Introduction - Most variants identified by genome-wide association studies (GWAS) are located in non-coding regions of the genome without clear indications of their function. Enhancer activity disruption is presumed to be the underlying mechanism for most of these GWAS variants. Epigenomic profiling, including ATACseq, is one of the main tools used to define enhancers. Because enhancers are overwhelmingly cell-type specific, inference of their activity is greatly limited in complex tissues that include multiple cell types. Newly developed multiomic assays, probing both open chromatin and gene expression within the same single nuclei, enables the study of the correlations (links) between these modalities at single cell resolution. Current best practices to infer the regulatory effect of cis-regulatory elements (cCREs) involve removing biases associated with ATACseq peak coverage and GC content. As proposed by Ma et al. 2020, a null distribution of Gene-Peak correlations is built using ATACseq peaks of matching coverage and GC content, drawn from chromosomes excluding the one hosting the tested gene. The resulting distribution of Pearson correlation values is then scaled, providing Z-scores for the cCRE and each matched trans-links. This is done under the assumption that these trans-ATACseq peaks should not have a regulatory effect on the tested gene (i.e. they are independent). This strategy has been broadly adopted by popular single nuclei multiomic workflows such as Signac. **Results** - Here we uncovered limitations and confounders of this approach using the publicly available 10X PBMC multiomic dataset. We found a strong loss of power to detect a regulatory effect for cCREs with high read counts in the dominant cell-type. We showed that this is largely due to cell-type specific trans-ATACseq peaks correlations creating bimodal null distributions. Further, contrary to the expectation of increased power with higher cell counts, we showed that down-sampling the dominant cell-type generally increases Z-scores for gene-peak links specific to the dominant cell-type. We tested alternative models and concluded that the simplest (i.e. using directly the correlation coefficient without building a null distribution) has the strongest predictive value for the regulatory effect of a cCRE when compared to Epimap predictions and CRISPR validation data.

PB3070*. Making population-scale toxicogenomic analysis performant and cost-effective using REVEAL Biobank.

Authors:

S. Sarangi, U. Mudgal, M. Colosimo, M. Peterson, Z. Pitluk; Paradigm4, Waltham, MA

Abstract Body:

The scale and complexity of human beings' exposure to environmental toxicity has a major impact on public health across the world. Clinical trials, whether for investigative purposes or drug development, are complicated by the variable exposure of participants to environmental hazards, including their historical medicines usage. Understanding the interplay between genomic loci, environmental hazards and medicines may allow the selection of patients who are more likely to benefit from interventions. Additionally, validating the influence of toxins on diseases and disorders should help raise awareness and mitigate our footprint on the environment.

Performing large toxicogenomic studies using data sources such as the UK Biobank (UKBB) and the Comparative Toxicogenomic Database (CTD) can often be challenging due to extensive computational resources, high cost of analyses, and building complex pipelines. REVEAL Biobank offers a scalable, highly-performant, and cost-effective analytics solution that is easy to deploy and use. In the recently concluded MCBIOS 2022 conference, we had presented results of a toxicogenomic analysis performed using REVEAL Biobank, UKBB (Application ID: 51518), and the CTD. In that work, we calculated associations between 10,138 variants across 71 genes common among chemical-gene interactions for 5 chemicals (NO₂, NO_x, SO₂, Pb, and Asbestos), and 779 phenotypes (across cardiovascular, metabolic disorders, among others). The cost of this analysis was \$12.5 for ~10 million logistic regressions. In this study, we extended our previous work from two perspectives: 1) performance & scalability; 2) improve understanding of chemical-gene interactions. We demonstrated scalability and performance of REVEAL Biobank in computing a GWAS by creating a design of experiments space to measure time and cost contingent on three inputs - number of covariates, number of mutations, and number of phenotypes. The ranges used for the inputs were - covariates - 10-30; mutations - 10-100 thousand; phenotypes - 500 - 2500. To improve understanding of the influence exerted by toxins on disease-relevant genes, we conducted a Polygenic Risk Score (PRS) computation on the top significant associations identified from the GWAS and linkage disequilibrium (LD) analyses. Population-scale toxicogenomic studies using tools such as GWAS, LD, and PRS are imperative to build network maps and elucidate the complex mechanisms of chemical-gene interactions and their impact on public health.

Omics Technologies Posters - Thursday

PB3071. Massively parallel reporter perturbation assays uncover temporal regulatory architecture during neural differentiation

Authors:

A. Kreimer; Rutgers Univ., Piscataway, NJ

Abstract Body:

Gene regulatory elements play a key role in orchestrating gene expression during cellular differentiation, but what determines their function over time remains largely unknown. Here, we perform perturbation-based massively parallel reporter assays at seven early time points of neural differentiation to systematically characterize how regulatory elements and motifs within them guide cellular differentiation. By perturbing over 2,000 putative DNA binding motifs in active regulatory regions, we delineate four categories of functional elements, and observe that activity direction is mostly determined by the sequence itself, while the magnitude of effect depends on the cellular environment. We also find that fine-tuning transcription rates is often achieved by a combined activity of adjacent activating and repressing elements. Our work provides a blueprint for the sequence components needed to induce different transcriptional patterns in general and specifically during neural differentiation.

PB3072. Max Read™: a novel high-throughput sequencing format for patterned flow cells

Authors:

N. van Wietmarschen, B. Brooks, L. LaMarca, D. Witters, R. Shultzaberger, M. Fabani, E. Glezer; Singular Genomics Systems Inc, San Diego, CA

Abstract Body:

Title Max Read™: a novel high-throughput sequencing format for patterned flow cells. **Background** Short read next generation sequencing (NGS) has advanced a multitude of applications, including RNA quantification, DNA fragment detection and counting, barcode sequencing, single-cell analyses, and proteomics. Typically, short-read NGS is performed by sequencing one round of single-end or paired-end reads on an array of DNA clusters. Here, we introduce the Max Read™ kit, allowing multiple sets of independent single-end or paired-end reads on the same patterned flow cell, enabling higher output of short reads. **Methods** A set of 8 poly-A-enriched RNA-seq libraries was prepared using the NEBNext Ultra II RNA Library Prep Kit (NEB) and the NEBNext Poly(A) mRNA Magnetic Isolation Module. For each library, 1 µg of input universal human reference (UHR), human brain (HBR), human kidney (KT), or human skeletal muscle (SMT) RNA (Invitrogen) was used. Each RNA-seq library contains distinct sequencing primer regions as well as universal primer sequences for clustering on Singular Genomics flow cells. Libraries were pooled and clustered simultaneously in one F2 flow cell. Library molecules went through clonal amplification on the patterned flow cell, allowing multiple templates to amplify within the same nanowell. The flow cell was then subjected to eight sequential rounds of primer binding and 50bp single-end sequencing on the G4™ Sequencing Platform, until all libraries were sequenced. **Results** The Max Read™ configuration with 8 independent sets of 50 bp single-end reads resulted in an average of 32 million reads per library, with an average of 84% of bases \geq Q30. This corresponds to >250 million reads per individually addressable lane, or >1 billion reads per F2 flow cell using the G4™ sequencer. Gene expression analysis demonstrates strong correlations between the Max Read™ format and NextSeq™ 2000 results using the same RNA input, while gene body coverage uniformity of the G4 Max Read™ and NextSeq™ 2000 results show similar mean distributions of coverage depth across the length of mapped transcripts. **Conclusions** The Max Read™ format enables up to eight independent single-end 50 bp reads on the same patterned flow cell by leveraging multiple unique sequencing primer binding sites on distinct library molecules. This study demonstrates the ability of achieving >1 billion 50 bp RNA-Seq reads with an average of 84% of base calls \geq Q30. The G4™ sequencer, which can run 4 flow cells in parallel, can produce up to 4 billion short reads using the Max Read™ format, providing a new, powerful method for high-throughput short read sequencing.

PB3073. Metabolomic analysis of vitreous humor from the eyes with different uveal melanoma prognostic subtypes defined by tumor gene expression profiling.

Authors:

F. Demirci¹, L. Tang¹, B. Beser², M. Kachman², H. Demirci²; ¹Univ. of Pittsburgh, Pittsburgh, PA, ²Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Uveal melanoma (UM) is the most common primary intraocular cancer observed in adults and exhibits distinctive genetic/molecular features. UM is an aggressive cancer, and despite advances in primary tumor management, survival rate remains low due to high rate of metastasis. A prognostic test currently available for UM involves the gene expression profiling (GEP) of tumor samples, often obtained by fine-needle aspiration biopsy (FNAB) prior to eye-preserving brachytherapy. GEP identifies two major prognostic UM subtypes (class 1 with low and class 2 with high metastatic risk). UM primarily arises from the choroid at the posterior eye segment. Posterior eye cavity is filled with vitreous, composition of which is influenced by microenvironment of posterior eye layers. Molecular analysis of vitreous may therefore provide important insights into the pathogenesis of posterior eye diseases and inform future management strategies. Changes in tumor behavior are believed to correlate with metabolic alterations upstream/downstream of altered gene expression and protein function. Since the metabolome can provide a snapshot of all biochemical processes occurring in a biological system, metabolomic profiling of vitreous may advance our knowledge of UM by providing an overall readout of tumor state/behavior. To examine whether metastasis-prone UMs develop distinct metabolic features that can be captured by vitreous profiling, we performed untargeted metabolomic analysis of vitreous samples obtained from UM-affected eyes during tumor FNAB procedure for GEP. We initially focused on ~80 samples analyzed together (both in positive and negative ion mode) on the same platform (Agilent 1290 Infinity II / 6545 Q-TOF LC/MS system with the JetStream Ionization (ESI) source). Data analysis for this platform follows a hybrid targeted/non-targeted approach using Profinder and Agilent's Find by Molecular Feature algorithm. A combined feature set was generated, followed by data QC/filtering, transformation/imputation, and association testing by controlling for FDR. While further analyses using more complex modeling frameworks are still underway to evaluate the prognostic value of vitreous profiling, our initial testing of individual metabolite associations with UM prognostic subtypes using ORIOGEN software has revealed multiple vitreous metabolites (most being unknown compounds) significantly differing between the eyes with GEP class 1 vs 2 tumors. Our results suggest the presence of vitreous metabolites that may differentiate tumor GEP-based UM subtypes and function as biofluid-based markers following further characterization.

Omics Technologies Posters - Wednesday

PB3074. Metagenomic analyses coupled with metabolic and deep immune profiling reveal coordinate effects on host-microbe interactions in chronic kidney disease

Authors:

S-C. Su¹, I-W. Wu¹, L-C. Chang²; ¹Chang Gung Mem. Hosp., Keelung, Taiwan, ²Florida Atlantic Univ., Boca Raton, FL

Abstract Body:

Perturbation of gut dysbiosis has been linked to chronic kidney disease (CKD), a gradual loss of renal function that was pathologically correlated with a sophisticated milieu of metabolic and immune dysregulation. However, the underlying host-microbe interaction is poorly understood. To address this, we performed multi-omics measurements, including systems-level gut microbiome, targeted serum metabolome, and high-dimensional immunotyping, in a cohort of 72 patients and 20 non-CKD controls. Our analyses on functional profiles of gut microbiome showed that loss of renal function decreased the diversity and abundance of carbohydrate-active enzyme (CAZyme) genes, whereas kidney failure increased the abundance of nitrogen cycling enzyme, virulence factor, and antibiotic resistance genes. Moreover, use of fecal metagenomic, serum metabolomic, and immune signatures resulted in distinct effects on differentiating mild and severe CKD from controls. Models generated using measurements of circulating metabolites (amino acids, bile acids, and short-chain fatty acids) or immunotypes were predictive of renal impairment but less so than many of the taxonomic or functional profiles derived from gut microbiota, with the CAZyme genes being the top performing model to accurately predict early stage of diseases. In addition, correlation analyses among systems-level microbiome, serum metabolome, and immune parameters revealed coordinated host-microbe relationships in CKD. Specifically, the highest fractions of significant correlations were identified with circulating bile acids by several taxonomic and functional profiles of gut microbiome, while immunotype features were only moderately associated with the abundance of microbiome-encoded metabolic pathways and serum levels of amino acids. Overall, our multi-omic integration revealed several signatures of systems-level gut microbiome in robust associations with host-microbe co-metabolites and renal function, which may be of etiological and diagnostic implications in CKD.

Omics Technologies Posters - Thursday

PB3075. Methods for screening candidate causal regulatory variants in primary immune cells by CRISPR ribonucleoprotein.

Authors:

M. Lorenzini^{1,2}, K. Sajeev^{1,2}, G. McVicker¹; ¹Salk Inst. for Biological Studies, La Jolla, CA, ²Univ. of California San Diego, La Jolla, CA

Abstract Body:

Non-coding variants that are causal for human traits, such as those implicated by GWAS, often have small effects on gene expression. Current methods for determining the function of candidate causal variants sacrifice statistical power and genomic context for screening throughput, resulting in the loss of biologically important information. To screen non-coding candidate sequences with power and versatility in situ, we have optimized a robust ribonucleoprotein method for CRISPR deletion in resting primary immune cells. We apply this method to determine candidate causal variants of type 1 diabetes at the *CTLA4* locus. Finally, we extend this method for direct capture of genomic edits to enable powerful, combinatorial Perturb-seq screening of regulatory sequences.

Omics Technologies Posters - Wednesday

PB3076. MHConstruct creates personalized full-length MHC locus haplotype sequences by finding optimal paths through a population variation graph.

Authors:

M. Mumphrey, M. Cieslik; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

BACKGROUND: The immune system is able to identify and eliminate malignant cells via presentation of neoantigens by the major histocompatibility complex (MHC). Loss of MHC function is a known mechanism allowing cancers to escape this immunosurveillance, however molecular characterization of MHC loss is hindered by the extreme polymorphism of the region. Classical genetic, transcriptomic, and epigenetic methods rely on the alignment of molecular sequences to a standard reference, which fails for the MHC locus where the average person's genome is highly divergent from the standard reference. While methods exist for personalized analysis of individual MHC genes, there is a lack of tools that allow for personalized analysis of the entire 5 Mb MHC locus, which contains many accessory genes and intergenic regulatory regions. Population variation graphs have been used to allow for DNA-seq analysis of large polymorphic regions, however there are few algorithms that allow for the analysis of other data types directly on population graphs.

