared to genes outside (OR=1.81). Next, using the linkage disequilibrium score regression we showed that a larger portion of schizophrenia heritability is explained by CRHs than non-tissue-specific elements, with enrichment of 3 against 0.43 on average. In addition, we also observed up to 11-fold enrichment in schizophrenia heritability compared to equivalent tissue-specific elements. This result is supported by schizophrenia-associated SNP enrichment (OR=1.29) and tissue-relevant GO pathway analysis. Our results demonstrate that CRHs in neurons constitute a useful model for understanding the 3D organization between CRMs and genes involved in the emergence of complex phenotypes such as schizophrenia.

PrgmNr 2904 - Developmental regulation of neuronal gene expression by Elongator complex protein 1 dosage

Elongator is a highly conserved protein complex required for transcriptional elongation, intracellular transport and translation. Elongator complex protein 1 (ELP1) is the scaffolding protein of Elongator and is essential for its assembly and stability. Familial dysautonomia (FD), a hereditary sensory and autonomic neuropathy, is caused by a mutation in *ELP1* that leads to a tissue-specific reduction of ELP1 protein. Our work to generate a phenotypic mouse model for FD led to the discovery that homozygous deletion of the mouse *Elp1* gene leads to embryonic lethality prior to mid-gestation. Given that FD is caused by a reduction, not loss, of ELP1, we generated two new mouse models by introducing different copy numbers of the human FD *ELP1* transgene into the *Elp1* knockout mouse (*Elp1*$^{-/-}$) and observed that human *ELP1*expression rescues embryonic development in a dose dependent manner. We then conducted a comprehensive transcriptome analysis in mouse embryos to identify genes and pathways whose expression correlates with the amount of *ELP1*. We found that *ELP1* is essential for the expression of genes responsible for the formation and development of the nervous system. Further, gene length analysis of the differentially expressed genes showed that the loss of *Elp1* mainly impacts the expression of long genes and that by gradually restoring Elongator their expression is progressively rescued. Finally, through evaluation of co-expression modules, we identified gene sets with unique expression patterns that depended on *ELP1* expression. Overall, this study highlights the crucial role of *ELP1* during early embryonic neuronal development and reveals gene networks and biological pathways that are regulated by Elongator.

PrgmNr 2905 - Differential methylation signatures in atypical parkinsonism syndromes

Disclosure Block: **P. Reho:** None.

Atypical parkinsonism (AP) refers to a group of heterogeneous, neurodegenerative disorders that include multiple system atrophy (MSA), Lewy body dementia (LBD), progressive supranuclear palsy (PSP), and corticobasal degeneration. Although AP syndromes are clinico-pathologically distinct entities, the clinical presentations commonly overlap and lead to delayed diagnosis. The causes of these disorders are poorly understood, and treatments are limited to supportive care. Despite recent discoveries of genetic risk factors, the role of epigenetic mechanisms is still largely unknown. Cytosine methylation changes DNA accessibility to the transcriptional machinery complex, finely modulating gene expression. These epigenetic events play essential roles during development and can vary across the lifespan in response to lifestyle, environmental factors, as well as genetic variation. We performed an epigenome-wide association study of 363 pathologically defined atypical parkinsonian patients and 131 neurologically healthy controls. We analyzed 230 LDB, 49 MSA and 84 PSP patients. The mean age of death was 78 years for control and LBD subjects, while 73 years and 65 years for PSP and MSA patient respectively. Males and females were equally distributed in our study cohort. We hybridized 450 ng of bisulfite-converted DNA, extracted from cerebellar cortex, to Infinium MethylationEPIC Beadchips (Illumina). The raw data were preprocessed in Genome Studio (Illumina) and exported to the R package â□□minfiâ□□ for further analysis. Low-quality samples (p-value > 0.01), probes located on X and Y chromosomes or that had SNPs at any CpG sites, and probes that failed in at least one individual were excluded from the study. A total of 772,295 probes were available for the analysis. We detected 6,314 differentially methylated probes (adj. p-value -8) located at the transcription start site of 4,571 genes: 2,813 (62%) were hypermethylated and 1,758 (38%) were hypomethylated in AP patients. Differential DNA methylations mainly affected biological processes implicated in neuron differentiation (GO:0030182, adj. p-value $7.55x10^{-15}$) and neurogenesis (GO:0022008, adj. p-value $2.58x10^{-15}$). Notably, differential methylation regions analysis detected 21 modulated probes at the promoter of *ZFP57* gene (Fisher $6.37x10^{-9}$). Preliminary results from our study show a cerebellar DNA hypermethylation signature in AP patients compared to controls, suggesting that epigenetic regulation plays an important role in AP pathogenesis. These insights may pave the way for the identification of new molecular pathways that could be targeted for the development of novel therapeutics.

PrgmNr 2906 - Dissecting multiple-signal GWAS loci and their regulatory roles in Alzheimerâ□□s Disease

View session detail

Author Block: **M. Ionita**, P. P. Kuksa, C. Chen, Y. Leung, L-S. Wang; Penn Neurodegeneration Genomics Ctr., Perelman Sch. of Med. at the Univ. of Pennsylvania, Philadelphia, PA
Disclosure Block: **M. Ionita:** None.
Introduction:
Recent large-scale genome-wide association studies (GWAS) have identified many genomic loci associated with Alzheimerâ□□s disease (AD), most of which are non-coding and pose the additional challenges of identifying underlying non-coding mechanisms and target genes. Robust methods are needed to perform a systematic screening of all genome-wide significant loci from AD GWAS (Kunkle et al, 2019; N=94,437) for multiple (primary and secondary) colocalized variants (genetic signals).
Method:
Using a custom version (https://github.com/matei-ionita/INFERNO_eCAVIAR) of the eCAVIAR method (Hormozdiari et al, 2016), we first identified genome-wide significant GWAS loci with gene-regulatory evidence based on tissue-specific GTEx expression quantitative trait loci (eQTL) data. Colocalized loci were defined as loci with cumulative region-level colocalization probability > 0.5 across tested single- and multiple- variant configurations. For these colocalized gene-regulatory loci, we then performed a multiple-signal analysis to identify all primary and secondary signals with corresponding target genes across 48 tissues.
Results:
We identified 89 non-HLA colocalized loci with 244 target genes across all tissues. We found that 48% of the colocalized AD GWAS loci had evidence for multiple signals in at least one tissue. 14% (1904/13583) of the tested locus-gene-tissue combinations satisfied the colocalization criteria and 14.2% (271/1904) of those had multiple underlying signals. Intriguingly, most colocalized variants (83%) were different from the tag GWAS variant.
We found that colocalized variants were primarily located within non-coding genomic regions, with 50% mRNA intronic, 34% long non-coding RNA, 6.9% UTR signals, with an average distance of 391kb between a colocalized variant and the target gene.
On average, we found 4.18Â±3.42 regulatory variants per identified locus across all tissues, suggesting multiple underlying tissue-specific mechanisms at each GWAS locus. Similarly, we observed tissue-specific effects on the target genes: each identified variant was found to be regulating on average 5.69 genes in 6.2 tissues.
When validated using matching tissue functional genomic data (FILER; Kuksa et al, 2021), the identified variants were located in open chromatin (for 78% of loci) and enhancer regions (for 68% of loci), confirming their active functional roles.
Altogether, our analysis of AD GWAS has identified both primary and secondary signals for the majority (55%) of target genes, including MTCH2, MADD, BIN1 in brain, digestive tissues and blood, recapitulating some of the reported molecular mechanisms for the disease.

PrgmNr 2907 - DNA methylation signature of *ASXL1* variants causing Bohring-Opitz syndrome (BOS)

View session detail

Author Block: **Z. Awamleh**[1], E. Charter-Diehl[1], S. Choufani[1], V. A. Arboleda[2], B. E. Russell[3], R. Weksberg[1]; [1]The Hosp. for Sick Children, Toronto, ON, Canada, [2]Univ. of California Los Angeles, Los Angeles, CA, [3]Univ. of California, Los Angeles, Los Angeles, CA
Disclosure Block: **Z. Awamleh:** None.
The additional sex combs-like (ASXL) gene familyâ□□encoded by *ASXL1*, *ASXL2*, and *ASXL3*â□□is crucial for mammalian development through transcriptional regulation of the *HOX* gene cluster. Pathogenic variants in *ASXL* genes are associated with three phenotypically distinct neurodevelopmental syndromes. Our previous work has shown that syndromic conditions caused by pathogenic variants in epigenetic regulatory genes show consistent patterns of DNA methylation (DNAm) in peripheral blood: DNA methylation signatures. With evidence of the role of ASXL1/2 in chromatin modification, particularly deubiquitylation of lysine (K119) on histone 2A, we hypothesized that pathogenic *ASXL1* variants underlying Bohring-Opitz syndrome (BOS) have a unique DNAm signature. We profiled whole-blood DNAm for 17 *ASXL1* variants, 1 *ASXL2* variant, 7 *ASXL3* variants, and 40 sex- and age-matched typically developing individuals, using Illuminaâ□□s Infinium EPIC array. Using linear regression modelling, we identified 763 differentially methylated CpG sites (q 10%) in individuals with BOS (n=8). Differentially methylated sites overlap 323 unique genes, including *HOXA5* and *HOXB4*, supporting the functional relevance of DNAm signatures. A machine-learning classification model based on the DNAm signature classified a validation cohort of BOS individuals (n=6) with *ASXL1* variants and controls (n=100) correctly, demonstrating 100% sensitivity and specificity. We used the model to classify variants of uncertain significance in *ASXL1* (n=3) as pathogenic or benign; each classification was congruent with the patientsâ□□ clinical phenotypes. We used the machine-learning classification model to classify *ASXL2* and *ASXL3* variants. The *ASXL2* variant classified as pathogenic, whereas the *ASXL3* variants classified as benign. This suggests that *ASXL2* has a DNAm profile overlapping the *ASXL1* DNAm profile, whereas *ASXL3* has a unique profile. Next, we used the DNAm data to investigate DNAm age acceleration using Horvathâ□□s epigenetic clock. We observed acceleration in DNAm age in individuals with pathogenic *ASXL1* variants and the BOS phenotype, and the individual with the pathogenic *ASXL2* variant, but not in individuals with benign *ASXL1* variants or any *ASXL3* variants. Our DNA methylation data provide unique insights into *ASXL* syndrome pathophysiology. The DNAm signature we generated is gene- and syndrome-specific. It classifies all individuals with Sotos, Weaver, and Kabuki syndromes as benign, accurately differentiating pathogenic *ASXL1* variants causing BOS from other neurodevelopmental disorders caused by pathogenic variants in chromatin modifying genes.

PrgmNr 2908 - Epigenome-wide association study of circulating IgE levels identifies novel targets for asthma

View session detail

Author Block: **K. Recto**[1,2], P. Kachroo[3], T. Huan[1,2], G. Lee[1,2], D. Lee[1,2], J. Gereige[4], C. Yao[1,2], S-J. Hwang[1,2], R. Joehanes[1,2], G. O'Connor[4], S. T. Weiss[3], D. Levy[1,2], D. L. DeMeo[3]; [1]Framingham Heart Study, Framingham, MA, [2]Population Sci. Branch, Natl. Heart, Lung, and Blood Inst., Bethesda, MD, [3]Channing Div. of Network Med., Brigham and Womenâ□□s Hosp., Harvard Med. Sch., Boston, MA, [4]Pulmonary Ctr., Boston Univ. Sch. of Med., Boston, MA

Disclosure Block: **K. Recto:** None.

Measurement of circulating immunoglobulin E (IgE) concentration is a valuable aid in diagnosing and treating IgE-associated conditions, most notably asthma and allergic diseases. Identifying novel epigenetic signatures associated with serum IgE is critical to improve the understanding of the molecular mechanisms underlying IgE regulation. To this end, we performed an epigenome-wide association study (EWAS) to identify differential DNA methylation CpG sites associated with circulating IgE levels from 3471 participants in the Framingham Heart Study (FHS). We identified 490 statistically significant CpGs at a false discovery rate (FDR) less than 5%. We next validated our results using two independent cohorts: the Childhood Asthma Management Program (CAMP; n=798) and the Genetic Epidemiology of Asthma in Costa Rica Study (CRA; n=821). Of the 490 FDR-significant CpGs from FHS, 193 loci also passed an FDR less than 5% in both CAMP and CRA cohorts. Gene ontology analysis of the closest gene to the associated CpGs revealed that many of the genes were enriched in pathways related to transcription factor binding, asthma, and other immune system processes. We then analyzed the expression of genes associated with the 193 IgE-associated CpGs (i.e. expression quantitative trait methylation loci; eQTMs), which identified 61 *cis*-eQTMs at an FDR less than 5%. Lastly, using results of genome-wide association studies (GWAS) of IgE and IgE-related diseases, including asthma and allergy, we performed Mendelian Randomization (MR) for the 490 IgE-associated CpGs from FHS with methylation quantitative trait loci (mQTLs) as instrumental variables. MR analysis revealed 13 loci as nominally significant (pFCER1A, a known susceptibility locus for IgE levels. The majority of these associated sites have been previously associated with inflammation, asthma, and other immune functions. To date, there have been no previously published EWAS of IgE that integrate both eQTM and MR analyses. As such, our findings build upon prior knowledge of IgE regulation by providing a deeper understanding of the multidimensional inter-relations of DNA methylation, gene expression, and IgE levels. The IgE-associated loci that we identifiedâ□□particularly those implicated by eQTM and MR analysesâ□□can be explored as promising therapeutic targets for asthma and IgE-related diseases.

PrgmNr 2909 - Genetic effects on brain traits impact cell-type specific alternative splicing during human neurogenesis

Geschwind[4], M. I. Love[1], J. Stein[1]; [1]UNC Chapel Hill, Chapel Hill, NC, [2]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [3]Univ. of California Los Angeles, Los Angeles, CA, [4]Univ California los Angeles, Los Angeles, CA
Disclosure Block: **N. Aygun:** None.
Genetic regulation of splicing is an important risk factor for neuropsychiatric disorders that can be discovered via splicing quantitative trait locus (sQTL) analysis. sQTL analysis is generally performed in bulk post-mortem adult tissue. However, genetic risk loci are enriched in developmentally active regulatory elements, and the impact of risk variants may be masked by heterogeneity in bulk tissue. Here, we performed RNA-seq on a homogeneous population of primary human neural progenitor cells (Ndonor = 85) and their 8-week differentiated, virally labeled, and sorted neuronal progeny (Ndonor = 74), and genotyped donors of each cell line on a dense array (Illumina Omni 2.5+Exome) followed by imputation to a common reference panel (1000 Genomes).We detected sQTLs via testing association between splice junctions and genetic variants located within a Â± 200 kb window from the start and end of junctions per cell-type. We identified 4,568/3,870 intron excisions within 2,275/2,042 sGenes associated with 5,873/4,396 conditionally independent sSNPs-intron junction pairs in progenitors/neurons, respectively (at 5% false discovery rate for a hierarchical multiple testing correction). 79.3%/73.4% of conditionally independent sQTLs in progenitor/neuron were not discovered in fetal bulk brain sQTLs or in adult bulk sQTL data from GTEx using LD-based overlap. Applying co-localization analysis, we observed 29, 20, and 34 brain related trait GWAS loci in total that co-localized with specifically progenitor/neuron sQTLs and sQTLs present in both cell types, respectively. 111 cell-type specific sQTL trait associated loci-intron junction pairs were not fetal bulk cortical sQTLs. For instance, a progenitor specific sSNP (rs1222218, p-value = 5 x 10-9) regulating a novel alternative exon skipping event for *ARL14EP* gene playing a role in axonal development, was colocalized with schizophrenia (SCZ) index SNP (rs1765142). Lastly, applying transcriptome-wide association study (TWAS) approach, we detected the cis-heritable impact of 372/370 intron junctions in progenitor/neuron significantly correlated with at least one brain related-traits. As an example, splicing of an intron of *MRM2* gene encoding a mitochondrial rRNA methyltransferase was associated with increased risk for SCZ specifically in progenitor cells (TWAS-Z: 6.54), but it was not significantly cis-heritable within neuron, fetal bulk or adult bulk data. With this study, we propose a list of novel cell-type and temporal specific genetically altered alternative splicing in the human brain that can be candidate pathways to uncover cellular mechanisms underlying neuropsychiatric disease risk.

PrgmNr 2910 - Leveraging the Mendelian Disorders of the Epigenetic Machinery to Systematically Map Functional Epigenetic Variation

View session detail

Author Block: **L. Boukas**[1,2], T. R. Luperchio[1], K. D. Hansen[2], H. T. Bjornsson[1]; [1]Dept. of Genetic Med., Johns Hopkins Sch. of Med., Baltimore, MD, [2]Dept. of Biostatistics, Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD

Disclosure Block: **L. Boukas:** None.

A long-standing problem in epigenetics is the identification of specific 'epigenotypes' that *causally* mediate disease phenotypes via the alteration of transcriptional states. While for many diseases statistical associations have been detected, it is challenging to rule out the influence of confounders like environmental exposures, and to decide whether these epigenetic changes are a cause or consequence of the disease process.

We propose an approach to overcome these issues, by leveraging the Mendelian Disorders of the Epigenetic Machinery (MDEMs). In MDEMs, a coding variant disrupts an epigenetic regulator, leading to epigenetic abnormalities, which give rise to the phenotype, likely through a perturbation of the transcriptome. Although each MDEM has a different causative gene, at the phenotypic level MDEMs share common manifestations. We hypothesize that this phenotypic convergence results from shared epigenetic/transcriptomic alterations, and that identifying these will provide a catalog of loci/genes where epigenetic/transcriptomic variation is causally related to disease phenotypes. As proof-of-principle, we use mouse models of Kabuki syndromes type 1 and 2 (KS1 and 2; caused by haploinsufficiency of histone methyltransferases KMT2D and KDM6A, respectively), and Rubinstein Taybi type I (RT1; caused by haploinsufficiency of histone acetyltransferase CREBBP). We focus on the immune dysfunction exhibited by all three syndromes, which includes hypogammaglobulinemia and abnormal B cell development. We perform ATAC-seq and RNA-seq on sorted B cells from mutant mice, and from age- and sex-matched wild-type littermates from the same strain, thus controlling for both genetics and the environment.

We develop a new statistical approach for this kind of analysis, which we show provides us with increased power. We discover that 69% of promoters disrupted in KS1 are disrupted in KS2 also, with 67% of the shared KS1/2 promoters disrupted in RT1. This overlap is also present at enhancers, but to a lesser extent (51% shared between KS1/2, with 36% of those shared with RT1). We show that disruption of chromatin accessibility at promoters often leads to dysregulation of downstream gene expression, and find that genes whose promoters are disrupted in all three MDEMs are more likely to have dysregulated expression. Finally, we find that subtle expression changes in multiple, directly relevant genes, likely collectively contribute to the IgA deficiency and abnormal B cell development in these MDEMs.

In summary, we propose the study of MDEMs as a principled approach for systematically mapping disease-causing epigenetic variation in mammals.

PrgmNr 2911 - MeQTL Mapping for Present Cocaine Use and Persistent Cocaine Use in a Veteran Population

View session detail

Author Block: **Y. Cheng**[1], B. Li[2], A. Justice[3], K. Xu[4]; [1]Dept. of Biostatistics, Yale Sch. of Publ. Hlth., New Haven, CT, [2]Yale Sch. of Publ. Hlth., New Haven, CT, [3]Dept. of Internal Med., Yale Sch. of Med., New Haven, CT, [4]Yale Sch. Med., New Haven, CT
Disclosure Block: **Y. Cheng:** None.
Background. The influence of genetic variant on complex traits is potentially mediated through DNA methylation, referred to as Methylation quantitative trait loci (meQTLs). We recently reported significant DNA methylation aberrant in persons who persistently used cocaine. To further understand the mechanism of cocaine-associated DNA methylation, in this study, we performed a meQTL mapping for cocaine use in the Veterans Aging Cohort Study Biomarker Cohort (VACS-BC) (N=669). In this veteran population, 97.5% are male (n= 652) and 2.5% are female (n= 17), and the average age at baseline is 49.3 (SD=7.8).
Methods. Global ancestry for each sample was inferred using reference 1000 human genome. DNA methylation in whole blood samples was profiled by Illumina HumanMethylation 450K Beadchip. Present cocaine use was defined as self-reported â□□current use within 12 monthsâ□□ at a visit, and persistent cocaine use was defined as â□□current useâ□□ across 5 visits in a subset of the VACS-BC. We first conducted two separate EWAS scans for the 2 traits to select candidate CpG sites at p
Results. EWAS scans identified 497, and 499 candidate CpG sites for present cocaine use, and persistent cocaine use, respectively, while 3,058 and 4,507 meQTL clumps were further identified for the 2 corresponding traits. Nearby genes for the most significant clumped MeQTL included *MMP17* (cg22244940 - rs7487262, estimated effect = 1.59, p = 3.96e-239), *KIF25* (cg08476511 - rs58330252, estimated effect = -1.06, p = 9.42e-46), *BDNF* (cg10635145 - rs4922793, estimated effect = -0.34, p = 2.46e-17) for present cocaine use, *ATP8B4* (cg13399903 - rs7172615, estimated effect = 1.22, p = 2.37e-185) for persistent cocaine use. There were 12 and 23 pathways reaching nominal significance for the 2 traits, but they were not statistically significant after multiple test adjustments. Top ranked pathways included inflammatory bowel disease (p=0.011), cocaine addiction (p=0.014) for present cocaine use, IL-17 signaling pathway (p=0.006), viral carcinogenesis (p=0.006) for persistent cocaine use.
Conclusion. We identified a set of genetic variants significantly correlated with cocaine-use related DNA methylation. These findings deepen our understanding of genetic variants in cocaine-use related methylation alterations.

PrgmNr 2912 - Meta-analysis of gene expression data in Alzheimer's disease identifies sex-differential effects in multiple brain tissues

View session detail

Author Block: **J. Young**[1], A. Varma[1], L. Gomez[1], H. Dykxhoorn[1], B. Kunkle[1], L. Wang[2], E. R. Martin[2]; [1]Univ. of Miami, Miami, FL, [2]Univ. of Miami Miller Sch. of Med., Miami, FL
Disclosure Block: **J. Young:** None.
There are well-known epidemiologic, clinical, and neuropathological differences between men and women with Alzheimer's disease; however, the underpinnings of these differences are not well understood. Some studies point to sex differences in gene expression and the effects on AD, providing evidence of genes or pathways with sex-differential effects. We performed a meta-analysis of multiple studies, with gene expressions data on multiple brain regions to identify genes with sex-differential effects between AD cases and controls.We obtained array-based gene expression and covariate data from four datasets (GSE44772, GSE3300, GSE5281, SYN3157225). Gene expression data were normalized after stratifying datasets by tissue and sex using the Robust Multichip Averaging method. Outlier samples were detected and excluded using Principal Component Analysis. Probes with expression in the bottom 10^{th} percentile in over 80% of samples were excluded. Surrogate Variable Analysis was used to detect and adjust hidden batch effects within each dataset. Our initial analyses focused on three brain regions: dorsolateral prefrontal cortex (DLPFC 293 F/400 M), visual cortex (VC 96 F/162 M), and cerebellum (CBM 248 F/353 M). A fixed-effects inverse variance weighted meta-analysis was then used to combine cohort-specific association between AD and gene expression stratified by sex. This analysis resulted in the identification of sex-specific genes (FDR-significant exclusively in one sex). In addition, we applied a sex-interaction model that allowed us to identify genes with nominal significance in both sexes with a significant sex-interaction term. We analyzed the cross-tissue overlap of differentially expressed genes from both categories, sex-stratified and sex-interacting. We found three female-specific and 111 male-specific differentially expressed genes common to the three regions. From the sex-interacting genes, we found that two were differentially expressed in the three brain regions (*RIC8B* and *DOT1L*). Both genes showed highly significant evidence of association with AD in men and women, but the estimated effects (beta) in females in the three regions (RIC8B ranging 0.094-0.099; DOT1L ranging 0.110-0.162) were significantly larger than in males (RIC8B 0.047-0.057; DOT1L 0.026-0.047). In summary, we have performed a meta-analysis of multiple array-based gene expression studies and prioritized genes likely to have sex-differential effects on AD in multiple brain regions. Further analyses will include additional brain regions and RNAseq datasets, aiming to determine the mechanisms that underlie the difference between male and female AD patients.

Identification of risk variants for neuropsychiatric diseases within enhancers underscores the importance of understanding the population-level variation of enhancers in the human brain. Besides regulating tissue- and cell-type-specific transcription of target genes, enhancers themselves can be transcribed. We expanded the catalog of known human brain transcribed enhancers by an order of magnitude by generating and jointly analyzing large-scale cell-type-specific transcriptome and regulome data. Examination of the transcriptome in 1,382 brain samples in two independent cohorts identified robust expression of transcribed enhancers. We explored gene-enhancer coordination and found that enhancer-linked genes are strongly implicated in neuropsychiatric disease. We identified significant expression quantitative trait loci (eQTL) for 25,958 enhancers which mediate 6.8% of schizophrenia heritability, mostly independent from standard gene eQTL. Inclusion of enhancer eQTL in transcriptome-wide association studies enhanced functional interpretation of disease loci. Overall, our study characterizes the enhancer-gene regulome and genetic mechanisms in the human cortex in both healthy and disease states.

PrgmNr 2914 - Power-improved meta-QTL analysis reveals the complex regulation of molecular QTL associated with brain diseases

View session detail

Author Block: **B. Zeng**, J. Bendl, G. E. Hoffman, R. Roussos; Icahn Sch. of Med. at Mount Sinai, New York, NY
Disclosure Block: **B. Zeng:** None.
Co-localization of risk variants for brain diseases with molecular quantitative trait loci (QTL) aims to refine the credible sets of causal variants and link them to specific genes. Increasing sample size and performing trans-ethnic analysis can increase fine-mapping resolution, and enlarge the power of colocalization analysis. We developed a statistical method, called multivariate multiple QTL (mmQTL), to perform multi-tissue and trans-ethnic large-scale QTL analysis. We first perform dense simulations to demonstrate that mmQTL increases power to detect QTLs, controls the false positive rate in trans-ethnic analysis, and reduces the credible sets of causal variants. We then applied mmQTL on brain bulk RNA-seq (n=3,956 libraries from 2,119 unique donors) and cell-type specific ATAC-seq samples (n=1995 libraries from 646 unique donors) from neuronal and glial cell types. We identify 10,769 eGenes (genes with at least a genome-wide significant eQTL), of which 5,336 eGenes have multiple eQTLs. We detect 17,425 significant caQTL in the neuronal cell, and 15,746 in the glial cell. Functional analysis based on evolutionary scores and rare-variant burden reveals eGenes are more likely to be mutant tolerant than no-eQTL genes, indicating evolutionary constraints on gene expression in the brain. Non-primary eQTLs capture regulatory elements defined by ATAC-seq peaks and are enriched for neuro-degenerative diseases. We found that caQTLs are largely shared among brain regions, but not in cell types. Fine-mapped variants from the power-improved caQTL are enriched to disrupt TF binding sites, and there are different sets of TF genes affected in neuronal and glial cells. Lastly, we integrated the detected eQTL and caQTL to conduct caQTL-eQTL-GWAS colocalization analysis, and revealed the regulation patterns for some disease-associated genes in the human brain. In this study, we have created the largest brain eQTL and caQTL resources to date, and they should be valuable to the community in exploring the underlying biological mechanism in brain diseases.

PrgmNr 2915 - Sex differences in the human brain transcriptome of cases with schizophrenia

View session detail

Author Block: **Y. Ma**; Icahn Sch. of Med. at Mount Sinai, New York City, NY
Disclosure Block: **Y. Ma:** None.
Background: Schizophrenia differs between males and females in the course of the disease and the molecular mechanisms underlying these differences remain uncharacterized. Schizophrenia is a multi-factorial neurodevelopmental impairment of the brain that can be attributed to both genetic and environmental factors. Gene expression is a consequence of both the genetic and environmental factors that contribute to the pathophysiology of the disease. **Methods:** In order to address questions about how sex differences contribute to schizophrenia gene expression, we performed a large-scale multiscale embedded-gene coexpression network analysis (MEGENA) of RNA-seq data from 437 controls and 341 cases from two distinct cohorts from the CommonMind Consortium. **Results:** By performing a network analysis to reduce dimensionality and elucidate interactions among genes, we identified co-expressed gene modules and then characterized their enrichment for differential expression signatures for diagnosis, sex, and sex-by-diagnosis interaction. Sex-by-diagnosis interaction associated modules were more likely to be enriched for diagnosis differential expression signatures for both cohorts. Only a small number of modules were enriched for sex signatures, which show only partial overlap with the diagnosis effects. We found enrichment of co-expression modules for sex-by-diagnosis differential expression signatures, which were highly reproducible across the two cohorts and involve a number of diverse pathways, including neural nucleus development, neuron projection morphogenesis, and regulation of neural precursor cell proliferation. For the top sex-by-diagnosis interaction enriched module, we identified a significant enrichment for schizophrenia common genetic variation. CASKIN1 is a key regulator of this module that is reproduced among both cohorts. CASKIN1 has a reduced expression in schizophrenia patients and is also known as a synaptic scaffolding protein to play a role in signal transduction. **Conclusions:** The network approach has uncovered a number of gene modules and key regulators of schizophrenia. Our results indicate that any sex differences in schizophrenia gene expression signatures are likely small. This underscores the challenge of identifying robust sex-by-diagnosis signatures, which will require additional analyses in larger cohorts in the future.

PrgmNr 2916 - Sex-specific profiles of m6A RNA methylation in the brain of individuals with major depressive disorder

View session detail

Author Block: **H. Mitsuhashi**[1], C. Nagy[1], Z. Aouabed[2], P. Danthi[2], G. Turecki[3]; [1]McGill Univ., Montreal, QC, Canada, [2]McGill Group for Suicide Studies, Montreal, QC, Canada, [3]Mc Gill Univ, Montreal, QC, Canada
Disclosure Block: **H. Mitsuhashi:** None.
Introduction: Females are twice as likely to be diagnosed with Major Depressive Disorder (MDD); however, males are 3.5 times more likely to die by suicide. This is a striking example of sex differences in MDD, and mounting evidence suggests that it may be driven by sex-specific molecular mechanisms. Epigenetic mechanisms, which are altered in response to environmental factors, are known to be involved in the pathophysiology of MDD; however, little is known about the impact of the epitranscriptome. In recent years, RNA modifications have emerged as a dynamic and crucial mechanism in the post-transcriptional regulation of gene expression. Among the 150 known RNA modifications, N6-methyladenosine (m6A) is the most abundant and reversible RNA modification in mammalian messenger RNA (mRNA). Emerging evidence suggests that m6A plays an important role in the brain, including neurodifferentiation, neurogenesis, and memory and learning. Moreover, recent studies have linked m6A to molecular and behavioral responses to stress, making it an important candidate regulator of stress-related psychiatric disorders, including MDD. This study aims to describe the landscape of m6A in the human brain and to identify changes that may occur in the context of MDD. **Methods:** First, the postmortem stability of m^6A and the influence of age, RNA Integrity, and pH on global m^6A levels were investigated in human postmortem brain tissue. Next, we optimized a low-input m6a-seq method for human postmortem brain tissue and confirmed that the m6a-peaks are enriched in the known m6A GRACH motif and near 3â□□UTR and stop codon as suggested by the previous study. The ventromedial prefrontal cortex was obtained from male and female MDD and healthy control subjects to investigate the role of m6A in MDD. We performed m6A-seq and RNA-sq to investigate m6A at transcripts levels and the impact of m6A on gene expression. **Results:** Our results suggest that PMI does not significantly influence global m^6A levels, and m^6A is relatively stable in the postmortem brain. In our m6a-seq data, we identified ~25,000 m6A peaks in the human brain, and these peaks were enriched in genes related to neuronal and synaptic regulation. Moreover, our results show a distinct m6A profile in MDD and control, with a little overlap between males and females. **Conclusion:** This project will help us understand the role of m6A in stress-related psychiatric disorders and will serve as a much-needed example of sex-specific analysis in psychiatric research.

PrgmNr 2917 - Single Nuclei Sequencing of Human Putamen Oligodendrocytes Reveals Altered Heterogeneity and Disease-Associated Changes in Parkinsons Disease and Multiple System Atrophy

View session detail

Author Block: **E. Teeple**[1], P. Joshi[2], R. S. Pande[1], Y. Huang[1], A. Karambe[1], M. Latta-Mahieu[2], P. Sardi[3], A. Cedazo-Minguez[2], K. W. Klinger[4], A. Flores-Morales[2], S. L. Madden[1], D. Rajpal[1], D. Kumar[5]; [1]Sanofi, Framingham, MA, [2]Sanofi, Chilly-Mazarin, France, [3]Genzyme a Sanofi Company, Framingham, MA, [4]Sanofi Genzyme, Framingham, MA, [5]Framingham, MA

Disclosure Block: **E. Teeple:** Salary/Employment; Sanofi.

The role of oligodendrocytes in neurodegenerative diseases remains incompletely understood. We profiled 87,086 single nuclei from human brain putamen region for healthy control, Parkinsons Disease (PD), and Multiple System Atrophy (MSA). Oligodendrocyte lineage cells were the dominant celltype in the putamen and subpopulations clustered by transcriptomic variation found to exhibit diverse functional enrichment patterns. Oligodendrocyte heterogeneity was altered in disease-specific ways. Among profiled subpopulations, differences in expression of SNCA, HAPLN2, MAPT, APP, and OPALIN were observed for PD and MSA compared with healthy controls. Intriguingly, greater activation of unfolded protein response pathway gene expression was observed in PD versus MSA. Using network analysis, we identified specific PD- and MSA-correlated gene co-expression modules enriched with disease-relevant pathways, and the PD-correlated module was significantly enriched for Parkinsons Disease GWAS loci ($p = 0.01046$). Our analysis provides a broader understanding of oligodendrocyte functional biology and reveals distinctive oligodendrocyte pathological alterations associated with PD and MSA which may suggest potential novel therapeutic targets and new strategies for disease modification.

PrgmNr 2918 - TET1 mediated modulation of Alzheimerâ□□s disease

View session detail

Author Block: **M. Armstrong**, P. Jin; Emory Univ., Atlanta, GA
Disclosure Block: **M. Armstrong:** None.
Background: Human sequencing studies have identified roughly 30 risk loci associated Alzheimerâ□□s disease (AD). However, these loci only explain a portion of disease pathogenicity. Recent studies support a link between gene-environment interactions and AD, and published work from our lab indicates *TET1* mediates gene-environment interactions and *TET1* KO reduces stress response in mice [1]. Furthermore, DNA deep sequencing studies identified an enrichment of rare *TET2* variants associated with AD [2]. This study examines how knockout of the *TET1*, a DNA 5-hydroxymethylcytosine (5hmC) regulator, influences AD-associated transcription and pathological outcomes in the 5xFAD AD mouse model.
Methods: We measured cognitive/behavioral, 5hmC, and expression profiles of a *TET1* heterozygous knockout in the 5xFAD mouse model to examine the influences of *TET1* KO on AD pathogenicity.
Results: We show significant differences in behavior, cognition, 5hmC methylation and expression profiles of FAD/$TET1^{+/-}$ mice relative to WT and FAD. In relation to FAD, FAD/$TET1^{+/-}$ improved stress response in the Tail-Suspension Assay ($p = 0.0438$), and relative to WT mice, FAD/$TET1^{+/-}$ mice display a reduction in their latency to mount the platform in the Morris water maze ($p = 0.01$). Analysis of 5hmC capture data revealed 2536 differentially hydroxymethylated regions (DhMRs) upregulated in FAD/*TET1*+/- and 410 DhMRs downregulated relative FAD (FDR > 0.05). Analysis of the expression data highlighted 132 differentially expressed genes (DEGs) in FAD/$TET1^{+/-}$ relative to FAD (FDR > 0.05). Among the genes exclusive to the FAD/*TET1*+/- mice were *NR4A1*, *ARC*, and *APLP1*. Notably, *NR4A1* appeared in both the 5hmC and RNA-Seq data with increased levels of 5hmC and gene expression relative to FAD mice. Gene ontology analysis of RNA expression data identified significant changes in pathways involved in regulation of ion transmembrane transport, behavioral fear response, regulation of trans-synaptic signaling, and learning or memory.
Conclusion: Taken together, these results suggest *TET1* modulates AD-associated gene regulation, expression, and pathology.

PrgmNr 2919 - The Musculoskeletal 3D Epigenome Atlas

View session detail

Author Block: **M-J. Tsai**[1], S. Reppe[2], T. Sato[3], R. Gill[4], M. Wein[3], K. Gautvik[2], NHLBI TOPMed Bone Mineralization workgroup, Y-H. Hsu[1]; [1]Marcus Inst. for Aging research and Harvard Med. Sch., Boston, MA, [2]Oslo Univ. Hosp., Oslo, Norway, [3]Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, [4]Genentech, San Mateo, CA

Disclosure Block: **M. Tsai:** None.

Musculoskeletal (MSK) disorders are a common and costly problem for elderly populations worldwide, most of which are polygenic disorders. Although an increasing number of human genome-wide association studies (GWAS) and population-based biobank studies identified sequence variants associated with risks of musculoskeletal diseases, there is a lack of information about the cell types in human bone and skeletal muscle tissues. Moreover, it is not a trivial task to understand specific genes regulating the landscape and understanding their functional involvement in musculoskeletal biology, especially for non-coding related variants.To address this issue, we generated HI-C seq, ATAC-seq, and RNA-seq in human primary mesenchymal stem cells, pre-mature osteoblasts, matured osteoblasts, osteocytes, skeletal myoblasts, and myotubes obtained from bone and skeletal muscle biopsies. These data were then combined with publicly available DNase-seq and ChIP-seq in a handful of relevant cell types from the ENCODE and Roadmap Epigenomics projects. We established global maps of regulatory elements and 3D chromatin looping structure with high-resolution (2kb) in human MSK relevant primary cell types. We identified (1) MSK-specific active enhancer-like regions; (2) MSK-specific active transcription factor binding sites and downstream-regulated genes in the open chromatin regions; (3) MSK-specific active promoter-like regions and transcription factors for protein-coding genes; (4) MSK specific proximal and distal enhancer-promoter interactions via the high-resolution 3D loop structure with ATAC-seq and RNA-seq data. The 3D MSK gene regulatory circuits and landscapes are implemented into an online searchable browser, which provides target gene prediction for all available (~700 million) non-coding variants for relevant diseases, visualization for MSK cell-type-specific gene regulatory circuits annotation for every sequence variant observed so far. We also integrated all update-to-date GWAS findings from GWAS Catalog to provide post-GWAS analyses for in-silico functional annotation of associated variants and underlying causal variants and genes prediction. We plan to extend our 3D Epigenome Atlas with additional human primary musculoskeletal cell types with single-cell RNA-seq and single-cell ATAC-seq.In summary, by integrating cell-type-specific multi-omics data, we have established MSK gene regulatory landscapes and developed an online searchable browser that provides comprehensive epigenome annotation and visualization of the 3D genome chromatin interactions. The browser is publicly available.

PrgmNr 2920 - Unraveling the role of cell type specific noncoding variations in craniofacial disease

View session detail

Author Block: **E. Winchester**[1], T. Yankee[2], K. Child[3], J. Cotney[3]; [1]UConn Hlth.DMD/PhD Program, Farmington, CT, [2]UConn Hlth.Graduate Program, Farmington, CT, [3]UConn Hlth.Dept. of Genetics and Genome Sci., Farmington, CT
Disclosure Block: **E. Winchester:** None.
Craniofacial disorders such as orofacial clefting are common congenital defects which affect a significant percent of live births, posing a public health and financial burden to society. Previously, we have associated the role of noncoding genomic sequences of the developing face in the heritability of craniofacial morphology and oral clefting. The noncoding genome contains sequences called enhancers which facilitate expression of target genes through recruitment and binding of transcription factors. Enhancers are typically active in developmental stage and cell type specific patterns, controlling the spatiotemporal expression patterns of target genes. Enhancer sequence variation can alter expression of target genes to cause isolated phenotypes in the cell type of activity, ranging from normal morphological differences to malformations. While we have established the role of craniofacial-specific enhancers in normal morphology and disease through bulk craniofacial assays, the contributing cell types are unknown, limiting work in prevention and treatment of malformations. To uncover cell type-specific enhancers whose sequence variants contribute to normal facial morphology and malformations, we profiled regions of the genome that were accessible at the single nucleus level (snATAC-seq) in primary human craniofacial tissues from 7 distinct Carnegie stages (CS12-20; 4-9 weeks post conception). In our initial analysis of CS17, we identified 6 distinct cell types and their unique regions of accessible chromatin. Single nucleotide polymorphisms associated with orofacial clefting and normal facial morphological differences were interrogated for their enrichment in these cell-type specific accessible regions of chromatin and contrasted to similarly profiled regions from hundreds of tissues from the Encode Consortium. We observed that variants associated with normal craniofacial morphology are significantly enriched in mesenchyme-specific accessible regions. Interestingly, variants that are associated with risk for orofacial clefting showed differences in cell-type specificity based on the population ancestry; in studies of individuals of European ancestry, clefting variants were enriched in mesenchyme-specific regions while in East Asian ancestry variants were enriched in epithelial regions. These results indicate differences in molecular mechanisms underlying similar phenotypes in different populations. In further analysis of the remaining stages we will confirm these results and refine the window of human craniofacial development and specific cell types that contribute to craniofacial development and malformation.

PrgmNr 2921 - Widespread shifts in muscle gene expression associated with reduced gait speed in a non-human primate model of aging

View session detail

Author Block: **E. E. Quillen**, B. Frye, G. Li, J. Chan, M. Stainback, T. Register, S. Craft, L. Cox, C. Shively; Wake Forest Sch. of Med., Winston Salem, NC
Disclosure Block: **E.E. Quillen:** None.
Declining muscle mass leading to sarcopenia is a major contributor to increased morbidity and loss of independence among older adults. Gait speed is a reliable biomarker of overall musculoskeletal health as well as increased risk of disability and mortality among both humans and non-human primates. In a cohort of 28 female, middle-aged and older adult vervet monkeys (*C. sabaeus*) housed in the Vervet Research Colony at Wake Forest School of Medicine, we measured habitual gait speed and generated total RNA sequence data from contemporaneous muscle biopsies of the vastus lateralis. We focus here on mRNA. Following quality control, reads were aligned to the current version of the vervet transcriptome and lowly expressed genes filtered out resulting in > 9,000 transcripts which were TMM normalized and evaluated for association with gait speed while controlling for age. To account for the genetic relatedness of the vervets which are part of a larger pedigree, we fit a generalized linear mixed model including kinship as a random effect. 368 transcripts were significantly differentially expressed, of which 67% were upregulated in association with faster gait speed. The genes showing the greatest log-fold changes were also those with the highest average expression including genes encoding major contractile proteins in fast twitch (*MYH1*) and slow twitch muscle fibers (*TNNT1*, two transcripts). Additionally, major shifts were identified in the expression levels of energy metabolism genes including enzymes that catalyze ATP hydrolysis (*ATP2A3*), iron metabolism *(FTH1*), and mitochondrial activity (*IDH2*). To contextualize the 368 significantly associated genes, we compared them to previously generated muscle transcriptome data sets collated from the Gene Expression Omnibus (GEO) by SysMyo. We performed Fisherâ□□s exact tests to compare the enrichment of our 368 differentially expressed genes to 1000 randomly generated sets of 368 genes present in muscle. Empirical *p*-values

PrgmNr 2922 - Accurate identification of circRNA landscape and dynamic regulation during early neuronal differentiation

View session detail

Author Block: **F. Wang**, Y. Li, B. Yao; Dept. of Human Genetics, Emory Univ. Sch. of Med., Atlanta, GA
Disclosure Block: **F. Wang:** None.
Circular RNAs (circRNAs) are a class of endogenous single-stranded RNAs with a unique circularized structure derived mostly from back-splicing of exons in precursor mRNAs and have recently emerged as one of the pivotal regulatory RNAs in mammals. CircRNAs has been shown to undergo spatiotemporal regulation and play important roles during mammalian brain development. However, circRNA identification and quantification have been suffering from relatively low power and sensitivity, and prone to high false discovery rate at both experimental and computational level. Here, we employed a recent-established method in combination of poly(A) tailing and RNase R digestion (refer as â□□A-tailingâ□□) to effectively deplete linear RNAs for circRNA enrichment. By using A-tailing approach coupled with rRNA-depleted RNA-seq, we interrogated the genome-wide circRNAs landscape and their dynamic regulation during early neuronal cell differentiation using human neuroblastoma cell line SH-SY5Y. SH-SY5Y cells were assayed in a 17-day differentiation protocol by retinoic acid and BDNF treatment. Successful differentiation was validated at both cellular and molecular levels, with the differentiated cells showing expansive and branched neuronal phenotype and expression of neuronal markers including TUJ1, MAP2 and SMI31. Comparing with published circRNA profile in SH-SY5Y cells, our data displayed robust, sensitive and high confident identification that captured more than 19,000 previously undetected circRNAs in SH-SY5Y cells. During SH-SY5Y differentiation, 404 and 619 circRNAs were significantly downregulated or upregulated, respectively (FDR

PrgmNr 2923 - Alcohol Use Disorder is associated with DNA methylation-based shortening of telomere length and regulated by *TESPA1*: implications for aging

View session detail

Author Block: **J. Jung**, J. Wagner, F. W. Lohoff; Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD
Disclosure Block: **J. Jung:** None.
Chronic heavy alcohol consumption is associated with increased mortality and morbidity and often leads to premature aging; however, the mechanisms of alcohol-associated cellular aging are not well understood. In this study, we used DNA methylation derived telomere length (DNAmTL) as a novel approach to investigate the role of alcohol on the aging process. DNAmTL was estimated by 140 cytosine phosphate guanines (CpG) sites in 372 individuals with alcohol use disorder (AUD) and 243 healthy controls (HC), including various endophenotypes and clinical biomarkers. Exploratory genome-wide association studies (GWAS) on DNAmTL were performed to identify genetic variants contributing to DNAmTL shortening. Top GWAS findings were analyzed using in-silico expression quantitative trait loci analyses and structural MRI hippocampus volumes of individuals with AUD. DNAmTL was 0.11-kilobases shorter per year in AUD compared to HC after adjustment for age, gender, race, blood cell counts (p=4.0x10^{-12}). This association remained significant after additionally adjusting for BMI, and smoking status (0.05 kilobases shorter per year, p=0.002). DNAmTL shortening was strikingly associated with chronic heavy alcohol use (psTESPA1), at the genome-wide level (p=3.87x10^{-8}). The major allele C of rs4374022 driving the DNAmTL shortening was associated with decreased hippocampus volume (pp=0.04). Our study demonstrates DNAmTL-related aging acceleration in AUD and suggests a functional role for *TESPA1* in regulating DNAmTL possibly via the immune system with subsequent biological effects on key brain regions implicated in aging.

PrgmNr 2924 - Chromatin accessibility and gene expression during adipocyte differentiation identify context-dependent effects at cardiometabolic GWAS loci

Mohlke[2]; [1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Univ North Carolina, Chapel Hill, NC, [3]Carrboro, NC, [4]Univ. of Ulm, Ulm, Germany, [5]Univ. of Eastern Finland and Kuopio Univ. Hosp., Kuopio, Finland, [6]UNC-Chapel Hill, Chapel Hill, NC
Disclosure Block: **H.J. Perrin:** None.
Chromatin accessibility and gene expression in relevant cell contexts can guide identification of regulatory elements and mechanisms at genome-wide association study (GWAS) loci. To identify regulatory elements that display differential activity across adipocyte differentiation, we performed ATAC-seq and RNA-seq in a cell model of preadipocytes and of adipocytes at days 4 and 14 of differentiation. For comparison, we created a consensus map of ATAC-seq peaks in 11 subcutaneous adipose tissue samples. We identified 58,387 context-dependent chromatin accessibility peaks and 3,090 context-dependent genes between all timepoint comparisons (log2 fold change>1, FDR

PrgmNr 2925 - Deconvolution of genetic variation using high-quality *cis*-regulatory elements map of kidney cells

View session detail

Author Block: **S. Han**[1], Y. Muto[2], P. C. Wilson[2], B. D. Humphreys[2], M. G. Sampson[1], D. Lee[1]; [1]Boston Children's Hosp., Boston, MA, [2]Washington Univ. in St. Louis, St. Louis, MO
Disclosure Block: **S. Han:** None.
Genome-wide association studies (GWAS) have facilitated the discovery of disease- or trait-associated genetic variants that can ultimately lead to improved precision of clinical diagnosis and/or molecular pathogenesis in a translational medicine framework. However, identifying specific cell types within organs in which the GWAS variants exert their function remains a significant challenge, especially for the complex and heterogeneous kidney. To tackle this, we constructed high-quality maps of cis-regulatory elements (CREs) for kidney cells to deconvolute GWAS variants for kidney-relevant phenotypes. Specifically, we devised a computational framework using a sequence-based predictive model that maximally detects CREs by identifying open-chromatin regions with marginal read-mappings but harboring CRE sequence features. We applied this method to kidney ATAC-seq data. Our high-quality CRE maps have enabled us to detect >100,000 CREs for podocytes, a key rare (h_g^2]=9.3%). Heritability analysis using these CRE maps uncovered the differential contribution of specific cell types to two major kidney functional traits, UACR and estimated glomerular filtration rate (eGFR). As would be predicted from physiologic understanding, CREs for podocytes and proximal tubule cells (PT) had enriched proportion of SNP-heritability for UACR and eGFR, respectively (UACR: Pr[h_g^2]/Pr[SNPs]=6.8 for podocyte, 2.3 for PT; eGFR: Pr[h_g^2]/Pr[SNPs]=-1.9 for podocyte, 4.3 for PT. Moreover, we found the podocyte relevance of a known GWAS variant (rs17831251; OR=2.25, P=4.7Ã□10$^{â□□103}$) on *PLA2R1* associated with Membranous Nephropathy. Our CRE map showed strong podocyte-unique CRE that overlaps with the index variant, suggesting that the index SNP is potentially the causal variant perturbing podocyte-specific transcriptional regulation of *PLA2R1*. Taken together, we expect that the deconvolution of GWAS variants using the high-quality kidney CRE maps will provide cell-type relevance of GWAS variants on genetic effects not captured by single-cell RNA-seq alone. This will empower the functional interpretation of genetic variation associated with kidney traits and diseases.