METHODS: We have developed MHConstruct, a tool that allows for reconstruction of the linear diploid MHC locus on an individual basis. MHConstruct leverages the VG toolkit to create a population variation graph of the MHC locus using a database of 95 full length MHC locus sequences. A SNP array is then constructed containing the genotype for each SNP in each reference sequence used to construct the graph. To generate a personalized linear diploid reference from the graph, DNA-seq reads from an individual are aligned to the graph and all SNPs are genotyped. Genotypes are phased, and the viterbi algorithm is used to find the optimal path through the SNP array for each set of phased genotypes. The viterbi paths are then used to pull segments of the corresponding reference sequences to construct the optimal linear sequence given the available set of reference sequences.

RESULTS: MHConstruct was able to construct diploid reference sequences for the MHC locus that had a rate of variation less than ~1 SNP/kb, which is the expected level of variation across the standard reference genome in non-polymorphic regions. Phasing and switch error rates were further characterized using linked-read sequencing. Finally, we demonstrate the use of MHConstruct references with standard tools for bisulfite sequencing and CHIP-seq data.

CONCLUSIONS: MHConstruct creates personalized diploid reference sequences for the MHC locus that are as high quality as the standard reference is for other less-polymorphic regions of the genome. This allows for personalized molecular analyses of the entire MHC locus using standard approaches that require a linear reference.

Omics Technologies Posters - Thursday

PB3077. MiRNA regulates potential genetic pathways involved in diabetic retinopathy: Implication for an early disease risk prediction

Authors:

S. Vishwakarma¹, P. Goel¹, R. Papparu¹, M. Tyagi¹, R. Narayanan¹, S. Chakrabarti¹, I. Kaur²; ¹LVPEI, Hyderabad, India, ²Prof Brien Holden Eye Res. Ctr., L V Prasad Eye Inst., Hyderabad, India

Abstract Body:

Background: Diabetic Retinopathy (DR) is a common microvascular retinal disease and can be classified into non-proliferative (NPDR) and proliferative diabetic retinopathy (PDR). Hypoxia and hyperglycemia along with dysregulated genetic signaling and altered metabolic pathways, affect the microvasculature of retina in DR leading to neuroinflammation, neurodegeneration, and neovascularization. However, neurodegeneration as an early event in DR development has not been explored much. Herein, we assessed the regulation of genes involved in both early diabetic retinal change and late stages of DR for their role in early risk prediction. **Methodology:** Cadaveric human retinal tissues with and without a history of diabetes (n=15) were collected from Ramayamma International Eye bank, INDIA. Retinal tissues were stained with H&E and PAS stain for detecting early diabetes-induced microvascular changes in the retina. Blood samples were collected from NPDR, PDR, and age-matched control patients with prior informed consent. RNA was isolated from tissue and blood using Purelink Kit. Quality and quantity assessment was done by bioanalyzer and nanodrop respectively. Tissues and blood RNA samples (RIN \geq 7) proceeded for mRNA and miRNA global profiling respectively on the Agilent platform. mRNA data were compared with published data (GSE160130). MiRNA targets were predicted by *in-silico* tools. qRT-PCR (SYBR green) was done for validation. **Result:** HandE and PAS staining showed ganglion cell layer thinning and significant increase in the number of blood vessels and their thickness in diabetic retina compared to control. A total of 1217 differentially expressed genes including ncRNA were found in diabetic retina compared to control. Their comparison with published data of NPDR and PDR retina tissue, identified 702 mRNA, 62.04% mRNA were present in DM, NPDR and PDR. Approximately 26.7% of these genes were found significantly up-regulated in DM, NPDR, and PDR and are involved in apoptosis, chemokine signaling, neurodegeneration, AGE-RAGE signaling, Rho-GTPases pathway, cell cycle, and MAPK signaling, etc. Next, we identified regulatory miRNA from our data including hsa-miR-142-3p targets genes involved in cell migration, proliferation, and hematopoiesis, hsa-miR-19a-3p, and hsa-miR-18a-5p that regulate angiogenesis via endothelial cell regulation, apoptosis, and neurodegeneration. Besides these, many other miRNAs were found to regulate the activation of pathological pathways in early DR that needs further functional validations. **Conclusion:** This study underscores the potential role of miRNA in regulating neurodegeneration and early DR risk prediction.

Omics Technologies Posters - Wednesday

PB3078. Mitigating challenges of large-scale single cell data management, querying, and analysis with REVEAL SingleCell

Authors:

K. Sharma, C. Bragdon, U. Mudgal, Z. Pitluk, S. Sarangi; Paradigm4, Waltham, MA

Abstract Body:

Advancements in single cell technologies have allowed sustained exponential growth in the rate of published studies and datasets over the last decade. Individual studies have also increased in scale over time - during the first half of 2020, approximately 1,400,000 cells were added to the pool of public data every month - and this number continues to grow. New 'atlases' that try and standardize data across tissues are being generated frequently, and large multi-organ datasets from multiple patients such as Tabula Sapiens are being released as an effort to get closer to doing population-scale analyses. Complicating the growth in data generation is the proliferation of algorithms to help clean, integrate, harmonize, cluster, and analyze single cell datasets. While exciting and vital for addressing problems such as identifying sub-populations of cancer cells, these advances have created unique challenges. These include efficient storage and retrieval due to variable and inherent sparsity of data, rapid querying across hundreds of samples for co-expression of genes, running multiple algorithms at scale in one workflow due to the variability in results (e.g., for clustering), and handling multi-omics data within one platform. We had previously described REVEAL SingleCell, a computational platform for working with multi-omics single cell data (*BMC Genomics*, 2021). Here, we present new and improved features of REVEAL SingleCell developed to address the above challenges. We demonstrate scalability and performance by presenting results from two design of experiments spaces: 1) measuring time to load data using two inputs: % sparsity (1% - 100%) and number of cells (10,000 - 1 million); 2) measuring time for queries (e.g., co-expression of genes) using three inputs: % sparsity (1% - 100%), number of cells (5 - 100 million), and number of genes (1 - 300). We also present benchmarking performance numbers for cross-sample queries using metadata fields (e.g., cell type = epithelial), and computations (e.g, correlation between genes across thousands of cells, calculation of z-scores at scale). Finally, we show the use of iSets to enable the creation of custom atlases with samples spanning many projects that facilitate data reusability. Taken together, we provide useful benchmarks for software developers as the scale of single cell datasets increases.

Omics Technologies Posters - Wednesday

PB3079. Mitochondrial Genomic ratio (mitoscore) is an efficient biomarker to predict the implantation efficacy of human embryos

Authors:

S. Chettiar¹, J. Dattani², A. Patel³, D. Jhala⁴, F. Parikh⁵, R. Uppala⁶; ¹Gujarat Univ., Ahmedabad, India, ²Ministry of Hlth.and Family Welfare, Ahmedabad, India, ³GeneXplore Diagnostics and Res. Ctr. Pvt. Ltd., Ahmedabad, India, ⁴Sch. of Sci., Gujarat Univ., Ahmedabad, India, ⁵Jaslok Hosp., Mumbai, India, ⁶Genexplore Diagnostics and Res. Ctr., Ahmedabad, India

Abstract Body:

Objective: Single embryo transfer is gaining momentum in the clinical field of assisted reproductive technology (ART). However, selecting a single embryo for transfer is difficult as there is no reliable biomarker to predict the success of implantation and development. Here we discuss mitoscore as predictive markers by genomic rather than, visual, and metabolomic markers. This score is calculated using a ratio of the whole to mitochondrial genome, identified using next generation sequencing (NGS). In turn, this data educates an AI-based algorithm for the selection of embryos for enhanced implantation success through large dataset. **Design:** Couples undergoing infertility treatment and preimplantation genetic testing (*PGT*) were enrolled for the study with written consent. All grade I and II embryos were biopsied and subjected to NGS. The chromosome aneuploidy data and nuclear to mitochondrial genome ratio were analyzed using R-based machine learning and deep learning. To investigate the predictive power of the mitoscore and its correlation with clinical outcomes, observed data and predicted data were compared and statistically analyzed. **Material and methods:** Trophoctoderm biopsy leading to 3-6 cell source was subjected to NGS for 3000 embryos. The data of these 3000 embryos were processed via deep learning and machine learning algorithms like random forest, support vector machine, general linear model, and linear discriminant analysis. An additional neuronal network scope was added to the pipeline, giving a stimulus enhancement to the dataset and thus finetuning the data outcome. Opensource software package like the h2o R package was employed to perform R analysis and Box-Behnken design (BBD) using response surface methodology (RSM). **Results:** NGS data revealed the euploid status of the embryo and the ratio of the whole genome sequence to the mitochondrial genome. Ratios were plotted on a know graph ratio and values were converted to percentages. Embryos with more than 40% and less than 25% ratio were found to either have aneuploidy or were not selected for transfer. R^2 analysis also predicted with a confidence interval of 0.9921 that mitoscores above 37 and less than 28 were predictive of aneuploidy in any one/multiple chromosomes. With increasing dataset size, we intend to improve the sensitivity and specificity of the technology adapted with a positive prediction by machine DOE and R^2 analysis with superior confidence. **Conclusions:** From the experimental data, R package prediction through deep learning, and machine learning, it can be concluded that mitoscore values can be reliably employed as a biomarker for implantation efficacy of embryo.

Omics Technologies Posters - Thursday

PB3080. More bang for your buck! Universal Sequence Detection: A novel full spectrum variant genotyper for NGS data

Authors:

J. Van Den Akker, K. Wong, A. Rostamianfar, Z. Langley, M. Cusack, A. Ondov, A. Zimmer, A. Zhou, S. Topper; Color Hlth., Burlingame, CA

Abstract Body:

Reduced cost and interest in novel variant detection has led the field of clinical genetic testing to adopt NGS technologies over once widely-used genotyping arrays. However, some advantageous aspects of genotyping can now be applied to NGS technologies to improve known variant detection. Here, we describe a novel algorithm we developed, called Unique Sequence Detection (USD), which improves the sensitivity and efficiency of known variant detection in short-read sequencing data.

USD is a genotyping-based variant caller that utilizes a library of predefined unique sequences to accurately, efficiently, and repeatably genotype known variants from short-reads. USD is able to genotype the entire spectrum of variant types, from single nucleotide variants (SNVs) to complex structural variants (SVs).

USD operates in two phases: 1) a one-time unique sequence generation step where unique sequences are constructed based on previously well-characterized variants and 2), a pattern matching step where an alignment file is scanned to identify reads supporting the constructed unique sequences. Each sequence has three parts: a “core” sequence that spans the variant and needs to be matched exactly and left and right “flanking” sequences where some variation is tolerated to provide resilience against co-variants and sequencing errors.

Leveraging our existing library of clinically reported pathogenic variants, we found that USD can genotype challenging SNVs, small insertions and deletions (indels), and SVs that are often missed, called incorrectly, or require a special implementation of variant callers. These include known challenging variants with high GC content or near homopolymers, including *MSH2* c.942+3A>T. Our USD library also contains unique sequences to identify known breakpoints for complex SVs, including the hard-to-call Boland inversion (*MSH2* inversion exons 1-7). In a set of 1531 unique variants including SNVs, indels, MNVs, and complex SVs, USD achieved a sensitivity of 99.61% with a specificity >99.9%.

In conclusion, USD is a comprehensive genotyping algorithm that enables accurate detection of known variants of all sizes and complexities. It boosts detection of known pathogenic variants using either targeted or whole genome short-read sequencing, thereby reducing the need for manual review and special pipeline implementations for known challenging variant calls as well as improving overall pipeline efficiency. Importantly, subsequent observations of validated variants can be added regularly to the USD library, thereby continuously improving the overall sensitivity and efficiency of the clinical genetic test.

Omics Technologies Posters - Wednesday

PB3081. Multi-Omics Integration for Osteoporosis Prediction through Mixture-of-Experts Framework

Authors:

Y. Gong¹, J. Greenbaum¹, L. Jiang², A. Liu³, X. Zhang¹, H. Shen⁴, H-W. Deng¹; ¹Tulane Univ., New Orleans, LA, ²Tulane Univ. Sch. of Med., New Orleans, LA, ³Tulane Univ., Metairie, LA, ⁴Tulane Univ, New Orleans, LA

Abstract Body:

Abstract With the development of high-throughput omics measurement technologies, it is essential for researchers to integrate heterogeneous genomics and molecular information from multiple omics to develop more accurate disease-relevant prediction models. We will apply a mixture-of-experts deep generative model to integrate multi-omics profiles for normal/osteoporosis classification and novel osteoporosis-related biomarkers identification. We will use the miRNA sequencing, DNA methylation, and gene expression data in peripheral blood monocytes (PBMS) from Caucasian (n=558) and African American (n=359) men sampled from the Louisiana Osteoporosis Study (LOS). Subjects will be classified into normal/osteopenia groups based on their hip BMD (T-score <-1.0). Mixture-of-experts deep generative framework, a novel deep generative model-based framework with better performance than other conventional methods for dimension reduction, will be used for multi-omics profiles integration and osteoporosis diagnosis. Through this method, variational autoencoder (VAE) will be used to learn high-level representations in each omics data (gene expression, miRNA expression, and DNA methylation) and we will integrate all learned representations through the mixture of experts, which weight the learned representations to form the integrated ones. The integrated representations from VAE and phenotypes of the samples will be used to train the flexible neural forest model, which is a multi-layer feed-forward neural network for classification. We will then apply 5-fold cross-validation to assess the performance of the model. To reveal the potential biomarkers related to osteoporosis, we will select the features with the highest weight in the VAE framework. Gene Ontology (GO) analysis will then be used to identify the biological functions and related pathways of these features. Through the mixture-of-experts deep generative model, we will learn the representations of the complex multi-omics datasets and construct a classification model for osteoporosis prediction based on the learned representations. Further, based on this model, we will identify the significant biomarkers related to osteoporosis, which will provide novel insights into the pathological mechanisms of the disease. **Keywords:** osteoporosis, bone mineral density, deep learning, disease prediction

Omics Technologies Posters - Thursday

PB3082. Multi-omics integration via similarity network fusion to detect subtypes of aging

Authors:

M. Yang¹, S. Matan-Lithwick², Y. Wang³, P. De Jager⁴, D. Bennett⁵, D. Felsky⁶; ¹Univ. of Toronto and CAMH, Toronto, ON, Canada, ²Krembil Ctr. for Neuroinformatics, Ctr. for Addiction and Mental Hlth., York, ON, Canada, ³Rush Univ. Med. Ctr., Chicago, IL, ⁴Columbia Univ Med Ctr, New York, NY, ⁵Dept. of Neurological Sci., Rush Med. Coll., Chicago, IL, ⁶The Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract Body:

Background: Molecular subtyping of brain tissue provides insights into the heterogeneity of common neurodegenerative conditions, such as Alzheimer's disease (AD). However, existing subtyping studies have mostly focused on single data modalities, such as RNA sequencing (RNAseq), which provide incomplete neurobiological information on pathological processes. To remedy this, we applied similarity Network Fusion (SNF), a method capable of integrating multiple high-dimensional multi-'omics data modalities simultaneously. **Methods:** We analyzed human frontal cortex brain tissue samples characterized by five 'omic modalities: bulk RNAseq (18,629 genes), DNA methylation (53,932 cpg sites), histone H3K9 acetylation (26,384 peaks), tandem mass tag proteomics (7,737 proteins), and metabolomics (654 metabolites). SNF followed by spectral clustering was used for subtype detection, with subtype numbers determined by eigen-gaps and dip-test statistics. Normalized Mutual Information (NMI) was calculated to determine the contribution of each modality and feature to the fused network. Resulting subtypes were characterized by associations with 12 age-related neuropathologies and cognitive performance. **Results:** Fusion of all five data modalities (overlapping n=111) yielded four molecular subtypes (nS1=32, nS2=26, nS3=31, nS4=22); S1 exhibited lower episodic memory performance than other subtypes proximal to death ($t=4.7$, $p=1.5 \times 10^{-4}$). Histone acetylation (NMI=0.32) and RNAseq (NMI=0.16) contributed most strongly to this fused network; the top individual features were an acetylation peak in the promoter of CD200 and RNA abundance of PARP4. Secondary analysis fusing only RNAseq and histone acetylation (n=520) yielded five subtypes which were correlated with the fully integrated subtypes (Fisher's $p=5.0 \times 10^{-4}$) and strongly associated with AD neuropathology and episodic and semantic memory. Sensitivity analyses of all modality combinations and sample subsets found substantial influences of sample size and subtype number, but reinforced the importance of histone acetylation, RNAseq, and DNA methylation. **Conclusion:** We identified highly integrative molecular subtypes of aging derived from up to five multi-'omics data modalities simultaneously. These subtypes recapitulate some features of previous subtyping work in AD using single modalities, but also provide new molecular targets and shed light on the benefits and challenges of multi-omic integration and individual subtyping in this field.

Omics Technologies Posters - Thursday

PB3083*. Multiset correlation and factor analysis enables exploration of multi-omic data

Authors:

B. Brown¹, C. Wang², S. Kasela¹, F. Aguet³, D. Knowles¹, T. Lappalainen⁴; ¹New York Genome Ctr., New York, NY, ²Columbia Univ., New York, NY, ³Broad Inst., Cambridge, MA, ⁴KTH Royal Inst. of Technology & NY Genome Cntr, New York, NY

Abstract Body:

Multi-omics data promise to revolutionize biomedical research, providing insight into the coordination of molecular processes that cannot be gleaned from any lone 'omics mode. However, joint inference methods are lacking in either the number or type of modes that can be used, or in flexibility and efficiency. We developed Multi-set Correlation and Factor Analysis (MCFA), an unsupervised data integration method that enables fast inference of shared and private factors in multimodal data. MCFA is designed to overcome challenges that are common with 'omics data such as the large number of features relative to the sample size, disparate data types, and the unknown contributions of mode-specific technical factors. Moreover, MCFA requires no user-specified tuning parameters, is efficient enough to apply to thousands of samples, and has a strong connection to canonical correlation analysis. We have applied MCFA to 614 ancestry-diverse individuals, each profiled with 5 different genomics technologies as part of the TOPMED-MESA multi-omic pilot. We integrated RNA, methylation, protein, and metabolite data using MCFA, and further integrated genetic data by analyzing genetic associations with the inferred factors. We found extensive sharing across data modes: 30% of the total variance in protein expression is explained by the shared space; 17% for RNA expression and metabolites; and 8% for methylation. Samples cluster strongly by race and sex in the shared space, even though this is not true for the top PCs of individual modes and the shared space was inferred without genetic or sex chromosome features. Next, we evaluated the total phenotypic variance explained by each of our inferred spaces. The shared space captures 80% of the variance in race, 95% of the variance in sex, and 60% of the variance in age, while additionally capturing effects of sample cell-type composition, air quality measures, and inflammatory biomarkers. Private spaces often captured technical features such as batch but also captured variation in cell-type composition not explained by the shared space and, in the metabolite data, the month of sample collection. Our genetic analysis revealed association enrichment at known disease GWAS SNPs and *trans*-eQTLs for several factors. We further investigate one factor showing strong GWAS enrichment that is correlated with cell-type composition, inflammatory biomarkers and BMI, revealing a connection between global methylation patterns, lipid metabolism and related diseases. Our study provides a framework for further integrative analysis of multi-omic data, with inferred axes of molecular variation a promising future trait for GWAS and pheWAS studies.

PB3084. Neuroimmune insights through single-cell transcriptomics of paired brain and blood from living human subjects

Authors:

D. Liu, J. Fullard, L. E. Liharska, E. Cheng, L. Wilkins, N. Beckmann, B. H. Kopell, P. Roussos, A. Charney; Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Background: Genetic and clinical studies point to roles for the immune system in neuropsychiatric diseases, yet the mechanistic explanation for these observations remains unclear. Brain has a resident immune system that interacts with peripheral immunity, and under psychological and pathological conditions, cells moving dynamically between the central nervous system (CNS) and the peripheral circulation have been described. The exact nature of these interactions has not been characterized in the living human brain. This study aims to characterize the cellular and molecular basis of the CNS-periphery interaction, by analyzing the single-cell transcriptomes profiled on matched brain-blood specimens from living human subjects. **Methods:** The prefrontal cortex and peripheral blood were sampled simultaneously from donors during neurosurgical procedures, and were processed together on the same day for single-cell RNA sequencing. Following quality control, 105,833 immune cells from 13 brain-blood pairs were analyzed. Cell populations in the brain and the blood were compared with respect to cell type composition and cell transcriptional states, and were correlated for gene expression across the 13 pairs. **Results:** Both resident (microglia, macrophages) and peripheral immune cells (PICs, including T, B, natural killer (NK) cells, monocytes) were detected in brain samples. PICs detected in the two tissues displayed different cell type proportions, and the most notable difference was seen for the relative abundance of T cells and their subpopulations. Comparing gene expressions in brain PICs and their blood counterparts, brain PICs showed an up-regulation in pathways including immune signaling, stress response, apoptosis, and metabolism, whereas blood PICs expressed higher level of ribosomal genes and genes involved in defense response to antigens. Clustering brain and blood cells together identified transcriptional states that are broadly shared between tissues, with an exception of a brain-specific CD8⁺ T population. Across 13 brain-blood pairs, the cell types that showed the highest average gene-wise correlation with microglia were blood NK and CD4⁺ T cells. Data on repeatedly sampled donors showed that gene expression changes over time were only modestly correlated between tissues and were on average greater in brain as compared to blood. **Conclusions:** There are widespread differences and correlations between the CNS and the peripheral immunity at the cellular and molecular level. These insights highlight the potential to extract molecular information about the brain via a routine blood draw.

Omics Technologies Posters - Thursday

PB3085. New generative deep models to discover novel disease-gene associations in large-scale genomic cohorts

Authors:

R. Orenbuch, J. Frazer, M. Dias, K. Brock, D. Marks; Harvard Med. Sch., Boston, MA

Abstract Body:

Accurate and unbiased variant effect prediction can increase power to discover true gene-disease connections in both rare and common variant association studies, by weeding out mutations that are unlikely to cause disease. However, the majority of variants have no known consequence, as the rate of discovery of novel variants is greatly outpacing experimental and clinical validation of the contribution of individual variants to disease phenotypes. Building on our recent success in providing an orthogonal source of evidence for benign/pathogenic classifications for human variants with EVE, we have developed a model which combines deep-variation, across millions of years of evolution, with shallow-variation, across the human population, to address this. Here, we use our scores to increase our power to discover novel gene-phenotype associations from large-scale datasets, focusing on diseases of aging and related phenotypes in the UK Biobank. We investigate if our scores increase the amount of explained heritability in existing burden-testing methods and develop new methods that leverage the continuous nature of our scores and their level of uncertainty to increase our power to detect gene-disease associations with varying levels of penetrance. We both recapitulate known and discover novel genotype-phenotype associations and ultimately fill in the gap of unexplained heritability in these diseases.

Omics Technologies Posters - Wednesday

PB3086. New genotyping and sequencing methods for high throughput molecular blood group typing

Authors:

A. Franke¹, T. Steiert¹, H. El Abd¹, M. Wittig¹, C. Gassner²; ¹Christian-Albrechts-Univ. of Kiel, Kiel, Germany, ²Private Univ. im Fürstentum Liechtenstein, Triesen, Liechtenstein

Abstract Body:

Blood group antigens play an important role in transfusion medicine and can cause unwanted dangers for the recipient through immune reactions. For this reason, high throughput typing of donor blood is carried out in blood banks to allow for the most suitable donor-recipient-match possible. The standardized blood group antigen nomenclature is stored in the ISBT (International Society of Blood Transfusion) database in the form of alleles with their associated genetic variations. Thus, it is technically possible to determine blood group alleles/antigens, based on targeted genotyping and also targeted sequencing. Firstly, we present a SNP array-based approach that enables this process in high throughput at low per-sample costs. We validated the SNP array results using data from 57,531 antigens of an ethnically diverse reference sample set including the 1000-Genomes samples and provide the blood calls and underlying data as a resource and reference to the community. To demonstrate the utility of the blood group array in disease association studies, we genotyped a COVID-19 case-control panel to validate the previous ABO association and to test for an association with other blood group phenotypes. Secondly, we present another software tool and benchmarking study to call blood group alleles from targeted NGS or WGS data. Proof-of-principle WGS data for 500 clinically interesting samples was generated and analysed for novel blood group alleles.

Omics Technologies Posters - Thursday

PB3087. Novel Principal Component Analysis reveals rich gene expression contexts from snRNA-seq within and across cell-types.

Authors:

S. Carver¹, A. Gusev²; ¹Harvard Univ., Cambridge, MA, ²Dana Farber Cancer Inst., Longwood, MA

Abstract Body:

Background:Single cell genomics has advanced our ability to profile individual cells especially in terms of their cell type. Precisely subdividing cells by type instead of analyzing bulk sequencing data has allowed researchers to identify key cell types driving disease as well as unique cell type functionality. To move beyond canonical cell types, work has been done to identify cell states (sub-groupings of cells within cell type) or cell programs (cell subsets based on common functionality across cell types). However computational methods for identifying cell states are often not sufficiently justified and validating biologically meaningful cell states rather than states derived from technical noise is often difficult due to a limited ground truth data for novel states.

Methods:We propose novel methods based on hierarchical and conditional Principal Component Analysis (PCA) to identify biologically meaningful cell states and programs from single-cell transcriptomics and epigenomics. We benchmarked our approach against conventional methodologies such as consensus Non-negative Matrix Factorization (cNMF) and t-distributed Stochastic Neighbor Embedding (t-SNE). Method performance was evaluated using simulated data, followed by application in a multi-omic single-nucleus study from control and late-stage Alzheimer's Disease (AD) prefrontal cortex. The identified cell contexts were validated by consistency with snATAC-seq, association with AD pathology, and consistency with known cell types from larger external atlases.

Results:In simulated data, the PCA-based approaches performed best at identifying both states and programs, particularly for rare states and continuous programs. PCA could reliably identify contexts in as few as 10 cells, compared to greater than 600 cells for cNMF and t-SNE, respectively. Applied to real AD data, PCA substantially outperformed cNMF for identifying rare cell types and the two approaches were comparable for common cell types. Validating the identified cell programs using snATAC-seq from the same donors revealed >100 contexts with statistically significant biological structure ($p < 0.05$ by permutation test).

Conclusion:We demonstrate that snRNA-seq data is rich with biologically relevant gene expression contexts which are often missed by conventional approaches. We present a powerful framework for identifying and validating novel contexts using PCA and implicate new cellular processes in AD pathology. Further integration of novel contexts into disease data from Genome-Wide Association Studies is ongoing.

Omics Technologies Posters - Wednesday

PB3088*. Novel sequencing platform using an open fluidics architecture and mostly natural chemistry for cost-efficient whole genome sequencing.

Authors:

D. Lipson, O. Barad, D. Shem-Tov, F. Oberstrass, M. Pratt, G. Almogy; Ultima Genomics, Newark, CA

Abstract Body:

Advances in next generation sequencing over the last two decades have enabled cutting edge life sciences research as well as a rapidly growing set of clinical applications, ranging from carrier screening and prenatal testing to tumor profiling and early cancer detection. However, sequencing cost reduction has stalled in recent years limiting the widespread adoption of genomic-based diagnostics into standard of care.