PrgmNr 2926 - Engineering a synthetic humanized *RET* mouse to model Hirschsprung Disease

View session detail

Author Block: **R. Fine**[1], S. Chatterjee[1], J. Laurent[2], J. Boeke[2], A. Chakravarti[1]; [1]NYU Sch. of Med., Ctr. for Human Genetics and Genomics, New York City, NY, [2]NYU Sch. of Med., Inst. for Systems Genetics, New York City, NY

Disclosure Block: **R. Fine:** None.

Many human disorders are genetically multifactorial with no necessary and sufficient relationship between genotype and phenotype, as compared to Mendelian traits. An exception is Hirschsprung Disease (HSCR) which is characterized by the failure of enteric neural crest cells to colonize and innervate the intestinal tract, leading to bowel obstruction and death if left surgically unrepaired. Previous sequencing studies by our group have revealed that the majority of HSCR risk arises from coding and transcriptional regulatory variants in the gene encoding the tyrosine kinase receptor, RET, and its transcriptional gene regulatory network (GRN). Here, hypomorphic regulatory (enhancer) variants have lower penetrance, but higher risk, than pathogenic coding variants. Additionally, coding sequence variants in another 33 genes and loci with *RET* contribute to ~67% of population attributable disease risk. To understand the disproportionate contribution of *RET* coding and enhancer variants to HSCR, we are building mouse models with an intact *RET* human genomic locus. This enables direct modeling of coding and regulatory human variants in mice without the need for phylogenetic conservation. Our approach is to use â□□Big-DNAâ□□ technology in budding yeast and *E. coli* to synthetically construct these loci in a parallel manner. To date, we have constructed several loci of 60, 80, and 179kb lengths with defined haplotypes for the entire *RET* gene body and three major transcriptional enhancer HSCR-associated SNPs denoted as rs2506030, rs7069590, and rs2435357. We then use highly engineered Inducible Cassette Exchange â□□ICEâ□□ targeting vectors to insert these synthetic loci into mouse embryonic stem cells and ultimately derive mice. We are using the mouse genetic toolbox to cross-breed additional hypomorphic alleles of a second major node in the *RET* GRN, *EDNRB*, to test epistatic interactions. We have also established 5C-ID sequencing in CHP212 cells and discovered topological chromatin interactions between the three aforementioned enhancer SNPs and the RET promoter. We will combine this approach with cutting-edge single cell technologies in mice to understand the genetic rules by which variants specify regulatory changes to alter gene expression and, in turn, affect cell behavior and clinical penetrance of disease.

PrgmNr 2928 - Functional characterization of regulatory elements involved in mouse CD4$^+$ T cell differentiation

View session detail

Author Block: **K. Siklenka**, L. Li, A. Barrera, M. Parker, R. Venukuttan, Y-S. Kim, M. Gemberling, S. Snyder, C. A. Williams, G. E. Crawford, C. Gersbach, M. Ciofani, T. E. Reddy; Duke Univ., Durham, NC
Disclosure Block: **K. Siklenka:** None.
The adaptive immune system is an exceptional model for studying complex cellular phenotypes with a high degree of therapeutic significance. CD4$^+$ T helper cells are important mediators of both immunity and autoimmunity. With unique functions, T helper cells support other cell types in clearing of infection or by attenuating an immune response. Their dysregulation is often associated with chronic inflammation, autoimmune disease, and allergy. Over the past two decades, major advancements in genetics and genomic technologies have revealed that combinations of extrinsic and intrinsic factors govern T helper cells activation, differentiation, and immune function. Now, many datasets have detailed the genomic location of thousands of candidate regulatory elements involved in these processes; however, the functional contribution of those elements remain poorly understood and difficult to study. **Objective:** To empirically measure the activity and function of thousands of candidate regulatory elements involved in the differentiation of mouse T helper subsets. This comprehensive functional study of regulatory elements in primary immune cells will enable the characterization of both the genetic and epigenetic components responsible for regulating gene expression during an immune response. We anticipate these results will lead to improved design of therapeutic interventions for immune-related disease. **Approach:** We used the high-throughput reporter assay STARR-seq coupled with ATAC-seq to assay the regulatory activity of all open chromatin regions in mouse T helper type 1 (Th1), type 2 (Th2), type 17 (Th17), and T regulatory (Treg) cells *in vitro*. We applied a joint analysis model to those multiple STARR-seq datasets to identify active regulatory elements that are common or unique across each subtype. We analyzed sequence features and integrated gene expression and epigenetic datasets to determine what core motifs and chromatin context drive regulatory activity. We applied an orthogonal CRISPR-interference screen in mouse Th17 cells by targeting dCas9-KRAB to a subset of candidate regulatory elements during differentiation. We used FACS to enrich for cells containing gRNA that cause altered expression of the Th17 defining genes *Rorc* and *Il17a*. Using a transgenic T cell transfer model of Th17 differentiation coupled with dCas9-KRAB we targeted individual elements identified *in vitro* and confirmed their essentiality *in vivo* by characterizing cell phenotypes with flow cytometry. Together these results identify a set of functional regulatory elements that may offer an expanded understanding of the active regulome that governs an adaptive immune response.

PrgmNr 2929 - Human microglia regulome analysis defines the inherited risk loci in Alzheimerâ□□s Disease

Microglia are the brain resident macrophages with a range of both immune and neuronal maintenance related functions. They have been implicated as the main cell type contributing to Alzheimerâ□□s Disease etiology. The transcriptional regulation in human microglia has not been well explored thus far, limiting our understanding of the molecular and cellular mechanism in the AD etiology. Here we present a comprehensive and unique transcriptome and chromosome accessibility landscape atlas in primary human microglia (146 samples) representing both healthy and neurodegenerative states. Transcription factor (TF) regulatory network analyses identified SPI1, IRF1, and PURA as the most relevant TFs to AD. Utilizing the in-house generated microglia HiC data, we applied the Activity-By-Contact (ABC) method and identified 24,459 enhancer-promoter interactions which are highly enriched for AD common variants. We then explored the genetic regulation of transcription and chromatin accessibility and identified 7,302 eQTLs and 10,266 chromosome accessibility QTLs (caQTLs) (q

PrgmNr 2930 - Identification of bidirectional regulatory region between *FADS1* and*FADS2*

The *FADS1* and *FADS2* genes encode two fatty acid desaturases which act as rate-limiting enzymes in the biosynthesis process of long-chain polyunsaturated fatty acids (LC-PUFAs). These two genes are located on chromosome 11 in a head-to-head orientation, resulting in a potential shared regulatory region between them. Based on previous literature, this region could be a potential â□□bidirectional regulatory regionâ□□, which may regulate the gene expression on opposite direction simultaneously. Many studies have revealed that there were certain features harbored by such bidirectionally functional region, many of which are shown in the shared region of *FADS1* and *FADS2*, including the existence of CpG islands, lack of a typical TATA box, being a pair of genes arose by gene duplication events, and shared transcription factor binding sites. Furthermore, recent analysis using GTEx (Genotype-Tissue Expression) data also revealed that some identified eQTLs were uniformly found to be associated in contrary directions for *FADS1* and *FADS2* expression, which suggests that genetic variants within the *FADS* cluster may affect the transcription of these two genes in an opposite way. This inverse expression may be explained by steric hindrance caused by the binding of transcription factors targeting expression of one of the two genes. All these existing lines of evidence indicate the bidirectional regulation is possible in that shared region. Therefore, the purpose of this study is to investigate whether and how the shared region affect expression of the two genes. To our knowledge, this is the first study on the bidirectional regulatory region between *FADS* genes. If successfully elucidated, findings from this project will enhance not only our understanding of underlying mechanism of *FADS* expressions, but also bidirectional regulation of genes. In the long term, this project will also facilitate the development of genome-informed LC-PUFAs supplementation for preventing associated complex diseases.

PrgmNr 2931 - Incorporating local ancestry improves the identification of ancestry-associated methylation signatures and meQTLs in the African American population

View session detail

Author Block: **B. Li**[1,2], A. C. Justice[3,2], B. E. Aouizerat[4], K. Xu[5], H. Zhao[6]; [1]Yale Sch. of Publ. Hlth., New Haven, CT, [2]VA Connecticut Hlth.care System, West Haven, CT, [3]Yale Sch. of Med., New Haven, CT, [4]Bluestone Ctr. for Clinical Res., New York Univ., New York, NY, [5]Yale Sch. Disclosure Block: **B. Li:** None.
It is well known that there are widespread methylation differences across self-reported racial/ethnic groups in the human genome. However, few studies have aimed to identify ancestry-associated methylation marks in admixed populations. For admixed samples, the demographic information collected from participants is inadequate to precisely define population structure. Genetically inferred admixture provides a more accurate proxy of the heterogeneity of genetic admixture. We carried out three epigenome-wide association studies (EWASs) of DNA methylation on genetic admixture (local and global ancestry) and self-identified race/ethnicity in the Veterans Aging Cohort Study (VACS) (N=994). We identified 708, 30, and 1,284 CpGs significantly associated with self-reported race/ethnicity, global ancestry, and local ancestry, respectively. In replication analyses, the proportion of replicated CpGs associated with local ancestry was greater than those identified for global ancestry and race/ethnicity. Importantly, the identified ancestry-associated CpGs show a high SNP-based heritability (mean heritability=0.41) These CpGs are also significantly depleted in promoter regions and CpG islands while moderately enriched in the south shore of CpGs in the methylome. Furthermore, by incorporating SNP-based estimates of ancestry, we identified more methylation quantitative trait loci (meQTL) clumps for ancestry-associated methylations (N=2,352) than those identified from the model that assumes identical genetic effects across ancestry origins (N=1,784). The majority (71.4%) of meQTLs displayed significantly different genetic effects in the context of an African or European ancestry background. Inferred local ancestry can better characterize ancestral contributions to genetic architecture across the genome. Incorporating local ancestry information can better identify ancestry-enriched methylation in admixed populations. Determining meQTL by incorporating local ancestry can reveal ancestry-specific genetic effects on methylation. Taken together, these findings have important implications for conducting EWAS in admixed samples in the multi-ancestry cohorts.

PrgmNr 2932 - Sex differences in the intergenerational link between maternal and neonatal whole blood DNA methylation: An analysis in the Boston Birth Cohort

Intergenerational inheritance of DNA methylation (DNAm) variations could contribute to the inheritance of disease susceptibility across generations. No study has investigated patterns of intergenerational transmission of DNAm at the genome-wide scale. It is also unknown whether there are sex differences in maternal-neonatal DNAm patterns. This study included 396 mother-newborn pairs (45.5% male) from the Boston Birth Cohort. Genome-wide DNAm profiling was performed on maternal whole blood (obtained 24-72 hours after delivery) and neonatal cord blood samples using the Illumina MethylationEPIC BeadChip; 721,395 DNAm sites on autosomes and the X chromosome (ChrX) were eligible for analysis after quality control steps, including removing probes mapped to multiple genomic regions. **First**, using Spearmanâ□□s rank correlation, we estimated intergenerational concordance in genome-wide DNAm and found significant sex differences in mother-newborn correlations in DNAm patterns ($p=3.8Ã□10^{-8}$), with female newborns having relatively stronger correlations. Sex differences in correlations were attenuated but remained significant after excluding DNAm sites on ChrX (p=0.035). **Second**, we estimated sex differences in associations between maternal and neonatal methylation levels at each DNAm site using linear regressions adjusting for maternal age at delivery, maternal race/ethnicity, type of delivery, preterm delivery, maternal smoking, and surrogate variables. A significant interaction between newbornâ□□s sex and maternal DNAm was observed for 32 DNAm sites (FDREFHC2, *PCDH19*, *TSPYL2*, etc.) and the other 10 were mapped to 8 genes on autosomes (*ADCYAP1R1*, *UHRF1*, *KLF13*, etc.). In addition, 18 of these 32 DNAm sites showed stronger intergenerational correlations for female newborns. **Finally**, we calculated mother-newborn differences in methylation levels at individual DNAm sites and estimated their associations with newbornâ□□s sex using linear regressions adjusting for the same set of covariates. We observed 27,887 DNAm sites that showed significant associations with newbornâ□□s sex (FDRRBM3, *COL4A6*, *TSPAN7*, etc.), and the top 10 autosomal DNAm sites were mapped to 8 genes (*LOC644649*, *UBTF*, *FOXN3*, etc.). **Our study suggests** significant sex differences in the intergenerational correlations in whole blood DNAm, particularly pronounced for ChrX, with more similarity between mothers and female newborns.

PrgmNr 2933 - Studying Regulatory Variation In Founder Populations To Identify Functional Rare Variants

View session detail

Author Block: **S. Ramdas**[1], B. Heil[1], R. Kember[1], M. Bucan[1], C. D. Brown[2]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Univ Pennsylvania, Philadelphia, PA
Disclosure Block: **S. Ramdas:** None.
With increasing sample sizes, GWAS and sequencing studies are now able to identify trait-associated variants with low allele frequencies. However, interpreting the function of these rare variants remains challenging. The functional interpretation of common disease-associated variation has been aided by the identification of variants regulating gene expression. However, expression quantitative locus (eQTL) studies are currently limited by their sample sizes, which make the functional interpretation of rare non-coding variants from these studies a challenge. In this study, we attempt an alternate approach for the functional interpretation of rare variants using a genetically isolated (founder) population. Founder populations harbor an increased burden of functional variants rare in more heterogeneous populations, making it possible to characterize their functional impact with smaller sample sizes. In this experimental design, we study genes with extremely high or low levels of expression (called â□□expression outliersâ□□). We posit that identifying expression outliers in a founder population will allow us to determine regulatory variants of large effect otherwise not detectable in commonly-studied populations.
The Amish represent a genetic isolate whose European ancestors settled in the Americas starting in the 17th century. We analyze RNA-seq data from
lymphoblastoid cell lines (LCL) obtained from 97 genotyped samples of a large multi-generational pedigree; this represents the first transcriptomic study on the Amish population. We identify 1,209 genes with eQTLs in this
cohort. While we see an eQTL replication rate of 72% in larger cohorts of LCLs, we find 206 eQTL genes unique to the Amish population at loci harboring genetic variation that is rare in large European cohorts. The unique pedigree structure of our cohort enables us to identify genomic segments shared identical by descent and proximal to gene expression outliers. We identify more than 6,000 outliers for gene expression, splicing, or allele-specific expression; more than 100 of which are associated with specific cis-regulatory haplotypes. We then added orthogonal epigenomic information to prioritize truly causal regulatory variants within these regions. These methods and results allow us to prioritize disease variants by identifying variants of large-effect, and lead to a more comprehensive annotation of the regulatory genome.

PrgmNr 2934 - Understanding the interplay of pancreatic cancer GWAS risk loci and cellular stress

View session detail

Author Block: **K. E. Connelly**, J. Zhong, I. Collins, Pancreatic Cancer Cohort Consortium, Pancreatic Cancer Case-Control Consortium, H. Arda, L. Amundadottir; NIH, Bethesda, MD
Disclosure Block: **K.E. Connelly:** None.
Pancreatic ductal adenocarcinoma (PDAC), the third leading cause of cancer-related deaths, is often difficult to diagnose. Genome-wide association studies (GWAS) have identified common susceptibility variants at twenty risk loci for PDAC. At numerous PDAC risk loci, the most likely functional genes are associated with recovery from stress-induced inflammation and acinar to ductal cell de-differentiation *in vivo*. We hypothesize that cellular stress is a crucial component mediating risk at non-coding pancreatic cancer susceptibility loci. Unfortunately, the currently available model systems used for functional characterization of pancreatic cancer GWAS risk loci do not mimic the stress and inflammation environment known to be associated with epidemiological PDAC risk factors. Our work aims to establish chemically induced conditions *in vitro* that mimic cellular stresses (i.e., endoplasmic reticulum (ER), oxidative, inflammation) to better understand GWAS risk loci in a system that better reflects conditions conducive to carcinogenesis. In a pilot study using the immortalized human pancreatic duct epithelial cell line HPDE, we examined the effects of various stress conditions on the likely functional gene at the chr7p14.1 (rs12701838, P= 3.9×10^{-9}) PDAC risk locus. This risk variants map to the final intron of *SUGCT*. However, expression quantitative trait locus (eQTL) analysis and our chromatin capture data in PDAC cell lines suggest *INHBA*, located approximately 1MB downstream, is the likely functional gene. We observed a significant decrease in *INHBA* expression in HPDE cells by reverse transcription quantitative PCR (RT-qPCR) under ER stress conditions (tunicamycin). Additionally, we observe a significant dose dependent increase in *INHBA* expression when cells are exposed to exogenous tumor necrosis factor alpha (TNFÎ±) as an inflammation stimulus. Further studies are ongoing to better understand the role of *INHBA* and the GWAS risk variants under stress and the contribution(s) to PDAC risk. Moreover, using concentration and time course data from our pilot study, we aim to expand our study to examine the transcriptional and chromatin changes under the various stress conditions in a global manner to establish a resource for additional current and future GWAS risk loci.

PrgmNr 2935 - Widespread sex differences in placental DNA methylation

View session detail

Author Block: **M. Ouidir**, S. Chatterjee, K. L. Grantz, F. Tekola-Ayele; Epidemiology Branch, Div. of Intramural Population Hlth.Res., Eunice Kennedy Shriver Natl. Inst. of Child Hlth.and Human Dev., NIH, Bethesda, MD
Disclosure Block: **M. Ouidir:** None.
Sex differences are common in fetal development, adverse pregnancy outcomes, and subsequent health. Accumulating evidence suggests that sex-biased epigenetic mechanisms in placenta may have a key role in the early life, but data are limited. We investigated sex differences in placental DNA methylation among 301 women from the NICHD Fetal Growth Studies - Singleton cohort.
We tested association between placental genome-wide methylation (Illumina 450k) and fetal sex using linear regression, adjusting for maternal race/ethnicity, gestational age at delivery, the first ten genotype principal components (PCs), methylation sample plate, the first three methylation PCs and putative cell-mixture estimated using surrogate variable analysis components (n = 20).
We identified 5124 differentially methylated CpGs in placenta between males and females (FDR P FOXN3; LogFC = 0.63, P = 1.5e-110) and that in females was found for cg11643285 (*RFTN1*; LogFC = 0.29, P = 1.7e-69). The genes (n = 2067) annotating the differentially methylated CpGs were enriched in gene ontology biological processes such as cornification (adjusted-P = 2.2e-10) and epithelium development (adjusted-P = 2.2e-10) as well as hallmark gene sets such as estrogen response (adjusted-P = 2.8e-3) and myogenesis (adjusted-P = 2.8e-3). In the EWAS Atlas the differentially methylated CpGs overlapped with CpGs previously associated with prenatal environmental exposures, pregnancy complications (e.g., preeclampsia, gestational diabetes mellitus, preterm birth), fetal and childhood growth and development-related traits, and adult complex diseases; the top three phenotypes with the largest number of overlapping CpGs were aging (n = 528 CpGs), gender (n = 476), and smoking (n = 366).
In all, our findings highlight that sex-biased methylation is widespread in the placenta. Accounting for fetal sex in placental studies can facilitate development of molecular diagnostics and interventions for diseases that exhibit disparities by sex.

PrgmNr 2936 - Wnt sensitive regulatory elements in neural progenitors harbor neuropsychiatric disorder and brain structure heritability

View session detail

Author Block: **N. Matoba**[1], B. D. Le[1], J. Valone[1], J. M. Wolter[1], D. Liang[1], J. Mory[1], M. L. Bond[1], J. L. Stein[2]; [1]UNC at Chapel Hill, Chapel Hill, NC, [2]UNC Chapel Hill, Chapel Hill, NC
Disclosure Block: **N. Matoba:** None.
GWAS for neuropsychiatric disorders and brain related traits show enrichment of heritability in tissue-, and cell-type specific regulatory elements (RE)s. These REs are often measured in post-mortem tissue so REs that are responsive to specific stimuli and involved in trait variation, are likely missed. External stimuli, like signaling factors, lead to transcription factor (TF) translocation to the nucleus and binding to DNA which alters RE activity. Previous studies have found that genetic loci associated with risk for neuropsychiatric disorders and interindividual differences in brain structure are enriched in genes of the Wnt pathway, a diffusible signaling molecule involved in brain development and patterning.
Here, we performed ATAC-seq on primary human neuronal progenitors from 93 donors treated with 5 nM Wnt3a or vehicle control. Of 173,034 accessible chromatin peaks identified, 38.6% of peaks were significantly differentially accessible in cells treated by Wnt3a as compared to vehicle conditions ((|LFC|>0; FDR As expected, we found that Tcf7 and LEF1, the known effectors of the Wnt signaling pathway, were the most enriched motifs identified in Wnt3a responsive REs (BH-corrected P = 1.58 Ã 10^{-32}; 8.65 Ã 10^{-32}, respectively), providing strong support that chromatin accessibility is a proxy for TF binding in response to external stimuli.
We next estimated whether genetic variation associated with neuropsychiatric disorders and brain traits are enriched in Wnt responsive REs. Using a partitioned heritability approach, we found that Wnt responsive REs showed significant heritability enrichment for schizophrenia, neuroticism, intelligence, cortical surface area (FDRP = 0.034), consistent with the spatial gradient of Wnt ligand secreted from the medially located cortical hem. These results demonstrate that genetic elements responding to Wnt signaling are significant contributors to multiple brain traits and act preferentially in brain regions expected to have high Wnt signaling activity.
In this study, we show that stimulus responsive regulatory elements play important roles in neuropsychiatric disorders and brain traits. In the future, analyzing individual variants associated with chromatin accessibility in response to stimuli may help explain individual GWAS loci (response-QTL) and be applied for pharmacogenomics approaches to optimize drugs based on genotype.

PrgmNr 2937 - Accurate identification of circRNA landscape and microRNA network in human oligodendroglia differentiation

View session detail

Author Block: **Y. Li**[1], F. Wang[1], P. Teng[2], L. Ku[2], L. Chen[3], Y. Feng[2], B. Yao[1]; [1]Dept. of Human Genetics, Emory Univ. Sch. of Med., ATLANTA, GA, [2]Dept. of Pharmacology and Chemical Biology, Emory Univ. Sch. of Med., ATLANTA, GA, [3]Dept. of Biostatistics and Hlth.Data Sci., Ctr. for Computational Biology and Bioinformatics, Indiana Univ. Sch. of Med., Indianapolis, IN
Disclosure Block: **Y. Li:** None.
Circular RNAs (circRNA), a novel class of covalently closed and poorly conserved non-coding RNAs derived from pre-mRNA back splicing that play complex roles in epigenetic gene regulation, are highly enriched in human brain and dysregulated in various brain disorders. Although numerous neuronal circRNAs have been identified, circRNAs in oligodendroglia (OL), the type of cells solely responsible for myelin formation on neuronal axons that underlie rapid long-range communication and affected in many myelin disorders, remain unexplored. This is partly due to difficulties in obtaining sufficient amount of human OL cells as well as the need for improved experimental approaches and computational tools to identify confident circRNAs and their precise sequence components. We effectively enriched circRNA using Poly(A)-tailing coupled with RNase R treatment (A-tailing) and developed a comprehensive computational framework for accurate circRNA identification and quantification, termed CARP (CircRNA identification using A-tailing RNase R approach and Pseudo-reference alignment). Using these approaches, we obtained highly confident, full-length circRNA sequence and distinct isoforms with identical back-splice sites. We also established conditions for inducing differentiation of the HOG human OL cell line, which harbors transcriptomic composition recapitulating OL progenitor cells in the human fetal brain. Using CARP, we identified OL-specific circRNA landscapes dynamically regulated during differentiation, which are distinct from human neuronal circRNAs. The production of a subset of circRNAs are independent of their parental transcripts and are predicted to be regulated by RNA editing in cis-regulatory elements such as A-to-I editing in *Alu* elements or trans-factors such as RNA-binding proteins. Interestingly, we found a substantial amount of alternative circularization of circRNAs forming clusters within the same loci, which apparently could exert additive effects in sponging miRNA and/or RNA binding-proteins. Furthermore, we discovered circRNA-miRNA networks that are regulated during OL differentiation, which are predicted to target well-defined signaling pathways known to promoting OL differentiation. Together, our improved experimental and computational methods identified differentiation-regulated human OL-specific circRNA landscape and circRNA-miRNA networks that are predicted to advance human OL development.

PrgmNr 2938 - Integrative multi-omics analysis to predict gene regulatory networks from genetic risk variants to phenotypes of Alzheimerâ□□s disease and COVID-19

View session detail

Author Block: **S. Khullar**[1], D. Wang, Ph.D.[2]; [1]Univ. of Wisconsin - Madison, West Windsor, NJ, [2]Univ. of Wisconsin - Madison, Madison, WI
Disclosure Block: **S. Khullar:** None.
Background Genome-wide association studies have found many genetic risk variants associated with Alzheimer's disease (AD). However, how these risk variants affect deeper phenotypes such as disease progression and immune response remains elusive. Also, our understanding of cellular and molecular mechanisms from disease risk variants to various disease phenotypes is still limited. To address these problems, we performed integrated multi-omics analysis from genotype, transcriptomics, and epigenomics for revealing gene regulatory mechanisms from disease variants to AD phenotypes. Method The first step in our integrative analysis is to cluster gene co-expression networks and identify gene modules for various AD phenotypes given population gene expression data. Next, we predict the transcription factors (TFs) that significantly regulate the genes in each module, as well as the AD SNPs interrupting the TF binding sites on the regulatory elements. Finally, we construct a full gene regulatory network linking SNPs, interrupted TFs, and regulatory elements to target genes for each phenotype. This network thus provides mechanistic insights of gene regulation from disease risk variants to AD phenotypes. Results We applied our analysis to population data and predicted gene regulatory networks for three major AD-relevant brain regions: hippocampus, dorsolateral prefrontal cortex (DLPFC), and lateral temporal lobe (LTL). These region networks provide a comprehensive functional genomic map linking AD SNPs to TFs and regulatory elements to target genes for various AD phenotypes. Comparative network analyses further revealed cross-region-conserved and region-specific regulatory networks. For instance, AD SNPs rs13404184 and rs61068452 disrupt the bindings of TF SPI1 that regulates AD gene INPP5D in the hippocampus and lateral temporal lobe. However, SNP rs117863556 strongly interrupts the bindings of TF REST to regulate GAB2 in the DLPFC only. Furthermore, driven by recent discoveries between AD and Covid-19, we also found that many genes from our networks regulating Covid-19 pathways are also significantly differentially expressed in severe Covid patients (ICU), suggesting potential regulatory connections between AD and Covid. Thus, we trained a machine learning model to predict severe Covid and prioritized the highly predictive genes as a set of AD-Covid marker genes. Thus, our results provide a deeper understanding of the interplay among multi-omics, brain regions and AD phenotypes including disease progression and Covid response.

PrgmNr 2939 - Learning interpretable cellular and gene signature embeddings from single-cell transcriptomic data

View session detail

Author Block: **Y. Li**[1], Y. Zhao[1], H. Cai[2], Z. Zhang[3], J. Tang[4]; [1]McGill Univ., MONTRÃAL, QC, Canada, [2]Peking Univ., Beijing, China, [3]Fudan Univ., Shanghai, China, [4]HEC, MONTRÃAL, QC, Canada
Disclosure Block: **Y. Li:** None.

The advent of single-cell RNA sequencing (scRNA-seq) technologies has revolutionized transcriptomic studies. However, large-scale integrative analysis of scRNA-seq data remains a challenge due to unwanted batch effects and limited transferabilty, interpretability, and scalability of the existing methods.

We present single-cell Embedded Topic Model (scETM). Our key contribution is the utilization of a transferable neural-network-based encoder while having an interpretable linear decoder via a matrix tri-factorization. scETM simultaneously learns an encoder network to infer cell type mixture and a set of highly interpretable gene embeddings, topic embeddings, and batch effect linear intercepts from multiple scRNA-seq datasets. We demonstrate scETM on 6 scRNA-seq datasets and compared it with 7 state-of-the-art (SOTA) scRNA-seq modelling methods. In terms of clustering known cell types, scETM achieved consistently competitive ARI, NMI, and kBET scores compared to the SOTA methods. Batch-overcorrection analysis shows that scETM does not overcorrect batch effects while learning embedding preserving the biological signals in contrast to some of more aggressive batch-correction methods.

Furthermore, scETM confers remarkable cross-tissue and cross-species zero-shot transfer-learning performance achieving the highest ARI across all 6 transfer-learning tasks. For instance, scETM trained on Tabula Muris (TM) on heterogeneous tissues clusters quite well the Mouse Pancreas (MP) cells (ARI: 0.941; kBET: 0.339); scETM trained only on the MP dataset cluster reasonably well the TM cells from diverse primary tissues, implying that it does not merely learn cell-type-specific signatures but also the underlying transcriptional programs that generalize to unseen tissues. Transfer learning between human and mouse pancreas are also accomplished well, implying its ability to capture conserved functions. Transfer learning between mouse and human primary motor areas presents a challenge due to the evolutionarily divergent functions of brains. Nonetheless, scETM conferred a much higher ARI of 0.696 for the MusMOp to HumM1C transfer-learning tasks and ARI 0.167 for the HumM1C to MusMOp task compared to the SOTA methods.

By exploring the gene and topic embedding via UMAP, we find that scETM-learned topics are enriched in biologically meaningful and disease-related pathways for Alzheimerâ□□s disease and Major depressive disorder. Lastly, scETM enables the incorporation of known gene sets into the gene embeddings, thereby directly learning the associations between pathways and topics via the topic embeddings. A preprint is available at bioRxiv.

PrgmNr 2940 - ModTools: a computational toolbox for rapid detection of DNA modifications and replications using Nanopore sequencing

View session detail

Author Block: **Q. Liu**[1], D. Georgieva[2], D. Egli[2], K. Wang[1]; [1]The Childrenâ□□s Hosp. of Philadelphia, Philadelphia, PA, [2]Columbia Univ., New York, NY
Disclosure Block: **Q. Liu:** None.
Background: DNA base modifications play critical roles in gene regulation and genome function. Existing bisulfate-conversion or antibody-based techniques with short-read sequencing have inherent limitations to detect DNA modifications. Nanopore sequencing enable genome-scale modification detection, but the performance and running speed need substantial improvement: they take over one day to analyze even just one PromethION data set and often encounter errors to stop prematurely. Additionally, genome-scale detection of synthetically introduced modifications enables DNA replication analysis by Replipore sequencing, but computational methods are under-developed.
Methods: We develop ModTools with three main modules implemented in multi-threaded C++ . The first module is comparison-based modification detection (improved NanoMod): modified bases are identified by comparing Nanopore signals between paired samples with and without modified bases. The second module is model-based modification prediction (improved DeepMod): a deep-learning framework is first trained for a specific type of modification (such as methylation), and predictions are made on new samples. The third module is to detect DNA replication origins based on DNA base analogs (such as BrdU or IdU) during DNA replication: the peak of predicted DNA replication origins from multiple reads are summarized from this module.
Results: We evaluated ModTools on several Nanopore data sets with different Thymidine analogs at known positions, and found that ModTools is one order of magnitude faster than NanoMod with improved accuracy. ModToolsâ□□ deep-learning module is evaluated to detect 5mC (5-methylcytosine) on E. Coli and human genomes, and Thymidine analogs on several datasets of yeast genomes, and again ModTools is one order of magnitude faster and more accurate. Applied on the replication data of yeast, ModTools can precisely identify DNA replication origins: ~90% peaks identified by ModTools are known DNA replication origins.
Conclusion: ModTools can detect both DNA modifications and DNA replications from Nanopore sequencing data. ModTools is faster and more accurate than previous tools and can be scaled to the analysis of PromethION data, and thus have great potential to speedup genome-scale analysis of DNA modifications and replications.

PrgmNr 2941 - *De novo* mucins in mammals: How parallel evolution of exonic repeats leads to new function

View session detail

Author Block: **O. Gokcumen**[1], P. Pajic[1], S. Shichen[1], J. Qu[1], S. Knox[2], S. Ruhl[1]; [1]Univ. at Buffalo, Buffalo, NY, [2]Univ. of California, San Fransisco, San Fransisco, CA
Disclosure Block: **O. Gokcumen:** None.
Evolution of novel gene function is a fundamental question in biology. We hypothesize that exonic repeats and their copy number variation contribute substantially to de novo evolution of new gene functions. Mucin proteins are densely glycosylated molecules critical for mucus layer formation, cellular signaling, and microbial interactions both on epithelial surfaces and in mucous secretions. Functionally, mucins share proline-, threonine-, and serine-rich (PTS) repeats that serve as O-glycosylation sites. However, mucin proteins do not belong to a homologous gene family. Instead, several mucin proteins, although biochemically and functionally related, have evolved independently from different ancestral genes. The mechanisms through which these mucins evolved provide a fertile ground to study parallel evolution of novel gene functions. To understand the evolution of mucin function, we chose to study mucins in saliva, not only because they are readily accessible for noninvasive sampling, but also because our previous studies had shown that these molecules are highly variable, presumably due to dietary or pathogenic selective pressures. To this end, we performed a bioinformatics analysis of 49 mammalian genomes to identify 27 hitherto undescribed mucins, highlighting 15 instances of independent, lineage-specific mucin evolution. By integrating, bioinformatic, phylogenetic, proteomic, and immunohistochemistry approaches, we documented multiple instances of likely evolutionary convergence, where these novel mucins have recurrently gained highly glycosylated repeat domains along with salivary expression in a lineage-specific manner. Collectively, our results identified the secretory calcium-binding phosphoprotein (SCPP) gene locus as a hotspot for mucin formation in mammals, where the secretory and proline-rich nature of proteins encoded by genes in this locus provides fodder for recurrent gain of mucin function. Our results have broad implications for understanding the role of exonic repeats in the parallel evolution of new gene functions, especially those involving protein glycosylation.

PrgmNr 2942 - A spatially aware likelihood test to detect sweeps from haplotype distributions

View session detail

Disclosure Block: **Z.A. Szpiech:** None.

The inference of positive selection in genomes is a problem of great interest in evolutionary genomics. By identifying putative regions of the genome that contain adaptive mutations, we are able to learn about the biology of organisms and their evolutionary history. One conspicuous genomic pattern that results from a recent or ongoing sweep is reduced genetic diversity and the presence of a single haplotype at high frequency in the case of a â□□hardâ□□ sweep or two or more haplotypes at high frequency in the case of a â□□softâ□□ sweep. To capture these patterns, we develop a composite likelihood method that identifies recently completed or ongoing positive selection by searching for extreme distortions in the spatial distribution of the haplotype frequency spectrum. Furthermore, the method simultaneously infers two parameters of the sweep: the number of sweeping haplotypes and the 'width' of the sweep, which is related to the strength of selection. We demonstrate that this method outperforms the leading haplotype-based selection statistics. Then, as a positive control, we apply it to two well-studied human populations from the 1000 Genomes Project and examine the haplotype frequency patterns at the *LCT* and *MHC* loci. To facilitate use of this method, we have implemented it in user-friendly open-source software.

PrgmNr 2943 - A systematic evaluation of phasing algorithms for downstream analysis in ancestry testing

View session detail

Author Block: **A. Rojas-Munoz**[1], G. Gonzalez-Arroyo[1], A. Lopez Pineda[2,1], K. Numakura[3], Y. Matsuda[4], N. Katsanis[1,1], T. Takano[3], C. D. Bustamante[5,1,6,7], A. Ioannidis[8,1]; [1]Galatea Bio, Hialeah, FL, [2]Amphora Hlth., Morelia, Mexico, [3]Awakens, Tokyo, Japan, [4]AWAKENS, Inc, Berkeley, CA, [5]Stanford Univ. Background: In genetic ancestry testing, pipelines typically include raw data preprocessing, filtering, imputation of missing data, determination of haplotype phase, and the use of a genetic ancestry classification algorithm. Most phasing methods focus on improving metrics on test cases, but neglect to quantify performance for real world downstream applications. In particular, the quality of the phasing step for ancestry determination is typically not assessed. **Methods:** In this study, we have tested three state-of-the-art phasing algorithms for their ability to accurately infer local ancestry on data from a direct-to-consumer genetic testing research cohort. We compared Beagle (version 5.2), SHAPEIT (version 4), and Eagle (version 2) for their ability to effectively determine haplotype phase from both genotype array and NGS data. We evaluated phasing performance on the unphased version of the 1000 genomes dataset (version 3), using four metrics: 1) running time, 2) switch error rate as determined by comparison to the phased data, 3) phasing accuracy using the experimentally validated phasing data from individual N17828, and 4) local ancestry inference, where the ground truth was considered to be the continental-level populations. **Results:** We tested running time using 16 cores with multiple sample sizes, where the fastest phasing algorithm was SHAPEIT4 with 1 sample (18 s), and Beagle with 2,504 samples (515 s). When using 4 cores SHAPEIT4 was faster than Beagle by 36% with 2,504 samples (1119 s vs 722 s). Beagle had the lowest average error rate for 2,504 samples, and the best performance with the N17828 sample. Finally, the global ancestry inference was equivalently accurate across algorithms, when calculating admixture across the genome from a direct-to-consumer preexisting genetic cohort. Our ongoing analysis will further investigate the effect phasing algorithms have on local ancestry inference. **Conclusions:** Phasing algorithms are an important step in genetic applications pipelines. Understanding the effect of these algorithms in ancestry inference will help us determine the best alternative to use in industry-grade applications. The exponential growth of available genomewide data, alongside with the growth of cloud computing costs and architectures, makes it necessary to identify the best fit-for-purpose solution. We found that experiment-specific requirements would sway the final user to implement one pipeline over the alternative ones depending on their priorities.

PrgmNr 2944 - African ancestry polygenic risk scores improve Alzheimer disease risk prediction in individuals of African Ancestry

Disclosure Block: **F. Rajabli:** None.

Background: Recent genome-wide association studies (GWAS) in Alzheimer disease (AD) identified 37 significant genetic loci. However, most of these loci individually contribute a small amount of risk and have limited power to predict disease. One way to increase the prediction power is to aggregate the effect of these genetic risk variants. Polygenic risk score (PRS) is a valuable tool that combines the effect of each risk variant to improve the risk prediction of an individual from their genetic profile. Cross-population PRS studies showed that the over-representation of European ancestral populations in genomic research creates limited PRS transferability to non-European ancestral groups. Thus, the limited generalizability of PRS reduces its prediction power and may intensify healthcare disparities. In this study, we assessed and compared the PRS prediction accuracy of AD in individuals of African Ancestry (AA) using summary statistics from AA and non-Hispanic White GWAS studies. **Methods:** We generated PRS on a test dataset of 339 AA individuals (AD cases=111, controls=228) that was not included in AA GWAS study. First, we selected 'NHW markers' from the Kunkle et al. 2019 (pvResults: After p-value thresholding and clumping, we obtained 21 â□□NHW markersâ□□ and 32 â□□AA markersâ□□. PRS derived from the â□□NHW markersâ□□ failed to predict AD in the AA group (OR=0.82;pv=0.66) with the AUC 0.52, whereas the PRS scores of â□□AA markersâ□□ were significantly associated with AD (OR=2.46; pv=5.9x10-7) with the AUC of 0.67. **Conclusions:** We evaluated PRS scores based on 'EA markers' and 'AA markers' and found that African-ancestry PRSs improved AD prediction in individuals of African Ancestry. Our results show the impact of ancestral effects in PRSâ□□related research. PRS will help to develop AD prediction models for early identification in hopes of applying treatments to delay or prevent disease onset. Enhanced diversity in genetic studies is an essential step to create a transferable PRS across populations that will improve screening and prevention strategies.

Introduction: India is a diverse country with complex population sub-structure primarily shaped by its geography, language and social stratification. Past genetic studies on South Asian Indian population focused on a few selected subgroups of ethnically diverse populations to explore genetic admixture and migration patterns within geographical regions. Here we report the largest effort to date to tease apart the linguistic and socio-cultural diversity of all major subgroups residing within different geographical regions of India. **Methodology:** Unrelated subjects (N = 15,154) were recruited as part of an ongoing collaboration between the Regeneron Genetics Center and Global Gene Corporation to study genetic diversity across India. Subjects were recruited predominantly from five large states (Rajasthan, Maharashtra, Uttar Pradesh, Gujarat and Karnataka). Genotyping was performed using Illumina GSA-24v2-0_A2 arrays and exome sequencing. Array data was used to compute principal components (PCs). Dimensions of 20 PCs were further reduced to two axes using the Uniform Manifold Approximation and Projection (UMAP) method by considering the 10 nearest neighbors.**Results:** PC projections identified two large subgroups that were majorly defined by language. For example, the populations using Hindi dialect (Rajasthan and Uttar Pradesh) grouped separately from populations speaking Marathi (Maharashtra) or Gujarati (Gujarat). UMAP projections further segregated finer substructure within these populations by punctuating cultural differences within each state. For example, we observed differences between Hindi speaking â□□Tyagiâ□□ subgroups from Rajasthan and Uttar Pradesh. Although these groups originated from â□□Brahminsâ□□, geographical boundaries restricted gene-flow within each group. Further, we identified fine genetic differences between Marathi speaking populations from Maharashtra that recently diverged due to religious differences among different subgroups. Finally, exome sequencing identified drifted predicted loss-of-function and disease-associated variants of interest within each subgroup **Conclusion:** Understanding genetic diversity and architecture of disease from the Indian subcontinent, the second largest population in the world, is critical to advancing Precision Medicine for South Asian Indians throughout the world. This is the largest study to date to tease apart the linguistic, cultural and geographical differences that shape genetic diversity in India.

PrgmNr 2947 - Frequency enrichment of functional coding variants in a French Canadian founder population and its implication for inflammatory bowel diseases

View session detail

The genetic features of founder populations with recent bottlenecks, causing some deleterious variants to rise to higher frequencies, can enhance the power of rare variant association studies. French Canadians (FC) from Quebec represent a recent founder population characterized by rapid demographic and territorial expansion leading to regional founder effects. FC are known for their unique disease heritage comprising more than 30 Mendelian conditions with higher incidence and/or specific phenotypes or mutations. Yet, to date, a comprehensive characterization of functional variation in this population is still lacking. Here, using whole-exome sequencing data from 2,625 FC (patients with inflammatory bowel diseases (IBD), unaffected parents and controls), we describe the distribution and functional impact of coding variation in this founder population. We find that 13% of protein-coding variants present in our sample at an allele frequency (AF) between 0.002 and 0.01 are 2.5-100 times more frequent (Fisher-exact p-value 0.002 classified as pathogenic or likely pathogenic in ClinVar (p-value SLC12A6 c.2436+1delG, AF=0.0075 vs AF_NFE=8.8 x 10-5, 85-fold enrichment), Vitamin D-dependent rickets type 1 (*CYP27B1* p.Val88TrpfsTer71, AF=0.0034 vs AF_NFE=9.1 x 10-5, 37-fold enrichment) and Leigh Syndrome FC type (*LRPPRC* p.Ala354Val, AF=0.0029 vs AF_NFE=0.00011, 26-fold enrichment). Finally, we investigate whether rare protein-altering and -truncating variants, enriched in FC by the founder effect, contribute to the risk of IBD using trio and case/control cohorts. Our results and approach illustrate the value of exome sequencing in founder populations for understanding their genetic make-up and frequency of disease-causing mutations, which has important public health relevance.

PrgmNr 2948 - Gene duplication analysis reveals genome evolution and adaptation of *Taenia* species

View session detail

Author Block: **N. T. Grube**, G. H. Perry; Pennsylvania State Univ., State College, PA
Disclosure Block: **N.T. Grube:** None.
Gene duplication (GD) has been studied in many parasitic organisms and is an important evolutionary force contributing significantly to species evolution, facilitating increases in gene dosage effect and potential functional diversity of expanded gene classes. In fact, high rates of small scale GD and functional diversifications contributed to species divergence amongst infective tapeworms (*T. asiatica, T. saginata, and T. multiceps*), an epidemiologically important parasite group whose rapid diversification has led to evolutionary specializations during host-parasite co-evolution. However, GD remains poorly understood from a cross species comparative analysis. Cross species comparative GD analysis will assess how particular GD events contribute specifically to species pathogenesis in, for example, human vs non-human tapeworm variants. Here, we perform genome-wide analysis of GD in *Taenia* species using computational biological tools to assess predominant GD patterns and evolutionary contributions in human vs non-human specific lineages. We leverage six publicly available draft genomes of *Taenia* species maintained by wormbase.org, 4 specialized human genomes, *T. asiatica* (n=2), *T. solium* and *T. saginata*, and 2 non-human genomes, *T. multiceps* and *T. taeniaeformis*, for comparative whole genome sequence analysis. Genomes maintained undergo iterative genome and transcriptome updates providing valuable data for investigating GD in this parasitic species. We employ a variety of computational analysis to assess GD, gene divergence following duplication and contributions of GD to species pathogenesis in human vs non-human *Taenia* lineages.

PrgmNr 2949 - Genomic patterns of natural selection and introgression at the alcohol dehydrogenase gene region are associated with agriculture in ethnically diverse Africans

View session detail

Author Block: **M. McQuillan**[1], A. Ranciaro[1], M. Hansen[1], S. Fan[2], W. Beggs[1], G. Belay[3], D. Woldemeskel[3], S. A. Tishkoff[4]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Human Phenome Inst., Sch. of Life Sci., Fudan Univ., Shanghai, China, [3]Dept. of Biology, Addis Ababa Univ., Addis Ababa, Ethiopia, [4]Univ. of Pennsylvania Sch. of Med., Philadelphia, PA
Disclosure Block: **M. McQuillan:** None.
The alcohol dehydrogenase (ADH) family of genes encode enzymes that catalyze the metabolism of ethanol into the toxic intermediate, acetaldehyde. Nucleotide variation in ADH genes affects the catalytic properties of these enzymes and has been associated with a variety of complex human traits, including alcoholism and cancer. Some ADH variants, including the *ADH1B*48His* (rs1229984) mutation in the *ADH1B* gene, confer a reduced risk of alcoholism and are under strong positive selection in multiple human populations. The advent of Neolithic agriculture and the associated increase in fermented foods and beverages is hypothesized to have been a selective force acting on such variants. However, this hypothesis has not been tested in populations outside of Asia. Here, we use genome-wide selection scans to show that the ADH gene region is enriched for single nucleotide polymorphisms (SNPs)s showing strong signals of positive selection in multiple Afroasiatic-speaking, agriculturalist populations from Ethiopia, and that this signal is unique among Sub-Saharan Africans. We also observe strong selection signals at many putatively functional variants in nearby lipid metabolism genes, which may influence evolutionary dynamics at the ADH region. Finally, we show that the haplotypes carrying these selected variants were introduced into Northeast Africa from a West-Eurasian source within the last ~2000 years and may have experienced positive selection following admixture. Interestingly, these selection signals are not evident in nearby, genetically similar populations that practice a hunting and gathering or pastoralist subsistence lifestyle, even though they experienced non-African admixture at a similar time. Together, our results support the hypothesis that the emergence of agriculture has shaped patterns of selection at the ADH gene region, and enhance our understanding of how adaptations to diverse environments and subsistence strategies have influenced the African genomic landscape. Supported by NIH training grant T32ES019851, NIH grant R35GM134957-01, and ADA grant 1-19-VSN-02.

PrgmNr 2951 - Mutational biases in the SARS-CoV-2 virus genome

Disclosure Block: **F. Mostefai:** None.

The Severe Acute Respiratory Syndrome coronavirus 2 (SARS-CoV-2) is the highly mobile virus that led to the current ongoing COVID-19 pandemic. SARS-CoV-2 is a complex RNA virus from which genetic variants of concern are emerging all over the world. However, one important question is how SARS-CoV-2 has adapted to its human host since the first outbreak. In this study we are tracking the mutational patterns of the SARS-CoV-2 virus between and within infected individuals. We performed viral profiling on virus genomic data from the GISAID and NCBI repositories to understand the full scale of the virus' mutational diversity and characterize potential adaptation to human hosts. We used a computational genomics approach to curate and identify variants from SARS-CoV-2 consensus and RNASeq sequences. Using the identified variants, we tracked the viral mutational changes between (inter-host) and within COVID patients (intra-host). In our preliminary analysis of the pandemic first wave, we show that there is (a) a clear mutation bias towards fixation of C>U and G>U substitutions; (b) a selective advantage of the C>U substitutions that were not driven by the consequence on the coding proteins; (c) an excess of low-frequency G to U intra-host mutations that do not translate into higher fixation rates; and (d) a clustering of mutated positions with complementary substitutions U>G and A>C. Interestingly, in an analysis of the pandemic second wave sequences, we observed a reduction of the C>U mutational bias observed during the first wave. This result potentially reflects an evolutionary limitation of the virus mutational landscape. These results will help inform surveillance strategies for tracking emerging viral strains. Additionally, our observations will improve our understanding of the molecular mechanisms behind the adaptation of SARS-CoV-2 in response to the hostâ□□s defense strategy to fight infection.

PrgmNr 2952 - Novel unannotated protein-coding genes are expressed in multiple tissues

View session detail

Author Block: **W. Phu**[1,2,3], V. Luria[4], A. Karger[5], J. K. Goodrich[1,3], G. Tiao[1,3], A. O'Donnell-Luria[1,2,3]; [1]Program in Med. and Population Genetics, Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Div. of Genetics and Genomics, Boston Children's Hosp., Harvard Med. Sch., Boston, MA, [3]Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA, [4]Harvard Med. Sch., Boston, MA, [5]IT-Res. Computing, Harvard Med. Sch., Boston, MA

Disclosure Block: **W. Phu:** None.

In recent years, many protein-coding genes that were systematically missed by standard genomic algorithms have been discovered experimentally by proteogenomics tools such as proteomics or RiboSeq, highlighting that the identification of protein-coding genes in the human genome is incomplete. While a few unannotated genes have been shown to function in the nervous system, skin, gastrointestinal tract and male germline, the function and the evolutionary age of most unannotated genes remain unknown. We hypothesized that unannotated genes may provide additional candidate variants for rare disease diagnosis and assist in identifying new disease-causing genes. First, we found that, while some unannotated genes appear in many species and are thus evolutionarily ancient, most unannotated genes appear in few species (even just one) and are evolutionarily young. Thus, most unannotated genes are evolutionarily novel genes that arise by non-copying mechanisms (e.g. de novo from genomic DNA, lncRNAs that become coding, overprinting). Not being copied, such genes have no sequence similarity to genes in other species, which explains why they were missed by standard annotation tools. Second, we evaluated the expression patterns of a curated set of over 2,000 unannotated genes identified in previous proteogenomics studies, utilizing over 17,000 samples from the GTEx v8 dataset containing expression data from 54 human tissues. We determined in which tissues the individual genes were expressed, identified ubiquitous and tissue-specific genes, and explored how expression specificity correlates with gene evolutionary age. Third, we compared the expression levels of unannotated genes to the expression of Ensembl-annotated genes and of a control set of intergenic open reading frame (ORF) sequences. We found that most genes (60% of unannotated genes, 70% of annotated genes) are broadly expressed in >20 tissues. A fraction of genes showed higher tissue specificity: 14% of unannotated genes and 9% of annotated genes were expressed in 5 or fewer tissues; 7% of unannotated genes and 0.04% of annotated genes were expressed in exactly one tissue. To determine which unannotated genes are important for human disease, we will combine our expression data (abundance and tissue-specificity) with analysis of the variation in these genes in reference population and rare disease datasets. Thus, our expression analysis is the first step in elucidating the biological impact of the large number of overlooked novel human protein-coding genes.

PrgmNr 2953 - Overcoming constraints on the detection of recessive selection in human genes from population frequency data

View session detail

Author Block: **D. Balick**[1], D. M. Jordan[2], S. Sunyaev[3], R. Do[4]; [1]Brigham and Women's Hosp., Harvard Med. Sch., BOSTON, MA, [2]Icahn Sch. of Med. at Mt Sinai, New York, NY, [3]Harvard Med. Sch. and Brigham & Women's Hosp., Boston, MA, [4]Icahn Sch. of Med., New York, NY
Disclosure Block: **D. Balick:** None.
Identifying genes that evolve under recessive natural selection is a longstanding goal of population genetics research with important applications to gene discovery for traits and diseases. Unlike model organisms, identification of diploid selection coefficients in humans requires inference from natural population data. We assessed a range of population genetic and conservation-based measures designed to evaluate per-gene selective constraints and found that, while they are highly sensitive to genes under heterozygous selection, they ubiquitously fail to detect genes evolving under recessive selection. Additionally, more sophisticated likelihood-based statistics designed to explicitly infer recessive selection similarly lack power for any human gene of realistic length given the current size of population samples. However, extensive simulations suggested that enrichment of recessive genes may be detectable in aggregate for gene sets, but that this is sensitively dependent on the fraction of the whole genome that is recessive, an unknown quantity in humans. We designed a method to analyze genes in aggregate to identify enrichment for recessive purifying selection that is informed by population genetics simulations with realistic demography. Applying this to empirical gene sets successfully produced validating enrichments for strong recessive selection in genes previously inferred to be under recessive selection in a consanguineous cohort and in genes involved in autosomal recessive monogenic disorders, including in a set as small as 23 genes associated with effectively lethal recessive diseases. We created srMLgenes (https://jordad05.u.hpc.mssm.edu/srmlgenes), a publicly accessible tool that visualizes gene set enrichment patterns and allows users to upload their own human gene sets to search for recessive selection.

PrgmNr 2954 - PLIGHT: A tool to assess privacy risk by inferring identifying characteristics from sparse, noisy genotypes

View session detail

Author Block: **P. Emani**, G. GÃ¼rsoy, A. Miranker, M. B. Gerstein; Yale Univ., New Haven, CT
Disclosure Block: **P. Emani:** None.

The leakage of identifying information in genetic and omics data has been established in many studies, with single nucleotide polymorphisms (SNPs) shown to carry a strong risk of reidentification for individuals and their genetic relatives. While the ability of thousands or hundreds of thousands of SNPs (especially rare ones) to identify individuals has been demonstrated, here we sought to measure the informativeness of even a sparse set of noisy, common SNPs from an individual, by putting the genotype-based privacy leakage from an individual on quantitative footing. We present a computational tool, PLIGHT (â□□Privacy Leakage by Inference across Genotypic HMM Trajectoriesâ□□), that employs a population-genetics-based Hidden Markov Model of recombination and mutation to find piecewise matches of a sparse query set of SNPs to a reference genotype panel. Given the ready availability of auxiliary sources of noisy genotype data - such as acquiring small samples of environmental DNA or learning about someone's Mendelian diseases and physical characteristics - inference on sparse data becomes a genuine concern. We explore cases where query individuals are either known to be in databases or not, and consider both simulated â□□mosaicsâ□□ of genotypes (consisting of one or more source individuals) and actual genotype data obtained from swabs of coffee cups used by a known individual. Our findings are as follows: (1) Even 10 common SNPs (minor allele frequency > 0.05) often are sufficient to identify individuals in conventional genomic databases. (2) We are able to identify first-order relatives (parents, children and siblings) of query individuals with 20-30 common SNPs. (3) We find some potential for leakage of phenotypic information, based on a simulated attack by combining polygenic risk scores (PRSs) of the piecewise genotypic matches. We also found, for simulated mosaics of two individuals, that 20 common SNPs were often sufficient to find the correct identities of both component individuals. Finally, applying PLIGHT to coffee-cup-derived SNPs, we find that our tool is able identify the individual (when present in the reference database) using as little as 30 SNPs; when not present in the reference database, we use the inferred matches to the 30-90 query SNPs to perform a small degree of imputation of unobserved query SNPs. Overall, the tool could be used to determine the value of selectively masking released SNPs, in a way that is agnostic to any explicit assumptions about underlying population membership or allele frequencies.

PrgmNr 2955 - RaPID-Query: Towards a Fast and Accurate Real-Time Genealogical Search

View session detail

Author Block: **Y. Wei**[1], A. Naseri[2], D. Zhi[2], S. Zhang[1]; [1]Univ. of Central Florida, Orlando, FL, [2]Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX
Disclosure Block: **Y. Wei:** None.
Thanks to the growing sizes of genetic databases, genetic genealogical search has become a potential effective approach to help individuals finding missing family members or law enforcement agencies locating suspects. While the problem of n-vs-n Identity-By-Descent (IBD) segment calling is well-studied, no efficient and accurate method exists for the problem of 1-vs-n IBD segment calling. Current approaches are inflexible and time consuming as they lack the ability to extract the accurate IBD information from the database only related to the target individual. Here, a new method, Random projection-based IBD detection (RaPID) query, RaPID-Query, is introduced that identifies IBD segments above a certain target length between a query individual and a population panel. An extended PBWT-Query algorithm was developed that guarantees the quick detection of IBD segments, while the random projection and merge algorithm allows the tolerance of genotyping errors, mutations, or gene conversions in detected IBD segments. The trimming algorithm keeps the accuracy of IBD segment boundaries. The detection power and accuracy of 1-vs-n RaPID-Query being comparable to the state-of-the-art n-vs-n IBD detection methods are demonstrated using simulated data using msprime with realistic population genetics models. For benchmarking efficiency, it is showed that RaPID-Query takes only 3.05 seconds on a single core on average to query an individual haplotype against the entire UK biobank of ~1 million haplotypes for all 22 autosomal chromosomes. Compared to the PBWT-Query without tolerating mismatches, RaPID-Query showed a better separation of the familial relatedness. It is anticipated that, since RaPID-Query can be easily parallelized, a fast and accurate real-time genealogical search for millions of samples would be possible.

PrgmNr 2956 - A Decision Science Approach to Understanding Motives that Underly Interest in Genomic Sequencing Results

View session detail

Author Block: **B. B. Biesecker**; RTI Intl., Washington, DC
Disclosure Block: **B.B. Biesecker:** Grant/Contracted Research Support (External); NIH and SCID Compass. Salary/Employment; RTI Employment. Consultant/Consulting Fees/Other Remuneration; Fees for thesis advising.

People often want genomic information and find it useful even in the absence of clinical utility. The science of decision making provides some possible explanations about how people use available information in the context of their values to make optimal choices. In particular, decision makers act on various motives. First, people have a desire to learn or understand, such as when the information provides self-knowledge (as genomic information does), when the information is â□□knowableâ□□ (i.e., if genomic sequencing has been done), and when their need for certainty is high. Second, learning information can help people feel more self-competent and self-efficacious because they learn personal information that they perceive as relevant to improving their health. Similarly, learning information can lead to a greater sense of control over personally relevant outcomes, which is strongly associated with better health. Fourth, seeking genomic information can also satisfy social motives - such as adhering to social norms and expectations regarding the seeking of personal health information - and can provide reassurance and other emotional benefits. Understanding these four types of motivations may help clinicians and investigators to better understand clientsâ□□ choices and the utility of making genomic information available to patients/consumers even when it does not have clinical utility. Expected benefits such as increased positive affect and wellbeing or increased self-efficacy and perceptions of control are no less real than more (seemingly) concrete clinical utility benefits. Notably, these motivations to learn results from genomic sequencing are also similar to motivations to learn other types of health-related information. In both contexts, motivations to learn self-information come from well-known psychological processes that underlie decision utility. Better integration of psychological and clinical science can enhance understanding of both.

PrgmNr 2957 - Addressing Barriers to Access in an Adult Kidney Genetics Clinic

View session detail

Author Block: **K. Bogyo**[1], N. Vena[1], J. Radhakrishnan[1], H. Milo Rasouly[2], A. G. Gharavi[3], J. Nestor[1]; [1]Columbia Univ. Med. Ctr., New York, NY, [2]Columbia Univ., New York, NY, [3]Columbia Univ, New York, NY

Disclosure Block: **K. Bogyo:** None.

Introduction: Nearly 1 in 10 patients with chronic kidney disease have a genetic etiology, yet utilization of genetic services is limited and disproportionally impacts those from medically underserved populations. To address the barriers to accessing such services, an adult genetics clinic was developed within the Division of Nephrology at a large academic medical center in an urban setting.

Methods: A bi-weekly adult Kidney Genetics Clinic was created, staffed by genetic counselors (GC) and nephrologists. In addition to in-person appointments, televisits were introduced due to the COVID-19 pandemic. Two visit types were available: Full Genetic Consults (staffed by GC and nephrologist) or Genetic Counseling visits (staffed by a GC). In parallel, genetic education initiatives were developed via bi-monthly genetic seminars, monthly sign-out rounds, a CME course, and GC student rotations.

Results: Between June 2019 and April 2021, the clinic received 247 referrals averaging 11 referrals/month, which increased to 23 referrals/month in 2021. Of those referred, 189 patients (76%) scheduled an appointment, 89% of which were via telehealth (21% by GC only) with a median wait time of 19 days from referral to appointment.

Most patients were in the NY tri-state area (NY, NJ, and CT), but 9% were from 9 other states. Medicaid was the primary insurance in 24% of patients. Genetic testing was ordered for 124 patients (66%), was not indicated in 5 patients (3%), and was already ordered prior to the visit in 12 patients (6%). In 5 patients, testing was not done due to financial concerns (4%). Categories of tests ordered included small gene panels of fewer than 50 genes (37%), large panels (49%), exomes (3%), and others, such as single variant testing or microarray (11%).

A diagnostic finding was identified in 27% of patients, with the highest yield in those with either cystic kidney disease or suspicion of Alport syndrome. Referrals to additional medical specialists were made in 67% of patients with a diagnostic finding and referrals were made to research studies in those with a non-diagnostic finding. **Conclusions:** The Kidney Genetics Clinic successfully utilized telehealth to provide genetic services to a broad population during the COVID-19 pandemic. A significant number of underserved patients were able to complete genetic testing and counseling. The high uptake of genetic services by patients with Medicaid and low appointment and test cancellation rates due to financial constraints suggest that cost was not a barrier to genetic testing in nephrology. Provider education was integral in creating a successful clinic and identifying patients who would benefit from genetic services.

PrgmNr 2958 - Addressing barriers to patient data sharing: Exploring the effects of employing electronic consent to obtain genetic testing records through ClinGen's Patient Data Sharing Program

View session detail

Author Block: **L. Paul**[1], J. M. Savatt[2], M. E. Good[1], A. R. Heidlebaugh[1], D. Azzariti[3], D. Jae[4], D. H. Ledbetter[5], B. McLarney[4], H. L. Rehm[6], E. R. Riggs[2], C. L. Martin[2]; [1]Autism & Dev.al Med. Inst., Geisinger, Lewisburg, PA, [2]Geisinger, Lewisburg, PA, [3]Broad Inst., Cambridge, MA, [4]Invitae, San Francisco, CA, [5]Geisinger, Danville, PA, [6]Massachusetts Gen. Hosp., Boston, MA
Disclosure Block: **L. Paul:** None.
The NIH-funded Clinical Genome Resource (ClinGen) is working to define the clinical relevance of genes and variants. Sharing genetic and health data is critical to the scalability and success of these efforts. In 2014, ClinGen launched the GenomeConnect registry to give patients who have had genetic testing the ability to share their de-identified data with publicly available databases, like NCBIâ□□s ClinVar. GenomeConnect also partners with other registry programs to continue to expand patient data sharing. Participants consent online, provide health history via surveys, and upload a copy of their genetic report to their account. They can choose to receive updates about their results and connect with researchers and other participants.

As of April 2021, 3,377 participants have enrolled in GenomeConnect, 30% of whom (n=1,016) have uploaded genetic reports. To date, GenomeConnect has submitted 1,419 variants to ClinVar. Uploading a genetic report is a known barrier to participation. In a pilot survey of 98 GenomeConnect participants, not having a copy of their report (27.6%), and not knowing how to upload it (30.6.%) were the main limitations. To address these barriers, ClinGen piloted an electronic consent (e-consent) process with the Invitae Patient Insights Network (Invitae PIN), one of our registry partners that engages individuals living with or at risk of developing a health condition. The e-consent process allowed ClinGen to request participantsâ□□ genetic reports directly from Invitae, rather than participants uploading reports. As of April 2021, 1,072 Invitae PIN participants consented to data sharing via ClinGen, and 623 (58%) had their genetic reports uploaded via e-consent. Combined with participant-uploaded reports, this process resulted in a total report upload rate of 76% (n=817/1,072), a significant increase over the 30% upload rate seen in GenomeConnect (pTo date, ClinGen has contributed 681 unique variants from 410 Invitae PIN participants to ClinVar. Of those variants, 17% (n=113) were novel to ClinVar and 71% (n=481) came directly from reports uploaded through e-consent. The submission contained detailed health and case-level data such as inheritance, when available.

Patient data sharing benefits patients and the genetics community, but difficulties uploading test results can limit participation. ClinGenâ□□s collaboration with the Invitae PIN offered participants an e-consent process that allowed for a higher percentage of reports shared, and more variants and associated phenotype data being submitted to ClinVar. These lessons can be applied to other interfaces to continue to enhance ClinGenâ□□s patient data sharing efforts.

PrgmNr 2959 - Benefits, harms and costs of newborn genetic screening for hypertrophic cardiomyopathy: estimates from the PreEMPT Model

View session detail

Author Block: **L. Galbraith**[1], K. D. Christensen[2], M. Gooch[1], R. J. Hylind[3,4], P. M. McMahon[1], G. O'Brien[3], N. K. Stout[1,4], J. M. Yeh[5], A. C. Wu[4,3,1]; [1]Harvard Pilgrim Hlth.Care Inst., Boston, MA, [2]Harvard Pilgrim Hlth.Care Inst. / Harvard Med. Sch., Boston, MA, [3]Boston Children's Hosp., Boston, MA, [4]Harvard Med. Sch., Boston, MA, [5]Harvard Med. Sch. & Boston Children's Hosp., Boston, MA
Disclosure Block: **L. Galbraith:** None.

Background

Hypertrophic cardiomyopathy (HCM) is a leading cause of sudden cardiac death (SCD) in children, but is traditionally considered an adult-onset condition. Genetic screening can identify newborns with pathogenic variants for HCM, but whether the benefits of population testing justify the harms and costs are unclear.

Methods

The Precision Medicine Prevention and Treatment (PreEMPT) Model is a simulation model that projects the benefits, harms, and costs of newborn genetic screening and usual care. We developed an HCM module to estimate diagnosed and undiagnosed HCM cases through age 20, with benefits accruing from surveillance of newborns with pathogenic variants. We estimated the prevalence of pathogenic variants in *MYPBC3, MYH7, TNNI3, MYL2, TNNT2, TPM1, MYL3*, and *ACTC1* using data from clinical studies, ClinVar, and gnomAD. Newborns with identified variants underwent guideline-based surveillance. Survival benefit was modeled via reductions in deaths from beta blocker treatment and placement of implantable cardioverter-defibrillators (ICDs) in symptomatic children. Outcomes examined included SCD, heart failure, and operative mortality; ICD placements and inappropriate shocks; and genetic screening, surveillance and treatment costs. Genetic screening costs were estimated at $40 per newborn.

Results

Among a cohort of 3.7 million US newborns, newborn genetic screening was projected to avert 44 of 188 HCM-related deaths (95% uncertainty interval [UI]: 10-123) before age 20 years, including 41 of 153 HCM-related SCDs (95%UI: 9 to 122), but increased costs by $279 million (95%UI: $271 million to $289 million). Genetic screening also resulted in 227 more children (95%UI: 70-556) receiving ICDs, 84 of whom (95%UI: 3-256) would experience inappropriate shocks by age 20. The estimated number total number of life years gained from newborn genetic screening was 1,065 (95%UI: 537 to 2,2719), and cost $261,720 per life year gained (95%UI: $102,830 to $900,450).

Conclusion

Newborn genetic screening could reduce mortality, but at costs above typical thresholds for cost-effectiveness. Findings suggest that population screening of newborns for HCM variants does not provide good value, and that targeted approaches of high-risk populations may be more appropriate.

PrgmNr 2960 - Caregiversâ understanding of 22q11 Deletion Syndrome and their communication with their affected adult children about the syndrome

View session detail

Author Block: **J. Rice**[1], J. Pagano[1], L. Lichten[1], K. B. Coleman[2], O. Y. Ousley[1], J. F. Cubells[3]; [1]Emory Univ., Altanta, GA, [2]Emory Univ., Atlanta, GA, [3]Emory Univ Sch Med, Atlanta, GA
Disclosure Block: **J. Rice:** None.
Background. 22q11 Deletion Syndrome (22q11DS) affects 1 in 4,000 live births with a median age of mortality of 41.5 years old. However, the majority of research on caregivers for patients with 22q11DS has focused on their experiences at the time of diagnosis, which usually occurs during childhood. We examined the knowledge of parents or caregivers of adults with 22q11DS about the genetic, medical, and psychiatric aspects of 22q11DS, and their communication patterns with their affected adult children about the diagnosis. **Methods**. Semi-structured interviews were conducted via video conference with caregivers (n = 8), recruited through the Emory Autism Center and the Emory 22q11DS database. Interviews were transcribed verbatim, then analyzed for themes by two independent coders using MAXQDA 2020. **Results**. Overall, caregivers were knowledgeable about the medical aspects of 22q11DS, such as cardiac anomalies and intellectual disability, but not the genetic aspects, including inheritance patterns and recurrence risk. Caregivers were knowledgeable about psychiatric manifestations, however many noted first learning of that association at the time of onset of psychiatric symptoms in their adult children. Frequency of communication was variable, ranging from never to regularly. Common topics discussed include reproductive decision making and taking ownership of medical care. The majority of caregivers indicated the importance of educating their affected adult children about the syndrome, although one caregiver did not feel this was important. Common barriers to communication included patient attitude, intellectual disability and psychiatric conditions. **Conclusions**. Our findings highlight the need for resources targeted towards educating caretakers of adults with 22q11DS about the genetic and psychiatric aspects of the condition, and a role for providers in facilitating communication between familial caretakers and their affected adult children.

PrgmNr 2961 - Clinical benefits, cost-effectiveness and value of further research for population-based newborn screening for Li-Fraumeni syndrome

View session detail

Author Block: **N. Kunst**[1], N. K. Stout[1], G. Oâ□□Brien[2], K. D. Christensen[1], P. M. McMahon[1], A. C. Wu[1], L. Diller[3], J. M. Yeh[4]; [1]Harvard Med. Sch. & Harvard Pilgrim Hlth.Care Inst., Boston, MA, [2]Boston Children's Hosp., Boston, MA, [3]Harvard Med. Sch. & Dana-Farber Cancer Inst., Boston, MA, [4]Harvard Med. Sch. & Boston Children's Hosp., Boston, MA
Disclosure Block: **N. Kunst:** None.
Background: Li-Fraumeni syndrome is an inherited familial predisposition to an elevated risk of developing cancer during infancy and childhood associated with pathogenic germline mutations in *TP53*. A national program for Li-Fraumeni syndrome newborn screening (LFS-NBS) can identify infants who might benefit from cancer surveillance and potential early detection, but it may also lead to unnecessary medical follow-up. We evaluated the potential clinical benefits, cost-effectiveness and the need for further research to implement LFS-NBS population-wide in the United States. **Methods:** We used the Precision Medicine Policy and Treatment (PreEMPT) model to simulate the health outcomes and costs associated with LFS-NBS. The model utilized data from the Surveillance, Epidemiology, and End Results Program, ClinVar and gnomAD and clinical studies. We simulated a birth cohort of newborns under usual care and LFS-NBS and evaluated diagnostic and clinical outcomes, life years (LYs) and costs associated with Li-Fraumeni syndrome-related pediatric cancers (adrenocortical carcinomas, choroid plexus carcinoma, osteosarcomas, rhabdomyosarcoma). We further applied decision-analytic methods to assess the value of additional data collection before implementing LFS-NBS population-wide, assuming a $100,000/LY willingness-to-pay threshold. **Results:** In a 4 million newborn cohort, LFS-NBS would identify 894 individuals with deleterious *TP53* variants who would then undergo surveillance; 67 of these (95%UI, 39-108) would develop Li-Fraumeni syndrome-related cancer before age 20. LFS-NBS leads to an overall 7.2% decrease (95%UI, 4.0-12.1%) in cancer-related deaths, and a 25.3% (95%UI, 8.7-49.9%) decrease in 5-year survivors at risk for radiation-related mortality. Furthermore, LFS-NBS was associated with incremental costs of $38 million and 361 LYs gained, corresponding to $106,009/LY. Analyses also indicated that LFS-NBS had a 40% probability of being cost-effective, suggesting considerable uncertainty, and identified research studies with positive expected benefits. More specifically, additional research on the probability of a deleterious germline *TP53* variant from 200 rhabdomyosarcoma cases would result in a gain of 349 LYs, which was close to the maximum expected benefit of further research to improve evidence on LFS-NBS (416 LYs). **Conclusions:** Our study indicates high uncertainty in the decision about population-wide LFS-NBS using current evidence, despite the potential of this strategy to improve health. We identified research studies that are feasible and inexpensive, and could help guide decisions about universal newborn screening.

PrgmNr 2962 - Communication about risk, testing, and test results with and through family members: A survey of families with Huntingtonâ□□s disease

View session detail

Author Block: **J. Bollinger**[1], S. Jose[2], K. Stuttgen[3], A. McCague[4], M. Terkowitz[5], C. Weston[6], D. J. Mathews[1]; [1]Berman Inst. of Bioethics, Johns Hopkins Univ., Baltimore, MD, [2]Hlth.Policy and Management, Johns Hopkins Univ., Baltimore, MD, [3]Dept. of BioMed. Res. Ethics, Mayo Clinic, Rochester, MN, [4]Policy and Program Analysis Branch, NHGRI/NIH, Bethesda, MD, [5]Intitute for Clinical and Translational Res., Johns Hopkins Univ. Sch. of Med., Baltimore, MD, [6]Bloomberg Sch. of Publ. Hlth., Baltimore, MD

Disclosure Block: **J. Bollinger:** None.

Huntingtonâ□□s disease (HD) is an autosomal dominant, progressive neurodegenerative disease for which there is currently no cure. Many people who are at risk for HD want to know if they will develop the disease, but others do not. For those who do get presymptomatic genetic testing (PGT), their results often shape their decisions, relationships, and lives. Communicating with family members about HD risk and genetic test results can strengthen relationships, but can also lead to tension and distance within families. To improve our understanding of how individuals and families communicate about and are shaped by HD risk and the results of HD testing, we developed an online survey for individuals aged 14 years and older who have HD in their family or who are the parent, spouse or partner of someone with a family history of HD. Methods: An online Qualtrics survey was developed based on prior qualitative research. The survey explored if, how, when, and by whom information about family history, genetic testing, and test results were communicated within the family and the impact of those communications on family relationships. We recruited both through direct invitations to 102 at-risk probands who enrolled in the presymptomatic genetic testing program for HD at Johns Hopkins between1986-98 (plus 15 family members who participated in noted prior research), including a unique, coded link to the online survey which they were encouraged to share with family members; and via broad-based outreach to the wider HD community through advertisements posted on numerous HD-related websites. Data were collected from 7/2020-6/2021. A total of 224 individuals completed the survey: 178 â□□probandsâ□□ (those with a family history of HD including themselves and/or family members) and 46 â□□partnersâ□□ (those who are/were in a romantic relationship with an individual with HD or a family history of HD). More than two-thirds of at-risk probands (68%) had pursued PGT and 61% of partners reported that their partners had pursued PGT. While a majority of probands shared their PGT results with family members, 25% reported deliberately withholding results, and 21% believed that family members are withholding information about their own genetic test results. Overall, 45% of respondents reported that their decision to be tested (or not) strengthened their family relationships and 25% reported increased conflict and distance. These survey data will help improve our understanding of how information about HD is communicated within and through families, how it influences the trajectories of at-risk individuals and their families, and how care teams might best support their decision-making and communication.

PrgmNr 2963 - Cost-efficient risk assessment for COVID-19 at work and play using machine learning

View session detail

Author Block: **K. Tretina**; Meenta Inc., Boston, MA
Disclosure Block: **K. Tretina:** None.
While many countries have taken action to slow down the spread of COVID-19, in the United States much of the burden of testing falls on private labs at the cost of businesses. To many of these businesses, the potentially immense costs of testing seem excessive. Here, we are developing an app that uses machine learning to prioritize the testing of quarantined employees as a mechanism for getting employees back to work quickly. This app leverages a large database of symptoms and test results to predict the risk of SARS-CoV-2 infection in symptomatic people with high accuracy in real time, allowing businesses to properly allocate resources and often saving them thousands of dollars in reduced testing costs and increased employee return rates.

PrgmNr 2964 - Deciding to pursue pediatric whole genome sequencing: Exploring value from parents' perspectives

View session detail

Author Block: **K. Dunsmore**[1,2], L. Gotlib Conn[3,4,2], M. Zubairi[5], V. Venkataramanan[1], E. Liston[6,7], R. Kim[8,7], R. Z. Hayeems[1,9,2]; [1]Child Hlth.Evaluative Sci., Hosp. for Sick Children, Toronto, ON, Canada, [2]Inst. of Hlth.Policy, Management and Evaluation, Univ. of Toronto, Toronto, ON, Canada, [3]Dept. of Anthropology, Univ. of Toronto, Toronto, ON, Canada, [4]Evaluative Clinical Sci., Sunnybrook Res. Inst., Toronto, ON, Canada, [5]Dept. of Pediatrics, Faculty of Hlth.Sci., McMaster Univ., Hamilton, ON, Canada, [6]Ted Rogers Ctr. for Heart Res., Hosp. for Sick Children, Toronto, ON, Canada, [7]Div. of Clinical and Metabolic Genetics, The Hosp. for Sick Children, Toronto, ON, Canada, [8]Ted Rogers Ctr. for Heart Res., The Hosp. for Sick Children, Toronto, ON, Canada, [9]Ted Rogers Ctr. for Heart Res., The Hosp. for Sick Children, Toronto, ON, Canada

Disclosure Block: **K. Dunsmore:** None.

Objective: Health technology assessment calls for careful consideration of patient and societal values. Existing research has demonstrated that personal and societal values influence how individuals and families orient and respond to genetic testing. Data that reflect on these values in the context of whole genome sequencing (WGS) are only beginning to emerge. The objective of this study was to understand how personal, familial, and societal factors influence parentsâ decisions to pursue WGS and receive secondary findings for their child.

Methods: Embedded in the Ted Rogersâ Cardiac Genome Clinic (CGC) at the Hospital for Sick Children (Toronto, ON), parents of children with congenital heart defects or cardiomyopathies who were offered WGS were eligible to participate. Prior to the receipt of WGS results, telephone-based semi-structured interviews explored personal, familial, and societal factors that influenced parentsâ decisions to pursue WGS and receive secondary findings. Interviews were audio-recorded and transcribed verbatim. Guided by the social ecological model and Kohlerâs construct of personal utility, deductive and inductive coding identified core themes.

Results: We conducted 19 interviews with English-speaking mothers of children who were offered WGS. During decision-making, respondents described the personal value they expected to gain from WGS. Gaining an understanding of their childâs current and future health was perceived to be a central benefit and acted as a precursor to enabling cognitive, emotional, and behavioural control. However, parentsâ enhanced sense of control required a readiness to learn information related to both primary and secondary findings. Parentsâ decisions were also impacted by social relationships and norms; WGS was valued as a mechanism for mitigating blame and legitimizing disability.

Conclusion: Findings from this study shed light on the acceptability of the technology from parentsâ perspectives and may inform strategies for education, counselling, and health technology assessment.

PrgmNr 2965 - Diagnostic sequencing to support genetically stratified medicine in a tertiary care setting

View session detail

Author Block: **L. Bier**[1], N. Lippa[1], A. Revah-Politi[1], H. J. May[2], S. Kushary[1], N. Vena[2], J. L. Giordano[2], H. Milo-Rasouly[2], E. Cocchi[2], T. Sands[2], R. J. Wapner[2], K. Anyane-Yeboa[3], A. G. Gharavi[2], D. B. Goldstein[2]; [1]Inst. for Genomic Med., Columbia Univ. Irving Med. Ctr., New York, NY, [2]Columbia Univ. Irving Med. Ctr., New York, NY, [3]Dept of Pediatrics, Columbia Univ. Irving Med. Ctr., New York, NY
Disclosure Block: **L. Bier:** None.
Purpose: The goal of stratified medicine is to identify subgroups of patients with similar disease mechanisms and specific responses to treatments. To prepare for stratified clinical trials, genome-wide genetic analysis should occur across clinical areas to identify undiagnosed genetic diseases and new genetic causes of disease. **Methods:** To advance genetically stratified medicine we have developed and implemented broad exome sequencing (ES) infrastructure and research protocols at Columbia University Irving Medical Center/NewYork-Presbyterian Hospital (CUIMC/NYPH). **Results:** We enrolled 4890 adult and pediatric probands and identified a primary result in 568 probands. The cohort was phenotypically and demographically heterogeneous as enrollment occurred across multiple specialty clinics (i.e. epilepsy, chronic kidney disease, fetal anomaly). New gene-disease associations and phenotypic expansions were discovered across clinical specialties. **Conclusions:** Our study processes have enabled the enrollment and exome sequencing/analysis of a phenotypically and demographically diverse cohort of patients within one tertiary care medical center. Since all genomic data is stored centrally with permission for longitudinal access to the electronic medical record, subjects can be re-contacted with updated genetic diagnoses or for participation in future genotype-based clinical trials. This infrastructure has allowed for the promotion of genetically stratified clinical trial readiness within the CUIMC/NYPH healthcare system.

PrgmNr 2966 - Digital tools for delivering genomic services: A systematic review

View session detail

Author Block: **D. Assamad**[1], W. Lee[1,2], S. Shickh[2,3], S. Luca[1], M. Clausen[3], C. Somerville[1], A. Tafler[1], A. Shaw[3], R. Hayeems[1,2], Y. Bombard[2,3]; [1]Child Hlth.Evaluative Sci., The Hosp. for Sick Children, Toronto, ON, Canada, [2]Inst. of Hlth.Policy, Management, and Evaluation, Univ. of Toronto, Toronto, ON, Canada, [3]Genomics Hlth.Services Res. Program, Li Ka Shing Knowledge Inst., St. Michaelâ□□s Hosp., Unity Hlth.Toronto, Toronto, ON, Canada

Disclosure Block: **D. Assamad:** None.

Background: Patient-facing digital tools including chatbots are increasingly being used in practice to supplement genetic counseling. To inform efforts to develop, evaluate and scale the use of effective tools, we conducted a systematic review to synthesize existing evidence on the methods to develop and evaluate these tools.

Methods: A search of peer-reviewed, empirical literature from Jan 2010 - Mar 2021 yielded 5072 citations. MeSH terms included: telemedicine, AI, digital, virtual, eHealth, genetic testing/counseling. The primary outcomes were patient-reported usability (e.g., satisfaction) and outcomes of tool use (e.g., knowledge, psychosocial well-being). Secondary outcomes included system-related (e.g., service efficiencies), provider-reported (e.g., workflow integration), and diversity, equity, and inclusion (DEI) dimensions.

Results: In total, 3368 abstracts were screened; 87 papers met inclusion criteria. Seventy-one distinct tools were identified. Their intended clinical settings were: cancer (48%), adult non-cancer (17%), prenatal (17%), pediatric (8%), primary care (5%) & other (9%). Most tools involved multiple steps in the genetic service delivery pathway including education (86%), decision making (51%), psychosocial needs or values assessment (30%), clinical assessment (24%), return of results (16%), post-test counselling & management (16%), consent (1%) & sequencing & interpretation (1%). However, none covered all components of the pathway. Patient reported usability was measured in 72% of studies; of which, 69% reported their tool was acceptable, 53% as satisfactory & 23% reported that users would recommend their tool. As a result of digital tool use, 84% of studies reported an improvement in at least one of the following patient outcomes: knowledge, psychosocial wellbeing, behavioural/management changes, family related communication, decision making or level of engagement. Many studies reported on DEI outcomes including education level (85%), ethnicity (77%) & income (37%). However, other outcomes were less represented such as literacy levels (general, health or digital) (18%), insurance coverage (11%), marital status (10%), & religion (5%).

Conclusion: Although numerous digital tools are available, none that cover the complete genetic service pathway were found. Gaps also remain with respect to DEI considerations and the limited range of clinical settings the tools are designed to support, such as primary care or pediatrics. Findings identify priorities and strategies for developing evidence-based digital tools in genomic medicine.

PrgmNr 2967 - Emerging public policy and perspectives on biometrics (including DNA and facial imaging) in the US

View session detail

Author Block: **J. K. Wagner**; Geisinger, Danville, PA
Disclosure Block: **J.K. Wagner:** Salary/Employment; Geisinger Health System.
Background: DNA and facial imaging have become increasingly important to precision medicine. They are also both being used more frequently and in expanded societal contexts as biometrics (i.e., measurable human characteristics used to recognize the identity or verify claimed identity of an individual). While extensive efforts have been taken by the scientific community to ensure adequate protection of the privacy and security of DNA data, less attention has been given to the challenges posed for responsible stewardship of facial images and derived data. With increased availability of facial images for precision health and media coverage of the perils of facial recognition technologies, a better understanding of biometrics policy development and public policy perspectives regarding biometric data protections is needed. ***Methods:*** Congress.gov and OpenStates.org were used to identify federal and state legislative activity during the most recent two years related to the collection, use, or management of biometrics using eight search strings: DNA (D); genetic data (GD); genetic information (GI); biometrics (B); biometric data (BD); biometric information (BI); faceprint (F); and facial recognition (FR). Bills identified with multiple search terms and identical bills were consolidated. Information was extracted from each identified bill to enable subsequent qualitative analysis. Survey responses from a diverse sample of U.S. adults were obtained through quota sampling via Qualtrics Panels in late 2020. Descriptive statistics were calculated. **Results:** A total of 229 unique federal bills were identified. No bill was identified by more than four separate search terms, which occurred via two combinations: (BD, B, GD, GI) and (BI, BD, B, GD). Surveys were completed by 4,048 respondents with diverse political views (25% liberal, 39% moderate, 27% conservative). Most respondents (60%) indicated the COVID-19 pandemic has not changed their opinion regarding use of biometrics in society, but nearly half (49%) reported their opinion of biometrics is less favorable now than it was five years ago. While most expressed concerns about possible misuse of their personal information generally (50% very and 38% somewhat concerned), nearly one-third (31%) indicated that biometric data protection and privacy laws in the US are adequate. ***Conclusions:*** These preliminary findings of emerging public policy and perspectives can be used to design in-depth ELSI research that will facilitate an advanced understanding of the implications of precision health initiatives and further refinement of reasonable and effective data management and sharing practices and policy.

PrgmNr 2968 - Ethical issues in pediatric gene therapy research

View session detail

Author Block: **A. Bateman-House**[1], L. Shah[2], C. Hunt[1], Pediatric Gene Therapy and Medical Ethics (PGTME)Working Group; [1]NYU Grossman Sch. of Med., New York, NY, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY
Disclosure Block: **A. Bateman-House:** Grant/Contracted Research Support (External); Johnson & Johnson, Pfizer. Consultant/Consulting Fees/Other Remuneration; Alexion.
There are myriad ethical challenges surrounding gene therapy clinical trials conducted on children. Some of these challenges, such as insuring appropriate practices surrounding the process of obtaining informed consent by a surrogate decision-maker and assent from a capable child participant, are common to all human subjects research in pediatric populations. Others, such as the current irreversibility of gene therapy interventions and participants' resultant inability to effectively withdraw from research, are more specific to gene therapy. And some are specific to pediatric gene therapy clinical trials: for example, the challenges of working with pediatric trial participants who transition to adulthood during the multi-year follow-up period. Furthermore, there are evergreen research ethics issues of equity of access and appropriate risk/benefit balancing. We identify some of the most pressing ethical challenges, to promote increased awareness and understanding of them, and share nascent best practices for clinical research in this rapidly-evolving area.

PrgmNr 2969 - Genes to Mental Health Network Report: Stakeholder perspectives on research participation

View session detail

Author Block: **T. Crowley**[1], L. White[1,2], B. M. Finucane[3], S. Garcia-Minaur[4], G. M. Repetto[5], M. Fischer[6], S. Jacquemont[7], M. van den Bree[8], R. Gur[1,2], A. Maillard[9], K. Donald[10], A. S. Bassett[11], A. Swillen[12], D. M. McDonald-McGinn[13]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Perelman Sch. of Med. of the Univ. of Pennsylvania, Philadelphia, PA, [3]Geisinger Hlth.System, Lewisburg, PA, [4]Hosp. Disclosure Block: **T. Crowley:** None.

Background: Feedback from research study participants is rarely collected. Therefore, investigators have limited understanding regarding their motivation to participate. Gaining insight is relevant to the 22q community. G2MH surveyed perceptions of eligible stakeholders, including motivation for initial and continuing study involvement and opinions on investigation priorities. **Methods**: A REDCap survey was built in English on instruments from Vanderbilt and EURORDIS, translated into 11 languages using DeepL software, reviewed by 6 native speakers, and distributed by 22 advocacy groups including 22q11.2 organizations. **Results**: Respondents included 1,035 people from 29 countries. 704 completed the entire survey. 82% were unaffected parents. 44% previously participated in research. 77% reported a chromosome 22q11.2 affiliation. Top reasons for initially partaking included compensation, provider encouragement, free healthcare, and positive previous experiences. Motives for leaving included treatment risks/pain/result non-disclosure. Participants stayed for access to care/information, helping others, improving QOL. Importantly, participants wanted summaries of results/labs and flexible schedules. **Conclusions**: This study provides invaluable insight for planning research studies in partnership with stakeholders. Payment was an initial motivator for joining, as was encouragement from a clinician or caregiver, but participants ranked non-monetary benefits as reasons to remain engaged. Notably, satisfaction was high overall for those previously participating in studies. Stakeholderâ□□s identified lack of public funding for rare disease research, lack of public awareness, difficulty in generating interest in participation, and a paucity of study subjects due to low prevalence as obstacles to supporting such investigations. G2MH hopes to address these issues by analyzing data across rare CNVs including 22q11.2.

PrgmNr 2970 - Hearing in Generation Genome: Comprehensive Newborn Hearing Screening through SEQaBOO (SEQuencing a Baby for an Optimal Outcome)

View session detail

Author Block: **C. C. Morton**[1,2,3], J. Shen[4], S. S. Amr[1,2], K. T. Booth[2], M. Chau[5], Y. Chekaluk[6], K. Choy[7], M. S. Cohen[8], Z. Dong[5], K. E. Gregory[1], J. Hochschild[9], L. J. Johnson[1], M. A. Kenna[10], A. E. Lorenzo[1], L. McGrath[1], C. O. Mitchell[1], J. Perry[10], A. E. Shearer[10], M. E. Stenerson[8], A. B. Giersch[1]; [1]Brigham & Women's Hosp, Boston, MA, [2]Harvard Med. Sch., Boston, MA, [3]Univ. of Manchester, Manchester, United Kingdom, [4]Brigham & Women's Hosp., Harvard Med. Sch., Boston, MA, [5]The Chinese Univ. of Hong Kong, Hong Kong, China, [6]Brigham and Women's Hosp./Harvard Med. Sch., Brookline, MA, [7]Chinese Univ. of Hong Kong, Hong Kong, China, [8]Massachusetts Eye and Ear Infirmary, Boston, MA, [9]Harvard Univ., Cambridge, MA, [10]Boston Children's Hosp., Boston, MA

Disclosure Block: **C.C. Morton:** None.

Early genetic screening in congenitally deaf and hard-of-hearing (DHH) newborns or in non-penetrant DHH babies at birth is an integral component of a comprehensive newborn hearing screening (NBHS) program, which also includes testing for congenital CMV (cCMV) infection and physiologic hearing screening. Recently, compelling data have shown that genetic testing and physiologic screening in NBHS positively impact clinical outcomes and quality of life. SEQaBOO is a leading platform for assessing DHH newborns and evaluating parental attitudes concerning genomic medicine. Parents of newborns referred following a positive NBHS or at confirmatory diagnostic audiometry may enroll for SEQaBOO (comprehensive genome sequencing and variant interpretation, including optional ACMG secondary findings v3.0 for parents, plus annual surveys) or SEQaBOO surveys only. Annual surveys collect data on family medical history, health information and evolving attitudes on genomic medicine. Sequencing data and interpretation are possible prior to diagnostic audiometry and have influenced standard-of-care follow up; confirmatory genetic testing is required per SEQaBOO IRB protocol. Of 203 families approached, 73% (n=149) enrolled with >50% choosing to enroll in genome sequencing. Most NBHS referrals are unilateral and pass diagnostic audiometry with negative genetic results. Among SEQaBOO babies ultimately diagnosed as DHH (n=28), a genetic etiology of *GJB2* and *SLC26A4* variants was reported (n=6). For 13 babies, genetic diagnoses were inconclusive with only one pathogenic/likely pathogenic variant in a recessive gene with or without a second variant classified as VUS or a VUS in a gene associated with dominant DHH. SEQaBOO incorporates cCMV testing into genome sequencing analysis of babiesâ cord blood and confirmed known cases of cCMV (n=2). Genome wide CNV analysis revealed *STRC* and *OTOA* deletions from read count analyses. Additionally, our platform detected the incidental finding of a chromosomal translocation and can identify absence of heterozygosity. Nine cases have non-genetic etiologies. Three ACMG pathogenic secondary findings in adults were disclosed (*COL3A1*, *NF2* and *PKP2*). Feedback from parental surveys is positive with 61.5% of parents acknowledging the benefits of receiving genome sequencing results on themselves, 67.6% commenting on benefits to both themselves and their child and 62.6% stating that the genetic sequencing results have helped them understand their childâs DHH. Newborn screening has long been driven by technology and can now embrace integration of genetic tests to provide life-altering treatments and management to DHH infants.

PrgmNr 2972 - NHGRIâ□□s Inter-Society Coordinating Committee for Practitioner Education in Genomics: Multi-disciplinary genomics resource development

View session detail

Author Block: **D. Messersmith**[1], K. Jacoby Morris[1], S. Teixeira[1], R. L. Haspel[2,3]; [1]Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [2]Beth Israel Deaconess Med. Ctr., Boston, MA, [3]Harvard Med. Sch., Boston, MA
Disclosure Block: **D. Messersmith:** None.
Formed in 2013, the mission of the Inter-Society Coordinating Committee for Practitioner Education in Genomics (ISCC-PEG), hosted by the National Human Genome Research Institute, is to improve genomic literacy of healthcare providers by facilitating interactions among key stakeholders (genome.gov/iscc). Through ISCC-PEG, members collaborate to identify educational needs and potential solutions and develop resources to promote effective practice of clinical genomic medicine. There are currently 230 members representing over 130 organizations including companies, academic institutions, professional societies and government institutes. Members span the health professional spectrum including physicians, nurses, physician assistants, pharmacists, genetic counselors, and medical educators. Members share expertise and creative educational approaches to provide their colleagues who may not have genomics training with free teaching and self-study resources. Ongoing issues and work in progress are discussed via monthly project group calls, bi-monthly plenary calls, and during an annual meeting.

Members propose and initiate project groups to address specific areas in genomics education. The five current project groups focus on rare diseases, diversity and inclusion, direct-to-consumer genetic testing, obstetrics and gynecology, and pharmacogenomics. These multi-disciplinary teams have developed instructional tools, publications, professional society presentations, and social media campaigns. The ISCC-PEG Scholars program, initiated in 2020, pairs students with an interest in a genetics-related career with an ISCC-PEG member mentor to work on an educational project during a two-year term.

During June 7-11, 2021, 56 organizations collaborated with ISCC-PEG to disseminate healthcare provider genomics education resources through a social media campaign. The campaign hashtag #MedGeneEd21 provided a unifying theme in which contributors could tag their content. Through live engagement events, resource sharing and webpage promotion, the 5-day campaign was effective in disseminating resources and raising awareness with over 3 million impressions on Twitter.

Here we plan to present example resources, including self-study modules and case studies. We will also further describe the ISCC-PEG approach, data analytics of the social media campaign, and the positive impact of the committee to create and disseminate healthcare provider genomics education resources across healthcare communities.

PrgmNr 2973 - Polygenic risk scores change primary care providersâ preventive care of racially diverse patients: Results of a national survey with randomized case scenarios

View session detail

Author Block: **B. Kerman**[1], C. A. Brunette[2], A. A. Lemke[3], E. Harris[4], A. Antwi[5], N. Jones[2], J. L. Vassy[6]; [1]Harvard Med. Sch. at Brigham and Womens Hosp., Boston, MA, [2]VA Boston Hlth.care System, Boston, MA, [3]NorthShore Univ Hlth.System, Evanston, IL, [4]Harvard Med. Sch., Boston, MA, [5]VA Boston Hlth.care System, Boson, MA, [6]Harvard Med. Sch. at VA Boston Hlth.care System, Boston, MA
Disclosure Block: **B. Kerman:** None.
Background: Polygenic risk scores (PRS) may enable precision prevention if clinicians accept their use in medical decision-making, but their lower accuracy for non-European ancestry individuals poses equity concerns. To assess the impact of PRS on medical decision-making, and whether the impact differs by patient race, we conducted a national survey of U.S. primary care physicians (PCPs).
Methods: Between 4/18/21-5/13/21, we sent an online survey to a random sample of 27,000 physicians from 216,350 PCPs in the AMA database. Using case scenarios for atherosclerotic cardiovascular disease (ASCVD) and prostate cancer (PrCa) prevention, the survey asked how respondents would manage patients with no PRS (usual care) or a PRS indicating high or low risk. Respondents randomly received 1 of 4 surveys, which varied only by patient race in the ASCVD and PrCa cases [European- (white) or African-American (Black)]. Repeated measures across scenarios were analyzed using generalized estimating equations.
Results: Of 363 respondents (response rate 1.3%), mean (SD) age was 55 (13) years, 40% were women, and 35% reported non-white race/ethnicity. For ASCVD, PCPs were 5.2 times (95% CI 3.5-7.7) more likely and 49% (95% CI 36%-59%) less likely to prescribe a statin to patients with a high-risk and low-risk PRS, respectively, compared to usual care (both p0.05). Similarly, for PrCa, PCPs were 18 times (95% CI 7.5-42.8) more likely and 41% (95% CI 24%-55%) less likely to recommend prostate-specific antigen (PSA) screening for patients with a high-risk and low-risk PRS, respectively, compared to usual care (both p0.05). A majority identified cost (84%), insurance discrimination (64%), and lack of clinical guidelines (63%) as severe or moderate barriers to the use of PRS; only 34% identified PCP time as a barrier. Less than half (40%) somewhat or strongly agreed they felt confident in their clinical use of PRS.
Conclusions: A national sample of PCPs reported that PRS results would change their decision-making around disease prevention. We found no evidence that PCPs considered the variable performance of PRS by ancestry in using PRS results to change medical decision-making. Health system-level barriers may impede PRS uptake.