We have recently introduced a novel sequencing platform that enables whole-genome sequencing at an initial cost of \$100 per genome (\$1/Gb), by employing a novel open fluidics architecture in combination with a mostly-natural sequencing by synthesis (mnSBS) chemistry that together enable the longer read advantages of non-terminating nucleotides and the throughput and scalability of optical endpoint scanning at a significantly lower consumable cost. Beyond the initial implementation, this novel architecture provides multiple dimensions for continuous reduction sequencing cost even further in the not-distant future.

We evaluated the performance of the new platform by generating whole-genome sequence data for the seven Genome-in-a-Bottle reference samples HG001-7 at 40X, demonstrating read length of ~300bp, good coverage uniformity across the genome, and high base quality (Q30 >85%). Variant calling was performed by an updated version of DeepVariant that was optimized to use base quality information that is unique to the system, and demonstrates 99.7% concordance on single nucleotide variants and >97% concordance on InDel variants in non-repetitive genomic regions, with further improvements expected from enzyme evolution and additional optimization of the sequencing workflow.

We additionally demonstrated the applicability of the platform for other high-throughput applications including single-cell RNA-seq, deep (~100X) WGS of cell-free DNA for residual disease monitoring, whole-genome methylation analysis and agnostic pathogen profiling. The continuous drive for sequencing affordability and ubiquity will undoubtedly lead to deeper genomic insights and further integration of sequencing assays into clinical practice.

Omics Technologies Posters - Thursday

PB3089. NTSM: Fast sample swapping detection and ancestry estimation on unprocessed heterogeneous raw sequencing data

Authors:

J. Chu^{1,2,3}, J. Rong^{2,3}, X. Feng^{2,3}, H. Li^{2,3}; ¹Boston, Boston, MA, ²Dana Farber Cancer Inst., Boston, MA, ³Harvard Med. Sch., Boston, MA

Abstract Body:

Due to human error, sample swapping in large cohort studies with heterogeneous data types (e.g. mix of Oxford Nanopore, Pacific Bioscience, Illumina data, etc) remains a common issue plaguing large-scale studies. At present, all sample swapping detection methods require costly and unnecessary (e.g. if data is only used for genome assembly) alignment, positional sorting, and indexing of the data in order to compare similarly.

Instead of alignment, the similarity between raw data samples can be determined using a set of carefully curated SNP sequences indexed into a time and memory-efficient k-mer counting algorithm. These counts can be compared via a likelihood ratio-based test very quickly, with an accuracy determined by the coverage of the data and the error rate of the data type. This first pass QC method, independent of downstream analysis, can save an immense degree of computational time and is robust enough to be used on many data types combinations.

In addition, as a crude form of variant calling, the method can also be used to determine population-level ancestry analysis quickly and generically find approximate sample ancestry via a population-based PCA without requiring extensive variant calling. Population-level PCA analysis of this type also usually requires the same data types to be used in this kind of analysis, due to the requirements of carefully tuned variant calling algorithms, which is unnecessary in our streamlined, robust, k-mer counting-based methodology. Other QC metrics, such as error rate estimation can be determined from this information, providing useful utility in downstream analysis.

Omics Technologies Posters - Wednesday

PB3090. ODER: Optimising the Definition of Expressed Regions, a publicly available R package to improve annotation of RNAseq data and investigate novel transcription using short-read RNA-sequencing data

Authors:

J. Brenton¹, E. Olagbaju¹, K. Montgomery¹, S. Sethi², L. Collado-Torres³, S. Guelfi⁴, D. Zhang¹, M. Ryten⁵; ¹Univ. Coll. London, London, United Kingdom, ²Astex Pharmaceuticals, Inc., Cambridge, United Kingdom, ³Lieber Inst. for Brain Dev., Baltimore, MD, ⁴Verge Genomics, San Francisco, CA, ⁵UCL Great Ormond Street Inst. of Child Hlth., London, United Kingdom

Abstract Body:

Incomplete annotation of the human transcriptome remains a problem facing modern genetic research with the choice of gene annotation source or version affecting variant interpretation, quantification of RNAseq expression and downstream differential gene, splicing and quantitative trait analyses. We developed Optimising the Definition of Expressed Regions (ODER), a publicly available R package (<http://bioconductor.org/packages/release/bioc/html/ODER.html>) which addresses this problem by using short-read RNAseq data to re-annotate known genes. ODER leverages the derfinder R package (<http://bioconductor.org/packages/release/bioc/html/derfinder.html>) to assess base-level coverage, identify contiguous blocks of transcription, termed expressed regions (ERs) and connect these expressed regions to known genes. ODER requires two input files per sample, a BigWig and junction file. A typical ODER pipeline consists of four functions. First, using the BigWig coverage data, ODER improves the identification of ERs by varying two parameters, the mean coverage cutoff (MCC), defined as the minimum read depth that an individual base pair requires to qualify as being expressed, and the maximum region gap (MRG), defined as the maximum number of base pairs between two ERs below which they are merged. These are varied to find the minimum difference between ERs and the user-provided “gold standard” exon definitions. Second, using junction files, ODER finds overlaps between optimised ERs and junction reads, short reads mapping to the reference annotation with a gapped alignment, to connect ERs to known genes. Third, ERs are filtered for those that overlap a single or two non-intersecting junctions. ER boundaries are then trimmed to match the exon boundaries of the overlapping junction/s. Finally, ODER generates a count matrix, which provides the mean coverage over each ER. Testing of ODER’s accuracy with small RNA-seq data sets demonstrated ERs could be defined accurately with only ten polyA-selected RNA-seq samples, increasing its value. ODER has already been applied to short-read RNA-seq data generated by the Genotype-Tissue Expression Consortium data to identify potential novel coding exons and 3’UTRs (<https://rytenlab.com/browser/app/vizER>; <https://astx.shinyapps.io/F3UTER/>). Thus, ODER provides users with an efficient means of leveraging user-generated and public short-read RNA-sequencing data for the identification of novel exons which can then be studied using targeted and more expensive long-read RNA-sequencing approaches.

Omics Technologies Posters - Thursday

PB3091. On statistical modeling of single-cell RNA-seq data accounting for technological and biological dropouts.

Authors:

I. Mukhopadhyay¹, P. Mondal²; ¹Indian Statistical Inst., Kolkata, India, ²Michigan State Univ., East Lansing, MI

Abstract Body:

Analyzing single-cell RNA-seq data is challenging due to proper mathematical modeling of biological factors that influence the observed expression levels in the data. The transcription level is a transient process affected by spatial effects, cell cycle, cell types, and other environmental factors. Moreover, a low amount of initial cDNA before amplification adds to considerable noise in the data making it difficult to analyze. A typical dataset contains a large number of zero expressions, also known as dropouts. Moreover, the bimodal pattern of the expression level adds additional complexity to analyze the data. We propose a statistical model that simultaneously takes care of all these factors to fit a distribution on the expression levels of individual genes. Our model is based on a gene-wise unimodal or bimodal Gaussian distribution coupled with a generalized linear model with a probit link. We identify the gene-specific and cell-specific effects on overall dropout probability and overall expression levels. We aim to distinguish the zeros arising due to technical errors from zeros appearing due to biological factors. We have also developed a method for testing differential expression between two groups taking care of all intricacies of single-cell RNA-seq data and evaluated asymptotic properties. Our model can be readily used for other downstream analysis that can be performed using single-cell RNA-seq data. Extensive simulation and real data analysis validate the performance of our methods.

Omics Technologies Posters - Wednesday

PB3092. Optimizing microbiome extraction methods for human intestinal resections.

Authors:

E. P. Ryu¹, W. A. Koltun², G. S. Yochum², E. R. Davenport¹; ¹Pennsylvania State Univ., University Park, PA, ²Pennsylvania State Coll. of Med., Hershey, PA

Abstract Body:

Fecal samples are typically used as a proxy for the human gut microbiome. While fecal sampling is non-invasive and convenient, microbiome diversity varies along the intestinal tract and the fecal microbiome does not fully capture this variation. This issue may be particularly impactful for host genetic-microbiome studies, as host genetic variants are more likely to interact with taxa residing on the mucosal layer of the intestinal lining than those in the lumen. As a result, the microbiome collected from intestinal tissue resections may provide greater insight into the associations between host genes and microbes compared to fecal samples. The caveat is that there are no standardized protocols for characterizing the microbiome from tissue. This is problematic for two reasons: 1) tissue samples are low microbial biomass environments, so the microbiome is prone to kit contamination, and 2) the vast amount of host DNA can wash out microbial DNA. This second issue can make the PCR amplification standard in 16S rRNA gene sequencing studies particularly challenging, as primers can bind to off-target regions in the host DNA. To address this gap, I am performing a comprehensive benchmarking study to identify the ideal i) DNA extraction kit, ii) tissue sample type, and iii) 16S rRNA gene primer set for generating microbiome data from human tissue samples. First, I am comparing three kits that have been previously used to extract the microbiome from intestinal biopsies: Zymo Quick-DNA, DNeasy Blood & Tissue, and DNeasy PowerLyzer PowerSoil. Second, I am using two sample types: full-thickness terminal ileum resections and corresponding mucosal scrapings. Samples have been acquired from the Inflammatory Bowel Disease Tissue Biobank at the Penn State Milton S. Hershey Medical Center (n = 4 full-thickness and n = 2 mucosal lining per kit, for a total n = 18). Finally, I am testing two 16S primer sets: standard V4 Earth Microbiome Project primers, and V1 primers, which have been reported to have superior performance in samples with heavy host DNA contamination. Evaluation across methods will include identifying the extent of kit contamination for each DNA extraction kit, total material extracted, and amount of host DNA off-target amplification in the 16S rRNA gene sequencing results. This study will be one of the first to compare these three DNA extraction kits, different sample types, and different primer sets for intestinal tissue microbiome extraction. Establishing tissue microbiome extraction protocols will facilitate investigations of host genetic-microbiome associations and push the field towards examining the host genes most closely involved with the microbiome.

Omics Technologies Posters - Thursday

PB3093. OrphaID: a new platform for rare intellectual disabilities in Orphanet in partnership with ERN-ITHACA

Authors:

M. Amin¹, A. Olry¹, V. Serriere-Lanneau¹, C. Zweier², A. Hugon³, B. Popp⁴, C. Rodwell¹, C. Lucano¹, H. Ali¹, A. Rath¹, A. Verloes³; ¹INSERM, US14-Orphanet, Paris, France, ²Univ Erlangen-Nürnberg, Erlangen, Germany, ³Robert DEBRE Univ. Hosp., Paris, France, ⁴Univ. of Leipzig Hosp. and Clinics, Leipzig, Germany, Leipzig, Germany

Abstract Body:

Background: Intellectual disability (ID) is a group of heterogeneous disorders affecting up to 3% of worldwide population and characterized by significant impairment in cognition and behavior which can be associated with other syndromic or dysmorphic features. The heterogeneity of intellectual disabilities and rarity of most forms render the genetic diagnosis challenging in most cases. Hence, stemmed a need for developing a comprehensive list of curated intellectual disability related genes and associated phenotypes. **Methods:** Orphanet, which is the largest portal for rare diseases in the world has partnered with the European Reference Network on Rare Congenital Malformations, Autism and Rare Intellectual Disability (ERN-ITHACA) in order to develop a platform (OrphaID) for curated intellectual disability related genes and phenotypes. This list of intellectual disability-related genes is curated in partnership with ERN-ITHACA and SysID/SysNDD (www.sysid.dbmr.unibe.ch). **Results:** OrphaID currently (March 2022) contains 803 Orpha-coded ID phenotypes linked to 1390 curated ID-genes. This will allow systematic and comprehensive access to and retrieval of ID specific information within Orphanet. The list of OrphaID entries is linked to both internal (e.g. genes information, classification, HPO signs) and external resources (e.g. SysNDD, OMIM). It can be searched or filtered by gene, disease or OMIM number and the results can be downloaded in different file formats (excel, csv and txt). **Conclusion:** OrphaID is a valuable tool for all users (patients, researchers and clinicians) with interest in rare intellectual disabilities. The platform is freely accessible at <https://id-genes.orphanet.app/ithaca/>.

Omics Technologies Posters - Wednesday

PB3094. Outcomes from the Care4Rare Canada unsolved research pipeline for 950 patients with non-diagnostic exome sequencing data

Authors:

K. Boycott¹, T. Hartley¹, K. Kernohan¹, D. Dymant¹, E. Soubry¹, C. Marshall², M. Couse², R. Mendoza², J. Dowling², M. Acker², F. Bernier³, M. Innes³, B. McInnes³, J. Parboosingh³, R. Lamont³, P. Au³, A. Lehman⁴, M. Waqas⁴, A. Mohajeri⁴, Care4Rare Canada Consortium; ¹Univ. of Ottawa, Ottawa, ON, Canada, ²Univ. of Toronto, Toronto, ON, Canada, ³Univ. of Calgary, Calgary, AB, Canada, ⁴Univ. of British Columbia, Vancouver, BC, Canada

Abstract Body:

Progress toward the discovery of the genetic basis of every rare disease (RGD) has been substantial over the past decade secondary to the introduction of exome sequencing, with the identification of 250-300 new disease-gene associations every year. However, despite our increased understanding of the mechanisms of RGDs, one-third of patients remain undiagnosed because the molecular mechanism underlying their rare disease is either not yet recognized within, or is outside of, the coding genome. We recruited 950 unsolved patients with a suspected RGD who had non-diagnostic exome sequencing data from either the clinical or research setting. Reanalysis of the existing exome data from the proband, and in most cases additional family members, provided a diagnosis in a known disease gene for 82 families (9% of the cohort) and identified novel candidate genes in 195 families (21%), of which 79 have been validated as disease-causing (8%) using data-sharing and laboratory investigations. Participants remaining without a diagnosis or compelling candidate were considered (based on phenotype and sample availability) for an unsolved multi-omics research pipeline. The outcome of the first 133 families has shown a total gain in diagnostic yield of 13.5% (18/133) (11% for short-read genome sequencing (15 of 133 analyzed thus far), 8% for transcriptome sequencing (2 of 26), and 8% for long-read genome sequencing (1 of 14)) above and beyond what could be detected in the exome sequencing data, suggesting that disease mechanisms beyond the reach of the exome are important contributors to the unsolved cohort. Additional analysis of these data will likely further increase their contribution to the diagnostic yield. Leveraging opportunities to promote international sharing of deeper levels of clinical and 'omic data and utilizing new technologies to understand RGDs is an important path forward to complete the morbid anatomy of the human genome and enable diagnoses for all patients with a RGD in the coming decade.