PrgmNr 2974 - Population carrier frequency estimates may improve genetic counselling for rare autosomal recessive syndromes due to biallelic variants in cancer risk genes

View session detail

Author Block: **J. Powers**[1], E. Trujillo[1], L. Conway[1], K. N. Maxwell[2]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Univ Pennsylvania, Philadelphia, PA
Disclosure Block: **J. Powers:** None.
Background: Several genes lead to different disease states depending on pattern of inheritance. Germline pathogenic variants (PV) in a subset of cancer predisposition genes not only associate with adult-onset autosomal dominantly (AD) inherited cancer risk in the monoallelic state, they also lead to life-limiting autosomal recessive (AR) childhood diseases when present in the biallelic state. However, prior studies have suggested that genetic counselling in cancer risk clinics often does not include the reproductive risk implications associated with the carrier state of a PV in cancer risk genes (CRG).**Methods:** To better facilitate genetic counselling regarding the reproductive risk implications associated with AD inherited CRGs, we used population-based data to calculate the estimated carrier frequencies in different ethnicities for genes that lead to AD cancer risk/AR disease. Genes were selected if they had: 1) well-established AD cancer risk, and 2) known causative role in AR disease. All variants in selected genes were identified in gnomADv.3.0 and classified according to ACMG rules. Population carrier frequencies were collapsed by gene and determined by summation of allele frequencies assuming Hardy-Weinberg equilibrium. Language found on reports from five clinical diagnostic laboratories was reviewed.**Results:** Carrier frequencies in seven ancestry cohorts were determined for *ATM, BRCA1, BRCA2, BRIP1, FH, MLH1, MSH2, MSH6, NBN, PMS2, RAD51C,* and *RAD51D*. *BRCA1/2* in the Ashkenazi Jewish (AJ) population had the highest carrier frequency at 1.32% and 1.29%, respectively. Excluding AJ, carrier frequencies across ethnicities were 0.19±0.08% (range 0.06-0.28%) for *BRCA1* and 0.31±0.10% (range 0.17-0.43%) for *BRCA2*. *ATM* had the next highest average carrier frequency at 0.31±0.12% (range 0.16-0.48%). *MLH1* and *MSH2* had the lowest, both at 0.03±0.01% (range 0.01-0.04% for both genes). Average carrier frequencies were less than 0.10% for *FH* and *RAD51D*, and between 0.10-0.20% for the remaining. On review of test reports, all labs described reproductive implications of the AR disease associated with the CRG. No labs provided discrete carrier frequency data nor disease prevalence. Oonly one lab discussed possible need for carrier testing. **Conclusions:** More robust characterization of carrier frequencies will better assist genetic counselors in facilitating discussions about reproductive risks of AR diseases in the setting of a PV in any above-mentioned CRGs, assuming their partner is not a known carrier. Future studies are needed to assess genetic providersâ behaviors surrounding discussion of risks as well as patient comprehension.

PrgmNr 2975 - Preparing primary care providers to utilize direct-to-consumer genetic test results in the creation of an individualized healthcare plan

View session detail

Author Block: **K. Glenn**; Clemson Univ./VCOM, Clemson, SC
Disclosure Block: **K. Glenn:** None.
Direct-to-consumer genetic testing (DTCGT) companies offer the average person a chance to unlock their genome to explore their ancestry, genetic traits, and health risk reports. The results always come with a stern suggestion to contact a healthcare provider if there are any questions or concerns. However, most primary care providers do not have a genetics-focused practice and may find themselves unsure of what to do with the unsolicited test results of a concerned patient. The purpose of this study is to explore medical studentsâ knowledge retention of DTCGT and how it uses genetic risk assessment in the formulation of test results. Using a pre and post-module assessment, this study aims to determine the effectiveness of an online course that trains future providers to use patient-initiated direct-to-consumer genetic test results in creating a personalized healthcare plan.

PrgmNr 2976 - Prevalence and Correlates of Parental Decisions about Direct-to-Consumer Genetic Testing for Adult-Onset Inherited Cancer Syndromes in their Children

View session detail

Author Block: **G. McDonnell**[1], B. N. Peshkin[1], J. G. Hamilton[2], J. Brower[3], H. Ovadia[2], L. Friedman Ross[4], R. Sacca[2], B. A. Tarini[5], B. S. Wilfond[6], S. M. Domchek[3], S. Vittone[7], S. Campbell[1], K. P. Tercyak[1]; [1]Georgetown Lombardi Comprehensive Cancer Ctr., Washington, DC, [2]Mem. Sloan Kettering Cancer Ctr., New York, NY, [3]Univ. of Pennsylvania, Philadelphia, PA, [4]Univ. of Chicago, Chicago, IL, [5]Children's Natl. Hosp., Washington, DC, [6]Seattle Children's Hosp., Seattle, WA, [7]Georgetown Univ. Sch. of Nursing and Hlth.Studies, Washington, DC

Disclosure Block: **G. McDonnell:** None.

Direct-to-Consumer (DTC) genetic testing for mutations in adult-onset inherited cancer syndromes (e.g., breast, ovarian, colorectal cancers) is available. Although parentsâ□□ use of DTC testing to identify their childrenâ□□s risk status is controversial, it is precluded neither by some companiesâ□□ practices nor federal regulations. At present, very little is known about parentsâ□□ decisions on DTC testing for their children. This study examined pediatric DTC testing attitudes and behaviors in parents and correlates of testing in their children. The sample was drawn from a research registry, with invitations sent to N=591 adults with a pathogenic variant in a target gene (BRCA1/2, MLH1, MSH2/6, PMS2, MUTYH): N=142 likely had a child in the study age range. Overall, N=134 adults visited the study website, and 80 parents (60% of visitors; 95% female, 94% white) with children 10-21 y.o. participated. The survey included validated measures of pediatric genetic testing knowledge, attitudes, and beliefs, general and cancer-specific parent-child communication, and opinions about the pros/cons of DTC pediatric testing. In parents, 83% informed their children of the parentâ□□s mutation, and 56% talked openly about pediatric testing. Informing children about parental risk and talking about testing were highly associated (R=0.52, p=65): cons were lack of healthcare provider engagement (Mdn=19), lack of required genetic counseling (Mdn=22), and unmet psychosocial needs (Mdn=38). In sum, high risk parents commonly inform children about heritable cancer risks, most discuss genetic testing, and 10% also test children by DTC. Genetics professionals may see an increase in children referred for service after DTC testing. Outcome studies are needed to better inform practice and policy in this area.

PrgmNr 2977 - Public knowledge, perceptions, and attitudes towards direct-to-consumer genetic testing: A national web-based survey

View session detail

Author Block: H. Andrighetti, J. Furnival, J. Hunsanger, S. Bradley, A. Baker, B. Knorr, **S. D. Crawford**; SoundRocket, Ann Arbor, MI
Disclosure Block: **S.D. Crawford:** None.
The next decade will hold vast advances in genomics, and with it, genetic testing will become more common, both clinically and direct-to-consumer (DTC). DTC genetic testing (DTCGT) has progressed from a focus on ancestry and traits (so-called â□□recreationalâ□□ testing) to a range of offerings that increasingly impact medical care, up to and including whole genome sequencing. As this testing becomes both more accessible and clinically relevant, it is important to study public knowledge, perceptions and attitudes of DTCGT, and how these shift over time.
In May 2021, we conducted a national study that included a random sample of over 750 participants selected to match the U.S. Census demographics on gender, age, race/ethnicity, and geographic region. In this self-administered web-based survey, participants were asked about their familiarity with genetic terminology, experiences with genetic testing, and opinions on DTCGT. To examine current perceptions of DTCGT, participants were asked how strongly they agree with a list of 13 potential barriers to DTCGT (e.g.: concerns about privacy of genetic information) and 10 potential motivators for DTCGT (e.g.: learning about risks for specific genetic conditions).
We will describe the current landscape of genetic testing experiences among a nationally representative sample, and explore the most commonly endorsed current barriers and motivators to pursuing DTCGT. Additional analyses will include discussion of changes in perspectives over time, and comparisons based on age, gender, race/ethnicity, marital status, education level, proactive health behaviors, family history, genetics knowledge, and genetic testing experiences.
These data will serve as a snapshot of the current landscape of public knowledge, perceptions, and attitudes towards DTCGT, and as a baseline for an ongoing cross-sectional study to monitor how public perspectives change over time as the DTCGT space evolves. This exploratory study may give insights to those working both in the DTCGT space, and in clinical genetics, identifying knowledge gaps that may exist and ideal targets for public education and outreach as these tests become increasingly ubiquitous. In sharing these initial results, we hope to initiate a conversation around the appropriate priorities for our next stage of research.

PrgmNr 2978 - Returning Polygenic Risk Score-Based Results to Parents - Parentsâ Understanding of and Response to Reported Risk

View session detail

Author Block: **J. J. Connolly**[1], I. A. Holm[2], M. Behr[1], M. del Rosario[3], H. Hain[1], M. H. Harr[4], H. Hakonarson[4]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Boston Children's Hosp, Boston, MA, [3]Boston Children's Hosp., Boston, MA, [4]Children S Hosp. of Philadelphia, Philadelphia, PA
Disclosure Block: **J.J. Connolly:** None.
Polygenic risk scores (PRSs) have the potential to improve healthcare by identifying individuals at risk for common complex conditions. Use of PRSs in clinical practice, however, requires careful assessment of the needs and capabilities of patients, providers, and healthcare systems. To this end, the electronic Medical Records and Genomics (eMERGE) network is conducting a pragmatic trial, which will return PRSs to 25,000 pediatric and adult participants. All participants will receive a risk report that includes a PRS calculation classifying them as either high risk (~3% per condition) or not. Returning PRSs to children is particularly novel, and eMERGE is leading a number of studies to inform best practices for PRS-based reporting in pediatrics. Here, we performed qualitative analyses from semi-structured interviews with 48 parents who received hypothetical risk reports, wherein children were classified as high risk for type 2 diabetes and asthma. Parents were assessed on their comprehension of absolute- versus relative-risk framing (overall risk perception); 2) likelihood to follow risk reduction recommendations; 3) perceived value of the information presented; 4) psychosocial impact (stress/anxiety); and 5) education/support needed. Analyses revealed miscomprehension of several important study parameters across all ethnic groups, and highlight the need for targeted educational material to formatively support report development.

PrgmNr 2979 - Secondary Findings in Minors Case Series: Recommendations for Clinical Care and Research

View session detail

Author Block: **M. Similuk**[1], A. Katz[2], M. R. Setzer[1], S. Miner[3], J. Yan[1], M. Kamen[4], C. Jodarski[4], L. Jamal[3,5], K. Jevtich[1], Y. Yu[1], R. Duncan[1], B. Seifert[4], R. Ghosh[4], S. Holland[1], M. A. Walkiewicz[1]; [1]Natl. Inst. of Allergy and Infectious Diseases, NIH, Bethesda, MD, [2]Natl. Human Genome Res. Inst., Bethesda, MD, [3]NIH Clinical Ctr. Dept. of Bioethics, Bethesda, MD, [4]Med. Sci. & Computing at the Natl. Inst. of Allergy and Infectious Diseases, NIH, Bethesda, MD, [5]Natl. Cancer Inst., NIH, Bethesda, MD
Disclosure Block: **M. Similuk:** None.
Background and Purpose: Increasingly, secondary findings (SF) are being returned to individuals in clinical and research settings. As an opportunistic screening result, a SF infers a lower positive predictive value for disease compared to a sequencing result identified through diagnostic testing, and as such clinicians can benefit from structured guidance on navigating the complexities of SF management. While Katz and colleagues recently articulated a SF management framework for adults (PMID: 32619490), there is little, and often conflicting, professional guidance for how SFs should be managed in pediatric settings. There is a need for clearer guidance given special nuances including the inability for the proband to provide consent, the possible value that this information may have for the proband and other family members, and developmental considerations for both the medical and psychosocial case management. In the National Institutes of Allergy and Infectious Diseases (NIAID) Centralized Sequencing Program at the National Institutes of Health Clinical Center, we have elected to return SF from exome and genome sequencing in minors by default. Here we synthesize specific findings from our cohort with empirical evidence and guidance from the literature.
Methods: 864 pediatric participants received exome or genome sequencing with SF analysis from 2017-2021.
Results: Seventeen SF were returned in 16 minor patients (1.9%). Three-quarters of the SF (13/17, 76.5%) were associated with potential childhood onset of disease. SFs in the following risk categories were identified: disorders with high or near complete penetrance (*FBN1*, *RET*; 4/17, 23.5%), disorders with low or moderate penetrance (*BRCA2*, *DSC2*, *MHY7*, *PKP2*; 8/17, 47.1%), disorders with low intensity interventions (*LDLR*, 4/17, 23.5%), and disorders with typical childhood presentations (*OTC*; 1/17, 5.9%).
Discussion: We present three primary themes with illustrative cases to demonstrate the nuances encountered in pediatric SF: (1.) Medical evaluation and risk assessment: SF interactions with indication for testing (Case A: Primary finding - *CYBB;* SF - *OTC*). (2.) Considerations for disclosures: family understanding and adaptation to SF (Case B: Primary finding - *CTLA4;* SF - *BRCA2* and *LDLR*) (3.) Opportunity for adult relatives at risk (Case C: SF - *PKP2*).
Conclusion: We synthesize guidance on adult SF management, the evolving empirical literature on pediatric adjustment, and genetic testing ethics to create an illuminating pediatric SF case series with recommendations for clinical care and future research.

PrgmNr 2980 - Strategies to address the health and social care needs of rare disease patients: A comparative analysis of two Canadian provinces

View session detail

Author Block: **W. Lee**, R. Z. Hayeems; The Hosp. for Sick Children, Toronto, ON, Canada
Disclosure Block: **W. Lee:** None.
Background: Rare diseases are a serious public health challenge that affects not only patients and families, but also the health care system and society. A comprehensive approach to rare diseases is needed to address gaps that exist in diagnosis, prevention, care, treatment, social support, and research. While many countries have developed national policies and strategies, Canada is lacking a comprehensive national strategy for addressing the unmet health and social care needs for these patients. In 2015, a national rare disease advocacy group, Canadian Organization for Rare Disorders (CORD), introduced Canadaâ□□s Rare Disease Strategy. Their final report identified five areas as high priority in rare disease, but CORDâ□□s recommendations have not been fully endorsed or adopted by the federal government. While a national strategy is lacking, several Canadian jurisdictions have developed and implemented their own policies and programs that address one or more of CORDâ□□s five key areas.
Methods: Using the World Health Organization Health Systems Framework, which outlines the five essential functions of health systems, we conducted a comprehensive review of the academic and grey literature to describe and compare the approaches to rare disease care in two provinces: Alberta and Ontario. Using directed content analysis, CORDâ□□s five priority areas were used to describe the extent to which existing provincial programs address the gaps and challenges faced by the rare disease community.
Results: Documents included in the comparative analysis included government reports, policy documents, reports from professional associations or patient advocacy groups, peer-reviewed articles, and media reports available as of April 5, 2021. The comparative analysis revealed that while both provinces have similar programs in place in terms of their objectives, there is evidence of more comprehensive patient access to diagnostic services and essential medicine in Ontario compared to Alberta. While understanding the reasons underlying the discrepancies between the provinces was not one of the main objectives of this analysis, differences in the health care system structure (i.e., centralized vs. decentralized) and the number of rare disease patients in the two provinces may be contributing factors. The analysis also identified common challenges across the two provinces related to workforce shortages and limited health information systems.
Conclusion: The learnings from this comparative analysis combined with international rare disease strategies can inform the development of a pan-Canadian rare disease strategy.

PrgmNr 2981 - The complexity of diagnosing rare disease: An organising framework for health services and health economics research based on real world evidence

View session detail

Author Block: **R. Z. Hayeems**[1,2], C. Michaels-Igbokwe[3], V. Venkataramanan[1], T. Hartley[4], M. Acker[1], M. Gillespie[4], W. J. Ungar[5,2], R. Mendoza-Londono[5,6], F. P. Bernier[7,8], K. M. Boycott[9,10], D. A. Marshall[3,11]; [1]Child Hlth.Evaluative Sci., The Hosp. for Sick Children, Toronto, ON, Canada, [2]Inst. of Hlth.Policy, Management and Evaluation, The Univ. of Toronto, Toronto, ON, Canada, [3]Cumming Sch. of Med., Univ. of Calgary, Calgary, AB, Canada, [4]Dept. of Genetics, Childrenâ□□s Hosp. of Eastern Ontario, Ottawa, ON, Canada, [5]The Hosp. for Sick Children, Toronto, ON, Canada, [6]Dept. of Pediatrics, The Univ. of Toronto, Toronto, ON, Canada, [7]Alberta Childrenâ□□s Hosp., Calgary, AB, Canada, [8]Alberta Childrenâ□□s Hosp. Res. Inst., Univ. of Calgary, Calgary, AB, Canada, [9]Childrenâ□□s Hosp. of Eastern Ontario, Ottawa, ON, Canada, [10]Childrenâ□□s Hosp. Eastern Ontario Res. Inst., Univ. of Ottawa, Ottawa, ON, Canada, [11]Oâ□□Brien Inst. for Publ. Hlth., Univ. of Calgary, Calgary, AB, Canada
Disclosure Block: **R.Z. Hayeems:** None.
Purpose: To facilitate robust health services and economic analyses of clinical exome and genome sequencing, the purpose of this study was to establish a framework for organizing diagnostic testing trajectories for rare disease patients. **Methods:** Embedded within a large Canadian rare disease cohort study (Care4Rare SOLVE), we collected diagnostic investigations prior to exome sequencing from medical records of 228 patients. Medical geneticist experts participated in a five-step consensus-building process to develop a real-world data-driven framework for organizing the complex range of observed tests. Experts categorized tests as *indicator* or *non-indicator* based on their specific contribution to diagnosing rare disease. In addition, indicator tests included those that were higher cost, potentially invasive, less accessible, and ordered/interpreted by a sub-specialist and non-indicator tests included those that were lower cost, non-invasive, locally accessible, and ordered/interpreted by a generalist. Face validity of the resulting SOLVE Framework was assessed using case vignettes that spanned a range of phenotypic indications for testing. **Results:** Most cases had symptom onset at birth (42.5%) or during childhood (43.4%) and had intellectual disability (73.3%). On average, the time spent seeking a diagnosis prior to sequencing was 2290 days [SD=2138] and included up to 71 diagnostic tests. Agreement across experts on indicator vs. non-indicator test categories ranged from 83%-96%. Observed tests, including 186 unique indicator and 39 unique non-indicator tests across cytogenetic/molecular (n=112), biochemical (n=73), imaging (n=28), electrical (n=7), and pathology (n=5) test categories comprised the SOLVE Framework. **Conclusion:** Real world diagnostic testing data can be ascertained and organized to reflect the complexity of the journey for patients with rare disease. Informed by a robust sample of 228 rare disease patients from multiple clinical settings, the SOLVE Framework will improve the accuracy and certainty associated with economic assessments of genomic sequencing by providing a consistent approach to categorising and comparing patient trajectories. The application of this framework to the economic evaluation of the complete SOLVE cohort is underway.

PrgmNr 2982 - The cost of good health: Poverty association with differential gene expression

View session detail

Author Block: **N. Arnold**[1,2], J. Resztak[2], A. Alazizi[2], S. Dubaisi[2], R. J. Thorpe Jr[3], N. Noren Hooten[4], M. K. Evans[4], D. F. Dluzen[5,1], R. Pique-Regi[6], F. Luca[6]; [1]Morgan State Univ., Baltimore, MD, [2]Wayne State Univ., Detroit, MI, [3]John Hopkins Univ., Baltimore, MD, [4]Natl. Inst. on Aging, NIH, Baltimore, MD, [5]NIH, Silver Spring, MD, [6]Wayne State Univ, Detroit, MI
Disclosure Block: **N. Arnold:** None.
PURPOSE Psychosocial factors exert a powerful influence on health status and contribute to health disparities among marginalized populations. For example, overall life expectancy at birth throughout the United States tracks with poverty level, educational attainment, economic security and other upstream social determinants of health. Socioeconomic status (SES) and psychosocial factors are documented to affect gene expression in peripheral blood mononuclear cells, suggesting a molecular mechanism for some health disparities. Here we investigated the effects of poverty among Baltimore City residents participating in the Healthy Aging in Neighborhoods of Diversity across the Life Span (HANDLS). **METHODS** We examined 239 participants of the HANDLS cohort study in Baltimore whose reported household income was either above or below the 125% federal poverty line for 2004. This population sample was composed of 119 African Americans and 120 white, for a total of 119 men and 120 women. We performed RNA sequencing in peripheral blood mononuclear cells to assess differential gene expression patterns associated with poverty. **RESULTS** We identified 15 genes differentially expressed when testing for poverty while controlling for race, sex, and age. When focusing on women, we found that individuals living in poverty had increased expression for 9 genes and decreased expression for 11 genes compared to individuals living above the poverty line. GSEA identified an enrichment for Herpes simplex virus infection pathway and B cell mediated immunity in genes differentially expressed in women living in poverty. **CONCLUSIONS** Our study suggests that poverty status influences gene expression in the immune system. Improving health outcomes for at-risk populations is achievable by understanding the link between poverty and identifiable biological mechanisms that influence disease.

PrgmNr 2983 - The Effect of Genetic Testing as Part of Personalized Lifestyle and Habit Change Coaching

View session detail

Author Block: **L. Fensterheim**[1], N. Vani[1], J. Ruby[1], K. Hood[1], L. Dodo[1], R. Bennie[1], L. PÃ©russe[2]; [1]Newtopia Inc., Toronto, ON, Canada, [2]Laval Univ., Quebec, QC, Canada
Disclosure Block: **L. Fensterheim:** Salary/Employment; Newtopia Inc.
Background Genetic testing can be used as part of lifestyle intervention programs to provide personalized recommendations with the hope of improving adherence and facilitate changes in lifestyle behaviors. However, little is known about the impact of such testing on the effectiveness of a lifestyle coaching experience. **Objective** To evaluate whether targeted genetic testing improves weight loss outcomes from a personalized lifestyle and habit change coaching experience. **Methods** This was a retrospective study of participants who engaged for at least 4 months in a personalized habit change coaching program between January 1, and February 28, 2020. Participants were required to have an initial body mass index (BMI) of at least 28 kg/m^2. All participants were offered genetic testing to optimize the delivery of the personalized coaching. The following three candidate gene variants were assessed based on their documented association with obesity: DRD2/ANKK1 rs1800497, FTO rs9939609 and MC4R rs17782313. Two main outcomes were considered: percent weight loss achieved at 12 months (%WL12) and achieving a minimum of 5% weight loss at 12 months (5%WL12). A generalized linear model was used to assess whether %WL12 differed between those who received genetic testing versus those who did not. A logistic model was also used to assess the impact of genetic testing on 5%WL12. Age, sex, ethnic background, initial weight, and personality type were controlled for in all analyses. **Results** A total of 2297 participants (52% female) met the criteria for inclusion. On average (mean Â± SD), participants were 45.4 Â± 10.7 years and had a BMI of 34.1 Â± 5.7 kg/m^2, respectively. The covariate adjusted %WL12 was significantly higher (p = 0.001) in those taking the test (4.0 Â± 0.3) compared to those who did not (3.2 Â± 0.2) The likelihood of achieving 5%WL12 had 1.3 times higher odds in participants taking the genetic test (OR= 1.3; 95%CI: 1.08-1.59) versus those who did not. **Conclusion:** These results suggest that targeted genetic testing can improve the effectiveness of a lifestyle coaching program when properly integrated in terms of the weight loss achieved in response to the experience.

PrgmNr 2984 - The physical costs and psychosocial benefits associated with moving to a White neighborhood for African American male children

View session detail

Author Block: **J. Del Toro**[1], L. Gaydosh[2], M-T. Wang[1], L. Schneper[3], C. Mitchell[4], S. McLanahan[3], D. A. Notterman[3]; [1]Univ. of Pittsburgh, Pittsburgh, PA, [2]Vanderbilt Univ., Nashville, TN, [3]Princeton Univ., Princeton, NJ, [4]Univ. of Michigan, Ann Arbor, MI
Disclosure Block: **J. Del Toro:** None.
For youth of color, moving to an affluent neighborhood introduces a paradox: Positive psychosocial adjustment in exchange for physiological dysfunction. According to skin-deep resilience (Brody et al., 2013), persistence in achieving upward social mobility produce favorable psychosocial outcomes yet also predispose youth of color to racial discrimination, which over time increases allostatic load (Chen et al., 2015), metabolic syndrome (Miller et al., 2020), and likelihood of developing diabetes (Brody et al., 2016). However, studies examining risk exposure for such youth have relied on colorblind approaches as they have not acknowledged that upward social mobility entails shifting into a predominantly White context. Moreover, socioeconomic inequality is problematic for African American male children as those who grow up economically advantaged are more likely to fall to the bottom of the socioeconomic ladder and those at the bottom of the socioeconomic latter are less likely to climb up relative to other racial and gender groups (Badger et al., 2018). Thus, to extend the literature, we examined the physiological and psychosocial consequences associated with moving to a White neighborhood for African American and White male children in the US.
950 African American and 331 White males participated in two waves of the Fragile Families and Child Wellbeing Study, a national cohort study of children primarily from unwedded parents. Children participated when they were on average ages 9 and 15. Data at each wave included the U.S. Census tract percentage of White residents, self-reported depressive symptoms and delinquency, and salivary telomere length. Using our data, we estimated multi-level models in which we nested time within participants and accounted for city random effects.
After controlling for covariates, increases in the percentage of White residents predicted decreases in depressive symptoms and delinquency between ages 9 and 15 among African American males. However, increases in the percentage of White residents predicted telomere length shortening between ages 9 and 15 for African American males. Changes in the percentage of White residents did not predict depressive symptoms, delinquency, or telomere length for White males.
We found that the racial composition of the neighborhood context is crucial in shaping youthâ□□s developmental trajectories. While we support propositions that upward social mobility can predispose youth of color to racial discrimination, acknowledging the racial composition of the context is necessary to understand the dynamics that youth face when their families aim to live a better life for their children.

PrgmNr 2985 - The White Ceiling: Qualitative Study of Genetic Counseling Studentsâ Perceptions about Cultural Competence Training

View session detail

Author Block: **T. Rai**, S. Capasso, J. Duffy; Bay Path Univ., Longmeadow, MA
Disclosure Block: **T. Rai:** None.
Objective: This qualitative research was conducted to study the perception of current and recently graduated genetic counseling students from the classes of 2018 to 2022, on the CCT provided by their programs. According to the NSGCâs own Professional Status Survey, over the last 20 years, the population of professional genetic counselors who identify as White/Caucasian has held steady at 90% or more, despite years of JEDI focused efforts by the NSGC, other professional groups, and individuals. It is evident that it will be a while before we see significant results. The next best tool in ensuring patient centered care is delivered to our ever-diversifying patient population is by providing quality and effective cultural competence training (CCT) to our students.
Methods: A survey comprising 15 questions directed at answering the research question of the studentsâ perceptions of the type, quality, and effectiveness of CCT was created. Invitation for participation was sent through the NSGC listserv, social media, program directors, professional organizations, and word of mouth. After a 6 weeks collection period, 73 valid responses were received representing 33 of the 55 total US and Canadian Accreditation Council for Genetic Counseling (ACGC) accredited schools. The responses were uploaded into Dedoose ver 8.3.47b, a qualitative analysis software, and the material was scoured for common themes.
Results: The participants were from the classes of 2018 (*n*=3, 4.1%), 2019 (*n*=7, 9.6%), 2020 (*n*=13, 17.8%), 2021 (*n*=34, 46.6%), and 2022 (*n*=16, 21.9%), and 78% of the participants had more than a year of shadowing and direct patient counseling experience. Pre-CCT, students professed to having political, religious, SES, cultural/ethnicity/race, gender, and disability biases. The sub-themes that emerged from this study focused around the overarching themes of diversity and self-awareness. Students highlighted the lack of diversity in course topics and materials, the representative populations that are highlighted, invited speakers, and lecturers and program leadership. Students also expressed how programs failed to be self-aware by using language that fell into the trap of stereotyping and generalizing, lecturers failing to address and provide spaces to discuss xenophobic, racist, and culturally insensitive comments made in class, failing to provide opportunity to discuss course material, not making CCT classes or events a priority, and by overcompensating and causing students to dread going into clinic for fear of saying the wrong things.

PrgmNr 2986 - Views on the training needs of genetic assistants vary widely

View session detail

Author Block: **R. Rider**[1], L. Cubano[1], E. B. Madden[2], K. Jacoby Morris[3], R. Rowley[4], T. A. Manolio[2]; [1]Div. of Genomic Med., NHGRI, Bethesda, MD, [2]NHGRI, Bethesda, MD, [3]Ed. and Community Involvement Branch, NHGRI, Bethesda, MD, [4]Div. of Genomic Med., Bethesda, MD
Disclosure Block: **R. Rider:** None.
Introduction: Genetic assistants (GAs), often called â□□genetic counseling assistants,â□□ are a growing part of the workforce. We sought to identify opinions on the training needs of GAs and attitudes about GA training programs (GATPs). **Methods:** Links to a survey on training needs of GAs and attitudes about GATPs were emailed to members of the National Society of Genetic Counselors, 16 state genetic counseling (GC) professional organizations, and genomic medicine researchers. Proportions of responses with 95% confidence intervals were calculated and compared. Results were stratified by profession (GA vs. GC) and work setting (clinical vs. lab). Open-ended responses were coded to identify emerging themes. **Results:** Respondents (*n*=375) primarily included GCs (*n*=211) and GAs (*n*=125). While 73% had at least one GA in their work setting with a bachelorâ□□s degree, 16% worked with at least one GA with an associate degree or lower. For those in work settings that require GAs to have a bachelorâ□□s, similar numbers favored keeping that requirement vs. hiring someone without a bachelorâ□□s if they attended a GATP (53% [45-60] vs. 47% [39-55]). Although 37% preferred hiring those who completed GATPs, 55% were neutral. Most believed GATPs should focus on general background knowledge, with almost all skills to be learned on the job. Most skills (65%) were rated as unneeded by 25%-45% of respondents. While 47% felt that GATPs should require enrollment in or completion of a bachelorâ□□s, 29% felt an associate or lower would be appropriate and 11% felt that programs were needed at multiple levels. Almost half (44%) believed GATPs could be a burden that discourages candidates from becoming GAs. Minor differences by profession and work setting emerged, *e.g.*, those in clinical settings tended to rate GATPs as helpful more often than those in labs (67% [61-72] vs. 52% [40-63]). In the qualitative data, the most common theme was the concern that GATPs could become barriers to becoming a GA or a GC. Some worried that these barriers could ultimately reduce workforce diversity in genetic counseling. The next most common themes were that GAs in different settings have different training needs and that GATPs may be unnecessary, *e.g.*, repetitious of prior education or superfluous. **Conclusions:** While many agreed that GATPs could be useful, there was no consensus on specifics such as general knowledge and skills needed by GAs, target GATP audience, or ideal GATP content. Neither profession nor work setting explained the range of opinions about training needs or the concern that GATPs could become barriers. Better understanding of the nuances of GA training needs is vital to designing GATPs.

PrgmNr 2987 - Yield of genomic disease given the identification of a secondary finding

View session detail

Author Block: **A. Katz**[1], H. Shiferaw[2], C. Hong[3], L. G. Biesecker[4]; [1]Natl. Human Genome Res. Inst., Bethesda, MD, [2]NIH, Gaithersburg, MD, [3]Natl. Inst.S OF HEALTH, BETHESDA, MD, [4]Bethesda, MD
Disclosure Block: **A. Katz:** None.
A secondary finding is a genomic variant of potential medical value that is unrelated to the primary reason for testing. Here we define yield as the fraction of those with confirmed disease (clinicomolecular diagnosis) divided by those with a secondary finding. The yield of a secondary finding depends on the probability of pathogenicity of the variant (used here as a conditional probability) and the prior probability of the disorder. Using a Bayesian framework, we determined the posterior probability of disease (yield) given the identification of a secondary finding for each disorder associated with the ACMG recommended list of secondary findings genes. The hypothetical scenario we evaluated is an individual (for whom no clinical information is available) has received a secondary finding result. To determine the posterior probability of disease based on a genomic result alone (yield), we estimated the following parameters for each disorder: 1) the prior probability, which is the population prevalence of the disorder; 2) the probability that a pathogenic variant is identified by diagnostic sequencing in an individual who meets clinical criteria for the disorder; 3) the probability that an unaffected individual harbors a pathogenic variant associated with the disorder. Best estimates for parameters 1) and 2) were determined via literature review. Parameter 3) was determined by the frequency of individuals whose sequence data are in gnomAD who harbor variants that meet ACMG criteria for Pathogenic or Likely Pathogenic (with adjustments for disorders in which affected individuals may be included in gnomAD, such as hereditary breast and ovarian cancer syndrome). We focused on disorders displaying an autosomal dominant inheritance pattern. Applying Bayes theorem with the parameters noted, we calculated the posterior probability of disease when a pathogenic variant is identified in a genomic screening context. Among the ACMG recommended list, variants in familial hypercholesterolemia (prob=60%, RR=120.4 [95% 64.7-223.9]) had the highest yield and hereditary paraganglioma-pheochromocytoma syndrome (prob=0.065%, RR=400.2 [95% 25.0-6395.2]) had the lowest yield. As expected, the yield varies greatly depending on the population prevalence of the disorder. Our results are consistent with the notion that individuals with secondary findings have a high relative risk of disease (compared to the general population) but also underscore the distinction of a secondary finding from a genomic disease. Our calculated posterior probability of disease (yield) can be useful in the evaluation and management of individuals with secondary findings.

PrgmNr 2988 - A 3-part Phase 2 study of HST5040, an investigational oral therapy that reduces toxic coenzyme A metabolites in methylmalonic and propionic acidemias (clinicaltrials.gov NCT04732429)

View session detail

Author Block: **G. F. Cox**[1], M. Y. Waller[1], A. J. Armstrong[1], M. P. Hayes[1], K. A. Chapman[2]; [1]HemoShear Therapeutics, Charlottesville, VA, [2]Children's Natl. Hosp., Washington, DC
Disclosure Block: **G.F. Cox:** Major Stockholder/Ownership Interest; CANbridge, Deep Genomics, HemoShear. Consultant/Consulting Fees/Other Remuneration; Blueprint, CANbridge, Chiesi, Exonics/Vertex, Sanofi Genzyme, Ultragenyx.
Methylmalonic and propionic acidemias (MMA and PA) are organic acidemias caused by sequential enzyme deficiencies in the catabolism of propionic acid generated from certain amino acids (valine, methionine, isoleucine, and threonine), odd-chain fatty acids, cholesterol, and gut flora. Both disorders are characterized by frequent acute metabolic decompensations in early childhood involving metabolic acidosis and hyperammonemia, and long-term sequelae including intellectual disability, renal insufficiency (MMA>PA), and cardiac disease (arrhythmias and cardiomyopathy, PA>MMA). Current treatments do not address the underlying cause of these multisystemic diseases, although liver and/or kidney transplant have been shown to reduce the frequency of acute metabolic decompensations and improve quality of life. HST5040 (2,2-dimethylbutanoic acid) is a small molecule that diverts coenzyme A (CoA) from propionyl-CoA pathways via the formation of HST5040-CoA. In cultured MMA and PA patient primary hepatocytes, HST5040 reduces propionyl-CoA, methylmalonyl-CoA, and the derived toxic metabolites: 2-methylcitric acid, methylmalonic acid, and propionyl-carnitine. HST5040 is a liquid formulation that may be administered orally once daily and has high bioavailability. Nonclinical studies have shown broad tissue and organ biodistribution of HST5040, including to the CNS. A Phase 2 study was initiated in March 2021 and plans to enroll 12 US patients (6 MMA-mutase and 6 PA) age 2 and older in a 3-part sequential study design. Part A is a within-patient, dose-escalation study to identify the optimal dose of HST5040 based on reductions in disease-related biomarkers and safety. Part B is a randomized, double-blind, placebo-controlled crossover study involving two 3-month treatment periods to confirm changes in biomarkers and identify acute clinical responses. Part C is an open-label extension study to collect long-term safety and efficacy data, and in addition, may enroll additional patients who are post-transplant or have CblA or CblB deficiency. The primary endpoint for Part A and B is the change in plasma 2-methylcitric acid, a toxic metabolite derived from propionyl-CoA that inhibits the TCA cycle and impairs energy production. Secondary endpoints include other disease-related biomarkers, frequency of acute metabolic decompensations, measures of cognitive, behavioral, cardiac, and renal function, oral intake, and quality of life. The Phase 2 study design was presented at the 2021 ACMG meeting, and an update will be provided. The study is posted on clinicaltrials.gov (NCT04732429).

PrgmNr 2989 - Characterization of CRISPR gene editing in the brain of ataxia mouse models with targeted PCR-free Nanopore sequencing

View session detail

Author Block: **B. P. Simpson**[1,2], C. M. Yrigollen[1], P. T. Ranum[1], B. L. Davidson[1,2]; [1]CCMT, Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA
Disclosure Block: **B.P. Simpson:** None.

Gene therapies using Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) are being developed to treat a myriad of previously intractable genetic disorders. Adeno-associated virus (AAV) vectors are often used to deliver the Cas nuclease and guide RNA (gRNA) to the affected tissues and cells. The potential consequences of CRISPR editing includes small indels, large deletions, inversions, translocations, and integrations of the AAV genomic sequence. We are developing AAV-CRISPR strategies to treat spinocerebellar ataxia type 2 (SCA2), an autosomal dominant neurodegenerative disease caused by a CAG trinucleotide repeat expansion in *ATXN2*. The successful translation of gene editing therapies into the clinic necessitates accurate methods to interrogate and predict editing events.

High AAV vector integration into endogenous DNA following CRISPR-mediated cleavage in the hippocampus and peripheral tissues has been previously reported using PCR-based assays. To eliminate the size and sequence specific bias of amplification by polymerase-based sequencing, and to closely examine AAV integration sequences, we used Oxford Nanopore Technology to sequence the genomic DNA of SCA2 transgenic mouse models treated with AAV-CRISPR. Both mouse models contain either 72 or 127 CAG repeats within the human *ATXN2* transgene, thereby further making PCR of the GC-rich repetitive sequence inefficient and unreliable for assessing editing.

Native DNA from brain regions of mice injected with AAV-CRISPR was used to generate long read sequencing libraries. The human *ATXN2* transgene was targeted for sequencing using Cas-mediated enrichment. Nanopore MinION sequencing runs resulted in long reads with a mean length of ~10 kb and target coverage as high as 3500x (~1% aligned reads) after alignment to the mouse genome and transgenic allele. Mice treated with dual-gRNAs flanking the CAG repeat sequence were shown to contain deletions of the expected 460 bp size at a low frequency of ~3%, suggesting the majority of loci were unedited or repaired as small indels. We detected AAV-CRISPR delivered cargo sequence integration at the target locus with a frequency of ~10-13% for a single gRNA site. Integrated sequences ranged from whole, 4.8 kb AAV genomes to partial fragments with slightly higher coverage of AAV inverted terminal repeat (ITR) sequence.

PCR-free target enrichment and sequencing strategies offer an unbiased assessment of native and edited genomic sequence, important for assessing CRISPR-mediated DNA editing. Our Nanopore sequencing results are important for development and safety considerations of CRISPR gene editing therapies for SCA2 and other disorders.

PrgmNr 2990 - CRISPR targeting of the dominant*Coch*p.A449T mutation in a patient-derived skin fibroblast cell line and in a new humanized mouse model

View session detail

Author Block: **H. Romi**[1], N. G. Robertson[2], S. Vijayakumar[3], C. Gurumurthy[4], B. Kleinstiver[5], R. Sherwood[6], M. Ivanchenko[7], K. Booth[7], D. Corey[7], C. C. Morton[8]; [1]Boston Children's Hosp., Boston, MA, [2]Brigham and Women's Hosp. & Harvard Med Sch., Boston, MA, [3]Creighton Univ., Omaha, NE, [4]Univ. of Nebraska Med. Ctr., Omaha, NE, [5]Massachussetts Gen. Hosp., Boston, MA, [6]Brigham and Women's Hosp., Boston, MA, [7]Harvard Med. Sch., Boston, MA, [8]Brigham & Women's Hosp, Boston, MA
Disclosure Block: **H. Romi:** None.
Dominant gain-of-function mutations in *COCH* are causative of the adult-onset progressive sensorineural hearing loss (HL) and vestibular disorder, DFNA9. Our efforts are focused on disruption of an autosomal dominant *COCH* mutation using CRISPR-Cas9 strategies, specifically targeting the mutant allele, while keeping the normal allele intact, which would enable adequate hearing function. Our efforts are envisioned to have a broader scope in establishing methods for gene therapy in other forms of autosomal dominant HL with gain-of-function or dominant-negative pathomechanisms, as these tend to have late-onset presentation providing a window of opportunity for therapeutic intervention. We studied a family segregating post-lingual progressive autosomal dominant non-syndromic hearing loss with the novel missense variant p.A449T in *COCH*. Pedigree analysis confirmed segregation of p.A449T in all affected family members. Using a skin biopsy from a carrier of the p.A449T variant, we generated a fibroblast cell line. Through co-transfection with a plasmid carrying SaCas9-KKH and *COCH* guide-RNA expression plasmid, we were successful in creating indel disruption only in the mutant allele with an editing efficiency of 43% of the mutant allele, and no disruption of the normal allele. These *in vitro* studies are poised to be continued in our current *in vivo* targeting experiments. We have also created a humanized mouse model for the p.A449T variant (*Coch*$^{A449T/+}$). This is the first *Coch* mouse model to be established with a variant in the 3â□□ region of the vWFA domain. DFNA9 individuals with this 3â□□ variant display an earlier onset of hearing loss, typically in the first to second decades of life, as compared to individuals with variants in the more upstream 5â□□ LCCL domain of cochlin. Therefore, by creating the A449T mouse model, we will be able to conduct our CRISPR intervention studies pre- and post-hearing loss at earlier time-points compared to our existing mouse model with a variant in the 5â□□ region of the gene. Auditory Brainstem Responses (ABRs) as well as Distortion Product Otoacoustic Emissions (DPOAE) analyses of 9-month-old mice have shown significantly elevated thresholds for both *Coch*$^{A449T/+}$ (heterozygous) and *Coch*$^{A449T/A449T}$ (homozygous) mice, as compared to their *Coch*$^{+/+}$ (wild-type) littermates, at all tested frequencies. Mice at even younger ages are currently being evaluated. The present goal of this aspect of the project is to perform round window micro-injection of CRISPR-Cas9 and guide RNA into these mice and to measure hearing in different experimental groups, who receive treatment vs. sham injections.

PrgmNr 2991 - Haplotyping SNPs for allele-specific gene editing of the mutant huntingtin allele using long-read sequencing

View session detail

Author Block: **L. Fang**[1], A. M. Monteys[1], A. DÃ¼rr[2], M. Keiser[1], C. Cheng[1], A. Harapanahalli[1], P. Gonzalez-Alegre[1,3], B. L. Davidson[4], K. Wang[5]; [1]Children's Hosp. of Philadelphia, PHILADELPHIA, PA, [2]Sorbonne UniversitÃ©, Paris, France, [3]Univ. of Pennsylvania, Philadelphia, PA, [4]The Children's Hosp. of Philadelphia, Philadelphia, PA, [5]Childrenâ□□s Hosp. of Philadelphia, Philadelphia, PA
Disclosure Block: **L. Fang:** None.

Huntington's disease (HD) is an autosomal dominant neurodegenerative disease caused by CAG repeat expansions in the huntingtin (HTT) gene. Although trials of disease-modifying treatments are now on the horizon, the clinical care is focused on symptom management. We previously reported allele-specific deletion of the mutant HTT by CRISPR/Cas9 in a mouse model and human cell lines. Allele selectivity is achieved by targeting heterozygous SNPs that create or eliminate a Protospacer Adjacent Motif (PAM). However, given the lack of knowledge on haplotype structure in HD populations, a comprehensive analysis of all potential targeting sites is lacking and the optimal personalized editing strategy for HD individuals is unknown. To address this, we developed a multiplexed targeted long-read sequencing approach to sequence a 10.4 kb genomic region flanking exon-1 of HTT and created necessary computational tools (AmpBinner and AmpRepeat) to de-multiplex the data, detect repeats, and phase the reads. We applied this approach to two independent HD cohorts (974 individuals from the US and France), detected SNPs, analyzed haplotypes and potential editing sites for various enzymes. In the haplotype structure analysis, we showed potential founder effects in unrelated HD individuals from different continents. Based on the haplotype analysis, 23% of HD individuals of European ancestry can be edited by targeting one SNP (rs2857935). Up to 56% HD individuals of European ancestry can be potentially edited by combinatorial targeting of multiple SNPs. Our results provide the first haplotype map of the region surrounding exon-1 of HTT in HD cohorts. Our workflow can be applied to other repeat expansion diseases to facilitate allele-specific gene editing.

PrgmNr 2992 - Human genetic diversity modifies therapeutic gene editing off-target potential

View session detail

Author Block: **L. Y. Lin**[1,2,3], S. Cancellieri[4], J. Zeng[1,2,3], F. Masillo[4], M. Nguyen[1,2,3], N. Bombieri[4], S. A. Maitland[5], M-F. Ciuculescu[1], V. Katta[6], S. Q. Tsai[6], M. Armant[1], S. A. Wolfe[5], R. Giugno[4], D. E. Bauer[1,2,3], L. Pinello[7,3]; [1]Boston Childrenâ□□s Hosp., Boston, MA, [2]Dana-Farber Cancer Inst., Boston, MA, [3]Harvard Med. Sch., Boston, MA, [4]Univ. of Verona, Verona, Italy, [5]Univ. of Massachusetts Med. Sch., Worcester, MA, [6]St. Jude Children's Res. Hosp., Memphis, TN, [7]Massachusetts Gen. Hosp., Boston, MA

Disclosure Block: **L.Y. Lin:** None.

CRISPR gene editing holds great promise to modify somatic genomes to ameliorate disease. In silico prediction of homologous sites coupled with biochemical evaluation of possible genomic off-targets may predict genotoxicity risk of individual gene editing reagents. However, standard computational and biochemical methods focus on reference genomes and do not consider the impact of genetic diversity on off-target potential. Here we developed a web application called CRISPRme that explicitly and efficiently integrates human genetic variant datasets with orthogonal genomic annotations to predict and prioritize off-target sites at scale. The method considers both single-nucleotide variants (SNVs) and indels, accounts for bona fide haplotypes, accepts spacer:protospacer mismatches and bulges, and is suitable for personal genome analyses. We tested the tool with a guide RNA (gRNA) targeting the *BCL11A* erythroid enhancer that has shown therapeutic promise in clinical trials for sickle cell disease (SCD) and Î²-thalassemia (Frangoul et al. *NEJM* 2021). We find that the top predicted off-target site is produced by a non-reference allele common in African-ancestry populations (rs114518452, minor allele frequency (MAF) = 4.5%) that introduces a protospacer adjacent motif (PAM) for SpCas9. We validate that SpCas9 generates indels (~9.6% frequency) and chr2 pericentric inversions in a strictly allele-specific manner in edited CD34+ hematopoietic stem/progenitor cells (HSPCs), although a high-fidelity Cas9 variant mitigates this off-target. Our work illustrates how genetic variation may modify the genomic outcomes of therapeutic gene editing and provides a simple tool for comprehensive off-target assessment. CRISPRme is available at http://crisprme.di.univr.it.

PrgmNr 2993 - Long-term, sustained efficacy and safety from a phase 1/2 clinical trial of an AAV8-mediated liver-directed gene therapy in adults with glycogen storage disease type Ia

Disclosure Block: **J. Mitchell:** Grant/Contracted Research Support (External); Ultragenyx Pharmaceutical Inc..

Glycogen storage disease type Ia (GSDIa) results from a deficiency of glucose 6-phosphatase (G6Pase) which is essential for glycogenolysis and gluconeogenesis. DTX401 is an adeno-associated virus serotype 8 (AAV8) vector expressing the human G6Pase gene (*G6PC*). This global, open-label, phase 1/2, dose escalation gene therapy trial (NCT03517085) is evaluating the safety and efficacy of a single DTX401 intravenous infusion in adults with GSDIa. Three patients in Cohort 1 received DTX401 2.0 x 10^{12} gene copies (GC)/kg, and three each in Cohorts 2, 3, and 4 received DTX401 6.0 x 10^{12} GC/kg. Cohort 4 was recently enrolled and includes a prophylactic steroid regimen to prevent transaminase elevation related to the immune response to DTX401. In the nine patients enrolled in Cohorts 1 through 3, mean (SD) total daily cornstarch intake reduction from baseline to Week 52 was 65.5% (22.3) and from baseline to last visit (range: 60 weeks to 131 weeks) was 78.8% (20.1), both *p*12 GC/kg dose (dose by ddPCR 1.0 x 10^{13} GC/kg) as the optimal biological dose for the pivotal phase 3 trial expected to start in the second half of 2021.

PrgmNr 2994 - NMD-dependent approach restores CFTR function in primary nasal cells harboring nonsense variants

View session detail

Author Block: **A. Bowling**[1], C. Merlo[2], L. Huang[3], N. West[2], S. Patel[2], G. R. Cutting[4], N. Sharma[4]; [1]Dept. of Genetic Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD, [2]Div. of Pulmonary and Critical Care Med., Dept. of Med., Johns Hopkins Hosp., Baltimore, MD, [3]Ionis Pharmaceuticals, Inc., Carlsbad, CA, [4]Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Disclosure Block: **A. Bowling:** None.

Nonsense mutations remain difficult to therapeutically target, as they introduce a premature termination codon (PTC) in the mRNA resulting in degradation by nonsense mediated mRNA decay (NMD). Readthrough agents can overcome PTCs by introducing an alternate amino acid at the PTC. These therapeutics are likely to be most effective when mRNA does not undergo NMD and protein processing defects can be corrected. Additionally, antisense oligonucleotide (ASO) therapy can be used to inhibit NMD by targeting ASOs to factors in the NMD pathway, resulting in gene silencing and production of stable mRNA. Cystic fibrosis (CF), an autosomal recessive disorder caused by mutations in *CFTR,* is an ideal model system to study readthroughs, as triple combination (elexacaftor-tezacaftor-ivacaftor) can be used to correct protein defects. In this study, we tested readthrough in the presence of triple combination on human nasal epithelial (HNE) cells harboring L88X, which evades NMD. Additionally, we treated HNE cells bearing W1282X with ASOs to factors in the NMD pathway, and tested readthrough and triple combination. Cells were conditionally reprogrammed and grown at air liquid interface. CFTR function observed in WT HNE cells was 13.1Â±1.5ÂµA/cm^2 (n=12, 3-11 observations per sample). In L88X/F508del HNEs, untreated cells generated 6% of WT function. Triple combination alone restored function to 83% of WT, consistent with expected recovery of F508del CFTR. Cells treated with readthrough G418 and triple combination did not result in additional recovery of function. ELX-02, a readthrough currently in Phase II clinical trials, with triple combination exhibited a robust increase in CFTR current, up to 123% of WT. In W1282X/W1282X HNEs, untreated cells generated 1% of WT function, consistent with disease severity. Cells treated with G418 and triple combination restored function to 10% of WT. Treatment with SMG1-ASO alone did not improve function. Interestingly, when SMG1-ASO was applied in combination with G418 and triple combination, CFTR exhibited a significant increase in current, corresponding to 18% of WT. Additionally, we tested CFTR function in airway cells that are the native site of *CFTR* expression. Since splicing is essential for NMD, these cells stably express W1282X-*CFTR*-expression minigene, containing all *CFTR* exons and select abridged *CFTR* introns. Treatment with SMG1-ASO, G418, and triple combination showed significant recovery of CFTR function ($\hat{I}\Delta Isc_{treated}$=98.1ÂµA/cm^2, $\hat{I}\Delta Isc_{untreated}$=3.4ÂµA/cm^2). This work demonstrates the potential of readthrough therapeutics to target PTC-causing mutations, where NMD is evaded or can be inhibited through ASO treatment.

PrgmNr 2995 - Patient-focused drug development for a single intravenous dose of HMI-203 gene therapy in adult mucopolysaccharidosis (MPS) II, or Hunter syndrome, patients

View session detail

Author Block: **J. Haroldson**[1], C. Witalisz[1], R. A. Martin[2]; [1]Homology Med.s, Bedford, MA, [2]Private Consultant, New Florence, MO
Disclosure Block: **J. Haroldson:** Major Stockholder/Ownership Interest; Homology Medicines.
Introduction: MPS II, a rare lysosomal storage disorder caused by mutations in the IDS gene, is comprised of two subtypes: one with progressive cognitive decline and survival into the teens (neuronopathic form) and the other without cognitive impact and survival into the third or fourth decade (non-neuronopathic form). Both subtypes have debilitating peripheral manifestations. HMI-203 is an investigational AAVHSC-mediated gene therapy that provides functional copies of the IDS gene. Preclinical data in the MPS II mouse model support its potential to address both the peripheral and CNS manifestations of MPS II. Ahead of its planned first-in-human clinical trial in adults with MPS II in 2021, Homology Medicines sought to better understand the burden of disease directly from patients to inform meaningful clinical outcomes and ensure a patient-focused drug development plan. Recent focus by other drug developers is on young neuronopathic patients, with the hope of preventing or reversing the cognitive delay that enzyme replacement therapy (ERT) cannot address. The disease burdens for all MPS II patients are significant, and in the adult population, the peripheral aspects of the disease are poorly understood, and therefore have gone unaddressed despite years of weekly ERT. **Methods**: We conducted 1:1 interviews with 7 MPS II adults using a standardized questionnaire to collect qualitative data to understand the most burdensome aspects of the disease and perceptions about current and future therapies. **Results**: Median age of patients was 26 (range 24-36) years. Most Burdensome Daily Symptoms Experienced by MPS II Adults: Limited mobility and range of motion 7/7; Pain 6/7; Hearing loss 6/7; Difficulty walking or standing 3/7. Current Therapies to Manage MPS II Symptoms: ERT 7/7; Surgeries 7/7; Supportive therapies (PT/OT, chiropractic) 6/7; Hearing aids 4/7; Cardiovascular 4/7
All patients received weekly ERT and cited it as their most beneficial therapy but noted its expense and the time and inconvenience required for weekly infusions. Patients wished that ERT more adequately addressed symptoms including pain, range of motion, hearing loss and chronic fatigue. All patients desired a potential one-time gene therapy that could alleviate the burden of weekly ERT and provide at least equal therapeutic benefit. **Conclusions**: MPS II patients are burdened by weekly ERT infusions and disease manifestations that ERT does not address. Based on the results of this study of MPS II patient experiences, Homology aims to incorporate patient-focused endpoints into its Phase 1/2 clinical evaluation of HMI-203 including the potential to discontinue ERT.

PrgmNr 2996 - Somatic CAG expansion in Huntington's disease is dependent on the MLH3 endonuclease domain, which can be excluded via splice redirection

View session detail

Somatic expansion of the CAG repeat tract that causes Huntington's disease (HD) is thought to contribute to the rate of disease pathogenesis. Therefore, factors influencing repeat expansion are potential therapeutic targets. Genes in the DNA mismatch repair pathway are critical drivers of somatic expansion in HD mouse models. Here, we have tested, using genetic and pharmacological approaches, the role of the endonuclease domain of the mismatch repair protein MLH3 in somatic CAG expansion in HD mice and patient cells. A point mutation in the MLH3 endonuclease domain completely eliminated CAG expansion in the brain and peripheral tissues of a HD knock-in mouse model (*Htt*^{Q111}). To test whether the MLH3 endonuclease could be manipulated pharmacologically, we delivered splice switching oligonucleotides in mice to redirect *Mlh3* splicing to exclude the endonuclease domain. Splice redirection to an isoform lacking the endonuclease domain was associated with reduced CAG expansion. Finally, CAG expansion in HD patient-derived primary fibroblasts was also significantly reduced by redirecting *MLH3* splicing to the endogenous endonuclease domain-lacking isoform. These data indicate the potential of targeting the MLH3 endonuclease domain to slow somatic CAG repeat expansion in HD, a therapeutic strategy that may be applicable across multiple repeat expansion disorders.

PrgmNr 2997 - Sorbitol reduction in *SORD* deficient fibroblasts and iPSC-derived motor neurons using an antisense oligonucleotide (ASO) treatment strategy

View session detail

Author Block: **J. Medina**[1], A. P. Rebelo[2], C. Yanick[1], J. Yue[1], R. Shiekhattar[1], M. Saporta[1], S. Zuchner[2]; [1]Univ. of Miami Miller Sch. of Med., Miami, FL, [2]Univ Miami, Miami, FL
Disclosure Block: **J. Medina:** None.
Recent findings have concluded biallelic mutations in *SORD*, whose gene product sorbitol dehydrogenase is the second enzyme in the polyol pathway, as the most frequent form of recessively inherited neuropathy. The polyol pathway is a two-enzyme mechanism activated in high glucose conditions, converting glucose to fructose. Aldose reductase, coded by *AKR1B1*, reduces glucose to sorbitol, which is then oxidized by sorbitol dehydrogenase into fructose. Without a functional form of sorbitol dehydrogenase, sorbitol accumulations are thought to be a catalyst for axonal damage evidenced by changes in cellular osmolarity, oxidative stress and decreased NADPH levels. Our study aims to develop genetically based treatments for *SORD* deficient cells by targeting *AKR1B1* RNA transcripts and preventing sorbitol accumulations. Using an antisense oligonucleotide (ASO) approach, we have achieved up to 80% reduction in *AKR1B1* gene product in patient fibroblasts. Currently, ASO efficacy is being investigated in an iPSC-derived motor neuron model system. Various ASO modifications and length are currently being investigated as we optimize knockdown efficiency and ASO treatment dose in both control and patient fibroblasts. *AKR1B1* transcript knockdown efficiency has been analyzed using standard western blot and RT-PCR. Intracellular sorbitol measurements are being analyzed using D-sorbitol colorimetric assay. Preliminary findings suggest a significant reduction in *AKR1B1* transcripts leading to a reduction in intracellular sorbitol accumulations. Current studies are investigating potential off-target ASO effects using comparative RNA sequencing of post-treatment patient fibroblasts and iPSC-derived motor neurons.

PrgmNr 2998 - Towards precision genome editing in an inborn error of polyamine metabolism

View session detail

Author Block: **O. Akinyele**, A. Munir, M. Johnson, J. C. Zhang, A. Arockiaraj, C. V. Land, D. Kemaladewi; Univ. of Pittsburgh, PITTSBURGH, PA
Disclosure Block: **O. Akinyele:** None.
The polyamines putrescine, spermidine and spermine, are ubiquitous polycationic molecules crucial for gene expression, signal transduction and cell proliferation. Abnormal accumulation of polyamines due to mutations in *SMS* gene encoding spermine synthase protein causes Snyder-Robinson syndrome (SRS), a rare X-linked recessive disorder which manifests as mental retardation, thin habitus, and low muscle tone (hypotonia) with no available treatments. Here, we aim to study the molecular mechanisms underlying the pathophysiology and develop a therapeutic strategy for SRS. First, we characterize a novel SRS mouse model carrying a missense mutation in the *Sms* gene, leading to a glycine-to-serine substitution (G56S) in the SMS protein. We observe a complete loss of SMS transcript and protein levels in the G56S brain, skeletal muscles, and liver. Subsequently, we quantified the level of tissue polyamines using mass-spectrometry and observed a significant increase in the spermidine content in the G56S skeletal muscles and brain. Our data so far indicates that the G56S mice recapitulate the molecular and biochemical signatures found in patients. We are currently employing a combination of imaging (MRI, micro-CT), functional (grip strength, open field, Morris water maze, fear conditioning), and histopathological techniques to evaluate the structural and functional abnormalities in the brain, bone, and skeletal muscles. In parallel, we are testing the feasibility of Prime Editing technology, the newest addition to the CRISPR/Cas toolbox, to correct the causative mutation and restore the polyamine levels. Successful completion of this project could open door to precision gene therapy for inherited diseases for which no treatment is currently available.

PrgmNr 2999 - A deeply sequenced public resource of diverse human genomes

Diverse populations are often excluded from genomic studies due to a lack of resources supporting their analysis. The 1000 Genomes Project (1kGP) and Human Genome Diversity Project (HGDP) are among the most valuable genomic resources because of the breadth of global diversity they capture and their open sharing policies that allow release of unrestricted individual-level data. These two resources have only recently been sequenced to high coverage and have not been well harmonized in the past. 1kGP is a larger and more widely used dataset containing related individuals while HGDP spans a greater depth of diversity, though with fewer individuals from each population. HGDP therefore fills some major geographic gaps not represented in 1kGP, for example in the Middle East, Oceania, parts of sub-Saharan Africa and the Americas.

In this study, we harmonized a set of over 4,000 recently sequenced high quality whole genomes from HGDP and 1kGP (mean depth across populations=33X). We jointly called variants consisting of SNPs, indels, and SVs. After comprehensive QC leveraging the gnomAD filtering pipeline, we identified more than 155 million high-quality variants. As expected, African populations have significantly more genetic variants than out-of-Africa populations (6.1M versus 5.3M variants/individual). We ran principal components analysis (PCA) across this diverse set of populations at the global and subcontinental level. To allow projection of cohorts onto a unified reference PC space, we developed a pipeline for sharing our PC loadings to align biobanks that cannot share individual data. This resource is already being used in the COVID-19 Host Genetics Initiative and Global Biobank Meta-analysis Initiative consisting of at least 20 biobanks. We are also phasing this callset to serve as a haplotype resource for use in phasing and imputation pipelines, including in GWASpy, a cloud-based, open-source, scalable GWAS pipeline that we developed (https://github.com/atgu/GWASpy).

In sum, we demonstrate substantial added value from this joint-called dataset compared to prior resource use via variant intersection. Alongside releasing this dataset without restriction, we are providing tutorials for conducting many of the most common quality control steps and analyses with these data in a scalable compute setting. This jointly called reference panel contains individual level data from a globally-representative set of individuals and will serve as a key resource to support research of diverse ancestry populations. Including more diverse populations in statistical genetics leads to equitable genomic studies which contribute to increased global health equity.

PrgmNr 3000 - A web-based application interface for UK Biobank phenotype exploration

View session detail

Author Block: **M. Ryals**, E. Dalby, M. Permenter, L. Pi, J. Sabourin, E. Wagner, L. Hou, L. Li; BioStat Solutions, LLC, Frederick, MD

The UK Biobank (UKBB) is a rich resource of phenotypic and genetic information for approximately 500K participating individuals. However, the raw tab-formatted phenotype data that is provided by UKBB requires extensive processing to be used in genetic association or other downstream analyses. Without prior programmatic experience, it can be difficult to extract meaningfully-coded phenotypes from the raw data. Examples of the mapping required include processing the phenotype field IDs, subject-level coding, repeat visits, and subject coding indices for a given phenotype field. These formatting steps require frequent referral to UKBB source material. To address this issue, we have created an R-Shiny application interface that can easily query, assess, and extract desired phenotypic information without the need for programmatic querying or running external code. The application allows a user to easily select fields at the index- or instance-level for available phenotypes and will then export an analysis-ready table for downstream genetic associations or phenotype-level studies. In addition, the application has a user-friendly method for viewing and querying UKBB disease-mapping rules for the ICD9, ICD10, primary care, and other available coding schema used on the UKBB backend for creating and refining disease phenotypes. This R-Shiny application can be easily expanded to include more data, such as disease affection status defined using the PheCode mapping recommendations , and medication usage grouped based on the Anatomical Therapeutic Chemical (ATC) Classification System. By providing an accessible interface for phenotype extraction, we hope to allow a wide audience of researchers to easily navigate and process the extensive bank of knowledge in UKBB for further analyses.

PrgmNr 3001 - An Extensible Prototype for MultiOmic Clinical Reporting

Documenting the relative contributions of annotated expressed variants, structural variants, T cell receptors and variant interactions will be critical for subtyping disease states in the clinical context. As such, we have integrated multi-omics data into easily digestible comprehensive clinical reports. For each data type we have vignettes that are presented to clinicians and patients for the 5 most significant findings from that data type, as well as large scale data (in some cases genome wide) that is computationally accessible (and visually from R markdown or shiny apps) through an SQL database. For clinical researchers and healthcare professionals interested in mining and combining large scale datasets, we have also formatted these data types into the Observational Medical Outcomes Partnership (OMOP) tables. This should allow data sharing with a variety of electronic medical record systems, especially noting new initiatives by Google and others. All of this work is easily accessible on Github and some complex pipelines are often available in Workflow Description Language. We welcome individual and institutional collaborators interested in this extensible prototype for multi-omic clinical reporting.

PrgmNr 3002 - Characterizing repeat expansion variation in the Undiagnosed Disease Network cohort

View session detail

Author Block: **S. Fazal**[1], M. C. Danzi[2], U. Undiagnosed Disease Network[1], S. Zuchner[3]; [1]Univ. of Miami, Miami, FL, [2]Dakota Dunes, SD, [3]Univ Miami, Miami, FL
Disclosure Block: **S. Fazal:** None.
Expansions of short tandem repeats (TRs) are responsible for over 40 known diseases, most of which primarily affect the nervous system. We hypothesize these represent only a fraction of the pathogenic repeat expansions that exist and that they may be responsible for explaining a proportion of the missing heritability of rare monogenic diseases. ExpansionHunter Denovo (EHDn) was used to identify large TRs genome-wide in a control cohort of 2,504 genomes from the 1000 Genomes Project. This control TR profile was compared to individual disease genomes in an outlier analysis pipeline to identify TRs that are rare and expanded in cases. After processing and filtering through this pipeline, each case results in a list of candidate sites, which may be pathogenic. We processed ~2500 genomes from the Undiagnosed Disease Network (UDN) through this outlier pipeline. We found that 47% of genomes have at least 1 candidate TR with a mean of 1.5 candidate TRs per sample and a maximum of 14 candidate TRs per sample. We explored whether any known disease-causing repeat expansion loci were part of these candidate sites and found that 162 genomes were flagged for having a potentially pathogenic repeat expansion in one of nine known loci. Many of these are either heterozygous for a recessive condition or the specific sizes do not cross the known pathogenic threshold. We plan to further validate these results using repeat primed PCR (rpPCR) or gel electrophoresis. Finally, we found 339 novel candidate TRs in this cohort, 60% of which are observed in at least two genomes. These are excellent candidates for pathogenicity, and we are developing pipelines to further filter these down based on mechanistic characteristics and similarity of patient phenotypes. Importantly, our results will help to close the diagnostic gap in rare unsolved diseases.

PrgmNr 3003 - Development of a comprehensive, locus specific, database for ENPP1 Deficiency (generalized arterial calcification of infancy/autosomal recessive hypophosphatemic rickets (GACI/ARHR2) to clarify the clinical relevance of variant data

View session detail

Author Block: **C. Nester**[1], G. Khursigara[1], C. R. Ferreira[2], L. M. Chunn[3], S. A. Mercurio[3], M. J. Kiel[3]; [1]Inozyme Pharma, Boston, MA, [2]Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [3]Genomenon Inc., Ann Arbor, MI

Disclosure Block: **C. Nester:** Salary/Employment; Inozyme Pharma.

Ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1) is a critical enzyme in the biochemical pathway that produces extracellular pyrophosphate (PPi) and adenosine, potent inhibitors of mineralization and neointimal proliferation, respectively. Biallelic loss of function variants in the ENPP1 gene cause ENPP1 Deficiency, a rare disorder characterized by pathological mineralization, arterial stenosis, and morbidities due to cardiovascular, pulmonary, skeletal, neurological and hearing complications. ENPP1 Deficiency is associated with 40-60% mortality early in life, and over 80% of surviving patients will develop hypophosphatemic rickets (ARHR2) or osteomalacia by age 25. Accurate and timely diagnosis is challenged by the rarity of the disease and heterogeneity of its clinical presentation. Differentiating ENPP1 Deficiency from other diseases is further complicated by the absence of a dedicated database of known *ENPP1* variants and associated clinical data.

Using a novel approach to systematic curation of genetic evidence, we have identified and analyzed all previously reported cases of GACI/ARHR2 and collated and interpreted all associated genetic variants in *ENPP1*. This technique combines automated indexing of medical literature with aggregation of population frequency databases and variant prediction algorithms followed by manual annotation and curation of this information. In total, 2,333 articles were reviewed, revealing 89 unique *ENPP1* variants identified in over 100 patients, including patients not yet published. Each variant was interpreted according to ACMG guidelines. At the time of initial analysis, 56 of these variants were classified as pathogenic/likely pathogenic (P/LP), representing a 107% increase in P/LP *ENPP1* variants documented in ClinVar. Of the P/LP variants, 59% (33/56) were missense variants, the majority of which occurred in the phosphodiesterase domain of ENPP1 (20/33). Each patient was annotated with a detailed description of their phenotypic presentation and clinical outcome. Among the patients identified with P/LP variants, the most observed phenotypes included arterial calcification, hypertension, hearing impairment, and cardiomegaly. Our analysis revealed substantial heterogeneity in disease severity, even among patients with the same variant.

This comprehensive database of *ENPP1* variants will increase the diagnostic yield of genetic testing. Establishing a locus-specific variant database and disease-specific patient database provides an important tool for the scientific and patient community to better understand this rare disease and identify novel therapeutic options.

PrgmNr 3004 - Examination of clinical features among 200,632 UK Biobank participants harboring deleterious germline variants in *NF1* and *SPRED1*

View session detail

Author Block: **A. Pemov**, J. Kim, D. Stewart; Natl. Cancer Inst., Rockville, MD
Disclosure Block: **A. Pemov:** None.
Background. Large-scale exome sequencing data linked to electronic health records (EHR) and broad ascertainment of participantsâ clinical phenotypes provides yet another opportunity to investigate genotype-phenotype correlations, improve the estimates of prevalence and penetrance of Mendelian disorders, and ultimately, advance disease prognosis, risk stratification and care for patients. **Methods.** Utilizing a genome-first approach, we identified deleterious variants in *NF1* and *SPRED1*, the causative genes in neurofibromatosis type 1 (NF1) and Legius syndrome (LS), in the exomes of 200,632 UK Biobank (UKBB) participants. We grouped deleterious variants in two tiers. Tier 1 included pathogenic/likely pathogenic variants as classified in ClinVar; and tier 2 included all remaining loss-of-function variants (nonsense, frameshifting indels and canonical splice sites). We then examined EHR for the participants carrying deleterious variants in these two genes. **Results.** We identified 43 and 25 participants carrying tier 1 and tier 2 deleterious *NF1* variants, respectively. In tier 1 and tier 2 groups, 14 and 7 participants had a âneurofibromatosisâ diagnosis in their EHR, respectively (14/43 tier 1 (33%), and 21/68 tier 1 and 2 combined (31%) variants). Highly suggestive features of NF1 (e.g., cafÃ©-au-lait macules (CALM), freckling, Lisch nodules, macrocephaly, learning delay, neurofibromas) were absent from the participantsâ records, including those diagnosed with âneurofibromatosisâ. For *SPRED1*, we observed 3 and 18 participants with tier 1 and tier 2 variants, respectively. None of the participants had records of an LS diagnosis. Highly suggestive clinical features, such as CALM, freckling, macrocephaly and learning delay were absent from their EHR as well. The prevalence ranges of deleterious variants in these two genes were close to the previously reported: 1/2,951-1/4,666 (*NF1*) and 1/9,554-1/66,877 (*SPRED1*). **Conclusions.** Among 200,632 exome-sequenced UKBB participants, only about one-third of those harboring clearly deleterious variants in *NF1* were diagnosed with âneurofibromatosisâ, and none of 21 participants with clearly deleterious variants in *SPRED1* were diagnosed with LS. These findings highlight difficulties that exist in identifying and diagnosing rare diseases in human populations using the EHR. Follow-up clinical evaluation of deleterious variant carriers would be necessary to establish reliable genotype-phenotype connections and refine the estimates of the prevalence and the penetrance of these disorders.

PrgmNr 3005 - Improving RNAseq Splice Junction Prioritization in Rare Disease Analysis

View session detail

Author Block: **B. Weisburd**[1,2], V. Ganesh[1,2,3,4], S. DiTroia[5,2,3], F. Aguet[1], G. Tiao[6,2], H. L. Rehm[2,1], A. O'Donnell-Luria[1,2,3]; [1]Broad Inst., Cambridge, MA, [2]Massachusetts Gen. Over the past 5 years, multiple groups have developed tools and approaches for diagnosing rare disease cases using RNA-seq data - demonstrating that analyses of gene expression, splice junctions, and allele-specific expression can significantly increase diagnostic yield. Splice junction analyses in particular, are uniquely useful for interpreting deep intronic variants, and other variants of uncertain significance. However, there are remaining challenges with deploying and scaling splice junction analysis pipelines to rare disease cohorts.

First, in order to be considered a diagnosis, the splice junction outlier must be matched with an underlying causative genomic variant. For many outliers, no such variant is found. Second, even after parameter optimization, current splice junction prioritization approaches yield many 10s to 100s of significant outliers per sample. These two issues together lead to prohibitive amounts of manual review being necessary to consider all splice junction outliers in each case.

Here we present a pipeline that lessens the burden of downstream manual review and improves splice junction prioritization. The pipeline first aligns all RNA-seq samples to GRCh38 by running the STAR v2 aligner [Dobin 2013]. We use identical parameters to those used in the GTEx v8 release [GTEx Consortium 2020] to enable comparison of our case samples with tissue-matched GTEx controls. To do this comparison, we apply the outlier detection approaches described in [Cummings 2017] and [Mertes 2021], yielding a list of candidate splice junctions. Next, we apply Portcullis [Mapleson 2018] to filter junctions and exclude technical artifacts which decreases the candidate splice variant list by ~30%. Then, for cases where short or structural variant calls are also available from exome or genome data, we annotate the splice junctions with information about any rare variants present within 10kb of each splice junction. Finally, we re-prioritize the candidate junctions based on these additional annotations, yielding a smaller set of junctions for manual review.

We present the pipelineâ□□s accuracy based on truth data derived from previous publications and show the results from applying this pipeline to over 100 unsolved cases in a heterogeneous rare disease cohort. With this strategy, we reduce the number of splice junctions and variants requiring analysis to achieve diagnosis.

PrgmNr 3006 - Improving the imputation quality of French-Canadian genomic data

View session detail

Author Block: **J. Pelletier**[1], J-C. Grenier[2], p. raphael[3], J. Hussin[1]; [1]MontrÃ©al Heart Inst., MontrÃ©al, QC, Canada, [2]5000 rue BÃ©langer, MontrÃ©al, Canada, H1T 1C7, Montreal, QC, Canada, [3]UdeM, MontrÃ©al, QC, Canada

Disclosure Block: **J. Pelletier:** None.

Imputation in genetics is the statistical inference of unobserved genotypes. This process is influenced by variants localization, recombination, and the demographic history of the population, however, this last factor isnâ□□t generally considered in current imputation strategies. In the French-Canadian population, the complex demographic history could impact genotype imputation procedure with current reference cohorts. In this project, we test whether the use of more varied reference cohorts increases the quality of imputation in this founder population. To characterize the quality of imputation for the French-Canadian population, we used two reference cohorts: TOPMed and Haplotype Reference Consortium (HRC). The imputation is made on the 30,000 genotyped individuals from the CARTaGENE project. Our preliminary results show that the number of sites imputed with high quality is significantly higher with TOPMed compared to HRC. However, by using the same genotyping chip for Canadian sub populations from other provinces, we note that the imputation is less efficient for the French-Canadian founder population. Finally, by analyzing the imputed variants with respect to their imputation scores, we find that variants specific to the founder population were possibly wrongly attributed with a bad quality score. We therefore confirm that the use of TOPMed makes it possible to improve the imputation of genetic data from French Canadians, but there remains a gap with non-founder populations, potentially due to allele frequencies mismatch from the mean frequencies in the reference cohorts used for the imputation. Other quality criteria may be needed for imputation in the French-Canadian population and in other human founder populations.

PrgmNr 3007 - Making Discoveries with Kids First Variant Database

View session detail

Author Block: **Y. Guo**[1], J. Costanza[2], C. Botek[2], M. Brown[1], D. Higgins[1], Y. Zhu[3], B. Farrow[3], A. Heath[3], A. Resnick[3], V. Ferretti[2], Kids First Data Resource Center; [1]The Children's Hosp. of Philadelphia, Phiadelphia, PA, [2]Ctr. Hosp.ier universitaire Sainte-Justine, Montreal, QC, Canada, [3]The Children's Hosp. of Philadelphia, Philadelphia, PA

Disclosure Block: **Y. Guo:** None.

The Gabriella Miller Kids First Pediatric Research Program (Kids First) aims at facilitating researchers to uncover new insights into the biology of childhood cancer (CC) and structural birth defects (SBD), including the discovery of shared genetic pathways between these disorders. Kids First has two initiatives, which are whole genome sequencing (WGS) of biospecimens from families with CC/SBD, and establishing Kids First Data Resource. Kids First Data Resource Center (KFDRC) developed Kids First Data Resource Portal (KFDRP; https://portal.kidsfirstdrc.org/), which is a centralized platform to search, view, analyze, and identify currently accessible data from both Kids First and collaborative cohorts, incorporating omics and phenotypic information of 23 studies and 20,097 participants. Recently KFDRC released two new KFDRP components named Variant DataBase (VDB) and Variant WorkBench (VWB), enabling users to query, mangle, analyze and visualize germline genomic variants. The first release of VDB on 1/21/2021 includes ~216 million unique variants in a matrix of more than 26.5 billion individual-chromosomal position occurrences from over 5,000 participants in 6 studies. While VDB provides a quick variant summary, VWB supports scripting languages such as Python, Spark, SQL and MarkDown as in-depth analysis tools enabled by Apache Zeppelin notebooks. In addition to variant calls and phenotypic information such as Human Phenotype Ontology (HPO) terms and Mondo IDs, VWB hosts rich external variant annotations in the public domain, such as Cancer Hotspots, ClinVar, COSMIC, dbNSFP, gnomAD, TOPMed, as well as gene-phenotype links provided by OMIM, HPO, Orphanet, and the Deciphering Developmental Disorders Project. Users can also visualize analysis results in multiple chart styles, display local figures, import custom datasets as temporary query tables, and export analysis results to local drives. In an effort to screen fibroblast growth factor receptors (FGFR) genes for deleterious variants in a Kids First cohort of kidney and urinary tract defects, we identified a likely pathogenic de novo variant in FGFR3 by running a series of PySpark/SQL scripts in VWB. We first restricted gene symbol to begin with â□□FGFRâ□□ and required at least 19 out of the 20 variant consequence predictions to be damaging/deleterious/detrimental, then checked the variantâ□□s genotype status in other family members, and confirmed it is absent from any public database such as gnomAD/TOPMed/ClinVar. FGFR3 (OMIM *134934) has been linked to multiple autosomal dominant genetic disorders and two of them (#149730 and #612247) involve clinical phenotypes in the genitourinary system.

PrgmNr 3008 - NCBI ALFA Release 2for900 Million Variantsand Allele Frequencyfrom 200KdbGaPSubjects

Disclosure Block: **L. Phan:** None.

NCBI Allele Frequency Aggregator (ALFA) aims to provide the largest and most comprehensive aggregated variant datasets with allele frequency from dbGaP studies as open-access. dbGaP has over two million subjects and up to billions of variants along with thousands of phenotypes and molecular assay datasets. This unprecedented volume and the variety of data hold huge opportunities to exploring and studying genetic variations within human populations and identify genetic factors that influence health and diseases to improve diagnosis, treatment, and prevention.

ALFA Release 2 has over 900 million variants, including 300 million novel variants not in dbSNP Build 154. The data was generated from 79 dbGaP studies that included 192 thousand subjects and 5.8 trillion combined genotypes. Allele frequencies are available for 12 populations, including European, Hispanic, African, Asian, and other diverse population ancestries.

Allele frequencies are available for 86% of variants in dbSNP Build 155 (920M rs), 86% (334K rs) ClinVar small variants, and 99% (22K rs) of variants in the dbGaP GWAS catalog.

This massive amount of data is available as open-access from NCBI for variant interpretation and analysis. It is accessible by web search, FTP download, retrieval using API, and TrackHubs for genomic browsers. Please visit the ALFA homepage for more information about the project, releases, tutorials, and past presentations. ALFA website: https://www.ncbi.nlm.nih.gov/snp/docs/gsr/alfa/

PrgmNr 3009 - NIA Genetics of Alzheimerâ□□s Disease Data Storage Site (NIAGADS): 2021 Update

View session detail

Author Block: **H. Issen**[1], A. Kuzma[1], O. Valladares[1], E. Greenfest-Allen[1], C. Klamann[1], P. Gangadharan[1], Z. Katanic[1], A. Wilk[1], Y. Zhao[2], L. Qu[2], M. Moon[1], A. Lerro[1], J. Manuel[1], P. Keskinen[1], C. Thomas[1], S-Y. Chou[3], W-P. Lee[1], Y. Leung[1], A. C. Naj[2], C. J. Stoeckert Jr.[1], G. D. Schellenberg[4], L-S. Wang[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA, [3]Dept. of Economics, Lehigh Univ., Bethlehem, PA, [4]Univ Pennsylvania Sch Med, Philadelphia, PA

Disclosure Block: **H. Issen:** None.

Background: NIAGADS is a national genomics data repository that facilitates access of genotypic and sequencing data to qualified investigators for the study of the genetics of Alzheimerâ□□s disease (AD) and related neurological diseases. Collaborations with large consortia and centers such as the Alzheimerâ□□s Disease Genetics Consortium (ADGC), Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium, the Alzheimerâ□□s Disease Sequencing Project (ADSP), and the Genome Center for Alzheimerâ□□s Disease (GCAD) allow NIAGADS to lead the effort in managing large AD datasets that can be easily accessed and fully utilized by the research community.
Method: NIAGADS is supported by National Institute on Aging (NIA) under a cooperative agreement. All data derived from NIA funded AD genetics studies are expected to be deposited in NIAGADS or another NIA approved site. NIAGADS manages a Data Sharing Service (DSS) that facilitates the deposition and sharing of genomic data and association results with approved users in the neurodegenerative research community. In addition, researchers are able to freely use the NIAGADS Alzheimerâ□□s Genomics Database (www.niagads.org/genomics/) to search annotation resources that link published AD studies to AD-relevant sequence features and genome-wide annotations.
Result: As of June 2021, NIAGADS houses 76 datasets comprised of >90,000 samples including GWAS, sequencing, gene expression, annotations, deep phenotypes, and summary statistics. Qualified investigators can retrieve ADSP sequencing data with ease and flexibility through the NIAGADS DSS. As of June 2021, the ADSP and other contributing studies have completed whole exome sequencing (WES) of 20,504 samples and whole-genome sequencing (WGS) of 16,906 samples. Raw WES and WGS files, quality controlled VCF files, and phenotype data files are available via qualified access. The next round of sequencing currently underway will generate around 18,000 additional genomes to be released at the middle of 2022.
Conclusion: NIAGADS is a rich resource for AD researchers, with the goal of facilitating advances in Alzheimerâ□□s genetics research. By housing datasets from many projects and institutions, NIAGADS enables AD researchers to meet their research goals more efficiently. Datasets, guidelines, and new features are available on our website at https://www.niagads.org.

PrgmNr 3010 - Phenome-wide association analysis of rare and common variation in 455,000 UK Biobank exome sequences accessible through public data portal

View session detail

Author Block: **Q. Wang**[1], K. Carss[2], R. S. Dhindsa[1], A. Harper[2], A. Nag[2], I. Tachmazidou[2], D. Vitsios[2], S. Deevi[2], J. Okae[2], S. Wasilewski[2], S. Katherine[2], S. Petrovski[2], AstraZeneca Genomics Initiative; [1]Ctr. for Genomics Res., AstraZeneca, Waltham, MA, [2]Ctr. for Genomics Res., AstraZeneca, Cambridge, United Kingdom
Disclosure Block: **Q. Wang:** Salary/Employment; AstraZeneca.
We adopted the exome sequences from ~455K UK Biobank participants to study the contribution of both rare and common protein-coding variation to thousands of phenotypic endpoints.
We performed a gene-based collapsing PheWAS and separately a variant-level PheWAS across ~17K binary/quantitative phenotypes, evaluating a range of genetic architectures. These analyses were conducted on our cloud-based platform. Overall, we identified 1,517 gene-phenotype relationships for binary phenotypes and 1,301 gene-phenotype relationships for quantitative phenotypes that were significantly associated (p-9), reflecting 125 and 378 distinct genes, respectively. On comparing with the OMIM database, among the significant findings for binary (clinical) phenotypes, 81% are previously known, 9% are known disease genes but represent novel phenotypic associations, and 10% are novel disease genes. The variant-level analysis yielded 5,178 significant (p-9) non-synonymous variant-phenotype relationships for binary phenotypes and 34,561 significant (p-9) non-synonymous variant-phenotype relationships for quantitative phenotypes, involving 586 and 3,860 distinct genes, respectively. Interestingly, 79% (1,197/1,517) and 46% (596/1,301) of the significant gene-phenotype relationships identified in the collapsing analysis for binary and quantitative phenotypes, respectively, were not detected in the corresponding single-variant analysis, demonstrating the complementarity of the two analytical approaches.
We will illustrate AstraZenecaâ□□s use of these data to rapidly validate and inform safety profiles of potential drug targets, identify novel targets, predict drug repositioning opportunities, and study prevalence of molecular endotypes. We also introduce a data portal to visually navigate this rich resource of PheWAS summary statistics for 19K genes and across 3.2M protein-coding variants. The portal supports the search of associations by gene, phenotype and variant, data visualisations to help interpret and explore the results, and ability to download focused results for further analysis.

PrgmNr 3011 - Real-world Evidence for Human Phenotype Ontology Concept Prevalence and its Association with Genetic Disorders from Electronic Health Records

View session detail

Author Block: **C. Liu**[1], C. Ta[1], J. Havrilla[2], K. Wang[3], C. Weng[1]; [1]Columbia Univ., New York, NY, [2]Children's Hosp. of Philadelphia, Philadelphia, PA, [3]CHOP, Philadelphia, PA
Disclosure Block: **C. Liu:** None.
Background: The Human Phenotype Ontology (HPO) is a powerful resource for annotating and analyzing human genetic disorders. However, it is mainly curated based on expertsâ knowledge and public case reports. There is a great demand for data-driven knowledge discovery of its conceptsâ prevalence and associations with genetic disorders, supported by real-world evidence. **Methods:** We first pre-processed unstructured clinical narratives from Columbia University Irving Medical Centerâs (CUIMC) electronic health record (EHR) data prior to 2020 February and indexed them together with relevant metadata using Solr. For each HPO concept, we queried for relevant notes by including both the conceptâs syntactic variations and synonyms, except when these terms were negated or family member-related mentions by using negation and family triggers. Concepts were aggregated at the patient level to calculate each conceptâs prevalence. The âsuspiciousâ high prevalence concepts were identified, and their queries were then examined and corrected if necessary. The whole process was iterated a few times until no âsuspiciousâ concepts were found. We further generated a patient-level summary of genetic disorders by applying a similar procedure to the concepts defined in OMIM and ORPHANET. The ratios of observed-expected co-occurrence frequency between HPO concepts and genetic disorders were calculated to reflect their associations. **Results:** A manual review of the HPO prevalence found the EHR-derived HPO prevalence was consistent with HPOâs original concept prevalence annotation. Additional evaluation based on the automated mapping between a subset of HPO and ICD codes indicates our pipeline based on information retrieval using unstructured narratives reached a similar accuracy as using structured billing codes but covered more phenotypes and genetic disorders. The bulk dataset, derived from all records, contains >10,000 unique HPO concepts (>20,000 terms) based on >2 million patients. To facilitate the analysis of phenotype-disease association for various purposes, we also stratified the data into the pediatrics dataset, genetic counseling dataset, neurology dataset, and whole-exome sequencing dataset. **Conclusion:** We have derived real-world evidence-based HPO prevalence and its association with genetic disorders using CUIMC EHR. The aggregated summary statistics have been integrated into our previously developed Columbia Open Health Data (COHD) for public access through a web application programming interface (API).

PrgmNr 3012 - Tools and Resources to Improve Understanding of Rare Genetic Conditions in Newborn Screening

View session detail

Author Block: **J. Taylor**[1], A. M. Brower[2]; [1]American Coll. of Med. Genetics and Genomics, Bethesda, MD, [2]American Coll. of Med. Genetics and Genomics, Dakota Dunes, SD
Disclosure Block: **J. Taylor:** None.
Newborn screening (NBS) is an essential public health program that began with phenylketonuria (PKU) and has expanded to over 35 core and 26 secondary conditions recommended for screening by the Secretary U.S. Department of Health and Human Services. New conditions are nominated by a community of researchers, clinicians, advocates, and families from the rare disease community for consideration at the federal level by the Advisory Committee for Heritable Disorders in Newborns and Children (ACHDNC) to the Recommended Uniform Screening Panel (RUSP) at an accelerated rate. Advocates are also pursuing the addition of conditions to NBS panels at the state level as well. To help rare disease stakeholders, the Newborn Screening Translational Research Network (NBSTRN) had developed several tools and resources to navigate NBS research and clinical information.
The Newborn Screening Conditions Resource (NBS-CR) is an interactive tool that is available online at nbstrn.org/tools/nbs-cr. This tool currently features 118 conditions including the 61 conditions currently on the RUSP, 20 conditions not on the RUSP but are being screened by at least one state, and 37 conditions that NBSTRN identified as candidates. The NR-CR is a centralized resource that links to facts and statistics from many resources including: OMIM, GeneReview, MedGen, ClinicalTrials.gov, NIH RePORTER, the ACMG ACT sheets, Genetic Alliance, as well as others for both screened and candidate conditions.
NBSTRN also hosted monthly webinars to facilitate information sharing between state newborn screening programs, researchers, clinicians, advocates, and federal partners about conditions recently added to the RUSP or conditions currently apart of pilot studies. Conditions on these calls include pompe disease, mucopolysaccharidosis type I, x-linked adrenoleukodystrophy, spinal muscular atrophy, Duchene muscular dystrophy, and many more. NBS stakeholder learn about: screening assay sensitivity and specificity, incidence of the condition and how it differs between states, other disorders that may be identified by the screening method, as well as treatment and clinical management of diagnosed patients. Genetic testing has become more prominent in NBS to reduce false positive rate or to provide more information to clinicians. Recently, these webinars have discussed how NBS programs classified genetic variants and how this information effects the management of these infants.
In conclusion, NBSTRN has developed tools and resources to advance research in rare genetic diseases that affect infants and children as well as the understanding of genetic medicine.

PrgmNr 3013 - Toward a gold-standard set for SNP to gene mapping

Disclosure Block: **E. Fauman:** Salary/Employment; Pfizer, Inc.

Genome-wide association studies (GWAS) have been hugely successful in identifying reproducible genetic associations for a wide range of traits, biomarkers and diseases. However, our ability to derive biological and medical insights from GWAS is restricted by our limited understanding of how lead variants link to causal genes and the downstream biology. Many methods have been developed in recent years to address this so called â□□SNP-to-gene problemâ□□, but such methods require an authoritative â□□gold standardâ□□ positive control set as a starting point. No large well-curated positive control set currently exists. In response to this gap the International Common Disease Alliance (ICDA) commissioned a working group to define and populate a positive control set of high confidence causal genes (ICDA working group 17). We report here for the first time the results of this effort. We started by analyzing previous high confidence causal gene annotations, including those for cis-protein QTLs, metabolite QTLs and well-studied diabetes loci. In bridging the causal chain from SNP to trait we considered both â□□bottom-upâ□□ genomic features, which link a variant to the causal transcript, and â□□top downâ□□ biological features, which link a causal transcript to the GWAS trait. We manually reviewed thousands of loci for hundreds of traits, prioritizing features such as cell-type specific open chromatin, direct experimental evidence, animal model systems, rare disease phenotypes, rare coding variants and known drug targets. We have manually curated a set of over 2500 gene-trait positive control assertions covering over 600 metabolite traits and 250 disease and other traits. These 2500 assertions implicate a total of over 750 unique genes. Each curated assertion is annotated with a specific rationale and a link to the most direct supporting evidence. Automated annotations for each assertion provide relevant mouse knock-out phenotypes, relevant rare disease phenotypes, known missense/coding evidence and relevant drug target information. As applied to the GWAS catalog, these 2500 gene-trait assertions nominate a probable causal gene for 13% of the 190,000 genome-wide significant SNP-trait entries. This initial set of positive control genes is intended to provide a framework for accumulating and annotating additional high confidence causal gene assignments. Studying the top-down and bottom-up features of these positive control genes should help advance the field in the development of improved SNP-to-gene methods, building out the causal chain from GWAS variants to observed phenotypes, thereby advancing our knowledge of biology and pathobiology.

PrgmNr 3014 - An individual with craniosynostosis, hypertelorism, and imperforate anus with normal cognition caused by a 7.4 Mb duplication on chromosome 6

View session detail

Author Block: **V. Keesee**[1], E. J. Bhoj[2], D. Li[3], H. Hakonarson[4], A. Sobering[5]; [1]SGU, St. George's, Grenada, [2]Philadelphia, PA, [3]CHOP, Philadelphia, PA, [4]Children S Hosp. of Philadelphia, Philadelphia, PA, [5]St. George's Univ., Great River, NY
Disclosure Block: **V. Keesee:** None.
We present a 29-year-old man who has normal cognition but had imperforate anus and craniosynostosis as an infant. A head structural malformation was first observed prenatally when ultrasound showed premature closure of the coronal and metopic sutures. He has hypertelorism and deformation of the orbital wall of the right eye; when right eye is neutral, it is a bit lower than it should be. His right audocanal is shorter than the left. He is prone to a right shoulder dislocation. All developmental milestones were on time, and he has excelled academically. He sought genetic diagnosis because of his appearance. Through proband-only exome sequencing and copy number variant (CNV) analysis, we identified an approximate 7 Mb tandem duplication of 6p.22.1 - 22.3. Cytogenomic microarray analysis (CMA) using a GSA-SNP array showed a 7.4 Mb duplication on chromosome 6. The CMA probes allowed estimation of the approximate breakpoints to be within chromosomal coordinates 20,582,144 to 28,040,581.This CNV was not detected by karyotype which was done when he was an infant. The duplicated segment includes many genes including a histone supercluster, and *HFE*. This individual has phenotypic overlaps with *TWIST*, *MID1*, and *SPECC1L*. Prior to exome sequencing we considered Opitz/GBBB as part of our differential diagnosis. To our knowledge, the individual we describe has a novel chromosomal abnormality, which has not been previously described.

PrgmNr 3015 - Development of a Genetic Diagnostic Algorithm for Individuals with Split Hand Foot Malformation

View session detail

Author Block: **Y. Wang**[1], H. Alrukban[1], L. Domeshek[2], E. Ho[2,3], L. Dupuis[1], G. Borschel[2], R. Mendoza-Londono[1]; [1]Div. of Clinical and Metabolic Genetics, The Hosp. for Sick Children and Univ. of Toronto, Toronto, ON, Canada, [2]Div. of Plastic and Reconstructive Surgery, The Hosp. for Sick Children, Toronto, ON, Canada, [3]Rehabilitation Sci. Inst., Univ. of Toronto, Toronto, ON, Canada
Disclosure Block: **Y. Wang:** None.
Background: Split hand foot malformation (SHFM) is a distal limb defect that affects the central rays of the limb and accounts for up to 17% of limb reduction defects. SHFM can occur in isolation or as part of a genetic syndrome with considerable genetic heterogeneity. Mechanisms of the disease include monogenetic and chromosomal, which leads to significant challenges for genetic diagnosis and counselling. Also, no current genetic diagnostic algorithm is available.
Methods: Through a retrospective chart review, we analyzed a cohort of 34 patients with SHFM who underwent genetic tests and treatment at the Hospital for Sick Children between 1970 and 2016. To the best of our knowledge, this is currently the largest cohort of SHFM patients reported in the literature.
Results: In our cohort, about half of the patients had involvement of both upper and lower limbs (47%, 16/34), followed by upper limbs only (38%, 13/34) and lower limbs only (15%, 5/34), most with right-sided involvement (72.7%). Three patients (9%) had SHFM with long bone involvement, of which two involve the upper limbs and one affects the fibulae. Complex SHFM with associated anomalies, including skeletal, ectodermal, neurological, gastrointestinal, and urogenital systems, was identified in 38% (13/34) of the cases. About a quarter of patients (24%, 8/34) had an affected first or second-degree relative. Of the 29 patients with upper extremities involvement, over half (55%, 16/29) had good functions and did not require surgical treatment. Of the 18 patients who underwent at least one genetic test, including karyotyping, chromosomal microarray and single-gene testing (TP63, DLX5, WNT10B), 5 cases (28%, 5/18) reached a genetic diagnosis (one patient with 10q24.32 duplication, one patient with 7q21.3q32 inversion, and three patients with a pathogenic TP63 variant).
Discussion: Combining the data from our cohort and the available SHFM cases reported in the literature, we propose an algorithm for the genetic diagnosis of SHFM. We categorize the SHFM into four categories: isolated SHFM, SHFM with preaxial involvement, SHFM with long bone involvement, and complex SHFM. For each category, we set the priority for karyotyping, chromosomal microarray, and single-gene testing base on the clinical presentations and family history. Whole-genome sequencing might be a future diagnostic and gene discovery tool to reveal both single-gene and structural variants, especially for complex SHFM. We believe the proposed algorithm will lead to a better understanding, management, and counselling of individuals with SHFM and their families by clinical geneticists and plastic surgeons.

PrgmNr 3016 - Missense variants affecting the actin-binding domains of *PLS3* cause X-linked congenital diaphragmatic hernia and body wall defects

Med, Houston, TX
Disclosure Block: **F. High:** None.

Congenital diaphragmatic hernia (CDH) is a relatively common and genetically heterogeneous structural birth defect associated with high mortality and morbidity. We describe eight unrelated families with a novel X-linked condition characterized by diaphragm defects, variable anterior body wall anomalies, and/or facial dysmorphism. Using linkage analysis and whole exome or whole genome sequencing, we identified novel missense variants in the actin binding domains of plastin 3 (*PLS3*), a gene encoding an actin bundling protein, that co-segregate with disease in all families. Loss-of-function variants in *PLS3* have been described previously in association with X-linked osteoporosis. To address these seemingly disparate clinical phenotypes, we performed *in silico* protein modeling and cellular overexpression experiments, which suggest that the affected residues in individuals with CDH are important for actin binding and result in disorganization of the actin cytoskeleton and a reduction in normal actin stress fiber formation. A mouse knock-in model of a variant identified in one of the families, p.W499C, shows partial perinatal lethality and recapitulates the key findings of the human phenotype, including diaphragm and abdominal wall defects. Both the mouse model and one surviving adult patient with a *PLS3* variant were observed to have increased, rather than decreased, bone mineral density. Together, these clinical and functional data in human and mouse reveal that specific missense variants affecting the actin binding domains of *PLS3* may have a gain-of-function effect and cause a new Mendelian disorder.

PrgmNr 3017 - Multiple independent genetic syndromes in a single patient

View session detail

Author Block: **D. Watson**; CHOP, PHILADELPHIA, PA
Disclosure Block: **D. Watson:** None.
We report on an 18-year old female patient with over 662 Mb regions of homozygosity presenting clinically with intellectual disability, ataxia, schizophrenia symptoms, retinal dystrophy, moderate to severe progressive sensorineural hearing loss (SNHL), congenital hypothyroidism, cleft mitral valve with mild mitral valve regurgitation, and some dysmorphic features. Exome analysis uncovered the following variants: 1) two variants in BBS6 potentially causative for Bardet-Biedl Syndrome 6; 2) a homozygous, known pathogenic variant in the stereocilin (STRC) gene associated with non-syndromic deafness; 3) a homozygous variant in dual oxidase 2 (DUOX2) gene associated with congenital hypothyroidism; and 4) a single variant in the troponin T2 (TNNT2) cardiac type gene related to a cardiomyopathy and manifestation of cleft mitral valve with mild mitral valve regurgitation. This patient was found to be the product of a consanguineous union of an unspecified but apparent first-degree relationship, explaining the multiple independent inherited findings. In summary we report an 18-year Indian girl with a variety of clinical symptoms that are not consistent for only one genetic condition, which is reinforced by the presence of multiple regions of homozygosity consistent with an apparent first- degree relationship. Genetic variants were found in four genes BBS6/MKKS, STRC, DUOX2, and TNNT2, not all of them were confirmed pathogenic but highly suspicious to explain the clinical findings. This case report is a good example of the use of research exome in the scenario of reported negative clinical exome.