Omics Technologies Posters - Thursday

PB3095. Overcoming FFPE hurdles to enable high quality hybrid capture libraries and somatic mutation detection in matched tumor-normal patient samples.

Authors:

S. Chavadi; NEB, Burlington, MA

Abstract Body:

Overcoming FFPE hurdles to enable high quality hybrid capture libraries and somatic mutation detection in matched tumor-normal patient samples.

In cancer genomics, a common source of DNA is formalin-fixed, paraffin-embedded (FFPE) tissue from patient surgical samples, where in most cases high quality fresh or frozen tissue samples are not available. FFPE DNA poses many notable challenges for preparing NGS libraries, including low input amounts and highly variable damage from fixation, storage, and extraction methods. Due to the high cost of sequencing and variability of coverage, regions of interest are often specifically enriched using hybrid capture-based approaches, but these methods require a high input of diverse, uniform DNA library to achieve the coverage required for somatic mutation identification in tumor samples.

We applied a multi-faceted approach to improving the yield, quality, and coverage from libraries generated from cancer patient sample sets. Using tumor-normal pairs, we evaluated the impact of our method on the sensitivity and accuracy of somatic variant detection. Matched frozen tissue provided a truth set of somatic variants for a particular tumor as well as a gold standard by which we could assess the quality of our FFPE hybrid capture libraries. Combining DNA damage repair and a novel enzymatic fragmentation mix upstream of library preparation not only reduced the false positive rate in somatic variant detection by repairing damage-derived mutations but also improved the library yield, complexity, coverage uniformity, and hybrid capture library quality metrics. The use of unique molecular identifier (UMI)-containing adaptors ensured accurate duplicate marking. Finally, a new PCR master mix boosts the library yield without compromising library quality in FFPE samples ranging from very poor quality to high quality. This combinatorial approach allows even the poorest quality FFPE samples to achieve high quality libraries with sufficient input for hybrid capture in our study.

Omics Technologies Posters - Wednesday

PB3096. PacBio HiFi sequencing provides highly accurate CpG methylation calls without bisulfite treatment.

Authors:

C. Saunders, D. Portik, R. J. Hall, D. Seifert, D. Diaz, A. Töpfer, K. Nyquist, A. M. Wenger; PacBio, Menlo Park, CA

Abstract Body:

PacBio long-read sequencing observes a polymerase in real time as it incorporates fluorescently labeled nucleotides to synthesize a DNA strand. Kinetic signatures from the sequencing polymerase, including pulse width and interpulse duration, correlate with chemical modifications to the canonical DNA bases. These kinetic signatures enable the accurate detection of 5-methylcytosine (5mC) at CpG sites from standard PacBio HiFi reads, without requiring bisulfite treatment or other modifications to sample preparation or sequencing. HiFi CpG methylation calls are consistent with orthogonal technologies, including a correlation of 0.95 with methylation results from short read whole genome bisulfite sequencing. Unlike short read bisulfite sequencing, HiFi sequencing has no observed depth bias against CpG islands, and the methylation calls are made in highly-accurate long (15-20kb) reads, facilitating the identification of cis genetic variants in phase with the methylation signal. Long HiFi reads can map to more CpG sites in the genome; when aligned to CHM13, methylation can be called on 11% more reference CpG sites compared to short-read sequencing. We demonstrate that methylation calls from HiFi reads can detect and characterize various clinically relevant conditions, including repeat expansions and imprinting disorders, highlighting their potential for rare disease and cancer research applications.

Omics Technologies Posters - Thursday

PB3097*. Paired whole genome and whole transcriptome sequencing of a large cohort of undiagnosed pediatric trios with neurological phenotypes

Authors:

R. Wang¹, Q. Zhang¹, K. Ramsey², K. Bluske¹, A. Chandrasekhar¹, Y. Shin¹, J. albay¹, S. Batalov³, D. hernandez¹, A. Crawford¹, M. Bainbridge⁴, M. Huentelman², R. Taft⁵; ¹Illumina, Inc, San Diego, CA, ²TGen, Phoenix, AZ, ³Rady Children's Hosp., San Diego, CA, ⁴Rady Children's Hosp., San Diego, CA, ⁵Illumina Inc, San Diego, CA

Abstract Body:

Whole transcriptome sequencing (WTS) for undiagnosed genetic disease provides an attractive addition to whole genome sequencing (WGS) by providing functional annotation of variants whose effects are difficult to determine otherwise. While the diagnostic rate for WGS ranges from ~30-60% depending on the clinical indications for testing, recent efforts to incorporate orthogonal data types such as RNA-seq have shown an increase in diagnostic yield particularly for variants of unknown significance, deep intronic variants, and splice-site adjacent variants.

We performed Illumina based WGS and WTS sequencing on 250 trios, where the pediatric proband showed signs of a neurological disorder, in collaboration with Rady Children's Hospital and Translational Genomics Research Institute (TGEN). We performed exhaustive analysis of multiple sample preparation methodologies, including side by side comparisons of ribodepletion and poly-adenylation library construction methods, and assessed fragment lengths, the impact of sample input type and amount, and the efficacy of targeted depletion of high abundance small RNAs.

Two strategies were applied to improve diagnostic yield and gauge their relative effectiveness. In an "RNA first" approach, we identified genes with outlier expression, splice junction usage, or exon utilization using blood based WTS. WGS data was used to identify nearby variants associated with retained introns and mis-spliced transcripts. In a "DNA first approach", we focused on variants of unknown significance and splice site adjacent variants outside of the typical +2 boundaries and investigated their relative effect on transcript abundance and splicing in the RNA-seq data. Using WTS data, variants of unknown significance (VUS) could be both ruled out or upgraded in their diagnostic classification. Our trio-based design allowed for confirmation of pathogenic splicing through segregation analyses within family members.

In this work we also assessed the need for standardized reporting of pathogenic splice variants for potential use in a clinical setting. Lastly, we share our experiences with quality control, annotation, and software implementation to integrate WGS and WTS data.

Omics Technologies Posters - Wednesday

PB3098. Papillary renal cell carcinoma (pRCC) functional heterogeneity unraveled by single nucleus sequencing (Sn-Seq) technologies

Authors:

R. Xin, Y. Zhu, Z. Peralta, M. Gibbons, V. Giangarra, S. Taylor; 10xgenomics, Pleasanton, CA

Abstract Body:

Renal cell carcinoma (RCC) is the most common type of kidney cancer worldwide with an approximate 20% mortality rate. Papillary renal cell carcinoma (pRCC), the second most common RCC, accounts for 10-15% of all RCCs. Compared to other subtypes, developing treatment for pRCC is challenging due to the inherent tumor heterogeneity, diverse molecular mechanisms and acquired drug resistance. To reveal the underlying mechanisms and identify specific biomarkers, we examined pRCC frozen tissues via single nucleus RNA sequencing (snRNA-seq) and single nucleus ATAC sequencing (snATAC-seq), using frozen tissue nuclei prepared by the 10x Genomics Chromium Nuclei Isolation kit.

Single cell sequencing technologies are powerful toolkits for characterizing tumor cell populations and the tumor microenvironment. However, accessing and working with tissues can be challenging as these require careful coordination with clinical sites. Enzymatic digestion-based single cell dissociation also introduces technical biases and biological artifacts. Single nucleus sequencing (Sn-Seq) provides an alternative strategy for profiling both gene expression profile and chromatin accessibility from frozen and fresh tissues.

Here, we profiled the transcriptome of more than 30,000 nuclei from two independent pRCC donors. To identify potential malignant cell populations, we compared our data with the single cell RNAseq datasets from three independent healthy donors (Human Cell Atlas: <https://data.humancellatlas.org/>) and characterized 9 distinct cell populations. Integration analysis identified 5 unique clusters of epithelial origin in the pRCC samples. Interestingly, we found SH3RF3 and TBC1D8, genes usually highly expressed in endothelial cells in these unique tumor clusters. Both type1 (such as MET) and type 2 (such as NFE2L2 and SETD2) pRCC markers were also overexpressed in these clusters, suggesting these cells are potentially malignant. Next, multiomic integration of snRNA-seq with snATAC-seq data revealed consistent gene expression profile and chromatin accessibility for the major cell types identified. We also performed CNV analysis based on snATAC-seq data and detected potential CNV events located in 41 distinct genomic regions, including copy gains of vascular growth factors (VEGFs) and genes in MAPK signaling pathway.

Our multiomic study revealed diverse molecular mechanisms underlying pRCC heterogeneity, spanning genomic aberrations, and dysregulation of signaling pathways. These findings highlight that adoption of a more standardized Sn-Seq workflow may facilitate the clinical research and the development of more effective pRCC therapies.

Omics Technologies Posters - Thursday

PB3099. Peripheral leukocyte transcriptome dynamics following ischemic stroke of large vessel and cardioembolic etiologies

Authors:

P. Carmona-Mora¹, B. Knepp¹, G. C. Jickling², X. Zhan¹, M. Hakoupiian¹, H. Hull¹, N. Alomar¹, H. Amini¹, F. R. Sharp¹, B. S. Stamova¹, B. P. Ander¹; ¹Univ. of California-Davis, Sacramento, CA, ²Univ. of Alberta, Edmonton, AB, Canada

Abstract Body:

Peripheral blood leukocytes mediate the response following Ischemic Stroke (IS) and display distinctive transcriptomic signatures that allow IS patients to be distinguished from controls. Dissecting the temporal dynamics of gene expression in peripheral leukocytes after IS can guide the refinement of diagnostic biomarker candidates and identify drug targets. RNA-seq was performed on peripheral monocytes, neutrophils, and whole blood samples (38 IS and 18 controls). A whole genome co-expression network analysis (WGCNA) was used to identify genes whose expression is associated with time after IS. Differential expression (DE) analyses were performed by binning patients into time point groups and per stroke etiology. Neural network analyses (SOM), were performed on DE genes to enable clustering into smaller groups based on their trajectory over time. WGCNA identified dozens of genes associated with time after stroke, including cell-specific markers and monocyte subtype and polarization markers. Some highly interconnected time-associated hub genes correlated with stroke severity. These include *TIA1*, a TNF- α repressor in monocytes, and constant and variable immunoglobulin genes in whole blood. DE analyses showed distinctive signatures for all sample types and at all time bins and IS etiologies, revealing many DE genes (DEGs) at only one time bin and IS cause. Unique patterns of temporal gene expression and pathways were distinguished for monocytes, neutrophils and whole blood with enrichment of interleukin signaling pathways for different timepoints and IS etiologies. SOM clustered DEGs as a function of time post-IS, revealing those that increase or decrease expression over time, or those peaking only at a specific time bin. SOM profiles identified important attributes of DEGs from opposite expression trajectories. In neutrophils, the toll-like receptor pathway is associated with a profile that decreases on day 1 and increases after 24 h in cardioembolic stroke. Whereas, for large vessel stroke, this pathway is enriched in a DE profile that decreases at all times compared to controls. Toll-like receptor signaling is a promising target for treating cardiovascular disease, impacting downstream pro- or anti-inflammatory molecules, like TNF- α , interleukins, and interferons. Consideration of time after stroke as a key variable enables the refinement of biomarker genes for diagnosis. This study identified potential time- and cell-specific biomarkers and drug targets. Our approach represents a model for assessing key genes in acute disease in a more strategic manner considering dynamic factors that influence pathophysiology and treatment selection.

PB3100. Perturb-seq analysis reveals key mediators of TNF α -induced transcriptional response.

Authors:

D. Tedesco, T. Liu, D. Hu, N. Isachenko, D. Deng, N. Dolganov, A. Chenchik; Cellecta, Inc., Mountain View, CA

Abstract Body:

To identify genes involved in TNF α induced transcriptional response, a 10X single-cell Perturb-Seq screen was run on HEK293-Cas9 cells with an 88-sgRNA pooled library. As a benchmark, a parallel screen was run with cells transduced in arrayed format with a subset of the sgRNAs of the pooled library. The 10X Perturb-Seq screen was carried out in triplicate with increasing amounts of cells/10X reaction, in order to determine: (a) the minimum number of cells/sgRNA required to cover the full complexity of the pooled library, (b) the maximum number of cells that can be loaded in the 10X reaction without losing single-cell resolution due to encapsulation of cell doublets. Transcriptional profiling identified TNFRSF1A, IKBKG, RELA, and CHUK as key mediators of TNF α transcriptional response in both the arrayed and pooled library screens. Increasing the number of cells per 10X reaction had a positive effect on the sgRNA library coverage, without adversely affecting the magnitude of the observed effect of TNFRSF1A, IKBKG, RELA, and CHUK knockout (KO) on TNF α mediated transcriptional response. Perturb-seq was confirmed as a promising technology for the efficient and scalable interrogation of many individual gene in one single experiment, enabling the identification of transcriptional profiles linked to specific gene-KOs.