PrgmNr 3018 - Seckel-6 Syndrome: A new severe phenotype

View session detail

Author Block: **H. Goodwin**, N. Hauser; INOVA Children's Hosp., Fairfax, VA
Disclosure Block: **H. Goodwin:** None.
Seckel syndrome comprises 6 different genes, each with a slightly different phenotype but all include the characteristic pattern of microcephaly and dwarfism. The only known cases of Seckel-6 syndrome were four cousins born to parents in a consanguineous Pakistani family. These cousins were homozygous for c.129G>A; p.W43X.They displayed significant microcephaly at birth with FOC -4SD to -6SD and short stature, heights were noted at between -2SD to -4SD. Developmentally, the cousins had speech delay but were able to talk by age 3 years of age, they had mild to moderate cognitive impairment, but their motor skills were normal. Our patient displayed significantly different and more severe features than what has been previously described. Our patientâ□□s case may contribute to an expansion of the phenotype for this condition.
The genetic testing done on our patient included a karyotype of 46,XX, FISH negative for trisomy 18, and a normal microarray, other than 8% homozygosity. The Comprehensive Primordial Dwarfism Sequencing Panel (U of Chicago) revealed a homozygous deletion in the CEP63 gene (c.712._730del; p.Val238Serfs*12).Our patientsâ□□ measurements at birth showed a birth weight of 1275g (-5.5 SD), length 38.5cm (-5.7 SD), and HC of 24.5cm (-7.9 SD). Her exam was notable for down slanting palpebral fissures, posteriorly rotated ears with small dysplastic ear lobes and a prominent anti-helix, a large prominent nose, microretrognathia, a short neck with redundant skin, shield shaped chest, ambiguous genitalia with a prominent vaginal/hymen tag, brachydactyly with contractures at the elbows and knees bilaterally, overlapping digits, widely spaced toes, and her scalp exam showed disorganized hair whorls.
She reached the 5-10th percentile for weight where she remained the majority of her life. She remained neurologically impaired, unlike the previously described children. She developed seizures by age 2 years that required anti-epileptics. Later, she became more aggressive with self-injurious behavior requiring medication. Neuroimaging was significant for a severe brain malformation with essentially absent normal cerebral formation. She developed hydrocephalus requiring a VP shunt and needed a cranioplasty for craniosynostosis by age 3 years. She passed away from complications of an infection at age 6 years.
Here we describe a case of Seckel-6 syndrome, with the typical findings of severe microcephaly and short stature, but several additional features not yet noted in the literature. It is possible our patientsâ□□ additional features could be due to another underlying genetic condition, or she may have demonstrated an expansion of the phenotype for Seckel-6.

PrgmNr 3019 - The Expanding Phenotype of WAGR Syndrome: Reconceptualization from a Syndrome to a Spectrum Disorder

View session detail

Author Block: **J. Kalish**, International WAGR Syndrome Association (IWSA), K. A. Duffy; Children's Hosp. of Philadelphia, Philadelphia, PA
Disclosure Block: **J. Kalish:** None.
WAGR syndrome is a disorder caused by a deletion affecting chromosome 11p13 and classically characterized by the presentation of the classic features Wilms tumor (WT), Aniridia, Genitourinary anomalies (GU), and Range of developmental delays. In addition to the classic WAGR phenotypic features, there has also been an associated risk for obesity and kidney failure. Various subgroups of patients with WAGR syndrome have been described, with the most common: â□□AGRâ□□ triad, to describe patients without WT development; and â□□WAGROâ□□ or â□□WAGR plusâ□□ to describe patients affected by obesity.The majority of previous investigations into WAGR syndrome have focused on specific features of the disorder, and only one previous study has performed a widespread evaluation into the clinical issues faced by patients with WAGR syndrome. In this study, we utilized the WAGR Syndrome Patient Registry to perform a comprehensive evaluation of self-reported health issues in 91 participants affected by WAGR syndrome. The main objectives were to evaluate the prevalence of classic phenotypic features, as well as identify any common health issues or features in the cohort.The classic WAGR features were common in the cohort, and previous associations with obesity and kidney failure were confirmed in this cohort. A high rate of issues beyond the classic WAGR phenotype were observed, which suggests the disorder would be better conceptualized as a spectrum disorder. In addition to the classic WAGR features, high rates of obesity, hypertension, and chronic kidney disease (CKD) were found, and cardiac and pulmonary features were common. Given these associations, patients with WAGR spectrum can be considered at risk for adverse cardiometabolic health and CKD in addition to the established WT risk. Internal GU anomalies and congenital anomalies affecting the kidney and/or urinary tract (CAKUT) were common in addition to external GU anomalies, suggesting a potential association between CAKUT and WAGR spectrum.In summary, we propose the concept of â□□WAGR Spectrumâ□□ which can be considered an umbrella term to describe the constellation of phenotypes presenting in patients affected by chromosome 11p13 deletions. Our results suggest a wide array of phenotypes and clinical issues in the largest cohort evaluated in this patient population and further suggest the complete phenotypic spectrum of WAGR syndrome has likely been underrepresented in past cohorts. These observations will augment the diagnosis and management of future patients with WAGR Spectrum.

PrgmNr 3020 - *ADAM6 (106329183_106736911)x3 gene variant in a Charcot Marie-Tooth patient with upper extremity involvement*

View session detail

Author Block: **V. RodrÃguez Machuca**; UdeG, Guadalajara, Mexico
Disclosure Block: **V. RodrÃguez Machuca:** None.
Introduction. Charcot-Marie-Tooth disease (CMT) encompasses a group of inherited disorders characterized by motor and sensory polyneuropathy. Most of these disorders exhibit an autosomal dominant pattern of inheritance and are classified with respect to neuroconduction studies into 3 major groups. CMT dominant intermediate disease type E (CMTDIE) presents the neurological features of CMT, along with manifestations of chronic kidney disease at an early age (proteinuria, segmental and focal segmental glomerulosclerosis (FSGS)). In addition to the deformity in pelvic limbs, the involvement of the hands is characteristic, observing a 'claw-like' appearance/disposition. **Aim.** To present a patient with CMTDIE and upper extremity involvement and the ADAM6 (14q32.33) (106329183_106736911)x3 gene variant. **Clinical summary.** Male patient, 32 years old. Non consanguineous parents, no family history of malformations or syndromes except for a similarly affected twin brother who declined further examination. Normal psychomotor development until the age of 5 years, with later neuromuscular deterioration. Physical examination revealed upper extremities with decreased strength, hyporeflexia, claw hands, areflexia and abolition of strength in lower limbs. Generalized muscle atrophy was also observed. **Material and methods.** Routine laboratory, neuroconduction studies, nuclear magnetic resonance, karyotype, Short Tandem Repeats (STRs) determination and CGH microarray. **Results.** Urinalysis and Blood chemistry showed a preserved renal function, no evidence of proteinuria. Electromyography NCV Conclusions. Few cases of CMTDIE have been reported. It is infrequent to find claw hands as presented by the patient, although it has been described. In the literature it has been reported that in this variant of CMT there is proteinuria and development of early chronic renal disease, however our patient did not present renal involvement. Noteworthy, according to our review of the literature, there are no reports associating the gene variant presented here with CMTDIE, although the chromosomal region in which this gene is situated has previously been implicated in the disease.

PrgmNr 3021 - *SETBP1 involvement in a neurodevelopmental disorder: A report from a reanalysis of a negative clinical exom*

View session detail

Author Block: **I. Barcelos**[1], D. Li[1], E. McCormick[1], M. J. Falk[2], M. He[3], H. Hakonarson[4]; [1]CHOP, PHILADELPHIA, PA, [2]CHOP, Philadelphia, PA, [3]Childrenâ□□s Hosp. of philadelphia, Philadelphia, PA, [4]Children S Hosp. of Philadelphia, Philadelphia, PA

Disclosure Block: **I. Barcelos:** None.

A range of clinical findings have been associated with heterozygous mutations in the SET-binding protein gene (*SETBP1*). Germline nonsense or truncating variants cause intellectual disability with speech delay, seizures, and mild facial dysmorphisms. Germline recurrent missense variants at residues 868-871, forming the critical consensus sequence of the degradation signal, have been associated with Schinzel-Giedion syndrome, a rare condition characterized by multiple malformations, severe neurological alterations, and increased risk of malignancy. Interestingly, however, somatic recurrent missense variants at residues 868-871 have been shown to cause atypical chronic myeloid leukemia through abrogating ubiquitination, which in turn results in reduced PP2A activity and increased proliferation rates. It was also reported that several affected individuals with germline missense variants outside the degradation-related critical motif exhibit a milder phenotype, including developmental delay, autistic features, and milder facial dysmorphisms. We report an 8 years old male who presented for an evaluation due to developmental delay, autism, hypotonia, hypospadias, and VSD. Previous clinical exome sequencing of this patient was non-diagnostic. We undertook reanalysis of the same WES data in the research setting where we identified a *de novo* missense mutation, c.2572G>A (p.E858K), in *SETBP1*, which was confirmed by Sanger sequencing. This variant was not found in population allele frequency databases, and is predicted to be deleterious by multiple algorithms. Functional assessments of the patient cells highlighted reduced mTORC1 signaling and aberrant autophagy, suggesting a disruption of coordinated action of PP2A and mTORC1 in regulating autophagy. The variant was classified to be pathogenic and this patient shares phenotypic characteristics with previously reported patients *SETBP1* mutations who are mildly affected. It has been well established that reanalysis of exomes may further increase the molecular diagnostic rate. In this report, we adapted our exome analytic pipeline to a patient with nonspecific developmental disorder and established molecular diagnosis, identifying a pathogenic variant in *SETBP1*. Our results demonstrate the benefit of reanalysis of previously obtained sequencing data in a patient who is otherwise lacking a clinical diagnosis.

PrgmNr 3022 - *TBCK*-related encephalopathy: Understanding the role of autophagy in the pathology of the disease

View session detail

Author Block: **S. Murali**[1], R. Angireddy[2], E. Bhoj[2]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Children's Hosp. of Philadelphia, Philadelphia, PA
Disclosure Block: **S. Murali:** None.

TBCK-related encephalopathy, also known as *TBCK* syndrome, is a rare pediatric neurodegenerative disorder affecting the central and peripheral nervous systems. It is an autosomal recessive disease caused due to homozygous loss-of-function mutations in the *TBCK* gene. Children affected by this syndrome show phenotypes of intellectual disability and hypotonia. Other symptoms include coarse facial features, global developmental delay (ranging from moderate to severe), difficulty breathing, epilepsy, osteoporosis, and hypothyroidism. TBC1 domain containing kinase (*TBCK*) gene, located on chromosome 4, encodes for the TBCK protein composed of three functional domains: an N-terminal Serine/Threonine kinase domain, a central TBC domain, and a C-terminal rhodanese homology domain (RHOD). The exact function of the TBCK protein is not known, but preliminary studies indicate that the TBC domain functions as a GTPase -activating protein for small Rab GTPases. Studies from patient-derived fibroblast show that the loss of *TBCK* modulates the mechanistic Target of Rapamycin (mTOR) pathway and significant reductions in the downstream effectors of the pathway were observed. *TBCK* patient fibroblast showed an increase in autophagy flux, providing evidence that autophagic-lysosomal dysfunction may play an essential role in the disease's pathophysiology. However, the exact function of this gene in the autophagy process is not known and remains to be explored. The present study is aimed to understand autophagy in *TBCK* neurons. We used human immortalized neural progenitor cell (NPC) line ReNcell VM to stably knockdown *TBCK* using lentivirus transduction of specific shRNA and differentiated NPC cells into dopaminergic neurons. Immunocytochemistry studies will be performed to visualize changes in the formation of autophagosomes and autophagy flux in dopaminergic neurons.

PrgmNr 3023 - A cross-disorder and evidence-based tiered ranking of candidate genes for neuropsychiatric disorders

View session detail

Author Block: **H. Shimelis**[1], M. T. Oetjens[2], M. Znidarsic[1], K. E. Wain[2], S. Myers[1], D. Ledbetter[1], C. L. Martin[2]; [1]Autism & Dev.al Med. Inst., Geisinger, Lewisburg, PA, [2]Geisinger, Lewisburg, PA
Disclosure Block: **H. Shimelis:** None.
Sequencing studies of cohorts with neuropsychiatric disorders (NPD) continue to identify many new NPD genes. These studies have revealed that categorical disorders, including intellectual disability (ID), autism spectrum disorder (ASD), and schizophrenia (SCZ), share genetic etiologies. Several databases have been created to catalogue rare variants in NPD probands, serving as a resource for researchers studying NPD. However, these databases generally use a single categorical NPD diagnosis in their approach, which is inconsistent with the known genetic overlap of these conditions and may underrepresent evidence for a given gene. To address this gap, the Developmental Brain Disorder (DBD) Gene Database (https://dbd.geisingeradmi.org/) uses a cross-disorder and tiered genotype-phenotype data mining approach to identify novel candidate genes and provide further evidence to genes previously implicated in NPD. Here, we present an update of the DBD Gene Database which contains data from 1172 studies published 2003-2020 representing 6481 individuals with pathogenic loss-of-function (pLOF) variants in 649 genes. pLOF and single gene copy number variants are curated from published sequencing studies across six NPD phenotypes: ID, ASD, epilepsy, attention deficit hyperactivity disorder, SCZ, and bipolar disorder. All genes are ranked into four tiers based on the number of cases with *de novo* pLOF variants: Tier 1, the strongest level of evidence, includes genes with three or more *de novo* pLOF variants; Tier 2, genes with two *de novo* pLOF variants; Tier 3, genes with one *de novo* pLOF variant; and Tier 4, genes with only inherited (or unknown inheritance) pLOF variants. Autosomal recessive (AR) genes are curated separately from LOF tier rankings. In our latest update from May 2021, 177 were ranked as Tier 1, 79 as Tier 2, 114 as Tier 3, 147 as Tier 4, and 132 as AR genes. To examine whether genes ranked as Tier 1 were novel or previously recognized as high-confidence genes in other databases, we compared Tier 1 genes to two NPD-related databases: SFARI gene and DDG2P (accessed May 2021). Of the 177 Tier 1 genes, 145 were listed as genes with the highest confidence of being NPD-related in at least one of the two databases while 32 were ranked lower (n=30) or not yet included (n=2). When we evaluated phenotypes of individuals with pLOF variants in Tier 1 genes, 96% (170/177) of genes were associated with 2 or more disorders. These results show that using a cross-disorder approach to NPD gene discovery increases the yield of genes with strong evidence of being NPD-related. Furthermore, our results show evidence for phenotypic heterogeneity in individuals with a pLOF variant in the same gene.

PrgmNr 3024 - A late-onset seizure phenotype in a mouse model of *CHD8* haploinsufficiency

View session detail

Author Block: **M. Krenzer**[1], L. Nguyen[1], C. Weiss[2], B. Bistis[1], M. R. Healey[3], M. Rosales Larios[1], D. Rivas[4], A. Bordey[1], J. P. Noonan[1], R. A. Muhle[5]; [1]Yale Sch. of Med., New Haven, CT, [2]Barnard Coll. of Columbia Univ., New York, NY, [3]Brown Univ., Providence, RI, [4]New York State Psychiatric Inst., New York, NY, [5]Columbia Univ.; New York State Psychiatric Inst., New York, NY
Disclosure Block: **M. Krenzer:** None.
Damaging variants in the chromatin remodeler *Chromodomain Helicase DNA-binding protein 8* (*CHD8*) are highly associated with an increased likelihood for autism spectrum disorder (ASD) diagnosis. People diagnosed with ASD are at risk of epileptic seizures and associated premature mortality. In phenotypic cohorts of people harboring *CHD8*-disruptive mutations, 13-30% reported abnormal electroencephalographic (EEG) activity or seizures, suggesting an etiologic link between damaging *CHD8* mutations and abnormal brain activity.

We developed a mouse model of *CHD8* haploinsufficiency by deleting exon 3 of *CHD8* via CRISPR gene editing. *Chd8*$^{+/-}$ mice express 40-60% of the gene product, have a reduced body weight, and a normal life expectancy. Here we report that more than 30% of *Chd8*$^{+/-}$ mice develop late-onset spontaneous seizures in adulthood during routine handling. These events range from mild staring spells to generalized tonic-clonic seizures, from which there is rapid recovery to baseline. Mice observed to have seizures have a normal lifespan relative to wild-type (WT) littermates and *Chd8*$^{+/-}$ mice that did not have behavioral seizures during handling. Seizures occurred in male and female mice, with male *Chd8*$^{+/-}$ mice having a younger age of onset than female *Chd8*$^{+/-}$ mice.

To assess the window of increased seizure susceptibility, we performed a pharmacological challenge assay with the $GABA_A$ antagonist pentylenetetrazole at 6, 11, and 13 months of age. We found that male *Chd8*$^{+/-}$ mice exhibited a significantly reduced seizure threshold and more severe seizures than WT littermates, with increasing severity in older age. Female *Chd8*$^{+/-}$ mice assessed in the same assay did not show a reduced seizure threshold compared to WT littermates, with seizure severity similar to WT male mice. Video-EEG recordings and EEG quantification at 12 and 18 months revealed a trend towards higher Delta power (1.6-4.0 Hz), reflecting an overall increase in relative slow wave brain activity.

To our knowledge, this is the first report of a late-onset seizure phenotype in a mouse model of *CHD8* haploinsufficiency. Our results show a male sex bias in seizure susceptibility to $GABA_A$ antagonism, pointing to an excitation/inhibition imbalance.

These results contribute to a better understanding of the complex interaction and presumed common mechanisms underlying both ASD and seizures. Our findings highlight the need to monitor people who carry damaging variants in *CHD8* or other genetic risk factors for late developing seizures that may impact health and quality of life.

PrgmNr 3026 - A screening pipeline to identify functional impacts of novel *KCNT1* variants in pediatric epilepsies

View session detail

Author Block: **C. D. Whelan**[1], Z. Zhu[1], T. Danker[2], M. Rizzo[1], V. Nguyen[1], D. R. Bearden[3], J. J. Cherry[1], C. A. Hinckley[1]; [1]Biogen Inc., Cambridge, MA, [2]NMI TT Pharmaservices, Markwiesenstrasse, Reutlingen, Germany, [3]Univ. of Rochester, Rochester, NY
Disclosure Block: **C.D. Whelan:** Salary/Employment; Biogen.
Rationale: Genetic variants at *KCNT1* are associated with a spectrum of epilepsies, including epilepsy of infancy with migrating focal seizures (EIMFS) and sleep-related hypermotor epilepsy (SHE). To date, over 30 distinct pathogenic missense variants at *KCNT1* have been reported in the literature. The majority of variants are hypothesized to exert a pathologic gain-of-function mechanism, increasing KCNT1 (Slack, KNa1.1) channel activity by multiple mechanisms.
Methods: In order to identify novel, potentially pathogenic variants, we analyzed genetic data from pediatric epilepsy patients screened via Invitaeâ□□s Behind the SeizureÂ® Epilepsy Panel (https://www.invitae.com/en/behindtheseizure/). *KCNT1* variants identified via the Invitae panel were subsequently expressed in xenopus oocytes; KCNT1 current-voltage relationships were then quantified with two-electrode voltage clamp recordings using the automated Robocyte system.
Results: We identified 88 unique *KCNT1* variants via the Invitae panel, including 12 patients with six previously reported pathogenic mutations, three patients harboring a novel, likely pathogenic, unreported variant, and 93 patients carrying 81 novel variants of unknown significance (VUS). We subsequently conducted a literature search, identifying 17 additional epilepsy-associated *KCNT1* variants for which in-vitro validation of a gain-of-function mechanism was not previously established. To validate a screening pipeline for uncharacterized, potentially pathogenic mutations, we compared the biophysical properties of novel and/or uncharacterized *KCNT1* variants with those of known, previously characterized pathogenic mutations. Relative to wild type KCNT1, we found increased currents at +70 mV for previously characterized EIMFS variants, while a common *KCNT1* missense single nucleotide polymorphism (T737M) minimally impacted current amplitude. Among previously uncharacterized *KCNT1* mutations, we identified 9 variants with gain-of-function increases in current amplitude.
Conclusions: Our dataset is the largest systematic characterization of *KCNT1* variants to date. These ongoing efforts have identified at least 9 previously uncharacterized *KCNT1* variants as gain-of-function, further supporting the therapeutic rationale for *KCNT1* down-regulation in EIMFS and SHE. Further studies systematically examining pathogenic and non-pathogenic variants will enable a deeper understanding of the structural basis of *KCNT1* gain of function.

PrgmNr 3027 - Autism spectrum disorder: *Magel2* gene variants

View session detail

Author Block: **J. Pascual**[1], O. J. Quincoces[1], S. Carlo[2], C. I. Hernandez[3], A. M. Alejandro[4], E. Albino[5], Y. Mojica[6], A. S. Cornier[7]; [1]Ponce Hlth.Sci. Univ., Ponce, PR, [2]Ponce Hlth.Sci. Univ., Cabo Rojo, PR, [3]Natl. Children's Hosp., Pediatrics Dept., Washington, DC, [4]Dept. of Biology, Univ. of Puerto Rico, Mayaguez Campus, Mayaguez, PR, [5]Univ. of Puerto Rico - Med. Sci. Disclosure Block: **J. Pascual:** None.

We are presenting the case of a 17-year-old female of Hispanic descent who was referred to the Genetics clinic when she was 13-year-old due to a diagnosis of autism spectrum disorder. Initial metabolic laboratory workup was negative as well as karyotype, analysis *Fragile X* and chromosomal microarray studies. Autism Disorder-Intellectual disabilities gene panel showed mutations on the *MAGEL2* and *SMARCA4* genes. *MAGEL2* is located in a chromosomal region strongly associated with *Prader-Willi syndrome* (PWS). Mutations in this gene have been associated with *Chitayat-Hall* (CHS) and *Schaaf-Yang* (SYS) syndromes. *SMARCA4* mutations have been associated with *Cofï¬n-Siris Syndrome* (CSS). Both CHS and SYS have been described as part of a phenotypic continuum underlining the possible pleiotropy that mutations in this gene produces. It has also been described that *MAGEL2* complete deletion mutations rather than truncating mutations lead to a milder phenotype. This suggests a possible dominant-negative effect or a leaky expression of the maternal *MAGEL2* allele which has been shown to happen with the *NDN* allele which is also found in the PWS region.

We believe that some clinical features present in this patient are due to the *MAGEL2* mutation. These features include skin picking, anxiety, autism spectrum disorder, intellectual disabilities, neonatal hypotonia, and distal digital hypoplasia. These clinical features are consistent with *MAGEL2* gene mutations described in the medical literature. The loss of heterozygosity in this autosomal dominant gene is responsible for some if not all of the patientâ□□s phenotype. Proteomic studies may provide more information to this genotype-phenotype correlation.

PrgmNr 3028 - Biallelic inframe deletion of human *SOX4* is associated with developmental delay, hypotonia and intellectual disability

View session detail

Disclosure Block: **A. Ghaffar:** None.

Background: Intellectual disability (ID) is defined as person's limitation in intellectual functioning and adaptive behavior with onset before the age of 18 years, having worldwide prevalence of 1-3%. Among the monogenic causes, autosomal recessive ID (ARID) genes are responsible for more than 50% ID. **Purpose:** The purpose of this study was to identify the genetic causes of early onset ID in a large Pakistani kindred (PKMR225), and to investigate the expression and functional importance of identified ID-associated gene in human brain. **Methods:** Physical examination for ID phenotype was assessed along with MRI and biochemical assays in patients. Whole exome sequencing (WES) was used to identify the candidate pathogenic variant in family PKMR225, further confirmed through sanger sequencing. In-silico analysis and 3-dimensional (3D) molecular modeling were performed to assess the impact of the identified deletion on the encoded protein using tools like; Clustal Omega, MetaDome, ITasser, PyMol. Finally, RNA-based expression analysis in brain was done using GTEx and UCSC single cell browser.**Results:** Both siblings of family PKMR225 have moderate to severe ID with global developmental delay and hypotonia, however they had normal range values for biochemical assay and no brain abnormality was observed in MRI. Through WES, we identified a novel in-frame homozygous deletion variant [c.730_753del24; p.(Ala244_Gly251del)] in *SOX4*, segregating with the phenotype in family PKMR225. SOX4 belongs to group C of the SOX transcription regulating family known to be involved in neurogenesis, skeletogenesis, cardiac and reproductive system development. In-silico analysis show loss of seven predicted hydrogen bonds supporting the probability of structural fold change in an intolerant and conserved region of SOX4. Further, with high overlapping RNA expression analysis of *SOX4* with *SOX11, DCX* and *TRB2* we showed the susceptibility of protein importance in neurogenesis. **Significance:** Our study represents the first report of ARID caused by biallelic pathogenic variant in *SOX4* occurring in non-HMG domain of protein. Previously, four de novo heterozygous variants in *SOX4*, specific to highly conserved structured HMG domain were reported in index cases with ID and mild facial dysmorphism. Thus, this study expands the mutational landscape of *SOX4* and the repertoire of the known genetic causes of ARID.

PrgmNr 3029 - Dysregulation of Canonical and Alternative Replication Protein A Complexes in Huntington Disease and Spinocerebellar ataxia Type 1 brains is associated with CAG instability and phenotype

Disclosure Block: **T. Gall-Duncan:** None.

Expansions of gene-specific CAG/CTG DNA repeats cause >15 neurodegenerative diseases, including Huntington Disease (HD) and spinocerebellar ataxia type 1 (SCA1). Inherited expansions continue to somatically expand as patients age, through a poorly understood mechanism. Larger expansions hasten disease onset and worsen severity and progression, so understanding the molecular processes of expansions is crucial to understanding pathogenesis. Somatic expansions may be regulated by tissue-specific expression of DNA repair proteins. Paradoxically, DNA repair proteins may exacerbate somatic expansions by incorrectly mediating repair of the expansion. We assessed the role of two single-strand DNA binding protein complexes in the expansion process. The canonical single-strand DNA binding complex in humans, replication protein A (RPA), composed of RPA1-RPA2-RPA3, is essential for DNA replication, repair, and recombination. Humans also express a poorly understood primate-specific alternative RPA complex (Alt-RPA) in which RPA4 replaces RPA2. Here we show RPA and Alt-RPA are differentially upregulated in HD and SCA1 patient brain regions, with Alt-RPA demonstrating up to 10-fold upregulation in the most affected brain tissues. In vitro repair of slipped-CAG structures, a DNA intermediate of expansions, shows that high concentrations of RPA enhance repair while high concentrations of Alt-RPA blocks repair. Coincidentally, while both Alt-RPA and RPA bind slipped-CAG structures, RPA efficiently melts slipped-DNAs while Alt-RPA does not. Conducting the first BioID interactomes for the RPA subunits we identified that RPA interacts with proteins known to protect against CAG-associated neurodegeneration, while Alt-RPA interacts with proteins which promote CAG-associated neurodegeneration and CAG expansions, including MSH3. We demonstrate that RPA overexpression completely inhibits somatic repeat expansions in vivo in the striatum of SCA1 mice, coinciding with reductions in biomarkers of CAG disease such as genome-wide DNA damage and mutant Ataxin-1 aggregation in striatal medium spiny neurons. Previously we demonstrated Rpa1 overexpression rescued motor phenotypes and ameliorated elevated DNA damage in cerebellar Purkinje neurons, in the same mice. Our new data demonstrate that somatic expansions in the striatum may contribute to SCA1 mouse phenotypes, and that RPA is an active player in suppressing CAG expansions and pathogenesis, effectively preventing somatic CAG expansions and molecular phenotypes through non-replication mechanisms. In contrast, Alt-RPA likely plays the opposite role by enhancing expansions and pathogenesis.

PrgmNr 3030 - Evaluating digenic inheritance of bi-allelic *PGAP2* and *PGAP3* variants in a case of Mabry syndrome

View session detail

Author Block: **M. D. Thompson**[1], X. Li[2], T. Kinoshita[2], Y. Murakami[2], C. Thomas[3]; [1]Univ of Toronto, Toronto, ON, Canada, [2]Osaka Univ., Osaka, Japan, [3]Yale Univ., TorontNew Haven, CT
Disclosure Block: **M.D. Thompson:** None.
At least six genes are associated with hyperphosphatasia mental retardation syndrome (HPMRS). Disruption of four phosphatidylinositol glycan (PIG) biosynthesis genes, *PIGV*, *PIGO*, *PIGW* and *PIGY*, expressed in the endoplasmic reticulum, result in HPMRS 1, 2, 5 and 6; disruption of the two post GPI attachment to proteins genes, *PGAP2* and *PGAP3*, destabilizes the glycophosphoinositol (GPI) anchored proteins (AP) association with the Golgi membrane, resulting in HPMRS 3 and 4, known as Mabry syndrome, the first of 21 glycophosphoinositol (GPI) disorders (IGD). Here we present a case report of a child with features of HPMRS whose genome underwent targeted exome sequencing to identify *PGAP2* c:284A>G homozygous variant of unknown significance and *PGAP3* c:259G>A homozygous variant of unknown significance. We conducted a rescue assay in *PGAP2* and *PGAP3* deficient CHO cell lines in order to assay the potential pathogenicity of these variants. In the rescue assay with the strong (pME) promoter, the PGAP2 variant almost abolished the activity in CHO cells and the mutant protein could not be detected. The mutation made the *PGAP2* protein unstable. Flow cytometric analysis showed that CD59 and CD55 expression on the *PGAP2* deficient cells transfected with the mutant *PGAP2* construct was not restored at all. We could not detect the decreased activity in *PGAP3* mutant with the strong (pME) promoter driven construct. Using the weaker promoter, the *PGAP3* variant may affect PGAP3 activity mildly. In this case of Mabry syndrome, therefore, the phenotype may be predominantly HPMRS4: resulting from autosomal recessive inheritance of NM_001256240.2 *PGAP2* c:284A>G. We discuss the strategies required to establish evidence of digenic inheritance in GPI deficiency disorders.

PrgmNr 3031 - Fibroblasts and lymphocytes are superior options to whole blood and other peripheral tissues for Mendelian neurological disease diagnosis through RNA-seq

View session detail

Author Block: **S. Chen**[1], M. C. Danzi[1], M. Synofzik[2], R. Schule[3], U. Ulmer[4], S. Zuchner[5]; [1]Dept. of Human Genetics, Univ. of Miami, Miami, FL, [2]Hertie Inst. for Clinical Brain Res., Tuebingen, Baden WÃ¼rttemberg, Germany, [3]Ctr. for Neurology and Hertie Inst. for Clinical Brain Res., TÃ¼bingen, Germany, [4]Hertie Inst. for Clinical Brain Res., Tubingen, Germany, [5]Univ. of Miami, Miami, FL
Disclosure Block: **S. Chen:** None.
Genetic diagnosis of patients with rare Mendelian diseases remains challenging. RNA sequencing (RNA-seq) data from patient cells is often additionally leveraged to aid identification of causal variants. RNA-seq data from the affected neural tissue would be most informative for such analyses, however collecting such samples from living patients is typically not possible. It is imperative to balance ease of collection of patient tissues with their clinical utility. Therefore, we evaluated whole blood, patient-derived fibroblasts and lymphocytes as candidate tissues because they are non-invasive and easy to collect from patients. To identify whether these tissues express genes related to three rare neurological Mendelian diseases (Charcot-Marie-Tooth (CMT), Ataxia and hereditary spastic paraplegia (HSP)) in healthy conditions, we analyzed RNA-seq data from three neural tissues (cortex, cerebellum and tibial nerve) and three peripheral tissues (whole blood, fibroblast, and lymphocyte). This data was accessed from the GTEx sequence repository. Unsurprisingly, neural tissues were found to reliably express a greater percentage of disease-related genes than the peripheral tissues at more than 80%. Encouragingly, fibroblasts and lymphocytes still expressed over 70% of these disease-related genes. Whole blood only had 30% of disease-related genes expressed. To reveal whether fibroblast and lymphocyte tissues can be used to diagnose HSP in a clinical setting, induced pluripotent stem cells (iPSCs), iPSC-derived cortical neurons, fibroblasts and lymphocytes were collected from HSP patients and processed for RNA-seq in addition to genomic sequencing. Gene quantification, splicing detection and differentially expressed gene (DEG) analysis were performed. Based on the splicing and DEG analysis results between four different groups, we identified a list of HSP causal genes that can be reliably detected in fibroblasts and lymphocytes. We also evaluated the potential benefits of using iPSC-derived neurons over fibroblasts and lymphocytes for diagnosis using sets of samples collected from the same patients. Taken together our results indicate that fibroblast and lymphocyte tissue have potential to be non-invasive yet accurate ways to diagnose HSP, CMT and Ataxia.

PrgmNr 3032 - Free Sialic Acid Storage Disease (FSASD) due to defective*SLC17A5*: A status update

View session detail

Author Block: **M. Huizing**[1], M. Hackbarth[2], M. Sabir[3], L. Wolfe[1], M. Wasserstein[4], D. Adams[5], M. V. Malicdan[1], W. A. Gahl[6], S. U. Walkley[7], FSASD Consortium; [1]NIH/NHGRI, Bethesda, MD, [2]NHGRI, ROCKVILLE, MD, [3]NIH NHGRI, Bethesda, MD, [4]Children's Hosp. at Montefiore, Albert Einstein Coll. of Med., Bronx, NY, [5]NIH, Bethesda, MD, [6]NHGRI (NIH), Bethesda, MD, [7]Albert Einstein Col Med, Bronx, NY
Disclosure Block: **M. Huizing:** None.
Free sialic acid storage disorder (FSASD) is an extremely rare, autosomal recessive, neurodegenerative, multisystemic disorder caused by defects in the lysosomal sialic acid (SA) exporter SLC17A5 (sialin). Lysosomal accumulation of free SA in FSASD results in enlarged lysosomes in some cell types and 10-100-fold increased urinary free SA. The clinical spectrum ranges from a severe infantile onset form, lethal in early childhood, to a mild form with subjects living into adulthood, also called Salla disease. In 2018, we initiated a multidisciplinary collaborative effort with clinical and scientific FSASD experts, the National Institutes of Health, and the patient advocacy group (S.T.A.R. Foundation) to overcome scientific, clinical and financial challenges facing the development of treatments for FSASD. Several disease-related facets are now under investigation:
Diagnosis: Around 200 FSASD cases are reported worldwide. FSASD is likely underdiagnosed, due to the rarity of the disorder, absence of routine urine SA testing, and non-specific clinical symptoms. We promote FSASD awareness, *SLC17A5* inclusion in gene panels, and access to SA testing.
Clinical Phenotype: FSASD clinical features include coarse facial features, organomegaly, and progressive neurodegenerative symptoms. Central hypomyelination with cerebellar atrophy and thinning of the corpus callosum are prominent imaging features. To identify diagnostic and clinical trial outcome markers, a FSASD patient registry was initiated and a pilot natural history study is ongoing.
Cellular Phenotype: FSASD pathobiology is poorly understood. To study cellular pathology and functional assays, a variety of live-dye, labeled substrate, and immunofluorescent assays are being tested in patient-derived cells.
FSASD models: Different FSASD cell types are being studied (fibroblasts, neuronal and iPS cells). SLC17A5 knock-out and knock-in mouse models are under investigation.
Therapy: There is no approved therapy for FSASD. We plan to pursue high throughput drug screening, SLC17A5 chaperone testing, and gene editing/therapy approaches.
Encouraged by the success of other collaborative efforts for rare diseases, we aim to accelerate data collection that incentivizes industry to further develop and commercialize FSASD treatments.

PrgmNr 3033 - Genetic evaluation of dementia with Lewy bodies implicates distinct disease subgroups

View session detail

Author Block: **Z. Shah**[1], K. Kaivola[2], R. Chia[1], S. Scholz[1], International LBD Genomics Consortium; [1]NIH, Bethesda, MD, [2]NIH, Bethesda, MD
Disclosure Block: **Z. Shah:** None.
The underlying genetics of dementia with Lewy Bodies (DLB) is not well understood, but studies have shown a strong association between the APOE locus and risk of developing Alzheimerâ□□s disease and DLB. However, there is inconclusive evidence on whether APOE independently drives Î±-synuclein pathology. In this study, we analyzed whole-genome sequence data from 2,466 DLB cases and 2,928 neurologically healthy, aged controls. We first performed an APOE-*Îµ4*-stratified genome-wide association study (GWAS) comparing 1,286 DLB cases without APOE ?4 to 2,271 controls without APOE *Îµ4* and 1,180 DLB cases with APOE ?4 to 657 controls with APOE *Îµ4*. GBA (rs2230288, p = 6.58x10-9, odds ratio [OR] = 3.41, 95% confidence interval [CI] = 2.25-5.17) was the only locus that reached genome-wide significance in the GWAS comparing DLB cases and controls without APOE *Îµ4*. There were no loci that reached genome-wide significance in the GWAS comparing DLB cases and controls with APOE *Îµ4*. Next, we divided 495 DLB cases into three groups based on the severity of the AD co-pathology: pure DLB (n=88), DLB with intermediate AD co-pathology (DLB + iAD, n=66), and DLB with high AD co-pathology (DLB + AD, n=341). For each of the groups, we examined the association of APOE *Îµ4* against the 2,928 neurologically healthy controls. We found that APOE *Îµ4* was strongly associated with DLB + AD (p = 1.29x10-32, OR = 4.25, 95% CI = 3.35-5.39) and DLB + iAD (p = 0.0011, OR = 2.31, 95% CI = 1.40-3.83), but not with pure DLB (p = 0.31, OR = 0.75, 95% CI = 0.43-1.30). Our findings suggest that APOE *Îµ4* is not an independent driver of Î±-synuclein pathology in pure DLB, but rather the association is explained with AD co-pathology. Moreover, GBA is the main risk factor for patients with DLB with little or no AD co-pathology. Future DLB genetic studies should consider the severity of AD co-pathology.

PrgmNr 3034 - Genome wide meta-analysis of suicide behaviors

View session detail

Author Block: **Q. S. Li**[1], A. Docherty[2], A. A. Shabalin[3], E. DiBlasi[4], S. Gopal[1], E. Daly[1], C. Canuso[1], FinnGen, International Suicide Genetics Consortium, W. Drevets[5], H. Coon[4]; [1]Janssen R&D, LLC, Titusville, NJ, [2]VCU, Richmond, VA, [3]Univ. of Utah, Salt Lake City, UT, [4]Univ. of Utah Sch. of Med., Salt Lake City, UT, [5]Janssen R&D, LLC, San Diego, CA

Disclosure Block: **Q.S. Li:** Salary/Employment; Johnson & Johnson.

Following the recently published genomic analysis of suicide death data from a large population-ascertained cohort (Docherty et al 2020), we have genotyped another ~1200 samples from the original cohort and added three cohorts of subjects with a history of suicide attempt as the clinical phenotype (FinnGen cohort and two Janssen clinical trial samples). We aim to identify genetic risk variants associated with suicidal behavior. For the expanded suicide death analysis using 3765 cases and 6572 populational controls genotyped using a matching array platform, and meta-analysis across both suicidal behavior phenotypes (n = 8315 cases and 256,478 psychiatric or populational controls), one locus in neuroligin 1 (*NLGN1*) passing genome wide significance threshold for suicide death phenotype compared to the general population was identified (top SNP rs73182688, with p = 5.48×10^{-8} before and $p = 4.55 \times 10^{-8}$ after mtCOJO analysis conditioning on major depressive disorder (MDD) (Howard et al., summary statistics without the 23andMe cohort). Conditioning on suicide attempt (suicide attempt summary statistics from ISGC excluding suicide death cohorts) did not significantly change the association strength ($p = 6.02 \times 10^{-8}$), suggesting this is a suicide death specific genetic risk locus. *NLGN1* encodes a member of a family of neuronal cell surface proteins. Members of this family may act as splice site-specific ligands for beta-neurexins and are putatively involved in the formation and remodeling of central nervous system synapses. MAGMA gene-set analysis of suicide death suggests enrichment of several immune related pathways such as MHC class Ib receptor activity ($p = 1.82 \times 10^{-7}$, Bonferroni adjusted p-value = 0.003), natural killer cell cytokine production ($p = 7.68 \times 10^{-6}$), positive regulation of interferon gamma secretion, $p = 3.39 \times 10^{-5}$). MAGMA gene-based association tests additionally identified *ROBO2* and *ZNF28* as being associated with suicidal behavior in the meta-analysis across 5 cohorts, among which *ZNF28* was also associated with suicide death. Based on the current analysis, total Liability scale h^2 for suicide death and suicidal attempt are 0.08 and 0.04, respectively. The genetic correlation of suicide death with suicidal attempt and MDD are 0.69 ($p = 1.58 \times 10^{-6}$) and 0.51 (p = 2.92 x 10-6), respectively. Bidirectional Generalised Summary-data-based Mendelian Randomisation (GSMR) analysis suggests that suicidal attempt and suicide death are both bi-directionally causal for MDD. In summary, three genome wide significant findings were identified in this study and immune-related biological pathways have been implicated by gene-set based analysis.

PrgmNr 3035 - Heterozygous Loss-of-Function Variants in TBCK Cause a Mild Neurologic Syndrome in Humans and Mice

View session detail

Author Block: **A. Diaz-Rosado**[1,2], A. Black[1], D. Nair[1], S. Murali[3], E. J. Bhoj[4]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Univ. of Pennsylvania, Phialdelphia, PA, [3]Univ. of Pennsylvania, Philadelphia, PA, [4]Philadelphia, PA

Disclosure Block: **A. Diaz-Rosado:** None.

TBC1 domain-containing Kinase (TBCK)-related encephalopathy, is a rare pediatric neurodegeneration disorder with no current treatments or therapies. Recessive homozygous loss-of-function mutations in this gene (*TBCK*) cause a wide spectrum of pathologies that include brain atrophy, seizures, hypotonia, respiratory failure and intellectual disability. However, although these pathologies are usually seen in homozygous patients, we here describe, for the first time, a milder undescribed phenotype that is seen in human TBCK LOF heterozygotes (TBCK-/+). Out of family testimonials, our group also found that in some of these individuals, the processing and execution of motoric functions was also disrupted (*apraxia*). Therefore, to test the possibility of a behavioral and molecular phenotype, we decided to employ our heterozygous mouse model (C57B/6J; TBCK-/+) to address this question. Both of our behavioral and molecular data suggest the presence of a mild neurologic syndrome that affects both the behavior and motor output of animals, while in humans, these results, concomitantly with our molecular data, have also revealed a metabolic phenotype that affects the levels of different markers like pAKT and pS6, and TBCK itself. Altogether, these results pinpoint the presence of a mild syndrome that not only has an impact upon heterozygous humans, but that can also have repercussions upon the motor dynamism of mice.

PrgmNr 3036 - Identification of a Novel *CNTNAP2*Variant in a Consanguineous Pakistani Family with Epilepsy

View session detail

Author Block: **K. Mattison**[1], N. Badshah[2], P. Chopra[3], H. R. Johnston[4], S. Ahmad[2], M. E. Zwick[4], A. P. Escayg[4]; [1]Dept. of Human Genetics, Emory Univ Sch. of Med., Atlanta, GA, [2]Inst. of Biotechnology and Genetic Engineering, Univ. of Agriculture Peshawar, Peshawar, Pakistan, [3]Emory Univ, Atlanta, GA, [4]Emory Univ Sch. of Med., Atlanta, GA

Disclosure Block: **K. Mattison:** None.

We performed whole-genome sequencing on two Pakistani brothers from a consanguineous pedigree of Afridi tribal heritage. The two brothers presented with epilepsy, intellectual disability, and autism spectrum disorder. Through WGS we identified approximately 80,000 variants within shared regions of homozygosity between the two brothers. Of these 80,000 variants, 615 had a minor allele frequency â¤ 0.001 and 21 of those variants had CADD scores â¥ 15. Four homozygous, exonic variants were identified in both affected brothers: *PDZD7* (c.1348_1350delGAG, p.Glu450del), *ALG6* (c.1033G>C, p.Glu345Gln), *RBM20* (c.1587C>G, p.Ser529Arg), and *CNTNAP2* (c.785G>A, p.Gly228Arg). We performed Sanger sequencing of these variants in the parents and two unaffected siblings. The *ALG6* variant was homozygous in one unaffected family member, indicating that it is unlikely to pathogenic. The *PDZD7, RBM20,* and *CNTNAP2* variants were found to be homozygous only in the affected brothers, consistent with the expected recessive mode of inheritance. Pathogenic variants in *PDZD7* and *RBM20* are associated with autosomal recessive non-syndromic hearing loss and autosomal dominant dilated cardiomyopathy, respectively, suggesting that these variants are unlikely to contribute to the neurological clinical presentation in the affected brothers. The clinical presentation of the affected brothers is consistent with that of previously reported patients with homozygous *CNTNAP2* variants, suggesting that the p.Gly228Arg change in *CNTNAP2* is likely causative. This is the first study on the genetic etiology of epilepsy within the Afridi tribe of Pakistan.

PrgmNr 3037 - Impaired *SNAPC4*function leads to global reduction of canonical splicing events and is associated with a disorder characterized by progressive spasticity, developmental delay, and speech dysarthria

Med., Houston, TX, [9]Baylor Col Med, Houston, TX, [10]NIH, Bethesda, MD, [11]NIH, Bethesda, MD, [12]Office of the Clinical Director, Bethesda, MD, [13]NHGRI (NIH), Bethesda, MD

Disclosure Block: **F.G. Frost:** None.

Introduction: Small nuclear RNAs (snRNAs) play integral roles in RNA splicing and are critical for cell function. Transcription of snRNAs is initiated by the small nuclear RNA activating protein complex (SNAPc), which binds to a promoter element upstream of snRNA genes and recruits transcriptional machinery. Zebrafish models that impair transcription of SNAPc subunits led to severe developmental defects or even embryonic lethality, demonstrating the critical role of the complex in development. Here we present 4 individuals from 3 families who presented with progressive spasticity, developmental delay, and dysarthria, each with bi-allelic deleterious variants in *SNAPC4*, encoding the SNAPc subunit.

Methods: Detailed clinical and biochemical phenotyping was performed on all probands. Exome and genome sequencing of the probands and their families was performed to identify candidate variants, which were validated by Sanger sequencing. Computational modelling was used to assess the spatial location of variants within the DNA-binding domain. The functional impact of *SNAPC4* variants were assessed using patient-derived fibroblasts and a HeLa *SNAPC4* deficient cell line, generated using CRISPR-Cas9 technology. SNAPc function was assessed by measuring relative snRNA expression with RT-qPCR, and global splicing function was evaluated using RNA-sequencing.**Results:** Four individuals with progressive spasticity, developmental delay, and dysarthria harbored bi-allelic, predicted pathogenic *SNAPC4* variants that segregated with disease. Two variants were in canonical splice sites, that were shown to introduce premature stop codons by cDNA sequencing of patient-derived fibroblasts. Three of the four missense variants are located in the DNA-binding domain of *SNAPC4*, demonstrated by protein modeling to be located on surface residues. Patient fibroblasts showed decreased expression of both *SNAPC4* mRNA and SNAPC4 protein, as well as altered expression of the *RNU1*, *RNU2*, *RNU4*, *RNU5*, *RNU6*, *RNU12*, and *RN7SK* snRNAs. Deficiency of *SNAPC4* in HeLa cells led to a broad decrease in snRNA expression and a decrease in the number of canonical alternative splicing events.**Conclusion**: Our work supports the role of *SNAPC4* in snRNA transcription and splicing in mammalian cells. The common clinical phenotypes and the alteration of *SNAPC4* and snRNA expression in patient cells support mutations in *SNAPC4* as a plausible explanation for disease in our cohort. Identification of additional affected individuals with *SNAPC4* mutations will be required to confirm the genotype-phenotype connection and future experiments will elucidate the underlying mechanisms of disease.

PrgmNr 3038 - Neurofilament light chain in cerebrospinal fluid as a potential novel biomarker in evaluating both clinical severity and therapeutic response in Niemann-Pick Disease, type C1

View session detail

Author Block: **N. Agrawal**[1], N. Farhat[2], A. Dang Do[2], C. Xiao[1], E. M. Berry-Kravis[3], N. Sinaii[4], R. Masvekar[5], B. Bielekova[5], F. D. Porter[6]; [1]NHGRI, NIH, Bethesda, MD, [2]NICHD, NIH, Bethesda, MD, [3]Rush Univ Med Ctr, Chicago, IL, [4]BCES, CC, NIH, Bethesda, MD, [5]NIAID, NIH, Bethesda, MD, [6]NIH, Bethesda, MD

Disclosure Block: **N. Agrawal:** None.