Omics Technologies Posters - Thursday

PB3101. Peruvian Hospital<Urban Antibiotic Resistance found in Local Wastewater

Authors:

L. Jaramillo Valverde¹, N. Pablo-Ramirez¹, V. Roa- Linares¹, C. Martinez-Jaramillo¹, S. Alvites-Arrieta¹, M. Ubillis¹, D. Palma-Lozano¹, S. Davison², A. Gomez², H. Guio¹; ¹UNIVERSIDAD DE HUANUCO, HUANUCO, Peru, ²Univ. of Minnesota, MINNESOTA, MN

Abstract Body:

BACKGROUND: Metagenomics studies all the genetic material of ecosystems, which can provide information about the presence of bacterial species, pathogens and virulence genes. Most studies of bacterial resistance in Peru have been carried out at the hospital level with limitations in culture methods and not at the community level (resistomes). Considering that many pathogens are not cultivable or bacterial culture media are not available, the objective of this project is to evaluate antimicrobial resistance genes (ARGs) due to the diversity and abundance of antimicrobial resistance genes based on metagenomic analyzes in urban wastewater from hospitals and community in a location of 2021. The present investigation is of an explanatory and experimental type, where wastewater samples will be taken from two health systems (MINSa and EsSALUD) and from the community. **METHODS:** In this study, a high-throughput sequencing-based metagenomic approach was applied to investigate the community composition of bacteria and ARGs in untreated wastewater from two different types of hospitals (MINSa - public and EsSalud - private hospital) and one form community. Here, we utilized metagenomic approaches to comprehensively reveal the diversity, abundance and hosts of ARGs in wastewater from three location. **RESULTS:** In total, 13 species and other less abundant taxa were identified from the microbiota of the wastewaters, with some different bacterial community compositions among the three locations. Total ARG analysis using the Antibiotic Resistance Genes Database (ARDB) and Comprehensive Antibiotic Resistance Database (CARD) revealed that the microbiota in the wastewaters from the three hospitals harbored different types and percentage of ARGs. Essalud - private reported the least bacterial diversity but the greatest diversity in resistance genes. *Prevotella copri* was the most abundant species is Essalud and probably influencing the pathogenesis of Rheumatoid Arthritis. Valdizan - public reported TEM beta- lactamase which as most prevalent ARG. More than 90% of resistance to ampicillin in *Escherichia coli* is due to the production of TEM. Finally, in urban waterlines we observed major number of pathway gene. **CONCLUSION:** In summary, our findings demonstrated a widespread occurrence of ARGs and ARG-harboring microbiota in untreated wastewaters of different hospital, suggesting that protection measures should be applied to prevent human infections. Concurrently, hospital wastewater should be treated more specifically for the removal of pathogens before its discharge into the urban sewage system.

Omics Technologies Posters - Wednesday

PB3102. PhaseDancer: Targeted assembly of the complex syntenic regions in non-human primates of the HSA2 fusion site.

Authors:

B. Poszowiecka¹, K. Gogolewski¹, P. Stankiewicz², A. Gambin¹; ¹Univ. of Warsaw, Warsaw, Poland, ²Baylor Coll. of Med., Houston, TX

Abstract Body:

We have developed a genome assembler for long error-prone read sequencing data targeted at regions enriched with segmental duplications (SDs). PhaseDancer follows a bottom-up paradigm by taking as an anchor short sequence to extend iteratively using greedy strategy. Reads mapped to the anchor sequence are first clustered and then one cluster is selected and subjected to assemble the anchor sequence for the next iteration.

This innovative approach enables the local de novo assembly in a significantly reduced time with an increased continuity when compared to the existing whole-genome de novo assemblers. Additionally, PhaseDancer is accompanied with the web application for visualizing every iteration of the algorithm, providing constant insight into the complexity of the processed sequences and enabling the incorporation of the expert decisions if needed. PhaseDancer has proven to be used for the local assembly of the highly variable genomic regions, improving the understanding of the structure variability of the mosaic genomic regions at the nucleotide level.

To validate the functionality of our tool, we have assembled the subtelomeric regions of chromosomes 2A and 2B of the chimpanzee, bonobo and gorilla genomes, significantly extending the reference sequences. Finally, we demonstrate PhaseDancer superiority over the existing tools in the analysis of evolutionary complex SDs.

Omics Technologies Posters - Thursday

PB3103. Phenome-wide gene prioritisation leveraging Knowledge Graphs, Graph Convolutional Networks and UK Biobank PheWAS.

Authors:

D. Vitsios¹, I. Melas¹, L. Middleton¹, B. Rozemberczki¹, R. Dhindsa², A. Harper¹, G. Edwards¹, S. Petrovski¹; ¹AstraZeneca, Cambridge, United Kingdom, ²Baylor Coll. of Med., Houston, TX

Abstract Body:

The growth of genomic datasets continues to fuel advances in human-validated target identification and validation, encompassing multiple layers of biological annotations. Best leveraging the wealth of available gene annotations to infer gene-disease associations is far from trivial. Here, we present Mantis-ML v2, building onto our previous work (Vitsios et al, AJHG 2020), but with two key novel advances. Firstly, we now leverage knowledge graphs to complement the existing structured gene features from dozens of annotation resources, including features selected via natural language processing. Secondly, we adopt Graph Convolutional Networks (GCNs), employing Stellargraph, to leverage the combined information from the knowledge graph and the structured features. Knowledge graphs capture relationships between genes such as protein-protein interactions, co-expression, signalling reactions etc., augmenting our structured knowledge-base of features. The underlying hypothesis is that genes closely interacting with each other are likely to have similar properties and potentially play a similar role in disease. The knowledge graph we constructed consists of 8.7M edges between genes and related entities and is a subset of AstraZeneca's Biological Insights Knowledge Graph (BIKG), combining data from 52 data sources. Graph-based gene features are also calculated on top of BIKG, capturing structural information such as gene importance, influence and clusters. Our GCN classifier is trained across hundreds of balanced datasets within Mantis-ML's robust semi-supervised learning framework, providing out-of-fold gene-disease associations across the entirety of the human exome. Our revised gene prioritisation model achieves significantly increased performance, with an overall 11.2% boost in classification power (median AUC=0.95 across 5,000 diseases from Human Phenotype Ontology and OpenTargets compared to AUC of ~0.85 from our original Mantis-ML). Notably, we provide refined gene-disease associations by statistically evaluating the overlap of top Mantis-ML v2 predictions against an extensive set of orthogonal genetic signals, derived from a phenome-wide association study (PheWAS) on ~450k UK Biobank participants. Accompanying all the results is an interactive web-resource with the scores and rankings specific to either a disease or gene. We expose the overlap of high-ranking Mantis-ML genes with those significantly associated within the UKB 450k exomes PheWAS, serving as both a means to cross-validate the new associations and to introduce a stronger form of gene prioritisation through the intersection of the two orthogonal statistics.

Omics Technologies Posters - Wednesday

PB3104. PIPseq, a novel and highly scalable technology based upon Pre-templated Instant Partitions (PIPs), is powering single-cell RNA sequencing into the million cell era

Authors:

K. Fontanez, A. Osman, R. Meltzer, C. Hayford; Fluent BioSci., Watertown, MA

Abstract Body:

Single-cell transcriptomics have revolutionized modern biology by providing unprecedented insight into the mechanisms of cellular differentiation and function in complex tissues and organisms. As scRNA-seq transitions from a discovery tool into translational applications requiring complex experimental design, multiple sample comparisons, and multivariable sample perturbations, there is a growing need for simple, highly scalable, cost-effective, library preparation methods. Current scRNA-seq methods have limited scalability. Droplet based applications generate one drop at a time, limiting throughput, and rely on complex, expensive instrumentation. Nano-well array based methods are limited by surface area, and therefore locked to defined manufactured consumables. Combinatorial barcoding enables high throughput transcriptomics but is limited by complex, labor intensive workflows. Fluent BioSciences has developed new methods for scRNA-seq enabled by Pre-templated Instant Partitions (PIPseq), that enables sensitive, efficient, and highly scalable scRNA-seq improving the accessibility and application of high-cell input single cell transcriptomics. Here we demonstrate single-tube PIPseq configurations accommodating 200,000 - 1M cell input and evaluate key performance metrics using model cell lines, peripheral blood mononuclear cells (PBMCs), and complex tissues. The PIPseq platform enables novel experimental paradigms not addressable with current platforms such as highly multiplex sample batching, targeted sequencing of large numbers of cell input, and identification of very rare cell populations from complex mixtures.

Omics Technologies Posters - Thursday

PB3105. Population diversity and selection of recent gene duplications detected using a complete human genome sequence

Authors:

D. Soto¹, A. Sekar¹, G. Kaya¹, M. Mastoras¹, E. Green², A. M. Andres³, M. Y. Dennis⁴; ¹Univ. of California Davis, Davis, CA, ²NHGRI (NIH), Bethesda, MD, ³Univ. Coll., London, United Kingdom, ⁴Univ. of California, Davis, Davis, CA

Abstract Body:

Human-specific duplicated genes (HSDs) are strong candidates for neurodevelopmental traits and diseases unique to our species. Assessment of the recently published T2T-CHM13 complete genome identified 417 genes embedded in recent segmental duplications (>98% sequence identity; SDs-98) with near fixed copy-number (CN=2) in the 1000 Genomes Project (1KGP), with 231 having evidence of expression in the fetal neocortex. This list includes genes with known roles in neurodevelopment, such as ARHGAP11B, as well as many other uncharacterized genes. Comparing CN across 1KGP populations, we also identified 174 genes that show stratification (VST>95th percentile), including those with previous evidence (e.g., KANSL1) and interesting new candidates (e.g., NPY4R, previously implicated in body-mass index). Examining our ability to detect SNVs and indels across SDs-98, we compared short- and long-read sequence data from eight individuals from the T2T Diversity Panel and observed a recall of <0.1 resulting in a depletion of total variants identified from 1KGP across these regions (12 variant/kbp) versus the unduplicated genome (38 variant/kbp). Using 1KGP variants in accessible regions (representing ~10% of SDs-98), we assessed signatures of natural selection by calculating Tajima's D and identified 22 protein-encoding genes showing consistent outlier values, including the SPDYE3 and PMS2P1 locus, which is CN fixed. To enable detection of variation across a set of 34 fixed HSD genes, we performed targeted capture PacBio HiFi sequencing in ~200 1KGP individuals from five populations. The approach yielded ~3 kbp length reads with average coverage >80×, from which we identified 20,043 biallelic SNVs (73.4% novel). Using a combination of dN/dS and Ka/Ks, we show that ancestral paralogs universally exhibit signatures of purifying selection while duplicate paralogs exhibit relaxed constraint, suggestive of neutrality or perhaps positive selection. We also identified ten regions with high levels of population differentiation (measured by FST), overlapping genes HYDIN2 and SRGAP2C, putatively due to local adaptation. Our approach highlights potential evolutionarily relevant human gene duplications, which will become priority candidates for future functional studies.

Omics Technologies Posters - Wednesday

PB3106. Population Scale Genetic Interpretation Software for Reporting Pathogenic and Likely Pathogenic Variants Impacting the ACMG59 Genes.

Authors:

R. Olson, J. Arroyo, J. Morales-Rosado, M. Arioti, P. Duffy, S. Safgren, K. Kolbert, N. Larson, H. Sicotte, K. Lazaridis, J. Olson, E. Klee; Mayo Clinic, Rochester, MN

Abstract Body:

Pathogenic (P) and Likely Pathogenic (LP) variants within the ACMG59 genes are medically actionable variants associated with successful intervention strategies capable of reducing the public health burden of common genetically inherited diseases, but manual population level screening is ultimately time consuming. In this work, we developed, validated, and utilized a Scalable Automated Variant Interpretation (SAVI) software to prioritize potentially reportable variants in the ACMG59 (+*LDLRAP1*) genes from 983 individuals having genome sequencing.

SAVI is Python based software to annotate variants within a sample VCF to prioritize all P and LP variants using information from CAVA sequence ontology, catalogs (HGMD, ClinVar, and gnomAD), and in silico tools such as REVEL and SpliceAI. SAVI compiles this information to generate two distinct metrics, an internally developed InDepth Score (IDS) and a Range of Pathogenicity Classification (RPClass), based on ACMG guidelines.

Performance testing of the IDS (1-6 likely P/LP, 29-59 unlikely P/LP) in 782 variants previously curated resulted in 99.5% variants with an IDS of 1-6 classified as P/LP, while 3.4% were reported as P/LP with an IDS of 29-59. In comparison, 82.6% of variants with an IDS of 1-6 were classified as P/LP and 8.6% of variants with an IDS of 29-59 were classified as P/LP by InterVar.

Using SAVI software, we successfully processed 983 population samples with genome sequencing enrolled in the Biobank study at the Mayo Clinic and completed manual curation of prioritized variants. ~7.3 million variants across the ACMG59 (+*LDLRAP1*) were identified after bioinformatic genome alignment and quality variant filtering. 258 discrete variants represented by 433 total variants (0.006%) within 335 samples (34%) were prioritized by SAVI. After manual curation, 42 discrete variants, found in 63 samples (6.4%) were classified as P/LP and therefore reportable to the patient following clinical variant confirmation. Three of the reportable variants had an IDS of 1-6 (100% P/LP), 39 had an IDS of 7-21 (45% P/LP), and all 169 variants with an IDS score 22-59 were classified as VUS/LB/B.

In summary, we have developed and implemented a tool that has a high degree of accuracy for minimizing the prioritization of non-reportable variants while maintaining sensitivity. Future goals are to support the ACMG73 gene set and begin processing the Mayo Clinic Project Generation study (55k samples). Additionally, we will continue to refine the prioritization scoring algorithm using machine learning to minimize the false positivity rate to further reduce the burden of preventative screening on a population level.