Niemann-Pick Disease, type C (NPC) is caused by recessive pathogenic variants in either NPC1 or NPC2 that lead to intracellular accumulation of glycosphingolipids and cholesterol. Patients with NPC can present with liver disease as neonates or with neurodegeneration at any age. There are currently no biomarkers that correlate well with disease severity and progression, thus monitoring is done using a clinical severity scale [NPC Neurological Severity Score (NSS)]. Neurofilament light chain (NfL) is a structural protein that exists only in neuronal axons and is currently being investigated in a number of neurodegenerative diseases as a potential biomarker, as it is released into cerebrospinal fluid (CSF) as a consequence of neuronal damage. In this study, CSF NfL levels were measured in 116 NPC1 participants. Both cross-sectional and longitudinal data were obtained. Samples obtained from 30 pediatric patients without NPC1 were used as controls. We found that the age-adjusted level of CSF NfL was significantly elevated at baseline (1198.49 Â±1553.11 pg/ml) compared to controls (374.09 Â±633.13; ps=0.28, 95% CI 0.10-0.44, p=0.003). When looking individually at five major domains included in the NSS, worsening symptoms in four of five domains (ambulation, fine motor, speech, swallowing) specifically correlated with increased CSF NfL levels. There was no correlation of CSF NfL levels with the cognition domain. Many of the patients in the study were also being treated off-label with miglustat or with the investigational drug 2-hydroxypropyl-Î²-cyclodextrin (HPÎ²CD, VTS-270). No correlation was observed between CSF NfL levels and treatment with intrathecal HPÎ²CD. In contrast, miglustat therapy was associated with significantly decreased CSF NfL levels (p

PrgmNr 3039 - Pre-clinical studies in induced Pluripotent Stem Cell (iPSC) lines with *SORD* mutations linked to a recessive neuropathy

View session detail

Author Block: **C. Yanick**[1], R. Maciel[1], J. Medina[1], A. P. Rebelo[2], M. Shy[3], S. Zuchner[2], M. Saporta[1]; [1]Univ. of Miami Miller Sch. of Med., Miami, FL, [2]Univ Miami, Miami, FL, [3]Univ. of Iowa, Iowa City, IA
Disclosure Block: **C. Yanick:** None.
Introduction: Recently, mutations in the gene coding for sorbitol dehydrogenase (*SORD*) were associated with a new form of recessive inherited neuropathy. To model this CMT type, we took fibroblast samples from patients and reprogrammed them into induced-Pluripotent Stem Cells (iPSCs). We are using these cells to perform assays to evaluate different therapeutic strategies for SORD related neuropathy. **Methods:** Fibroblasts were transduced using a Sendai Virus Reprogramming kit to express reprogramming factors. Immunocytochemistry for Oct4, NANOG, and SSEA3 was performed to confirm pluripotency of cells. RNA was tested to confirm exogenous genes were no longer present and karyotyping was performed on the iPSC lines. Intracellular sorbitol levels were measured via colorimetric sorbitol kit. Neurofilament Light Chain was measured via ELISA kit. RNA was sequenced by the UM Genomics Core lab. **Results:** Immunocytochemistry (ICC), RNA analysis, Sanger sequencing and karyotyping results showed that we have successfully generated iPSCs from fibroblasts for each of the 3 patients with biallelic *SORD* mutations. We were then able to differentiate these cells into motor neurons in 2D culture to carry out various characterization studies and therapy screenings. We were able to show that the SORD motor neurons show an increase in intracellular sorbitol content when compared to controls, replicating an important disease phenotype. The sorbitol content of patient motor neurons were roughly 2-fold higher than that of patient fibroblasts. Initial measurements of supernatant NFL levels show no increase between control and patient motor neurons. We are currently studying the impact of metabolic stress on the SORD motor neurons, their susceptibility to neurodegeneration and potential transcriptomic dysregulation. Our future plans include performing rescue experiments with various therapeutic strategies using both 2D and 3D cultures. These ongoing efforts include genetic therapies such as ASOs as well as using small molecules to target pathways involving sorbitol metabolism. **Conclusions:** Our results show that we were able to reprogram patient fibroblasts into iPSC lines and then differentiate those lines into motor neurons, that replicate disease phenotype, for our ongoing studies. The ongoing pre-clinical studies of small molecule and genetic therapies will demonstrate target engagement, biomarker availability and lead to translational applications in clinical trials.

PrgmNr 3040 - Truncating variants in the *SHANK1* gene are associated with a spectrum of neurodevelopmental disorders

Disclosure Block: **H.J. May:** None.

Purpose: In this study, we aimed to characterize the clinical phenotype of a *SHANK1*-related disorder and define the functional consequences of *SHANK1* truncating variants.

Methods: Exome sequencing (ES) was performed for six individuals who presented with neurodevelopmental disorders. Individuals were ascertained with the use of GeneMatcher and Database of Chromosomal Imbalance and Phenotype in Humans Using Ensembl Resources (DECIPHER). We evaluated potential nonsense mediated decay (NMD) of two variants by making knock-in cell lines of endogenous truncated SHANK1, and expressed the truncated *SHANK1* cDNA in HEK293 cells and cultured hippocampal neurons to examine the proteins.

Results: ES detected *de novo* truncating variants in *SHANK1* in six individuals. Evaluation of NMD resulted in stable transcripts, and the truncated SHANK1 completely lost binding with Homer1, a linker protein that binds to the C-terminus of SHANK1. These variants may disrupt protein-protein networks in dendritic spines. Dispersed localization of the truncated SHANK1 variants within the spine and dendritic shaft was also observed when expressed in neurons, indicating impaired synaptic localization of truncated SHANK1.

Conclusion: This report expands the clinical spectrum of individuals with truncating *SHANK1* variants and describes the impact these variants may have on the pathophysiology of neurodevelopmental disorders.

PrgmNr 3041 - Using*Drosophila melanogaster*to identify loci modifying Coffin-Siris syndrome mutations

View session detail

Author Block: **R. A. MacPherson**, T. F. C. Mackay, R. R. H. Anholt; Clemson Univ., Greenwood, SC
Disclosure Block: **R.A. MacPherson:** None.
Coffin-Siris syndrome (CSS) and Nicolaides-Baraitser syndrome (NCBRS) are rare disorders of chromatin modification associated with alterations of subunits within the highly conserved mammalian SWI/SNF complex. CSS and NCBRS patients typically present with intellectual disability, facial and digit abnormalities, seizures, and hypotonia. However, phenotypic presentation and disease severity varies within and across CSS- and NCBRS-associated mutations; individuals with identical genetic alterations do not necessarily present with identical phenotypes. We hypothesize that there are naturally occurring genetic variants segregating in the human population that serve as modifiers of disease severity. Identification of candidate genetic modifiers may lead to insights on the pathogenesis and treatment of CSS, NCBRS, and related disorders, but genome wide association analyses that are used to map genetic variants associated with common human diseases require large sample sizes that are not possible for rare diseases. Using a bipartite *UAS-GAL4* RNA interference system in the model organism *Drosophila melanogaster*, we have developed a CSS/NCBRS fly model and show that flies with reduced expression of CSS-associated fly orthologs exhibit changes in sleep, activity, and sensorimotor integration. We have identified genes co-regulated with CSS-associated fly orthologs that exhibit similar changes in behavior to our CSS fly models, suggesting that these co-regulated genes may serve as plausible candidate genetic modifiers for CSS and NCBRS. We are currently working to identify epistatic genetic interactions between CSS-associated fly orthologs and co-regulated genes.

PrgmNr 3042 - Biochemical consequence of deficient glycan extension in ALG3-CDG

Disclosure Block: **E. Paul Daniel:** None.

ALG3-CDG is a rare Congenital Disorder of Glycosylation (CDG) with clinical phenotype that includes severe neurological manifestations, immune deficiency and skeletal anomalies. The ALG3 enzyme is required to form lipid liked oligosaccharide (LLO)-Man6GlcNAc2 (Man6) from Man5. N-linked glycosylation is critical in aiding protein folding. Two major N-glycan structures, Man5 and Man9 can be transferred en bloc from LLO to nascent proteins, and the extension from LLO-Man5 to LLO-Man9 is the first and fastest Unfolded Protein Response (UPR) upon endoplasmic reticulum (ER) stress. Following glycan extension, UPR directs three pathway specific transducers: IRE1Î±, PERK and ATP6, which regulate downstream translation repression and activation of ER chaperones such as BiP (GRP78) and GRP94, to aide protein folding. The misfolded proteins bearing Man5 and Man9 are reported to be effectively degraded by ERAD mechanism.

We have used ALG3-CDG patientsâ□□ fibroblasts to measure the expression of UPR and ERAD markers by RT-PCR. We observed 1 to 2-fold increase in basal XBP1 splicing, along with 1-2 fold increase of the gene expression of downstream UPR reporters in ALG3-CDG cells, including GRP94, GRP78, OS9 and EDEM1, consistent with constitutional/chronic activation of UPR. When ER stress was induced by 1 mM DTT, 2-3 fold increase in GRP94 and BiP expression was detected compared with controls. Further, by ddVenus assay that uses an engineered misfolded fluorescent glycoprotein as a reporter, we found that ERAD activity was mildly increased in these cells. We show that N-linked Man3-4 released from cellular glycoproteins, are markedly increased while Man5 is not increased despite the accumulation of LLO-Man5 in ALG3-CDG cells. Similarly, the abundance of Man0-4 GlcNAc2 (Man0-4) is increased in ALG3-CDG plasma samples (n=10). In particular, increased N-linked Man3-4 was detected on purified plasma IgG, suggesting an association between altered glycosylation and chronic UPR and immune deficiency in these patients.

In summary, we provide evidence that there is constitutional activation of UPR in ALG3-CDG cells through IRE1Î± pathway. When ER stress is induced in vitro, both UPR and ERAD increase in these cells. N-linked Man3-4 are increased on both cellular proteins and secreted proteins in plasma, which can serve as important ALG3-CDG biomarkers.

PrgmNr 3043 - Bone cell functions in *PPIB* knock-out mouse model for type IX osteogenesis imperfecta are distinct from classical dominant OI

View session detail

Author Block: **Y. Liu**[1], T. Hefferan[2], N. Fratzl-Zelman[3], J. Marini[1]; [1]Section on Heritable Disorders of Bone & Extracellular Matrix, Natl. Inst. of Child Hlth.and Human Dev., NIH, Bethesda, MD, [2]Biomaterials and Histomorphometry Core Lab., Mayo Clinic, Rochester, MN, [3]Ludwig Boltzmann Inst. of Osteology at the Hanusch Hosp. of OEGK and AUVA Trauma Ctr. Meidling, 1st Med. Dept., Hanusch Hosp., Vienna, Austria
Disclosure Block: **Y. Liu:** None.
Osteogenesis imperfecta (OI) is a genetically heterogeneous bone fragility disorder. While most OI cases are caused by dominant mutations in type I collagen, other cases are caused by recessive defects in genes encoding collagen-interacting proteins. Cyclophilin B (CyPB), encoded by *Ppib*, is an ER-localized peptidyl-prolyl cis-trans isomerase (PPIase). It functions independently as the major PPIase catalyzing collagen folding. CyPB is also a component of the procollagen prolyl 3-hydroxylation (P3H1/CRTAP/CyPB). Mutations in *Ppib* cause recessive type IX OI, with a lethal to severe phenotype. We reported previously that *Ppib*$^{-/-}$ mice have abnormal type I collagen post-translational modification and crosslinks. Unlike other causal genes for OI, *Ppib* is expressed in both bone-forming osteoblasts and bone-resorbing osteoclasts. This study focuses on *Ppib*$^{-/-}$ bone cell functions, utilizing histomorphometry and qBEI analysis of 2-month male femoral tissue, RT-PCR and alizarin red staining of differentiated calvarial osteoblasts, and in vitro osteoclast differentiation.
Histomorphometry of femora from *Ppib*$^{-/-}$ mice reveals markedly reduced cortical bone width (pPpib$^{-/-}$ 5.8Â±1.9%, WT 10.4Â±2.7%; pPpib$^{-/-}$ osteoblast number and surface are significantly decreased (pPpib$^{-/-}$ KO mice have reduced osteoid volume (69%, pn vitro osteoblast mineral deposition is increased (Alizarin red staining, pSost, Mepe, Phex, Dmp1, vs WT. Furthermore, qBEI analysis of bone tissue yielded bone mineralization density distribution with increased CaMean, CaPeak (both pin vitro osteoclast differentiation.
Cyclophilin B/*Ppib* KO mice, modelling type IX OI, have bone cell functions distinct from classical dominant OI with collagen defects. *Ppib* KO bone has a low turnover cellular pattern with decreased osteoblast number and bone formation, increased mineralization, and normal osteoclast numbers.

PrgmNr 3044 - Distribution and frequency of the variant *rs10738445* of *BNC2* gene associated to Idiopathic Scoliosis in Puerto Rico

View session detail

Author Block: **N. GarcÃa TubÃ©ns**, E. G. RamÃrez Aponte, J. C. MartÃnez Cruzado; Univ. of Puerto Rico- MayagÃ¼ez Campus, MayagÃ¼ez, Puerto Rico
Disclosure Block: **N. GarcÃa TubÃ©ns:** None.
Idiopathic Scoliosis is a deformity of the spine, due to the growth of the person, shaped like an â□□Câ□□ or â□□Sâ□□; at a minimum Cobb angle of 10Â°. Recent studies have found a susceptibility allele rs10738445 increases the expression of the BNC2 gene especially in homozygous for the haplotype CC. The BNC2 protein is present in the myoblasts and uterus, spinal cord, bone, and cartilage tissue. Thus, suggesting that there is a relationship between the increase in the gene and the etiology of Idiopathic Scoliosis. Other findings suggest a functional role for BNC2 in the development and progression of spinal deformity in patients with Idiopathic Scoliosis. The SNP rs10738445 of the BNC2 gene appeared in the genomic study 1000 Genomes Project, and Puerto Rico showed a genotypic frequency of 0.53 for the haplotype CC. Using rt-PCR, 622 samples of the general population of Puerto Rico were genotyped for the SNP rs10738445. In this study, we obtained that the genotype CC of rs10738445 has a genotipic frequency of 0.059 in Puerto Rico, with a higher prevalence in the western area. The differences in genotype frequencies could be the result of the bias in the sampling of the Puerto Ricans that participated in the 1000 Genomes Project. We are planning to genotype patients diagnosed with Idiopathic Scoliosis and other spinal deformities for this variant in Puerto Rico.

PrgmNr 3045 - GPC6 haploinsufficiency in patients with skeletal anomalies

View session detail

Author Block: **N. Vasli**[1], A. EDWARD[1], M. J. Nowaczyk[2], C. Li[3], M. KOZENKO[4], D. J. Stavropoulos[5], E. McCready[2]; [1]Dept. of Pathology and Molecular Med., McMaster Univ., Hamilton, ON, Canada, [2]McMaster Univ, Hamilton, ON, Canada, [3]McMaster Children's Hosp, Hamilton, ON, Canada, [4]Dept. of Pediatrics, McMaster Univ., Hamilton, ON, Canada, [5]Hosp for Sick Children, Toronto, ON, Canada
Disclosure Block: **N. Vasli:** None.
Introduction Glypicans are a family of proteoglycans that are covalently bound to the plasma membrane by a glycosylphosphatidylinositol (GPI)-anchor. The mammalian genome consists of six glypicans (*GPC1 - GPC6*). Mutational analysis studies have revealed the role of GPCs in some congenital malformations involving bone growth and heart pattern formation (Fico and Dono, 2005). Biallelic loss-of-function mutations in *GPC6* which altered growth factor signaling and morphogen gradients leading to long bone growth retardation have been reported in patients with autosomal recessive omodysplasia (OMOD1) which is characterized by short stature, craniofacial dysmorphism, and variable developmental delay (Campos-Xavier et al., 2009). **Methods** In this study, a cohort of patients with heterozygous 13q31.3 microdeletions were examined. When DNA was available, compound heterozygosity for *GPC6* pathogenic variants was ruled out by Sanger sequencing of the *GPC6* exonic regions. The clinical indications for chromosome microarray testing were examined in each cohort patient. When available, clinical chart reviews were also performed. Associated clinical features from cohort patients were compared to those reported from previously published cases. **Results** The patients in this cohort had overlapping phenotypes. While skeletal anomalies such as short stature, scoliosis, and short fingers were common among the examined individuals, dysmorphic facies, neurodevelopmental and cardiac abnormalities were also apparent in several patients. Sanger sequencing did not identify pathogenic *GPC6* variants on the retained allele, suggesting that these clinical features are not the result of autosomal recessive omodysplasia. **Discussion** Despite the characterization of autosomal recessive *GPC6* mutations causing omodysplasia, our findings suggest that heterozygous *GPC6* deletions may also be associated with an increased risk of clinical phenotypes, albeit milder than those reported in patients with biallelic variants. These results suggest *GPC6* haploinsufficiency may represent a novel syndrome, characterized by short stature, skeletal anomalies, and variable neurodevelopmental and cardiac abnormalities.

PrgmNr 3046 - Molecular test of Paget's disease of bone in families not linked to *SQSTM1* gene mutations

Purpose: Paget's disease of bone (PDB) is a focal metabolic bone disorder characterized by an increased bone remodeling. Fifteen to 40% of PDB patients have a familial form with an autosomal dominant inheritance. Disease-causing mutations of the *SQSTM1* gene have been linked to PDB in about 40% of families whereas genes linked to the remaining families are unknown. Several single nucleotide polymorphisms (SNPs) have been associated with PDB in unrelated patient non-carriers of a *SQSTM1* mutation. The current clinical practice guidelines still recommend to measure total serum alkaline phosphatase (sALP) for PDB screening. In unrelated individual non-carriers of *SQSTM1* mutations, we previously developed a genetic test combining male sex with five genetic markers (rs499345, rs5742915, rs2458413, rs3018362, rs2234968), giving rise to an area under the curve (AUC) for PDB phenotype of 0.73 [0.69; 0.77]. A combination of male sex with total calcium corrected for albumin and Procollagen type I N-terminal propeptide (P1NP), had an AUC of 0.82 [0.73; 0.92]. Combining both genetic and biochemical tests increased the AUC to 0.89 [0.83; 0.95]. Objective: This study aimed at testing these genetic and/or biochemical tests of PDB, in families not linked to *SQSTM1* mutations with disease-causing genes yet unknown. Methods: We genotyped the 5 SNPs cited above and measured calcium corrected for albumin, P1NP in 181 relatives, with PDB or not, from 19 PDB families not linked to *SQSTM1* mutations. Bivariate and multivariate logistic regression models adjusted for sex were fitted to search for a molecular test that could best detect PDB in these families. A classification table was generated to establish a cut-off point for continuous variables. Results: Logistic regression estimates of our previous molecular test gave rise to a high sensitivity of 78%, 97% and 88% for the genetic, biochemical and combined test but the specificity was very low, 35%, 11% and 21%, respectively. We then generated in these families new logistic regression estimates but on the same parameters as mentioned above, for the genetic test giving rise to an AUC of 0.65 [0.55; 0.75], for the biochemical test with an AUC of 0.84 [0.74; 0.94], and for the combination test with an AUC of 0.89 [0.82; 0.96], the latter having a sensitivity of 96% and specificity of 57%. The best predictor was the P1NP. Conclusion: In PDB families not linked to *SQSTM1* mutations, the estimates of our previous molecular test gave rise to a poor specificity. Using new estimates, our genetic test was less likely to predict PDB in these families than our previous test but the biochemical and combined tests have similar predictive abilities than our former test.

PrgmNr 3047 - Neonatal presentation of Methylmalonic Acidemia (MMA) with only a single heterozygous mutation in MUT

View session detail

Author Block: **M. Racobaldo**[1], P. Morelli[2], T. Wiseman[1], C. Gordillo-Casero[1], K. Spence[1], A. Sanchez-Valle[3]; [1]Univ. of South Florida, Tampa, FL, [2]Florida State Univ. Coll. of Med., Tallahassee, FL, [3]Univeristy of South Florida, Tampa, FL

Disclosure Block: **M. Racobaldo:** None.

We present a female patient with a single missense mutation in the MUT gene involved in the pathogenesis of Methylmalonic Acidemia (MMA). This report will highlight the importance of clinical diagnosis in the absence of underlying molecular diagnosis and genetic testing in preconception and family planning. MMA is an inborn error of metabolism caused by a deficiency or absence of the enzyme methylmalonyl-CoA mutase (MCM), which is dependent on cobalamin. MCM is required in the breakdown of certain amino acids as well as odd chain fatty acids. MMA belongs to a group of conditions called organic acid disorders where there is a build-up of organic acids in the body that can be toxic when not treated. The effects of MMA usually appear in early infancy and can include vomiting, dehydration, hypotonia, developmental delay, lethargy, hepatomegaly, and failure to thrive. Long-term complications can include feeding problems, intellectual disability, chronic kidney disease, and pancreatitis.Our patient is a 10 months old female who presented to the Emergency Department at day of life 3 for tachypnea and decreased intake and was admitted to the Neonatal Intensive Care Unit for hypovolemic shock and severe metabolic acidosis. At 34 hours of life, her serum ammonia level was 932.5 umol/L (reference range T, p.Gly717Val missense variant results in a loss of function of the enzyme MCM. This mutation is associated with subtype mut(-), indicating partial loss of enzymatic function and B12 responsiveness; This patient has thus continued hydroxycobalamin injections. At her at clinic visit 8 months old, her weight was in the 35th percentile and methylmalonic acid level was 89,600 nmol/L (normal 87-318 nmol/L). She has developmental delays. MMA is an autosomal recessive disease known to be caused by homozygous or compound heterozygous mutations in the MUT gene. Only one mutation was found in this patient; It is assumed that another unknown variant is present given her disease phenotype. Her parents are currently pregnant and aware of the limitations of testing without knowing this second variant. The literature shows that more contributing mutations for MMA have been identified [Forny et al 2014]; our patient is evidence that there is more to be done.

PrgmNr 3049 - Prevalence and Type of Gastrointestinal Symptoms in the Adult Skeletal Dysplasia Population

View session detail

Author Block: **E. M. Carter**, C. L. Raggio, H. LoTurco, D. McInerney; Hosp. for Special Surgery, New York, NY
Disclosure Block: **E.M. Carter:** None.
Skeletal dysplasias are a heterogeneous group of >450 genetic disorders that affect the size and shape of the skull, trunk, and extremities to varying degrees, and are frequently associated with dwarfism. Clinical observations and patient-reported concerns indicate that gastrointestinal (GI) manifestations are an issue for this population, but quantitative information regarding prevalence and severity of GI symptoms is limited. We examined the frequency and characteristics of GI symptoms in adults with skeletal dysplasias by reviewing their responses to a self-administered questionnaire that measures perceived severity of GI symptoms, the Gastrointestinal Symptom Rating Scale (GSRS). This IRB-approved retrospective review included GSRS responses from 101 adults with a clinical and/or genetic skeletal dysplasia diagnosis. Participant demographics, medication history, and ambulatory status were collected from medical records. Responses from 73 females, 27 males, and 1 transgender man were included. The most common skeletal dysplasias were osteogenesis imperfecta (OI, n=51, 50.5%) and achondroplasia (n=13, 12.9%). Average age was 41.5Â±14 yrs, average height was 136.6Â±22.1 cm, average weight was 58.3Â±20.1 kg, and average BMI was 31.57Â±9.8 kg/m^2. Fifty-five (54.4%) ambulated independently, 23 (22.8%) used an assistive device, and 23 (22.8%) were wheelchair-bound or non-ambulatory. Participants took an average of 3.23Â±2.80 medications, most commonly ibuprofen (n=20, 19.8%) and acetaminophen (n=18, 17.8%). Compared to published GSRS reference data, our cohort scored higher on reflux, diarrhea, and total scores, and lower on abdominal pain and indigestion scores; none reached statistical significance. Though OI respondents had more severe symptoms across all domains, only reflux was significant (p=0.009). Achondroplasia scores were higher for indigestion, constipation, diarrhea, and total scores, and lower on abdominal pain and reflex scores than the general population; only diarrhea was significant (p=0.034). There were no statistically significant differences in any of the domain or total GSRS scores across ambulatory status groups. Height positively correlated with abdominal pain domain score (p=0.033). The number of medications positively correlated with all GSRS scores (p=0.013). Adults with skeletal dysplasias do not report more severe GI symptoms than the general population. Future studies should include larger numbers of individuals with specific skeletal dysplasia diagnoses and investigate the clinical significance between GI symptoms and other quality of life measures in adults with skeletal dysplasias.

PrgmNr 3050 - RNA-seq identifies novel regulatory variants underlying Glycogen Storage Diseases

View session detail

Author Block: **A. Iyengar**[1], X. Zou[2], S. Clarke[1], J. Dai[1], R. Gibson[1], K. Patterson[3], A. Safi[1], D. S. Bali[4], W. Majoros[5], A. S. Allen[6], T. E. Reddy[1], G. E. Crawford[1], P. Kishnani[4], University of Washington Center for Mendelian Genomics; [1]Duke Univ., Durham, NC, [2]durham, NC, [3]Univ of Washington, Seattle, WA, [4]Duke Univ Med Ctr, Durham, NC, [5]Duke Univ., DURHAM, NC, [6]Duke Univ, Durham, NC
Disclosure Block: **A. Iyengar:** None.
Genetic causes for Glycogen Storage Diseases (GSDs) are often unclear after targeted DNA sequencing despite clear clinical and biochemical diagnoses and known causal genes. This has substantial implications for early therapeutic interventions that could improve prognosis. Genetic testing typically assumes that genetic disease is caused by coding mutations, leading to missed non-coding or regulatory pathogenic variants. We aimed to detect such variants in autosomal recessive GSD IX and IIIa patients with a known pathogenic variant on only one allele. Using whole-genome sequencing and targeted PacBio long-read RNA-seq, we identified a novel non-coding variant and mechanism underlying GSD IX (phosphorylase kinase deficiency) in two siblings. Whereas GSD IX patients typically present with A on one allele of *PHKG2*, but the second pathogenic variant was unknown. RNA-seq confirmed the predicted splice event on transcripts from the 1st allele, and also identified inclusion of a 76bp cryptic exon on transcripts from the 2nd allele. Both splice events caused frameshift and a premature stop codon; however, some transcripts from the 2nd allele remained normal, potentially explaining the siblingsâ higher PhK activity. We hypothesized that the 76bp cryptic exon was caused by a leaky cryptic splice site T>G variant (rs1433965292, MAF=0.00002) ~1kb downstream of exon 6 in *PHKG2*. To test this, we used a CRISPR/Cas9 approach to generate T/T, T/G, and G/G HEK293T cell lines. RT-PCR of the mutant (T/G and G/G) lines amplified both the normal transcript and that containing the cryptic exon. G/G lines showed PHKG2 expression, and T/G lines predominantly expressed the normal transcript. This is consistent with nonsense-mediated decay of only the transcripts containing the cryptic exon. A homozygous mutant G/G line showed 25% PhK activity compared to a wild-type T/T line, and experiments are underway to confirm this effect in several independent clones. Additionally, in a patient with GSD IIIa, characterized by debranching enzyme (AGL) deficiency, PacBio RNA-seq identified exon 23 skipping in 32% of *AGL* transcripts. This causes a premature stop codon in exon 24/35. Targeted long-read Oxford Nanopore DNA sequencing identified a 1.5kb deletion including a portion of exon 23, which likely explains exon 23 skipping. Further characterization of these variants and their effects will provide insight into the utility of RNA-seq as a diagnostic tool in the genetics clinic.

PrgmNr 3051 - Spectrum of Germline and Somatic Mitochondrial DNA Variants in Tuberous Sclerosis Complex

View session detail

Author Block: **K. GIANNIKOU**[1], K. Martin[2], A. Abdel-Azim[1], T. R. Hougard[3], Y. Tang[3], J. MacKeigan[2], D. J. Kwiatkowski[1], H. C. Lam[3]; [1]Cancer Genetics Lab., Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, [2]Coll. of Human Med., Michigan State Univ., East Lansing, MI, [3]Div. of Pulmonary and Critical Care Med., Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA
Disclosure Block: **K. Giannikou:** None.
Background: Tuberous Sclerosis Complex (TSC) is an autosomal dominant genetic disease causing multisystem growth of hamartomatous tumors in brain, heart, skin, lung and kidney and it is known to be due to genetic alterations in either *TSC1 or TSC2*. While the nuclear genome has extensively been studied in TSC, there is limited knowledge regarding the role of mitochondrial DNA (mtDNA) in TSC pathogenesis. **Aim:** To examine the prevalence and spectrum of mtDNA variants in TSC patients and correlate them with clinical features and disease severity since mtDNA variants may act as a disease modifier contributing to tumor development and the remarkable phenotypic heterogeneity seen in TSC. **Methods:** We analyzed mtDNA from buccal swabs from 102 TSC patients (44 male, 54 female, 4 unknown, median age: 31 years; 11 familial cases) using deep coverage amplicon massively parallel sequencing (median read coverage: 7,349). mtDNA analysis was also performed in 100 TSC related tumors (58 kidney angiomyolipoma, 24 SEGA, 11 cortical tubers, 2 LAM, 5 TSC-RCC) with matching normal sample (n=9) from 70 patients; 80 tumors had exome data available. Alterations in mitochondrial copy number were determined by qPCR in tumor and matching normal. **Results:** A median of 21 non-synonymous mtDNA variants were identified in 102 buccal swabs, with high homoplasmy (median: 99.62% allele frequency) mainly missense of unknown significance. A pathogenic variant (UUR;MT-TL1; m.3243A>G, heteroplasmy 12%) was identified in one male TSC patient. Five VUS small indels with >97% heteroplasmy were identified in five individuals. Large mtDNA deletions were not detected. Analysis of TSC tumors demonstrated similar spectrum of mtDNA variants as seen in buccal swabs. mtDNA variants did not correlate with any pathological TSC features. qPCR analysis did not reveal changes in mitochondrial content between tumors and corresponding normal tissue. **Conclusions:** Our study provides insight into the mtDNA landscape of TSC for first time, demonstrating that mtDNA genome is stable within the tumors analyzed and across different tissues.

PrgmNr 3052 - 7 day-old boy presenting with anuria and electrolyte imbalance: Novel, disease-associated variant identified in *SLC5A1* gene

View session detail

Author Block: **E. Beals**[1], P. Bizargity[1,2]; [1]Donald and Barbara Zucker Sch. of Med. at Hofstra/Northwell, Hempstead, NY, [2]Northwell Hlth., New Hyde Park, NY
Disclosure Block: **E. Beals:** None.
The solute-like carrier 5a1 (SLC5A1) gene provides instructions for producing a protein called sodium/glucose cotransporter protein 1 (SGLT1). The SLC5A1 gene is located on chromosome 22q12.3; loss of function mutations in this gene can cause the intestinal monosaccharide transporter deficiency known as glucose and galactose malabsorption syndrome (GGM, OMIM 606824). This rare genetic disorder presents in infancy with abdominal bloating, life-threatening osmotic diarrhea, and dehydration. Here we present a 7-day-old full-term male weighing 7 lb 15 oz, who was transferred from an outside hospital for 2 days of non-bloody diarrhea, hyperkalemia (6.4 mmol/L), and anuria. The patient had previously been breast-feeding, taking formula well, and stooling daily. He was born at term to nonconsanguineous parents and has one healthy older sibling. On initial exam he was lethargic with a soft, nondistended abdomen and no dysmorphic features. His laboratory work up revealed hypoglycemia and a high anion gap metabolic acidosis with pH 7.17, pCO2 31 mmHg, bicarbonate 12 mmol/L, and an anion gap of 18 mmol/L. His lactic acid was 3.1 mmol/L. He was hypernatremic to 183 mmol/L, his blood urea nitrogen was 116 mg/dl, and his creatinine was 4.3 mg/dl. Metabolic work up including plasma amino acids, urine organic acids, and acylcarnitine profile were nondiagnostic. A renal ultrasound showed mildly echogenic kidneys and a voiding cystourethrogram demonstrated normal anatomy. The patient received peritoneal dialysis, electrolyte repletion, airway management with intubation, and total parenteral nutrition. Once he recovered from acute kidney failure, he was extubated and started on oral feeds. The patient had intractable diarrhea with every feeding and his stool was found to be elevated in reducing substances. Endoscopic biopsy of his upper duodenum showed normal histology. Rapid whole exome sequencing revealed a novel, homozygous variant (c.826 T>C, p. W276R) in the SLC5A1 gene, classified as likely pathogenic. Both parents are heterozygous carriers. The patient was started on a carbohydrate-free, fructose-based formula, after which his condition stabilized and he began to gain weight. An estimated 300 individuals are affected by pathogenic mutations in the SLC5A1 gene, with a total of 56 mutations reported. Most patients are the product of consanguinity and present at birth with diarrhea and dehydration. To our knowledge, this variant has not been previously reported as pathogenic nor benign and has not been observed in large population cohorts. In silico analysis supports that this missense variant has deleterious effects on protein structure/function.

PrgmNr 3053 - Ascertainment context is crucial: The penetrance of age-dependent monogenic disease variants depends on ascertainment context

View session detail

Author Block: **U. T. Mirshahi**[1], K. Colclough[2], C. F. Wright[3], A. R. Wood[3], R. Beaumont[3], J. Tyrrell[3], T. Laver[3], R. Stahl[1], A. M. Golden[1], J. Goehringer[1], T. F. Frayling[3], A. Disclosure Block: **U.T. Mirshahi:** None.

BACKGROUND: Accurate penetrance of monogenic disorders is often unknown due to a phenotype-first approach to genetic testing. Here, we use a genotype-first approach in four large cohorts with different ascertainment contexts to accurately estimate penetrance of the three commonest causes of monogenic diabetes, Maturity Onset Diabetes of the Young (MODY). We contrast *HNF1A*-MODY / *HNF4A*-MODY which causes an age-related progressive diabetes and *GCK*-MODY, which causes life-long mild hyperglycemia. **METHODS**: We analyzed clinical and genetic sequencing data from four different cohorts: 1742 probands referred for clinical MODY testing; 2194 family members of the MODY probands; 132,194 individuals from a US healthcare-based cohort; and 198,748 individuals from a UK population-based cohort. **RESULTS**: Age-related penetrance of diabetes for pathogenic variants in *HNF1A* and *HNF4A* was substantially lower in the clinically unselected cohorts compared to clinically referred probands (ranging from 32% to 98% at age 40yrs for *HNF1A,* and 21% to 99% for *HNF4A*). The background rate of diabetes, but not clinical features or variant type, explained the reduced penetrance in the unselected cohorts. In contrast, penetrance of mild hyperglycemia for pathogenic *GCK* variants was similarly high across cohorts (ranging from 89 to 97%) despite substantial variation in the background rates of diabetes. **CONCLUSIONS**: Ascertainment context is crucial when interpreting the consequences of monogenic variants for age-related variably penetrant disorders. This finding has important implications for opportunistic screening during genomic testing.

PrgmNr 3054 - Challenges in Classifying Clinically Relevant Germline *RTEL1* Variants

View session detail

Author Block: **A. S. Thompson**, M. Niewisch, L. J. McReynolds, S. A. Savage; Natl. Cancer Inst., Rockville, MD
Disclosure Block: **A.S. Thompson:** None.
RTEL1 (regulator of telomere elongation helicase 1) is a DNA helicase essential for DNA replication, recombination, and telomere homeostasis. Common intronic *RTEL1* SNPs are associated with brain tumor susceptibility whereas rare coding variants cause telomere biology disorders (TBDs). TBD-associated *RTEL1* variants have been reported in dyskeratosis congenita (DC), Hoyeraal-Hreidarsson syndrome (HH), and familial pulmonary fibrosis and are inherited in autosomal dominant (AD) and autosomal recessive (AR) patterns. Bioinformatic predictions of deleteriousness are often required for *RTEL1* variants because of their rarity and lack of high throughput assays. This results in most variants being classified as variants of uncertain significance (VUS).
Clinical presentations and survival (Kaplan-Meier estimates) were compared between patients with AD or AR *RTEL1* variants (44 affected individuals from 14 families) participating in the National Cancer Instituteâ□□s IRB-approved study of Inherited Bone Marrow Failure Syndromes (NCT00027274). We also performed a comprehensive literature review of disease associated *RTEL1* variants and of rare variants (MAFPatients with AR *RTEL1* variants showed significantly lower overall survival than those with AD *RTEL1* variants (p=0.00048). Of 246 variants in 52 publications, 91 (37%) LP *RTEL1* variants were identified. 42 (17%) disease-associated variants were classified as LB. The remaining disease-associated variants (113, 46%) in the literature were classified as VUS due to MAF >1%, limited clinical data, and/or insufficient bioinformatic predictions. Loss of function (LOF) variants accounted for ~2% of rare *RTEL1* variants present in gnomAD.
Our results suggest that the frequency of rare LOF *RTEL1* variants in the general population may be more common than expected. Patients with AD *RTEL1* genotypes show significantly better survival than AR *RTEL1* genotypes. Functional studies are required to classify the majority of novel disease-associated variants to further understand disease etiology.

PrgmNr 3055 - Colorblindness gene implicated for myopia in highly aggregated Pennsylvania Amish families

View session detail

Author Block: **A. M. Musolf**[1], D. Stambolian[2], J. E. Bailey-Wilson[3]; [1]NIH, Baltimore, MD, [2]Univ. of Pennsylvania, Philadelphia, PA, [3]NIH/NHGRI, Baltimore, MD
Disclosure Block: **A.M. Musolf:** None.
Family studies offer good power to identify highly penetrant genetic variants that are rare in a population but enriched within a family; such studies have experienced a renaissance with the advent of affordable whole genome sequencing (WGS). Myopia (nearsightedness) has become a major health concern, reaching epidemic proportions in some countries. It is also the second leading cause of blindness worldwide. Although myopia is known to be caused by both environmental and genetic factors, its genetic etiology remains unclear. GWAS studies have identified common variants of low to moderate effect associated with myopia, yet much of the heritability is still missing.
This study uses a family-based approach; we performed WGS on 97 individuals from 7 extended Pennsylvania Amish families with prior evidence of linkage to myopia. Founder populations such as the Amish also allow for utilization of exclusive genomic architecture, like unique haplotypes, to better identify potential risk variants. The Amish also have low exposure to some known environmental myopia risk factors.
We performed genetic linkage analysis on these families assuming an autosomal dominant risk allele with 90% penetrance with no phenocopies. We identified 88 genome-wide significant variants across the families, localized to 4q13.1, 5p15.33, 8q21.3, and 9p24.1; 26 of these localized to the *CNGB3* gene at 8q21.3, including the only two exonic variants, which are predicted damaging. *CNGB3* is an excellent candidate as it is expressed in the eye and is causal for both achromatopsia (total colorblindness) and progressive cone dystrophy. Functional analysis of *CNGB3* is currently planned.

PrgmNr 3056 - Comparative analysis of the contribution of copy number and single nucleotide variants to the pathogenesis of idiopathic hypogonadotropic hypogonadism

View session detail

Author Block: **M. Stamou**[1], H. Brand[2], M. Wang[1], I. Wong[2], L. Plummer[1], M. F. Lippincott[1], R. Balasubramanian[1], M. E. Talkowski[2], S. Seminara[1]; [1]Harvard Reproductive Sci. Ctr., The Reproductive Endocrine Unit and The Endocrine Unit of the Dept. of Med., Massachusetts Gen. Hosp., Boston, MA, [2]Ctr. for Genomic Med., Massachusetts Gen. Hosp.; Dept. of Neurology, Massachusetts Gen. Hosp. and Harvard Med. Sch.; Program in Med. and Population Genetics, Broad Inst. of MIT and Harvard, Boston, MA

Disclosure Block: **M. Stamou:** None.

Introduction: Our group studies Idiopathic Hypogonadotropic Hypogonadism (IHH), a rare form of hypogonadism in which mutations in over 30 genes have been identified as contributing or causing the infertility phenotype. Although identification of single nucleotide variants (SNVs) in these genes has transformed the understanding of the genetics of this condition, the contribution of structural variation to IHH has not been well quantified. In this study, we examined the prevalence of copy number variants (CNVs) in known IHH genes using the worldâ□□s largest cohort of IHH patients. **Methods:** We used exome sequencing (ES) from 1,394 IHH probands to analyze CNVs in 36 known IHH genes using GATK-gCNV, a high sensitivity CNV calling pipeline. We prioritized CNVs with a site frequency Results: A total of 11 IHH genes harbored rare CNVs (size range: 400bp to 9.6 MB) affecting 32/1394 IHH probands (2.3% of the cohort). None of the affected probands carried more than 1 CNV. The CNVs included 24 deletions that disrupted 7 genes (*ANOS1, FGFR1, GNRHR, GNRH1, SEMA3A, TCF12 and NDNF*) and 8 duplications that affected 5 genes (*ANOS1, PROKR2, NSMF, PROP1 and IGSF10*). Half of the deletions detected (12/24) were single gene deletions and the rest were multigenic, including well-known contiguous gene deletion syndromes such as the Xp22.3 contiguous gene deletion syndrome (n= 5). In contrast, most duplications (6/8) encompassed only one single gene. Inheritance was discernible in 10 pedigrees which revealed 4 *de novo* deletions, 5 X-linked recessively inherited deletions and 1 dominantly inherited duplication which did not segregate appropriately. Comparative analysis among the four most prevalent IHH genes (*FGFR1, CHD7, ANOS1* and *GNRHR*) showed that while *ANOS1*, *FGFR1* and *GNRHR* mutational spectrum include both SNVs and CNVs, *CHD7* mutations are exclusively SNVs. **Conclusions:** This comprehensive CNV analysis of known IHH genes in a large IHH cohort reveals only a modest CNV contribution (~2.3%) to IHH pathogenesis. The precise mechanisms through which both deletion and duplication events lead to IHH pathogenesis requires additional investigation. The absence of CNVs in nearly two-thirds of the known IHH genes may relate to strong negative selection at these loci and requires additional follow up evaluation.

PrgmNr 3057 - Density Volumetric Analysis of Cystic Lung Disease in Proteus Syndrome

View session detail

Author Block: **C. Ours**[1], M. Y. Chen[2], J. C. Sapp[1], A. Buser[1], M. Hodges[1], L. G. Biesecker[1]; [1]Natl. Human Genome Res. Inst., Bethesda, MD, [2]Natl. Heart, Lung, and Blood Inst., Bethesda, MD
Disclosure Block: **C. Ours:** None.
Background: Cystic lung disease is the second leading cause of death in Proteus syndrome after venous thromboembolism. This obstructive pulmonary disease is progressive and often complicated by restrictive lung disease secondary to scoliosis and chest wall deformities. Medical management is supportive while surgical approaches such as lobectomy may offer benefit for regionally limited disease. Pulmonary function tests can be helpful to monitor disease progression but have limitations, particularly in younger children. Radiographs and computer-aided diagnostics have been used to quantify other cystic lung diseases such as emphysema and lymphangioleiomyomatosis. We collected computed tomography (CT) images of the lungs to perform density volumetric analysis to quantify cystic lung disease in Proteus syndrome. Methods: Computed tomography images of the lungs were gathered from individuals enrolled on a Natural History Study of Proteus Syndrome (NCT00001403). These included imaging studies performed at the National Institutes of Health Clinical Center and other facilities. Post-operative images were not included. Cystic volumes of the lungs were measured using a computer-aided diagnostic system which algorithmically determines total lung volume and uses an adaptive Hounsfield unit threshold to define cystic volumes. The combined cystic volume was divided by total lung volume to obtain a percentage of cystic volume in the lungs. We defined cystic lung disease as individuals who had greater than 5% cystic volume. A linear mixed-effects model was used to estimate the annual increase in percent of cystic lung in children (0-15 years) and in adolescent and adult individuals (>15 years) with cystic lung disease separately. Results: There were a total of 76 CT imaging studies included from 26 individuals. The median age at earliest imaging was 11.4 years (IQR 10.4-22.7). Serial imaging studies (i.e., two or more) were available from 21 individuals. The median interval between most recent and earliest imaging was 5 years (IQR 2.4-8.4). Cystic lung disease was present in ten individuals (38%). Six individuals with cystic lung disease were less than 15 years old at time of earliest imaging. Four individuals underwent surgical intervention. The annual increase in cystic volume in young children was 6% (95% CI 3.0-9.2%) and in adolescent and adults was 1.1% (95% CI -0.9-2.8%). Conclusion: Cystic lung disease of Proteus syndrome is amenable to quantitation using algorithmic based approaches. Serial measurements demonstrate the progression of cystic volume over time. The rate of progression is greater in children compared to adolescents and adults.

PrgmNr 3058 - Determining the role of Frizzled pathway candidates genes in causing the rare inherited blinding disorder FEVR

View session detail

Author Block: **S. van der Ende**[1], J. M. Robitaille[2], C. R. McMaster[1]; [1]Dalhousie Univ., Halifax, NS, Canada, [2]Dalhousie Univ, Halifax, NS, Canada
Disclosure Block: **S. van der Ende:** None.
Familial exudative vitreoretinopathy (FEVR) is an inherited childhood blinding disorder with an estimated incidence of 1:10,000 affecting approximately 12,500 babies born worldwide per year. The primary cause of FEVR is an inability to vascularize the retina, with vision loss ranging from mild to severe. Secondary complications can occur in a subset of patients; they present unexpectedly and result in irreversible vision loss. Current best practices manage the disease and prevent vision loss, but only if diagnosed before complications arise. A genetic diagnosis is critical for early treatment, however, not all FEVR causative genes are known. Next-generation sequencing was performed on a 126 patient FEVR cohort and variants in known causative genes were identified in 50% of the patients. From the remaining patients, rare *DVL3* variants were identified in 4 separate patients. Effects of the *DVL3* patient-derived variants on known frizzled signalling pathways were investigated using cell based assays. The patient-derived *DVL3* variants were found to affect two different frizzled pathways: the canonical norrin/frizzled4 pathway and the frizzled/Ca2+ pathway. Curiously, the location of the mutations within the DVL3 protein dictates which pathway is affected: the N-terminal half affects norrin/frizzled4 signalling, and the C-terminal half affects the frizzled/Ca2+ signalling pathway. The norrin/frizzled4 pathway is the traditional FEVR mechanism; *DVL3* as a candidate FEVR gene introduces the frizzled/Ca2+ pathway as a new mechanism for FEVR pathogenesis.

PrgmNr 3059 - Diagnostic yield of CNV analysis in primary immunodeficiencies

View session detail

Author Block: **B. Seifert**[1], M. Similuk[1], M. R. Setzer[1], J. Yan[2], M. Kamen[2], C. Jodarski[1], L. Jamal[3], K. Jevtich[2], Y. Yu[1], R. Duncan[1], V. Kuram[1], J. Lack[1], R. Ghosh[1], S. M. Holland[1], L. M. Franco[1], M. A. Walkiewicz[1]; [1]NIH, Bethesda, MD, [2]Natl. Inst. of Allergy and Infectious Diseases, Bethesda, MD, [3]Natl. Inst. of Allergy and Infectious Diseases/ NIH Clinical Ctr. Dept. of Bioethics, Bethesda, MD
Disclosure Block: **B. Seifert:** None.
Background & Rationale: Primary immunodeficiencies (PID) include disorders affecting different aspects of the immune system. While exome sequencing (ES) can provide molecular diagnoses in many individuals with PID, calling of copy number variants (CNVs) in ES is not reliable due to variation in coverage. Therefore, chromosomal microarray analysis (CMA) can increase the diagnostic yield through detection of clinically relevant copy number variants (CNVs) pertaining to immunological phenotypes. Here, we provide the results of CMA in probands enrolled in the National Institute of Allergy and Infectious Diseases (NIAID) Centralized Sequencing Program at the National Institutes of Health.
Methods: Research-based ES was performed on 1,000 study probands. CNVs were evaluated via CMA on a subset of probands with a syndromic clinical presentation or a single high-priority variant identified by sequencing for a recessive condition. CMA was performed with a custom comparative genome hybridization array designed by Agilent Technologies in collaboration with NIAID, with clinical interpretation completed at Baylor Genetics.
Results: Among 1,000 probands undergoing ES, CMA was performed on 376 probands (37.6%). A clinically relevant CNV was detected in 18 probands (4.8%), and 104 probands (27.7%) harbored a CNV unrelated to the clinical phenotype of the patient. Twenty CNVs were detected in the 18 probands with clinically relevant CNVs. Nine of the twenty CNVs (45.0%) involved genes classified by the International Union of Immunological Societies (IUIS) as associated with inborn errors of immunity, of which 2 (10%) were upgraded in classification due to recently published literature evidence. Probands who received a diagnosis based on CMA results were more often male, younger in age, and more likely to have multiple organ systems affected in comparison to probands in whom a molecular diagnosis could not be established.
Conclusions: CMA had a diagnostic yield of ~5% in individuals with immunological phenotypes, highlighting the contribution of CNV detection to the diagnosis of PID in individuals who may receive an inconclusive or negative result by ES alone. Additionally, over half of the CNVs included genes unrelated to immunological phenotypes, underscoring the complexity of phenotypic presentation in patients with PID.

PrgmNr 3060 - Exome sequencing findings in patients with bronchiectasis within an immune system disorder cohort

View session detail

Author Block: **J. Yan**[1], R. Ghosh[2], M. Similuk[2], V. Kuram[1], J. Lack[1], M. R. Setzer[1], M. Kamen[1], C. Jodarski[3], L. Jamal[4], B. Seifert[5], K. Jevtich[1], Y. Yu[6], R. Duncan[1], D. Hunt[1], A. Borges[1], K. Kumar[1], K. Olivier[1], S. M. Holland[1], M. Walkiewicz[1]; [1]Natl. Inst. of Allergy and Infectious Diseases, Bethesda, MD, [2]NIH, Bethesda, MD, [34]Natl. Inst. of Allergy and Infectious Diseases/ NIH Clinical Ctr. Dept. of Bioethics, Bethesda, MD, [5]Natl. Inst. of Allergy and Infectious Diseases (NIAID), Bethesda, MD, [6]Ellicott City, MD
Disclosure Block: **J. Yan:** None.
Aims: Bronchiectasis, a permanent dilation of the airways, is a complex heterogeneous disorder. It can occur as a result of opportunistic infections in primary immune deficiencies (PID) and has distinct disease trajectories, ranging from recurrent pulmonary infections in the context of a specific PID to later onset with no known underlying illness. It has been attributed to an interplay between host genetic variation and environmental exposures with studies supporting multigenic etiology. The phenotypic spectrum is wide-ranging in disease subtype and severity, making treatment and understanding disease etiology difficult. Here, we present a framework for studying the molecular basis of bronchiectasis within a mixed cohort of individuals with suspected immune disorders and idiopathic bronchiectasis.
Methods: Individuals enrolled in the National Institute of Allergy and Infectious Diseases Centralized Sequencing Program (CSP) underwent exome sequencing with clinical-grade interpretation. All variants reported to patients were validated by Sanger sequencing.
Results: The CSP exome sequencing cohort included 341 probands whose clinical presentation included bronchiectasis. Of these, 114 (33.4%) were found to have a primary molecular diagnosis consisting of pathogenic or likely pathogenic variants in genes associated with the probandâ□□s immune disorder. Among probands with molecular diagnoses, the most common findings consisted of variants in *CFTR* (n=18, 15.8%), variants in genes related to primary ciliary dyskinesia (n=14, 18.9%), and variants contributing to PIDs, most commonly in *PIK3CD* (n=13, 11.4%), *STAT3* (n=12, 10.5%) and *STAT1* (n=7, 6.1%). The remaining (n=50, 43.9%) molecular diagnoses encompassed a range of immune dysregulation disorders including variants in *CXCR4, FAS, PIK3R1, BTK, CTLA4, AIRE, CARD11, CTNS, DOCK8, FOXN1, HMBS, IL17RC, IL2RG, IRF2BP2, MVK, NKX2-1, RAC2,* and *TNFRSF13B.*
Conclusion: Molecular diagnoses were described in 33.4% of probands with exome sequencing who had bronchiectasis. Findings are consistent with the heterogeneous nature of bronchiectasis and underscore both the multiplicity of PIDs that can result in bronchiectasis, as well as the unknown genetic contributions for the majority cases with bronchiectasis. Burden testing of rare variants contributing to risk of bronchiectasis and assessment of the effect of common variants on disease presentation are warranted to further understand the genetic architecture of bronchiectasis in order to aid in better diagnosis, risk prediction, and treatment.

PrgmNr 3061 - Genomic Analysis of Profound Childhood Hearing Loss in the Yoruba Population of Nigeria

Disclosure Block: **R. Faridi:** None.
Background There are hundreds of genes in which variant alleles are associated with sensorineural hearing loss in children. However, the causative genes and alleles of hearing loss in Sub-Saharan African populations are still largely unknown. It is widely assumed that there is great heterogeneity of mutations causing hearing loss in Sub-Saharan Africa because of the very old age and ancient admixture of the Sub-Saharan African population. The back-migration of non-Africans into Africa in recent history likely has also added to this heterogeneity. We aimed to further elucidate the variants causing hearing loss in indigenous Sub-Saharan Africans. **Methods** We ascertained 56 small families of Yoruba ethno-lingual ancestry in Ibadan, Nigeria, with at least one individual with non-syndromic, severe to profound, prelingual-onset, bilateral hearing loss that could not be attributed to nongenetic factors associated with hearing loss. We performed a combination of exome and Sanger sequencing analyses of their nuclear and mitochondrial genomes. **Results** No bi-allelic pathogenic variants were identified in *GJB2*, encoding connexin 26, a common cause of deafness in many other populations. Variants predicted to be pathogenic or likely damaging were identified in genes associated with nonsyndromic deafness (*COL11A1, ILDR1*, *MYO15A*, *TMPRSS3,* and *WFS1)*, nonsyndromic deafness or Usher syndrome (*CDH23*, *CIB2*, *MYO7A*, *PCDH15* and *USH2A*), and other syndromic forms of hearing loss (*CHD7, OPA1* and *SPTLC1*). Several rare mitochondrial variants, including m.1555A>G in the gene MT-RNR1, were detected in deaf subjects but not in 118 control Yoruba samples. **Conclusions** Pathogenic variants of *GJB2* play a limited role in the etiology of hearing loss in Sub Saharan African population. Twenty (33%) of 60 independent cases of hearing loss in this cohort of Yoruba families were likely caused by variant alleles of genes reported to underlie deafness in other populations. All identified pathogenic or likely damaging variants in individuals with hearing loss were private, most were detected in compound heterozygosity and 61% had not been previously associated with hearing loss. These results indicate an extremely high level of genetic heterogeneity and underscore the need for more large-scale studies to identify the genetic causes of hearing loss in Africa.

PrgmNr 3062 - Intronic mutations in Puerto Rican (Hispanic) children with rare genetic diseases: Understanding genotype and phenotype correlations at the individual level

View session detail

Author Block: **E. Albino**[1], G. Maldonado-Casalduc[2], W. De Jesus-Rojas[3,4]; [1]Univ. of Puerto Rico - Med. Sci. Campus, Sch. of Hlth.Professions, San Juan, PR, [2]Ponce Hlth.Sci. Univ., Sch. of Med., Dept. of Pediatrics, Ponce, PR, [3]Univ. of Puerto Rico, Med. Sci. Campus, Sch. of Med., Dept. of Pediatrics, San Juan, PR, [4]Ponce Hlth.Sci. Univ., Sch. of Med., Dept. of Pediatrics, San Juan, PR
Disclosure Block: **E. Albino:** None.
Introns are short sequences of genetic material involved in gene regulation, silencing and expression. Hereditary Hemorrhagic Telangiectasis (HHT), Primary Ciliary Dyskinesia (PCD), CFTR-Related Metabolic Syndrome (CRMS) and Ehlers-Danlos (EDS) classical type, are rare genetic diseases with significant associated comorbidities and live-term symptoms and pulmonary complications. Intronic mutations in these genes have been understudied in the Puerto Rican population. We present four pediatric cases with phenotypes associated with these diseases. Case 1 is an 18 y/o male with worsening epistaxis since childhood but normal hemoglobin levels and oxygen saturation. Case 2 is an 8 y/o female with chronic wet cough since birth, bronchiectasis on chest computer tomography and history of recurrent pulmonary infections due to *P. aeruginosa*. Case 3 is a 4 y/o male with persistent bronchial asthma, failure to thrive and intermittent episodes of constipation. Case 4 is a 12 y/o female with marfanoid habitus, joint hypermobility and interstitial lung disease. Cases were referred to a pediatric pulmonologist for evaluation and genetic testing was performed in all individuals. Intronic variations *ENG*, *RSPH4A*, *CFTR* and *COL5A1* were identified and associated with HHT, PCD, CRMS and EDS, respectively. A VUS, c.1428+5C>G (intronic), was identified in *ENG* and it affects a nucleotide within the consensus splice site of the intron. A homozygous, pathogenic variant, c.921+3_921+6del (intronic), was identified in *RSPH4A*. It does not directly change the encoded amino acid sequence but affects several highly conserved nucleotides within the consensus splice site of intron 2. A pathogenic (low penetrance) variant, c.1210-34TG[11]T[5] (intronic), were identified in *CFTR*. A VUS, c.2331+4G>A (intronic), was identified in *COL5A1*. This sequence change falls in intron 26 of the *COL5A1* and it affects a nucleotide within the consensus splice site of the intron. The four pediatric patients present phenotypes associated with the disease. The effect of intronic mutations in the phenotype of rare genetic diseases are not well understood. Access to genetic testing have been able to unmask previously unknown intronic variants in populations with a high degree of both homozygosity and admixture such as Puerto Ricans. Describing these variants and associating them with the phenotypes will help us to understand the pathophysiology of these diseases. Understanding the variants found in our population will contribute to a deeper characterization of the genetic contribution to human phenotypes and disease susceptibility.

PrgmNr 3063 - Mosaicism in a cohort of patients with immune disorders

View session detail

Author Block: **M. Kamen**[1], J. Yan[1], M. Similuk[2], C. Jodarski[3,1], M. Setzer[4], L. Jamal[5], B. Seifert[6], R. Ghosh[2], K. Jevtich[1], Y. Yu[7], R. Duncan[1], S. Holland[1], M. A. Walkiewicz[8]; [1]Natl. Inst. of Allergy and Infectious Diseases, Bethesda, MD, [2]NIH, Bethesda, MD, [34]Med. Sci. and Computing/NIAID, Bethesda, MD, [5]Natl. Inst. of Allergy and Infectious Diseases/ NIH Clinical Ctr. Dept. of Bioethics, Bethesda, MD, [6]Natl. Inst. of Allergy and Infectious Diseases (NIAID), Bethesda, MD, [7]Ellicott City, MD, [8]Bethesda, MD
Disclosure Block: **M. Kamen:** None.
Background and purpose: Genetic mosaicism describes the phenomenon of an individual having two or more cell populations with different genotypes all originating in a single zygote. While mosaicism is a known feature of cancer and chromosomal aneuploidy, the role of mosaicism in the pathogenicity of immune system disorders is not as well understood.
Objective: This study aims to evaluate our cohort of patients with disorders of immunity to understand the contribution of mosaic variants to disease pathogenesis.
Method: To date, the NIAID Centralized Sequencing Program has performed exome sequencing and issued clinical genetic testing reports on 1,797 families evaluated for immune disorders. All clinically relevant variants were validated by Sanger sequencing. Mosaicism was assessed by alternate allele fraction in exome data.
Results: Within this cohort, we have identified apparently somatic, gonosomal, or germline mosaic variants underlying molecular diagnoses in 30 (1.7%) out of 1,797 families (25 probands and 5 relatives). The variant allele fraction indicative of postzygotic mosaicism ranged from 11%-44%. Possible parental gonosomal mosaicism was detected in three families (0.17%) including unaffected or mildly affected individuals with mosaic variants in *NOD2*, *STAT1*, and *CYBB*. Two families with pathogenic *PIK3CD* variants were highly suggestive of gonadal mosaicism in the parents. Apparent somatic mosaicism in *ASXL1* was identified in three individuals likely due to myelodysplastic syndrome (MDS). One individual with MDS had two mosaic variants of uncertain significance in *ASXL1*. Additionally, our study detected apparently mosaic variants in the following genes related to immune deficiency: *NLRP3* (3), *KIT* (11), *ATM*, *CXCR4*, *IKBKG*, *ITGB2*, *JAK2*, *KRAS*, *IRF8*, *SAMD9L*, *SETBP1*, *TLR8*, and *TRPM4*.
Discussion: The presence of mosaicism in the context of immune deficiencies can have important implications. Genetic counseling of recurrence risk is impacted by the possibility of parental germline or gonosomal mosaicism. Due to technical limitations, the number of cases of mosaicism in this cohort is likely an underestimate. Follow-up studies are warranted to elucidate a more complete understanding of the role of mosaicism in disease severity, which may better inform prognostic and treatment decisions for immune disease.

PrgmNr 3064 - The complexities of germline *PARN* variants in telomere biology disorders and the population

View session detail

Author Block: **M. Thompson**, A. S. Thompson, L. J. McReynolds, S. A. Savage; Natl. Cancer Inst., Bethesda, MD
Disclosure Block: **M. Thompson:** None.
PARN encodes poly(A)-specific ribonuclease, a highly conserved 3â□□ exoribonuclease important in regulating the stability and maturation of RNAs; it acts by shortening the mRNA poly(A) tail through deadenylation. PARN also regulates the turnover of mRNAs and the maturation and stabilization of the RNA component of telomerase (TERC). *PARN* is one of at least 15 different telomere biology genes with clinically significant pathogenic germline variants. Pathogenic germline variants in *PARN* result in reduced levels of TERC by altering its stability and accelerating its degradation. Autosomal dominant and recessive inheritance of rare *PARN* variants have been identified in telomere biology disorders (TBDs) including dyskeratosis congenita (DC), Hoyeraal-Hreidarsson syndrome (HH), and familial pulmonary fibrosis.
To better understand the full scope of germline *PARN* (chr16:14529558-14726585, GRCh37/hg19, ENSG00000140694.12) variation in disease, we conducted a comprehensive literature review, curated *PARN* variants, and assessed evolutionary conservation. The Genome Aggregation Database (gnomAD, N=141,456) was used to identify rare variation (MAF in silico predictors (missense), or there was at least one deleterious prediction by HSF or SpliceAI (splice-site). All frameshift/nonsense variants were classified as deleterious.
There were 362 unique *PARN* variants with MAF PARN variants reported in TBD patients, including 10 splice-site, four intronic, 10 frameshift, 34 missense, seven nonsense, and one synonymous. Our schema classified 40 of the 66 as deleterious and 26 as tolerated. Thirty of the deleterious variants were present in patients with pulmonary fibrosis, five in DC, and five in HH. Thirteen of the 34 missense variants (38%) were at highly conserved residues with the same amino acid present in at least four distinct species. In general, *PARN* is highly conserved with primarily rare variants across all populations evaluated. Notably, commonly used *in silico* predictions of variant deleteriousness were not consistent across literature reported TBD-associated *PARN* variants. Studies to determine the extent to which *PARN* may be constrained are underway.

PrgmNr 3065 - Update to the NIAID Genomic Research Integration System Genomic Analysis Module - Lessons Learned

We report challenges and resolutions in performing a substantive update to the NIAID Genomic Research Integration System (GRIS), a web-based application which integrates patient clinical phenotypes, labs, pedigree information, and exome(WES) and genome(WGS) sequencing data. GRIS is used by molecular geneticists and researchers to explore disease-gene variant relationships. We updated the genetic repository and analysis module, *seqr*, to the latest version to enable variant searching in WGS (as the previous version supported only exomes) data across multiple large datasets. The updated *seqr* also enabled upgrading to the hg38 reference genome, a more accurate version with a richer set of annotations than the hg19 version. We first addressed issues resulting from differences in AWS and GCP Elastic Search (ES) and Spark clusters since *seqr* is customized to use GCP clusters. Since AWS provides different data node specifications and products, we were unable to use the same services. We setup Lambda functions in AWS to build our automated data pipeline. Second, updating to the hg38 version required updating our variant calling, QC, and annotation pipelines. We then mapped variants tagged in the hg19 version to the corresponding variants in hg38 and performed additional manual mapping where variant locations were updated in the newer version. This allowed us to migrate the annotated tags, notes, and audit trail associated with the analysis of these variants. We updated the code to accurately group variants retrieved from multi-project (stored in multiple indexes in the ES cluster) searches across these projects. However, such large-scale searches can return hundreds of thousands of variants, which can be computationally intensive as well as daunting for users. We therefore customized the search to establish thresholds and best practices for searching. We integrated Exomiser which prioritizes likely causative variants based on the variant's predicted pathogenicity, frequency of occurrence in multiple populations, and the degree to which the given phenotype matches the known phenotype of disease genes. GRIS also includes tracks for absence of heterozygosity. In addition to frequencies of variants reported in public genomic databases, frequencies of variants in GRIS patients are displayed. Allele details for the HLA locus genes, which play an important role in the immune system can also be retrieved. Our unique implementation intended for large scale collaborative sequencing and variant research includes over 4000 records linked to WES/WGS and continues to be successfully used by over 200 NIAID Intramural researchers and more recently by other NIH researchers.

PrgmNr 3066 - VEXAS Syndrome Genotype is Associated with Mortality Through Differential Regulation of Non-Canonical Translation of Cytoplasmic UBA1b

View session detail

Author Block: **D. Beck**[1], M. A. Ferrada[1], D. L. Bodian[2], N. T. Strande[3], D. Ospina Cardona[1], L. Wilson[1], P. Hoffmann[1], S. Savic[4], A. K. Ombrello[1], A. Werner[1], D. L. Kastner[1], P. C. Grayson[1]; [1]NIH, Bethesda, MD, [2]Geisinger, North Bethesda, MD, [3]Geisinger, Danville, PA, [4]Univ. of Leeds, Leeds, United Kingdom
Disclosure Block: **D. Beck:** None.
VEXAS or vacuoles, E1 activating enzyme, X-chromosomal, autoinflammatory somatic syndrome is a recently identified genetic syndrome caused by somatic, myeloid restricted, mutations in *UBA1*, which decrease cytoplasmic UBA1 function. Patients with VEXAS syndrome present with a combination of severe inflammatory and hematologic manifestations. We sought to better understand the prevalence, penetrance, and expressivity of pathogenic *UBA1* mutations to better define this disease. Prevalence estimates based on the DiscovEHR cohort predict 1/25,000 individuals carry a pathogenic variant in *UBA1*, with 100% penetrance. Via single center referrals, eighty-eight total patients were identified with pathogenic variants in *UBA1*. Median age at disease onset was 66 years (range 40-85). All patients had hematologic and inflammatory symptoms, were treated with glucocorticoids, and had vacuoles identified on bone marrow biopsy when available. Four disease causing variants were identified including c.118-1 G>C (2%); c.121 A>C, p.Met41Leu (16%); c.121 A>G, p.Met41Val (24%), and c.122 T>C, p.Met41Thr (58%). All mutations were somatic with a median variant allele frequency 72.7% (range 7.5-97%) in peripheral blood. On autopsy material, somatic mutations were restricted to the hematopoietic system and not present in visceral organs. Clinical evaluation of newly diagnosed patients was similar to the discovery cohort with a subset of new manifestations identified including recurrent infections, interstitial lung disease, and ANCA-associated vasculitis. The overall mortality was 27% with a median survival from symptom onset of 10 years. Death was more common in patients with p.Met41Val variant (50%) compared to patients with p.Met41Leu (18%) or p.Met41Thr (22%). UBA1b is the cytoplasmic isoform of UBA1 and is translationally initiated from p.Met41. Translation of the cytoplasmic UBA1b isoform was reduced with all VEXAS mutations, with p.Met41Val expression lowest compared to p.Met41Leu or p.Met41Thr, providing a mechanistic basis for genotype-specific mortality. There was no correlation between mutation burden and survival, but transfusion dependence independently correlated with mortality. Together, our work has defined VEXAS syndrome as a relatively common cause of severe inflammation and bone marrow failure in older adults. We have further uncovered a molecular and genetic correlate for disease severity. Given the high mortality rate and lack of effective medical treatments, patients with VEXAS should be considered for hematopoietic stem cell transplantation, with particular focus on patients with risk factors for increased mortality.

PrgmNr 3067 - 3C minus 2C: X-linked Ritscher-Schinzel/ Cranio-Cerebello-Cardiac syndrome with no cardiac or cerebellar malformation due to missense variant in*CCDC22*

View session detail

Author Block: **S. Basalom**[1], D. Chitayat[2]; [1]Royal Univ. Hosp., Saskatoon, SK, Canada, [2]The Prenatal Diagnosis and Med. Genetics Program, Dept. of Obstetrics and Gynecology and Div. of Clinical and Metabolic Genetics, Dept. of Pediatrics, The Hosp. for Sickkids, Univ. of Toronto, Toronto, Ontario, Canada., Toronto, ON, Canada
Disclosure Block: **S. Basalom:** None.
Ritscher-Schinzel syndrome (RSS) / Cranio - Cerebello- Cardiac syndrome (3C) is a rare syndromic form of intellectual disability associated with posterior fossa defects, cardiac malformations, and minor distal extremities and facial abnormalities. The condition is heterogeneous and recently, two causative genes have been identified - *KIAA0196* and *CCDC22* for Autosomal recessive and X-linked RSS, respectively. Here we report the 8th individual with hemizygous missense variant in *CCDC22*, who presented with severe developmental delay, dysmorphic features, cryptorchidism and oligodontia but with no cardiac or cerebellar involvement.The patient was seen by us at 4 years of age. He was born at term following uncomplicated pregnancy and delivery to a Caucasian mother. He is the eldest in a sibship of two and the parents are healthy and non-consanguineous. At birth he was noted to have bilateral cryptorchidism and nasolacrimal duct obstruction and both were surgically repaired early in infancy. At 4 years of age his weight was 18.7 kg (50th - 85th centile), his length 102.2 cm (15th - 85th centile) and his OFC 52.2 cm (+ 1SD). He had plagiocephaly with a metopic ridge and bitemporal narrowing. He had anterior hair upsweep with a high arched eyebrows, a high forehead with frontal bossing and hypoplasia of the supraorbital ridges. He had malar hypoplasia, a square shaped nose with depressed nasal bridge, narrow nasal root and anteverted nostrils. The eyes were deep-set with bilateral epicanthic folds and puffy eye lids. He had macrostomia, thin upper and lower vermillion, oligodontia and high arched palate. His ears were normal in position but had overfolding of the upper part of the auricles. He had pectus excavatum at the lower part of the sternum. There were webbing between the 2nd-3rd, 3rd -4th and 4th -5th fingers and clinodactyly of the 5th toes on both feet with partial syndactyly of 2nd and 3rd toes with the fourth toe overlapping the 5th toes. He could kick the ball poorly but could jump, skip and hop. He had a short attention span and had poor pincer grip. He had severe language delay, with the expressive language being more severe than the receptive. He was social and affectionate. An echocardiogram showed normal heart and brain MRI at 31 months showed normal cerebellum. WES identified a hemizygous *CCDC22* missense maternally inherited pathogenic variant [c.403C>T (p. Arg135Trp)]. To our best knowledge this is the third family, and eighth reported patient with X-linked recessive intellectual disability with features of RSS/3CC due to missense variant in *CCDC22* without cardiac or cerebellar involvement. Our case suggests changing the clinical spectrum of X-linked RSS/3CC.

PrgmNr 3068 - 45,X/46,XY Mosaicism: Retrospective Study of 77 Patients

View session detail

Author Block: **E. Alkhunaizi**; Univ. of Toronto, Toronto, ON, Canada
Disclosure Block: **E. Alkhunaizi:** None.

45,X/46,XY mosaicism is a disorder/ difference of sex development (DSD) posing a great clinical challenge due to the highly heterogeneous spectrum of clinical manifestations, genital abnormalities, gonadal dysgenesis, growth hormone dysregulations, psychological and educational impacts and query increased risk for gonadal malignancies. The full extent of the manifestations in both genders and the long-term outcomes are not fully delineated as previous reports studied small cohorts with limited follow-up.We performed a retrospective chart review of 77 patients with pre- or postnatal diagnosis of 45,X/46,XY mosaicism ascertained from the Hospital of Sick Children and Mount Sinai Hospital in Canada. Short stature was more significant in females than males (p=0.04) and 72% of patients had at least one Turner syndrome stigmata. Growth hormone-treated individuals did not show a significant increase in height compared to the untreated group. All females required puberty induction in contrast to the majority of males. Four females were diagnosed with gonadal tumors while none of the males.

This study represents the largest cohort of patients with 45,X/46,XY mosaicism published so far. It provides a comprehensive overview of the clinical spectrum, long-term outcomes, and the risk of associated tumors. It also highlights our experience with growth hormone therapy and indications for prophylactic gonadectomy.

PrgmNr 3069 - Case report: a boy with imperforate anus and cleft lip

View session detail

Author Block: **M. Park**, M. C. Byler, S. Gupta, S. A. Tatum, A. H. Meier, R. R. Lebel; SUNY Upstate Med. Univ., Syracuse, NY
Disclosure Block: **M. Park:** None.
We report a male child born with imperforate anus and a right incomplete cleft lip with a bifid uvula. The non-consanguineous infant was delivered at 39 weeks of gestation to a 28 year-old G2P1>2 Caucasian female. Prenatal ultrasound had detected the cleft lip. There was no other complication, and no known exposure to teratogens. Neonatal course was notable for discovery of imperforate anus and the patient spent one week in the NICU. Surgical correction of both abnormalities was undertaken. No other dysmorphism was identified. The childâ□□s father has a maternal half-brother who was born with imperforate anus, but there is no family history of facial clefting. Father and paternal grandmother both had reported third-decade hearing deficits, but no dysmorphic features. Chromosome microarray was performed on the patient and both parents. The patient was found to have a 158 kbp duplication at 22q12.3 involving part of the *MYH*9 gene (OMIM #160775). *MYH*9 encodes a heavy chain of non-muscle myosin which participates in cell adhesion, cytoskeleton maintenance, and cytokinesis. Variants of this gene are associated with platelet dysfunction, thrombocytopenia, hearing deficit, cataract and nephropathy, none of which have been observed in our patient. However, it is a candidate gene for non-syndromic cleft lip without cleft palate. *MYH*9-related disorders are caused by loss-of-function variants and inherited in an autosomal dominant (AD) manner. Partial duplication of the gene might have resulted in gene disruption and loss of function. The fatherâ□□s microarray analysis revealed a 161 kbp duplication at 22q12.3 involving all of the *MYH*9 gene, confirming the father as the origin of the duplication recorded in the patient. Additionally, the fatherâ□□s analysis showed a 64 kbp deletion at 6p24.4 involving the *GCNT*2 gene (OMIM #600429). This deletion was not transmitted to the patient, and is considered a variant of uncertain significance (VUS). The motherâ□□s microarray showed a 106 kbp duplication at 3q12.2 involving parts of the *ADGRG*7 (OMIM #612307) and *TFG* (OMIM #602498) genes. *ADGRG*7 encodes G-protein coupled receptor 128 which functions as a transmembrane receptor. *TFG*, also called TRK-fused gene, encodes a protein that participates in endoplasmic reticulum microtubules; it is also involved in the NF-ÎºB signaling pathway. She did not pass this variant, considered a VUS, to the patient.

PrgmNr 3070 - Diagnoses and discoveries from re-analysis of clinical exome sequencing data: The Care4Rare Canada experience

View session detail

Author Block: **T. Hartley**[1], E. Soubry[1], M. Acker[2], B. McInnes[3], A. Salman[4], Care4Rare Canada, D. A. Dyment[5], K. D. Kernohan[6], K. M. Boycott[7]; [1]Children's Hosp. of Eastern Ontario Res. Inst., Ottawa, ON, Canada, [2]The Hosp. for Sick Children, Toronto, ON, Canada, [3]Alberta Children s Hosp./Univ. of Calgary, Calgary, AB, Canada, [4]BC Children's Hosp. Res. Inst., Vancouver, BC, Canada, [5]Ottawa, ON, Canada, [6]CHEO, Ottawa, ON, Canada, [7]Children's Hosp. of Eastern Ontario, Ottawa, ON, Canada
Disclosure Block: **T. Hartley:** None.
OBJECTIVE: Recent studies have shown that the systematic reanalysis of exome sequencing data can yield additional diagnoses in 10-15% of cases. These studies have been limited, however, by small sample sizes (typically less than 50), and they often collect data from a single clinical laboratory. In 2015, Care4Rare Canada offered enrollment to any Canadian patient seen at a participating site with non-diagnostic clinically-performed exome sequencing data. Herein, we sought to report the results for 281 participants whose exome sequencing data had been re-analyzed through our research pipeline.
METHODS: Data was transferred from 11 clinical laboratories and run through a previously described Care4Rare bioinformatics pipeline. For all participants, we collected the original clinical laboratory reports, demographic information, and phenotypic information using PhenoTips. Family-based analysis was performed in collaboration with the referring clinicians and additional research was pursued as appropriate, including â□□matchmakingâ□□, segregation, and splicing studies. All compelling candidates were further examined to determine whether these variants were previously classified by the clinical laboratories, and if not, speculate on why these candidates might have been missed.
RESULTS: The mean age of probands at the time of the reanalysis was 12.5 years old (range 0 to 74) and they presented with a broad range of phenotypes; approximately half of our cohort had syndromic ID. The mean time between clinical analysis and our re-analysis was 20.9 months. Re-analysis yielded 15 diagnoses in known disease genes that fit the patientâ□□s presentation (5%). Of these, 4 of the diagnoses could have been made at the time of initial analysis and had been missed by the clinical laboratoryâ□□s workflow. Another 5 were made based on new genomic knowledge (newly curated disease gene-associations or published mutations). An additional 32 (11%) probands had compelling VUSs in known disease genes that the Medical Geneticist considered to be likely the cause of their patientâ□□s disease but required additional evidence to meet ACMG criteria for pathogenicity. Forty five (22%) had compelling variants in genes that are not yet associated with human disease. Of these, 28 (10% of total cases) have been resolved with patient matchmaking and represent novel disease-gene associations.
CONCLUSIONS: This study suggests there is significant utility in the re-analysis of non-diagnostic exome sequencing data for the identification of both molecular diagnoses (5-16%) and discoveries (10-22%).

PrgmNr 3071 - Exome CNV calling and analysis in a large cohort of families with undiagnosed rare genetic disease

View session detail

Author Block: **G. Lemire**[1,2], E. Evangelista[1], I. Wong[1], E. England[1,2], K. Chao[1], L. Pais[1,2], J. Goodrich[1], C. Austin-Tse[1], S. DiTroia[1], E. O'Heir[1,2], J. Fu[1], Broad CMG Collaborators, M. Babadi[1], S. Lee[1], A. N. Smirnov[1], L. Gauthier[1], S. Baxter[1], D. MacArthur[3,1], H. Rehm[1], M. Talkowski[1], H. Brand[1], A. O'Donnell-Luria[1,2]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Boston Childrenâ□□s Hosp., Boston, MA, [3]Murdoch Childrenâ□□s Res. Inst., Melbourne, Australia

Disclosure Block: **G. Lemire:** None.

The Center for Mendelian Genomics (CMG) at the Broad Institute has sequenced 7,719 families with a suspected genetic disease since 2016. Many had a chromosomal microarray and gene panel sequencing for known causes of disease prior to exome sequencing through the CMG. For typical rare variant analysis, exome sequencing data can be used to call SNVs and indels smaller than 50 base pairs, and standard chromosomal microarrays will detect CNVs larger than 50 kilobases. However, mid-sized CNVs are not detected in routine exome analysis of SNVs and indels but molecular diagnostic laboratories are increasingly including CNV calling on exome data in analysis. Detecting CNVs from exome data has been notoriously difficult due in part to the non-uniform distribution of captured reads secondary to biases introduced by PCR and capture steps and many different algorithms have been developed for this purpose. The Genome Analysis Toolkitâ□□s (GATK) CNV tool, the Germline CNV (gCNV) caller, uses a probabilistic framework to infer rare CNVs from read depth data in the presence of systematic bias. We used the gCNV algorithm to call CNVs across the Broad CMG cohort. While analysis is ongoing, we have diagnosed 138 previously unsolved families to date. The identified CNVs consisted of 109 deletions, 20 duplications and 9 complex CNVs. A CNV in a known gene that is consistent with the phenotype was identified in 114 families and a CNV in a novel candidate gene was identified in 24 families. Supporting genetic and/or experimental evidence were required to consider a CNV in a novel gene as the diagnosis in a given family, most often by additional families identified through Matchmaker Exchange. The predominant phenotype present in these families were neurodevelopmental disorders (67%) followed by neuromuscular disorders (19%). We estimate that about 50% of the CNVs that solved CMG cases would not have been detected by standard chromosomal microarrays. Calling CNVs from existing exome data increases the diagnostic yield for individuals that remain undiagnosed after standard testing approaches, providing a higher resolution alternative to arrays at a fraction of the cost of genome sequencing.

PrgmNr 3072 - Phenotypic spectrum of Down syndrome in 4,209 patients by profiling electronic health records

View session detail

Author Block: **J. Havrilla**[1], M. Zhao[2], I. Helbig[1], E. J. Bhoj[1,3], K. Wang[1,3]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Childrens Hosp. of Philadelphia, Philadelphia, PA, [3]Univ. of Pennsylvania, Philadelphia, PA

Disclosure Block: **J. Havrilla:** None.

Down syndrome (DS) is by far the most common and best known chromosomal disorder in humans, occurring one in every 700 newborns. It is a highly heterogeneous disease, with a wide range of phenotypic variation among affected individuals and diverse comorbidities. We sought to determine if we can characterize the phenotypic spectrum and subgroups of this highly heterogeneous disorder, through natural language processing (NLP) of electronic health records (EHRs).We examined physiciansâ clinical notes from the EHRs of 4,209 DS patients at the Childrenâs Hospital of Philadelphia and 7,845 controls. We mapped clinical data to Human Phenotype Ontology (HPO) terms using MetaMap and catalogued the most critical HPO terms related to DS patients, stratified by odds ratio as compared to controls, with appropriate adjustment of information content. We further examined associated HPO terms by age, in an attempt to surmise the typical age of diagnosis for prevailing traits, as well as minimum ages for diagnosis for traits such as speech delay, which cannot be diagnosed at the beginning of life. We also inferred higher-level, less specific HPO terms from our data to derive larger phenotypic groups.Using these tools, we confirm known clinical features in DS, including congenital heart disease, where we show a ventricular septal defect in 41% of all cases, which we find to be a leading cause of death during the first years of life. We demonstrate cortical cataracts in 42% of DS patients, heterotropia and strabismus in 40% of DS patients, and hearing impairment is prevalent in 51% of DS patients. These results suggest that our NLP-based analysis of EHRs can reproduce well known knowledge. Additionally, we also find lesser known characteristics of DS patients as we attempt to create a phenotypic spectrum to characterize the disorder and its subtypes. For example, we identified several rare, clinical features that are over-represented in DS but are not previously described, such as oliguria and miosis, both with odds ratio over 100.In summary, our analysis profiled the spectrum of phenotypic features in patients with DS in the form of standardized terminologies; we demonstrated that an NLP-based approach has face value and provided a quantitative measure of the HPO terms to facilitate future construction of phenotype-based patient sub-classification models, which will allow for clinical decision support and learning health systems.

PrgmNr 3073 - A partial Xq duplication in a newborn girl: A Case Report

View session detail

Author Block: **S. Mikkilineni**[1], M. Rahman[2], F. Shakil[1], C. KUMAR[1]; [1]Westchester Med. Ctr., Valhalla, NY, [2]WMC, Valhalla, NY
Disclosure Block: **S. Mikkilineni:** None.
Partial duplication of the long (q) arm of chromosome X is an infrequent occurrence with variable presentation. In essence, females harboring the dup(Xq) are less affected than males harboring the same duplication since the abnormal X chromosome is often preferentially inactivated in females. Females with dup(Xq) may exhibit short stature, variable dysmorphic features, developmental delay, hypotonia, feeding problems, hypomyelination, gonadal dysgenesis, secondary amennorhea, intellectual disabilities, poor language and mild scoliosis. Here we present a new case of a pre-term female baby born with intra-uterine growth retardation at 36 weeks 6 days by C-section. The infant was small for gestational age (SGA) born with a birth weight of 1.53 kg (

PrgmNr 3074 - A rare case of multiple mosaic marker chromosomes in a neonate with congenital diaphragmatic hernia and ventricular septal defect

View session detail

Author Block: **L. Schultz-Rogers**, K. Kaiser-Rogers, T. Felton, M. Gucsavas-Calikoglu, L. Ramkissoon; UNC Chapel Hill, Chapel Hill, NC
Disclosure Block: **L. Schultz-Rogers:** None.
Marker chromosomes are abnormal chromosomes that lack sufficient banding to be unambiguously identified by traditional karyotype analysis. Here we present a female neonate referred for karyotype and chromosome microarray analysis (CMA) due to congenital diaphragmatic hernia (CDH) and ventricular septal defect (VSD). G-band analysis of newborn cord blood demonstrated four cell lines containing 1-4 marker ring chromosomes (47~50,XX,+1~4r) and the absence of any 46,XX cells. CMA determined that the marker chromosomes were derived from chr. 6,11,13 and 20. The patterns from chr. 6, 11 and 13 were consistent with a ring as duplicated pericentric material from both the short and long arms was present. The pattern of triplicated material from chr. 20 suggests a more complex rearrangement as it contains two discontinuous interstitial regions from the short and long arm. FISH testing with centromeric chr. 6 and 11 probes or locus-specific probes targeting chr. 13 and chr. 20p11.21 and 20q13.2 confirmed the presence of four different markers and demonstrated they were distributed in various combinations. Together with the CMA and FISH, this patientâ□□s karyotype was described as 47~50,XX,+1~4r.ish r(6)(D6Z1+),r(11)(D11Z1+),r(13)(RP11-69J15+),r(20)(RP11-946M12 enh, RP11-381C11 enh). nuc ish(D6Z1,D11Z1,RP11-69J15)x2~3,(RP11-946M12, RP11-381C11)x2~4[200]. As parental testing was not performed, the inheritance of the markers is unknown, however 70% of marker chromosomes occur *de novo* (Liehr 2021). While the duplicated regions do not contain known triplosensitive regions per ClinGen, nor are there similarly reported duplications noted in the DECIPHER database, it is likely the multiple mosaic marker chromosomes identified in this patient are related to their phenotype. There have been 82 reported individuals with multiple marker chromosomes, and only 21 reported 4 or more markers making the findings in this patient exceedingly rare (Liehr 2021). Complex marker chromosomes such as the chr. 20 marker identified in this patient are also unusual and are predicted to constitute ~8% of identified markers (Liehr 2013). Individuals with â□¥4 markers have been reported with a wide range of phenotypes including developmental delay, hypotonia, dysmorphisms, and heart defects (Liehr 2021). The clinical presentation associated with the presence of mosaicism for multiple small marker chromosomes remains difficult to predict and will depend on the distribution of the cell lines within the tissues of the affected individual. This case highlights the importance of obtaining cytogenetic testing on patients with non-specific congenital abnormalities such as CDH and VSD.

PrgmNr 3075 - Assessment of Alzheimer Disease Related Plasma Biomarker Phosphorylated Tau 181 in Individuals of Diverse Ancestral Backgrounds

View session detail

Disclosure Block: **A.J. Griswold:** None.

Background. The use of plasma proteins as biomarkers for the differential diagnosis of Alzheimer disease (AD), and identification of preclinical AD, is well supported. Particularly, phosphorylated threonine 181 of the Tau protein (pTau181) is significantly higher in individuals with both clinical and neuropathologically confirmed AD relative to cognitively and pathologically intact age-matched controls. However, these observations have been made nearly exclusively in individuals of non-Hispanic European ancestry. Given notable differences in the genetic risk for AD across diverse African and Amerindian ancestries, and the lack of biomarker studies in these populations, generalizability of these findings is not assured. Therefore, the aim of this study is to explore the utility of pTau181 in discriminating clinically diagnosed AD from cognitively intact controls in ancestrally diverse African American and Puerto Rican cohorts. **Methods.** We measured pTau181 concentration in a cohort of 536 African American individuals (140 AD, 396 cognitively intact age-matched controls), 357 Puerto Rican individuals (165 AD, 192 controls), and 56 autopsy confirmed AD cases of European ancestry. Plasma was isolated from EDTA blood tubes using centrifugation and pTau181 measured using the pTau181 Advantage V2 Simoa chemistry assay on the Quanterix HD-X. Samples were randomized in plates, measurements performed in duplicate, and non-parametric Wilcoxon rank sum tests with Bonferroni multiple-comparisons p-value correction were used to test differences in pTau181 concentration. **Results.** Overall, the mean plasma pTau levels in AD cases was higher than controls in African Americans (2.51Â±1.47pg/mL vs 1.23Â±0.73pg/mL, $p_{corr}=7.9x10^{-25}$) and Puerto Ricans (2.39Â±1.19pg/mL vs 1.48Â±1.03pg/mL, $p_{corr}=4.5x10^{-16}$). Importantly, the pTau levels in the European ancestry autopsy confirmed cases (3.08Â±1.37pg/mL) were not significantly higher than in African American ($p_{corr}=0.10$) or Puerto Rican ($p_{corr}=0.26$) cases. **Discussion.** This study suggests that previous pTau181 findings will be generalizable and useful for all individuals, regardless of ancestry. Ongoing measurement and analysis of pTau181 and other AD biomarkers in these and other ancestrally diverse cohorts is currently underway to further expand these findings. Combining genomic and biomarker analyses in diverse individuals will ultimately help understand the underlying genetic risk and to refine clinical diagnoses in individuals of diverse ancestral backgrounds.

PrgmNr 3076 - Clinical utility of long read sequencing in resolving inconclusive diagnoses due to gene conversions and unknown phase

View session detail

Author Block: **R. Rajagopalan**[1], D. A. McEldrew[1], M. Luo[2], L. K. Conlin[1]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]The Children S Hosp. of Philadelphia, Philadelphia, PA

Short read next-generation sequencing (NGS) has revolutionized genomic diagnostics, but has inherent limitations in detecting variants in difficult to sequence regions (e.g. low complexity, repeats, and segmental duplications).There are several known disease-causing genes that are challenging to sequence using NGS, and thus, the spectrum of benign and pathogenic variation in these genes are not entirely known. Additionally, for autosomal recessive diseases, phasing of two variants generally cannot be determined without parental testing, which are often not available, leading to inconclusive test results. PacBio HiFi and Oxford Nanopore sequencing can produce very long reads (20kb to several hundred kb) with high accuracy, which will resolve many of these challenges faced by NGS. We chose three patients with nonsyndromic hearing loss and potentially diagnostic but inconclusive variants identified by an NGS panel. Causality of these variants could not be confirmed due to the unknown chromosomal phase, and in two cases additionally complicated by the presence of a pseudogene. We performed whole genome PacBio long read DNA sequencing to help in the interpretation of these variants. Patient 1 had a pathogenic two-exon deletion and a variant of uncertain significance in the gene *TRIOBP*. Patient 2 had multiple variants across exon 25 and intron 26, suggesting a 21kb gene conversion event between *STRC* and its pseudogene *STRCP1* along with a single nucleotide variant of uncertain significance in exon 8. Patient 3 had multiple variants in exons 23-25 on both haplotypes suggesting multiple gene conversions between *STRC* and *STRCP1*. Determining phase information from short read exome sequencing data is impossible as the variants in *TRIOBP* were 13kb away from each other, and the variants in *STRC* in patient 2 were 19kb apart. PacBio sequencing and long-read based phasing revealed that the two variants in the gene *TRIOBP* for Patient 1 occurred on the same allele and thus were not diagnostic. For both Patients 2 and 3, PacBio revealed that variants in *STRC* occurred on different alleles and confirmed size and extent of each gene conversion event and confirmed biallelic pathogenic variants for both patients. PacBio long-reads enabled the identification of the gene conversion event without having to perform additional assays and the variant backed phasing resolved the haplotypes readily. Results from these three patients support the significant promise of long-read sequencing in resolving some of the very challenging and frustrating issues in identifying and phasing complex variants.

PrgmNr 3077 - Comprehensive genetic testing of sensorineural hearing loss in children: understanding phenotypic factors that influence the diagnostic yield

Hearing loss (HL) is a common and heterogeneous sensory disorder in children with a genetic etiology suspected in >60%. Genetic testing is recommended for children with bilateral sensorineural HL (SNHL), which may lead to early interventions. Comprehensive genetic testing (CGT) panels allow interrogation of preselected genes. To evaluate the factors impacting diagnostic yield for children with SNHL, we analyzed the relationship between the genetic findings and clinical information.This study analyzed 474 unrelated probands tested with a tiered exome sequencing (ES)-based CGT at our institute. The CGT interrogated 121 SNHL-related genes for sequence and copy number variations (CNVs) if the first tier (*GJB2* testing) was negative. A total of 1147 reportable variants involving 119 genes were identified in 439 of 474 probands. Overall diagnostic yield was 44% (207/474), and 4 probands carried two genetic etiologies. CNVs or gene conversions accounted for 14% (45/327) of all causative variants, 71% of which were detected in *STRC*. Mutations in *GJB2* were the most common findings (37%, 78/211) leading to a wide range of phenotypes from congenital profound HL to postlingual mild HL, but were much less prevalent in some ethnic groups (13% in African Americans and 0% in Hispanics). The remaining 63% (133/211) involved 40 genes (most commonly *STRC* followed by *MYO15A)*. Phenotypic stratification showed that the diagnostic yield was higher in probands with congenital, severe or profound, flat, and symmetric HL, and lower in probands with postlingual, mild, ascending, unilateral HL, cochlear nerve deficiency, preterm birth, NICU admittance, and developmental delay. Among undiagnosed probands, 19% (50/267) had inconclusive findings due to partial phenotype overlap and/or limited variant evidence, and 56% (149/267) had a single heterozygous variant in a gene associated with autosomal recessive HL, of which 22% (33/149) had phenotypes consistent with the condition related to that genetic etiology. Reflex to ES was performed on 46% (122/267) of undiagnosed probands, and 4% (5/122) had diagnostic findings in 4 genes that were not included on our initial CGT panel (3 syndromic genes and 1 nonsyndromic gene). Two of these 4 genes were included in updated versions of the panel.Our relatively high diagnostic yield with heterogeneous results suggests that a tiered CGT panel provides an efficient way to diagnosis genetic causes of diverse childhood-onset SNHL. While the additional yield of ES was low it may be indicated in some undiagnosed probands in order to capture the broad spectrum of syndromic genes associated with SNHL as well as novel genes not included in CGT panels.

PrgmNr 3078 - Genome-wide Sequencing Ontario (GSO): An implementation pilot to improve rare disease diagnostics

View session detail

Mendoza-Londono[2], S. L. Sawyer[4], M. J. Somerville[2], K. M. Boycott[1]; [1]Children's Hosp. of Eastern Ontario, Ottawa, ON, Canada, [2]The Hosp. for Sick Children, Toronto, ON, Canada, [3]CHEO, Ottawa, ON, Canada, [4]Children's Hosp. of Eastern Ontario Res. Inst., Ottawa, ON, Canada
Disclosure Block: **M. Gillespie:** None.
Purpose: The Genome-wide Sequencing Ontario (GSO) pilot implementation project has developed an innovative, harmonized, and multi-institutional model for delivering and monitoring the performance of clinical genome-wide sequencing (GWS) in the forms of exome and genome sequencing. The first of its kind in Canada, the GSO pilot will collect data on performance, workflow and implementation outcomes to inform repatriation decisions in Ontario and serve as a model for jurisdictions for whom clinical GWS is a policy priority.
Methods: The GSO implementation pilot is using a hub-and-spoke model to provide clinical GWS to Ontarians. Sequencing and bioinformatics will be performed at SickKids, with analysis and reporting at both SickKids and CHEO (2/3 and1/3 of provincial volume, respectively). Guided by the principles of hybrid implementation-effectiveness study design, two prospective cohorts of patients will be enrolled over a two-year period. Cases enrolled in the implementation cohort (n=1320 singletons, duos, trios and quads drawn from peripheral hospital sites in Ontario) are offered exome sequencing (ES) to optimize the delivery of the current standard of care in Ontario. Cases enrolled in the evaluation cohort (n=650 trios from CHEO and SickKids) are randomized to receive exome or genome sequencing (GS). Collected data will include: patient age, phenotype, ethnicity, consanguinity, molecular testing history, sample processing and analysis time, number and characteristics of primary and secondary variants. Costs for each input related to the laboratory analysis will be calculated by multiplying resource use by unit price. For each additional patient with a pathogenic variant detected, we will determine the incremental costs of GS compared to ES. Descriptive statistics will be used to analyze process and outcome data. Point estimates for diagnostic utility and timeliness will be compared statistically for ES and GS.
Results: Since the launch of the GSO implementation pilot on April 1st 2021, 95 individuals or families with suspected rare genetic diseases have been submitted to the SickKids and CHEO laboratories to undergo clinical GWS. Sequencing has been initiated for 67 families and completed in 46 families.
Conclusion: GSO has developed a centralized approach for sequencing and bioinformatics coupled with a distributed, institution-based mechanism for data analysis, variant interpretation, and reporting. Process and outcome data gathered over the course of the two-year pilot will inform provincial and cross-provincial policy related to the long-term organization, delivery, and reimbursement of genome diagnostics.

PrgmNr 3079 - Going above and beyond in discovering *STRC* pathogenic variants in non-syndromic hearing loss: itâ□□s just the tip of the iceberg

View session detail

Luo[3]; [1]Div. of Genomic Diagnostics, The Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Div. of Human Genetics, Dept. of Pediatrics, The Children's Hosp. of Philadelphia, Philadelphia, PA, [3]The Children's Hosp. of Philadelphia, Philadelphia, PA
Disclosure Block: **J. Balciuniene:** None.
Pathogenic *STRC* variants cause DFNB16, a common type of childhood-onset hearing loss (HL). *STRC* is located in a segmental duplication region which includes a highly homologous pseudogene, *STRCP1*, and is prone to non-allelic homologous recombination leading to copy number (CN) changes, gene conversions, and fusion genes. Large biallelic deletions involving *STRC* are the most commonly reported pathogenic findings, while sequence variants (e.g. SNVs) are reported in a minority of cases due to genetic testing challenges caused by the presence of *STRCP1*. This has limited our understanding of the full extent of the diagnostic contribution of *STRC* to HL.
The Audiome is a comprehensive panel for genetic testing of pediatric non-syndromic HL, which uses exome-based NGS and array CGH platforms. In addition, it includes a *STRC*-specific module involving long range PCR followed by NGS to identify SNVs, and droplet digital PCR to identify CN changes. Final interpretations are based on integrative analysis of both *STRC*-specific approaches.
Audiome testing of 479 unrelated probands yielded diagnostic findings in 45% (216/479). *STRC* positive findings were identified in 5.6% (27/479) accounting for 12.5% of all diagnoses. Only 33% (9/27) of the *STRC* diagnoses were due to biallelic *STRC* deletions. A heterozygous *STRC* deletion and a hemizygous SNV accounted for 26% (7/27) and compound heterozygous SNVs were identified in 22% (6/27) of *STRC* diagnoses. In two of these patients, several rare heterozygous SNVs originating from *STRCP1* were found in multiple exons, suggesting a large gene conversion event. More complex *STRC* findings were identified in the remaining 18.5% (5/27) *STRC* patients. Two individuals carried a deletion on one allele and a non-functional *STRC-STRCP1* fusion on another allele. In three individuals, an apparently homozygous pathogenic variant was identified by NGS; however, the integrated analysis was consistent with the presence of *STRC* deletion on one allele, and *STRC* duplication on the other allele with one *STRC* copy carrying a pathogenic SNV, and the second copy being a non-functional *STRC-STRCP1* fusion.
While some pathogenic variants involving *STRC* can be detected by standard NGS and array CGH, the inclusion of this *STRC*-specific testing module resulted in a doubling of the number of *STRC*-related diagnoses. Without the *STRC*-specific testing, diagnoses would have been completely missed in 5 individuals, and 8 individuals would have yielded inconclusive results. Our integrated analysis helped to uncover the signatures of complex genomic changes and their potential mechanisms and could serve as a model for analyzing other similar gene regions.

PrgmNr 3080 - Molecular diagnosis as an incidental finding from preconception carrier screening