Omics Technologies Posters - Thursday

PB3107. Predicting the transcriptional activity and mechanism of action of small molecules using deep learning

Authors:

C. Barnhill, A. Petukhov, J. Chang, O. Botvinnik, J-H. Ju, S-G. Ji; BridgeBio Pharma, Inc., Palo Alto, CA

Abstract Body:

Predicting the effect of a small molecule on gene expression in silico offers a unique approach to discover therapeutic compounds and identify unintended off-target effects. Additionally, predicting the mechanism of action (MOA) of molecules that are transcriptionally active may yield a more specific understanding of which genes are affected. We present a deep learning approach to predict the transcriptional activity of small molecules based solely on the structural information contained in the graph representation of molecules using a graph neural network (GNN). Data from the Connectivity Map, a resource consisting of experimental data that profiles the effects of perturbagens (small molecules as well as gene overexpression and knockdown reagents) on transcriptional activity in human cell lines, was used to train two separate models. The first model is a regression task to predict the transcriptional activity score (TAS) of a compound. TAS is an aggregate measure that represents an upper bound of a compound's transcriptional activity across multiple cell lines. We applied a quality control (QC) process to the TAS dataset to remove outliers for any of six QC metrics specific to the dataset, yielding a final dataset of 22,032 compounds. We trained a GNN using Bayesian hyperparameter optimization with RMSE as the validation metric. The second model is a multilabel classification task to predict the MOA of a compound. Compounds in the dataset are annotated with MOAs based on literature review and the similarity of their transcriptional signatures. A single compound can have multiple MOA labels. We applied a separate QC process to the MOA dataset to remove duplicate compounds and restrict to MOAs with at least 10 unique compounds, yielding a final dataset of 28,204 compounds and 89 MOAs. We trained a separate GNN using Bayesian hyperparameter optimization with weighted average precision as the validation metric. We applied both trained models to compounds in the ZINC database to validate how this method might be used for discovery. ZINC is a dataset of over 997 million compounds for virtual screening of small molecules. Compounds in ZINC are labeled by their molecular weight (MW) and LogP (solubility) values. We restricted our analysis to a sample of one million lead-like compounds with MW between 250 and 350 Daltons and LogP between 1 and 3. We identified 3,184 molecules predicted to be transcriptionally active and with predicted class probability > 0.9 for at least one MOA. Experimental validation of these molecules is pending. This approach provides a new method to identify novel compounds that modulate gene expression in known MOAs.

Omics Technologies Posters - Wednesday

PB3108. Prokaryotic and viral genomes recovered from 787 Japanese gut metagenomes revealed microbial features associated with diets, populations, and diseases

Authors:

Y. Tomofuji¹, T. Kishikawa¹, Y. Maeda¹, K. Ogawa¹, Y. Otake¹, S. Kawabata¹, T. Nii¹, T. Okuno¹, E. Oguro-Igashira¹, M. Kinoshita¹, M. Takagaki¹, N. Oyama², K. Todo¹, K. Yamamoto¹, K. Sonehara¹, M. Yagita¹, A. Hosokawa³, D. Motooka⁴, Y. Matsumoto⁴, H. Matsuoka⁵, M. Yoshimura⁵, S. Ohshima⁵, S. Shinzaki¹, S. Nakamura⁴, H. Iijima¹, H. Inohara¹, H. Kishima¹, T. Takehara¹, H. Mochizuki¹, K. Takeda¹, A. Kumanogoh¹, Y. Okada^{1,6,7}; ¹Osaka Univ. Graduate Sch. of Med., Suita, Japan, ²Kawasaki Med. Sch., Kurashiki, Japan, ³Suita Municipal Hosp., Suita, Japan, ⁴Res. Inst. for Microbial Diseases, Osaka Univ., Suita, Japan, ⁵NHO Osaka Minami Med. Ctr., Kawachinagano, Japan, ⁶Graduate Sch. of Med., The Univ. of Tokyo, Hongo, Japan, ⁷RIKEN Ctr. for Integrative Med. Sci., Tsurumi, Japan

Abstract Body:

Microbial genomes recovered from the gut metagenome sequencing reads are important resources for studying the gut microbiome. However, the current populational diversity of the prokaryotic genomes is still limited because the number of microbial genomes recovered from populations other than European, North American, and Chinese is relatively low. The Japanese have unique dietary culture and habits, which resulted in the unique features of the gut microbiome. Recovering microbial genomes from the Japanese gut metagenome is necessary for obtaining deep insights into the Japanese gut microbiome and increasing the populational diversity of the databases. Here, we reconstructed 19,084 prokaryotic and 31,395 viral genomes from the 787 Japanese gut metagenome shotgun sequencing data as Japanese Metagenome Assembled Genomes (JMAG) and Japanese Virus Database (JVD) and made them publicly available. The JMAG and JVD are one of the largest microbial genome datasets for a single population and contribute to increasing the populational diversity of the microbial genomes. Utilizing these unique microbial genome databases, we explored the population-specific features of the gut microbiome. Population-specific enrichment of the *Bacillus subtilis* and β -porphyranase among the JMAG could derive from the Japanese traditional food natto (fermented soybeans) and nori (laver seaweed), respectively. Five food-associated bacterial species (four dairy-related species and natto-related *Bacillus subtilis*) were shared among the Japanese at the strain level and two dairy-related species were nominally associated with the East Asian-specific missense variant rs671:G>A in ALDH2 which was associated with dairy consumption. As for the viral genomes, 62.9% of the species-level clusters in the JVD were novel. The composition of the β crAss-like phages was low among Japanese but relatively high among the Africans and Oceanians. Several clades of the crAss-like phages decreased in rheumatoid arthritis, systemic lupus erythematosus, and inflammatory bowel diseases but increased in colorectal cancer. Analysis on the CRISPR sequences identified the viruses-prokaryotes interaction network and revealed that abundances of the viruses and their hosts tended to be positively correlated. In summary, we recovered the MAGs and viral genomes from the Japanese gut MSS data. We revealed the features of the Japanese gut metagenome, novel associations of the crAss-like phages to populations and diseases, and virus-prokaryote interaction. Our dataset which includes MAGs, viral genomes, and CRISPR spacers are publicly available (https://github.com/ytomofuji/JMAG_JVD).

Omics Technologies Posters - Thursday

PB3109. Proteoform inference using proteogenomic approach in non-small cell lung cancer and healthy control plasma proteomes reveals disease-associated protein isoforms

Authors:

M. Donovan, Y. Huang, J. Wang, A. Stukalov, T. Wang, A. Siddiqui, S. Batzoglou; Seer Bio, Redwood City, CA

Abstract Body:

Complexity of human biology far exceeds what is encoded in 20,000 protein-coding genes, however, this complexity may be largely explained by functionally distinct protein forms, or proteoforms, arising from alternative splicing, allelic variation, and post-translational modifications. Recent advances in proteomics are making it possible to analyze the plasma proteome at the level of individual isoforms at a scale not possible a few years ago. However, inference of proteoforms from detected peptides using bottom-up proteomic approaches remains challenging. Here we use the Proteograph™ Product Suite to perform quantitative proteomic experiments across a large cohort can improve proteoform inference by using peptide quantitative profiles. We performed a proteogenomic analysis of 80 healthy controls and 61 early-stage non-small-cell lung cancer (NSCLC) plasma samples to systematically infer proteoforms arising from alternative gene splicing and allelic variation. First, we hypothesized disease-associated proteoforms arising from alternative splicing would display differential abundance patterns. We performed a proteome-wide differential abundance analysis and identified four proteins with peptides with opposite patterns of abundance in NSCLC and healthy controls. Among these include BMP1, where inspection of the peptide locations relative to the known protein coding isoform models indicates the short protein isoform is associated with NSCLC samples and longer isoforms are associated with healthy samples. To identify other proteoforms arising from alternative splicing, we examined similarly abundant (i.e., covarying) peptides that also were sequentially clustered by implemented COrrelation-based functional ProteoForm (COPF) assessment with minor adjustments and additional filtering steps. We applied a post-translational cleavage detection strategy to 200 protein candidates with covarying peptides to test if covarying peptide clusters are disproportionately located on one protein terminus and identified over 20 proteoforms. Some identified proteoforms displayed opposite abundance patterns between the NSCLC and healthy samples, implying disease-associated function, including endostatin, a naturally occurring 20-kDa C-terminal short proteoform from type XVIII collagen (P39060) that has been shown to serve as an anti-angiogenic agent with evidence in treating NSCLC. These results demonstrate the identification of proteoforms offers increased opportunities to identify potential novel biomarkers for disease.

Omics Technologies Posters - Thursday

PB3110. Proteogenomic approaches improve genetic discovery across diverse human diseases.

Authors:

M. Koprulu, J. Carrasco-Zanini, E. Wheeler, N. Kerrison, N. Wareham, M. Pietzner, C. Langenberg; Univ. of Cambridge (MRC Epidemiology Unit), Cambridge, United Kingdom

Abstract Body:

Studying the plasma proteome as the intermediate layer between the genome and the phenome has the potential to identify disease causing genes and variants and improve our understanding of the underlying mechanisms. Here, we conducted a cis-focused proteogenomic analysis of 2,923 plasma proteins measured in 1,180 individuals using a novel antibody-based assay to identify disease causing genes across the human phenome and systematically refine causal genes at previously reported GWAS loci. We identify 1,553 distinct credible sets of protein quantitative trait loci (pQTL), a third of which (n=531) contained cis-pQTLs not previously reported. Of these, 182 signals were seen for 117 proteins never studied before, and 349 were detected despite proteins having been targeted in earlier, larger studies. We identified 224 proteins with robust evidence to contribute to the aetiology of 578 unique health outcomes using statistical colocalization, including proteins with potential for therapeutic interventions for type 2 diabetes (fibroblast growth factor 4 [FGFR4] and gastrin releasing peptide [GRP]). We demonstrated convergence between pQTL colocalisation and rare loss of function gene-burden evidence for disease associations of 25 proteins, including a role of TIMD4 in macrophage mediated LDL-cholesterol lowering. Proteogenomic evidence improved causal gene assignment; 480 of the credible sets overlapped with reported GWAS loci and highlighted different causal genes or refined longer lists of candidate genes for 40% of these loci.

Our findings demonstrate the ability of broad capture, high-throughput proteomic technologies to robustly identify new gene-protein-disease links, provide mechanistic insight, and add value to existing GWASs by enabling and refining causal gene assignment.

Omics Technologies Posters - Thursday

PB3112*. Pseudogenes limit the identification of common, functionally important transcripts generated by their parent genes

Authors:

E. Gustavsson¹, S. Sethi², Y. Gao², D. Zhang¹, J. Brenton¹, S. Garcia-Ruiz¹, R. Reynolds¹, A. Wernick^{1,3}, C. Arber¹, J. Evans^{1,3}, S. Wray¹, S. Gandhi^{1,3}, H. Houlden¹, C. Bento², H. Saini², J. Hardy¹, M. Ryten¹; ¹Univ. Coll. London, London, United Kingdom, ²Astex Pharmaceuticals, Cambridge, United Kingdom, ³Francis Crick Inst., London, United Kingdom

Abstract Body:

Genomic and transcriptomic studies are critically dependent on accurate gene annotations. However, this process can be complicated by highly homologous sequences which cause short RNA-sequencing (RNA-seq) reads to align to two or more genomic regions (multi-mapping). Given that the human genome contains 14,709 defective gene copies, termed pseudogenes, belonging to 3,491 parent genes of which 734 are known to cause Mendelian disease, this is a significant problem. The aim of this study was to investigate the impact of pseudogenes on transcriptomic analyses by focusing on the disease-relevant example of *GBA* and its expressed pseudogene *GBAPI*. By analyzing short-read RNA-seq data from the anterior cingulate cortex, we found that only $41.7 \pm 11.2\%$ of all reads mapping to *GBA* were uniquely mapping with $96.0 \pm 2.0\%$ of the multi-mapping reads being assigned to *GBAPI*. This led us to hypothesize that there are significant inaccuracies in the annotation of both genes. To address this, we generated targeted *GBA* and *GBAPI* PacBio SMRT isoform sequencing data from 12 regions of the human central nervous system (CNS) because of *GBA*'s importance in brain diseases. We identified 18 *GBA* transcripts with a novel open reading frame (ORF) and 7 novel *GBAPI* transcripts predicted to encode a protein. Focusing on *GBA*, we found that transcripts with a novel ORF collectively accounted for 15.8% - 31.7% of transcription, depending on tissue, and were all predicted to impact on catalytic function of *GBA* encoded beta-glucocerebrosidase. Transfection of novel transcripts into *GBA* knockout cells resulted in clear translation with no observed catalytic activity. Next, we used Oxford nanopore direct cDNA long-read sequencing data derived from the human CNS to analyse the transcription of other disease-relevant parent-pseudogene pairs, including *PTEN* and *PTENPI*, albeit in less detail. Again, we discovered inaccuracies in annotation, exemplified by novel transcripts of both genes. To generalise these findings further we performed annotation-independent re-analyses of public short-read RNA-seq data. Using data provided by the Genotype-Tissue Expression Consortium, we found that the proportion of parent genes with evidence of novel unannotated expression was significantly higher than that of protein coding genes without pseudogenes (Wilcoxon $p = 3.3e^{-12}$) and that this was a consistent finding across all human tissues. In summary, our results suggest systematic inaccuracies in the annotation of parent genes with significant implications for our understanding of disease-relevant genes.

Omics Technologies Posters - Wednesday

PB3113. PubCaseFinder: Implementation of the new function designing Mondo-based virtual gene panels to increase diagnostic efficiency for rare genetic diseases.

Authors:

T. Fujiwara¹, J-M. Shin¹, H. Saitsu², A. Yamaguchi³; ¹Database Ctr. for Life Sci., Kashiwa, Chiba, Japan, ²Hamamatsu Univ. Sch. of Med., Hamamatsu, Shizuoka, Japan, ³Tokyo City Univ., Setagaya, Tokyo, Japan

Abstract Body:

Next-generation sequencing-based diagnostic tests have been attempted for the diagnosis of affected individuals with suspected rare genetic diseases. Recently, virtual gene panels (VGPs), sets of causal genes associated with rare genetic diseases, have been used for the interpretation of the results of whole-exome sequencing (WES) and whole-genome sequencing (WGS). In the UK 100,000 Genomes Project pilot study on rare disease diagnosis, PanelApp which is a database containing VGPs has been applied for automated variant filtering to simplify and accelerate the time-consuming interpretation process of WGS results and improve diagnostic rates. PanelApp includes 332 VGPs of various granularities, such as the "Paediatric disorders" VGP containing 7019 causal genes and the "Amyloidosis" VGP containing 11 causal genes. However, the design of these VGPs of various granularities is a laborious task because they are curated manually. In this study, we implemented the new function in PubCaseFinder (<https://pubcasefinder.dbcls.jp>), a clinical decision support system for rare genetic diseases, to automatically design VGPs by using curated disease-gene associations (GPAs) and the Mondo disease ontology (Mondo). The MedGen, GenCC, and Orphadata databases provide publicly available curated GPAs for genetic diseases in OMIM and rare diseases in Orphanet. Mondo is an ontology, a standard and controlled vocabulary to represent knowledge in the domain, that integrates existing sources of disease definitions, such as OMIM, Orphanet, and Disease Ontology. It provides a hierarchical structure that can be used for classification or "rolling up" diseases to higher-level groupings. Using this feature, any VGPs can be created by grouping diseases at any hierarchy of about 25,000 diseases included in Mondo and grouping the causal genes related to those diseases. For example, PanelApp provides "Rare anaemia" VGP (99 genes), "Cytopenias and congenital anaemias" VGP (221 genes), and Severe Paediatric Disorders" VGP (2691 genes) related to anemia, while PubCaseFinder can provide "Hemolytic anemia" VGP (55 genes) and "Hematologic disease" VGP (395 genes) that PanelApp does not have. In this presentation, we report the details of the VGP design function implemented on PubCaseFinder and the evaluation of the diagnostic efficiency of the function using a set of affected individuals with suspected rare genetic diseases. As a result of the evaluation, we showed that our proposed Mondo-based VGPs contributed to improving the time-consuming interpretation process of WGS results and ultimately improving diagnostic efficiency.

PB3114*. Pyro-Velocity: Probabilistic and scalable RNA velocity inference from single-cell data

Authors:

L. Pinello¹, Q. Qin¹, E. Bingham¹, G. La Manno², D. Langenau³; ¹MGH/Harvard/BROAD, Charlestown, MA, ²EPFL, Lausanne, Switzerland, ³MGH, Charlestown, MA

Abstract Body:

Single cell RNA-seq assays have dramatically advanced our ability to study and model cellular differentiation and cell fate decision. RNA velocity is an analysis framework that has become fundamental in the toolbox of the single-cell research community. RNA velocity — the time derivative of the gene expression state — is a powerful technique used to predict cell fate based on spliced and unspliced reads from single-cell RNA-seq and RNA-processing kinetics models. However current RNA velocity models have several shortfalls: they do not provide any uncertainty estimation of the recovered velocity vectors and cell fate; they assume independent transcriptional processes for different genes and the required preprocessing choices (e.g. dimensionality reduction, KNN-smoothing) can dramatically influence their predictions and lead to misinterpretation of developmental order and cell fate, especially for non-expert users. To address these challenges, we propose Pyro-Velocity a probabilistic and end-to-end inference framework for RNA velocity based on variational inference that is scalable to millions of cells, based on unsmoothed data, and that naturally provides uncertainty estimation of cell fate based on a joint learning of transcriptional processes across genes. Our probabilistic framework also provides a natural estimation of uncertainty for kinetics parameters and latent time that can reflect sequencing noise or recapitulate biological processes like bifurcation points. In addition, Pyro-Velocity can be used to learn cell fate decisions from one dataset and predict RNA velocity to other datasets with similar biological contexts. We have tested and quantitatively evaluated Pyro-Velocity on several single-cell RNA-seq and lineage tracing datasets from developmental tissues and pediatric tumors. Our method outperforms available methods to infer RNA velocity based on observed fate supported by lineage information and/or latent time recovered with orthogonal methods. In addition, our method provides new visualizations to highlight uncertainty of the recovered vector fields or to show the parallel dynamic of key driver genes describing cell fate decision and commitment. In summary, Pyro-Velocity is a new probabilistic RNA velocity framework and a user-friendly and end-to-end software package to study cell fate decision in tumor and normal cells from single-cell RNA-seq data.

PB3115. pyTCR: a comprehensive and scalable platform for TCR-Seq data analysis to facilitate reproducibility and rigor of immunogenomics research

Authors:

K. Peng¹, J. Moore², J. Brito¹, G. Kao¹, A. M. Burkhardt¹, H. Alachkar¹, S. Mangul¹; ¹Univ. of Southern California, Los Angeles, CA, ²Orange Coast Coll., Costa Mesa, CA

Abstract Body:

T cells are crucial components of the adaptive immune system as they are activated after being exposed to antigens. During the activation, V (variable), D (diversity), J (joining) segments in the T cells receptor loci undergo VDJ recombination to create diverse repertoires for recognizing and binding to the epitopes of the antigens presented by major histocompatibility complex (MHC). With the development of high throughput sequencing, TCR-seq provides the opportunities to understand adaptive immune responses, and further helps with diagnosis, prognosis prediction, and treatment outcome prediction in a variety of diseases including cancer, autoimmune disease, infectious disease, and allergies.

Due to the diversity and complicity of the TCR repertoire, computational methods are needed are important in understanding the features. Existing tools have promoted the advancement in TCR analysis. However, the existing tools fail to provide easy to use interface for biomedical researchers with no or limited background. They don't offer integrative analysis as they provide disjointed commands instead. Moreover, the analysis is not comprehensive as other tools are usually needed in order to finish the analysis. Furthermore, existing tools have limited options to customize the analysis and visualization. An alternative solution is urgently needed in this field.

pyTCR is a comprehensive platform with a rich set of functionalities of TCR repertoire analysis for biomedical researchers. Our cloud-based easy-to-use platform is based on the interactive notebook with the enhancement of reproducibility and transparency, by providing comprehensive and integrative functions, and customizable manipulations. The platform that pyTCR utilizes is interactive notebooks which code and results are all available to the users. pyTCR provides basic sample statistics such as number of reads, number of clonotypes, and convergence, clonality analysis, overlap analysis, segment usage analysis, diversity analysis, and motif analysis. In each analysis type, metrics, visualization, and statistical analysis are provided, which offers a comprehensive solution to TCR analysis.

The existing gap between traditional biomedical research and bioinformatics provides a substantial barrier for biomedical researchers to utilize computational tools to analyze high throughput data. Our tool will illustrate the capacities of cloud-based notebooks as the solution to bridge the gap, where users with no to limited bioinformatics background or experience would be able to use notebooks to analyze the data with transparent analysis and reproducible results.

PB3116. Quantifying regional DNA methylation improves detection of biologically relevant associations in Alzheimer's Disease

Authors:

T. Eulalio¹, D. Nachun², S. Montgomery¹; ¹Stanford Univ., Stanford, CA, ²Stanford Univ., Redwood City, CA

Abstract Body:

DNA methylation is an epigenetic modification linked to numerous neurological diseases, such as Alzheimer's Disease (AD), however, a mechanistic understanding of methylation's role in these diseases remains elusive. DNA methylation at individual CpG sites is often aggregated across functional genomic regions, such as promoters or enhancers, to improve interpretability. Oftentimes, the average methylation value is used for downstream analyses such as detecting differential methylation or unsupervised learning. While this can provide valuable insights, averaging regional methylation to a single value is noisy and further fails to capture more complex methylation patterns, particularly in regions with high CpG density or a mixture of hypo- and hypermethylated CpGs. We hypothesized that these patterns could be better captured by using principal components analysis (PCA) to summarize regional methylation while retaining orthogonal and interpretable methylation signals for downstream analyses. We demonstrated the utility of this approach in the Religious Order Study/Memory and Aging Project (ROSMAP) dataset, a large dataset with methylation collected from the dorsolateral prefrontal cortex (DLPFC) of AD patients and controls. In addition to analyzing the bulk tissue data, we used cell type deconvolution to estimate the cell type-specific methylation signal for four major brain cell types; astrocytes, endothelial cells, neurons, and oligodendrocytes/oligodendrocyte progenitor cells. We compared the performance of the regional aggregation of CpGs with principal components to averaging in identifying differentially methylated genes (DMGs) and pathway enrichment of DMGs for AD-relevant biology. Regional PCA identified over ten times more differentially methylated genes than averaging in the bulk data and up to four times more in the cell type-specific datasets. The genes identified by regional PCA included over 159 AD-relevant genes found in the Open Targets database (overall association score > 0.11, 95th percentile) that were not identified using averages; including the highly-evidenced AD genes SORL1, ABCA7, and TREM2. In gene set enrichment analysis of DMGs in bulk tissues and cell type-specific data, differentially methylated genes identified by regional PCA were significantly enriched in up to nine times more Alzheimer's Disease terms than genes identified by averaging. In conclusion, we show that summarizing DNA methylation within genomic regions using PCA captured more biologically relevant signals than averaging and improves our understanding of the role of methylation in disease.

Omics Technologies Posters - Wednesday

PB3117*. Rapid whole genome and whole exome variant detection using a novel fluorescently labeled reversible terminated nucleotide sequencing system and GPU-based accelerated analysis

Authors:

T. Looney¹, K. Gouin¹, A. Tong¹, M. Fabani¹, A. Sethia², R. Shultzaberger¹, M. Samadi³, T. Zhu³, E. Glezer⁴; ¹Singular Genomics, San Diego, CA, ²NVIDIA, Santa Clara, CA, ³NVIDIA, San Jose, CA, ⁴La Jolla, CA

Abstract Body:

Background Next generation sequencing (NGS) has become an indispensable tool for the diagnosis of genetic disease, though there remains a need to reduce turnaround for time sensitive applications such as newborn genetic screening. Reducing turnaround requires faster sequencing and accelerated data analysis. We recently introduced the Singular Genomics G4 platform for rapid sequencing-by-synthesis (SBS), which can deliver four human whole genomes at ~30x coverage in under 19 hours. Here we present accelerated pipelines for whole genome and whole exome germline variant detection on the G4 that leverage the NVIDIA Clara Parabricks platform and custom DeepVariant models.

Methods The G4 sequencer employs a novel fluorescently labeled reversible terminated nucleotide chemistry in combination with a rapid acquisition camera to deliver a cycle time of ~2.5 minutes. To maximize speed and performance for germline variant detection, we trained custom DeepVariant models for exome and whole genome analysis using a warm start from the Illumina WGS or WES models, respectively, and data from genome in a bottle samples HG002-6 (2x150bp reads; multiple library preparation kits used in generation of exome data). We iteratively explored the DeepVariant parameters `alt_align_pileup`, `vsc_min_fraction_snps` and `vsc_min_fraction_indels` before validating performance on HG001. Finally, the validated models were adapted to run on the GPU-based NVIDIA Clara Parabricks platform for accelerated analysis.

Results The baseline DeepVariant Illumina whole exome model delivered a precision and recall of 99.23% and 98.36% for SNPs, and 97.73% and 92.02% for indels, respectively for HG001 at 100x coverage. The trained model showed improved performance for both SNPs and indels, with a precision and recall of 99.53% and 98.53% for SNPs, and 97.76% and 93.09% for indels, respectively from the same library. A similar improvement in performance was observed for the trained whole genome model. The models were adapted to Parabricks to deliver a fastq-to-vcf turnaround of 29 and 4 minutes for 30x whole genome and 100x whole exome analysis, respectively, on an 8 GPU AWS p4d.24xlarge instance.

Conclusions We have successfully trained and implemented accelerated DeepVariant whole genome and whole exome models for the G4, resulting in improved performance for both SNP and indel detection and a speed matching that of the fastest analysis solutions to date. We anticipate that the combination of rapid-SBS and GPU-based acceleration will significantly reduce turnaround for the most time sensitive NGS applications.

Omics Technologies Posters - Thursday

PB3118. RedSpa: a method for Reference-based domain detection in multiple-sample Spatial transcriptomics studies

Authors:

Y. Ma¹, X. Zhou²; ¹Univ. of Michigan, Ann Arbor, MI, ²Univ MICHIGAN, Ann Arbor, MI

Abstract Body:

Various spatially resolved transcriptomic technologies have enabled the characterization of tissue-specific transcriptomic landscapes, i.e., spatial domain detection. However, existing methods cannot simultaneously analyze multiple tissue slices to disentangle both the cell type compositions and the complex tissue architectures. Moreover, all of the standard domain detection methods perform dimension reduction on the gene expression matrix before domain detection, in which the low-dimensional embeddings may not be optimal. None of the current methods utilizes the information from well-established single-cell RNA-seq technologies to facilitate domain detection. Finally, the published methods can't deal with high-resolution large-scale spatial transcriptomics datasets with more than 100k measured spatial locations. To fill these gaps, we developed RedSpa, which leverages cell type specific gene expression information from single-cell RNA-seq (scRNA-seq) to detect spatial domains in multiple tissue slices. RedSpa iteratively optimizes the cell type composition matrix and spatial domain labels across tissue slices, while accounting for the within-slice and between-slice compositional similarities to ensure optimal clustering performance. We demonstrate the advantages of RedSpa through in-depth analysis of five spatial transcriptomics datasets generated from different technologies, species, and tissues. In real data applications, RedSpa achieves up to 78% clustering accuracy gain over existing domain detection methods. The accuracy gain brought by RedSpa allows us to reveal the transcriptomic landscape in complex tissues including the human prefrontal cortex, squamous cell carcinoma, spermatogenesis, mouse brain, and olfactory bulb.

Omics Technologies Posters - Wednesday

PB3119. Regulome-wide association study identifies chromatin accessibility associated with pancreatic cancer risk

Authors:

S. Liu¹, H. Zhong¹, J. Zhu¹, Y. Wu², L. Wu¹; ¹Cancer Epidemiology Div., Population Sci. in the Pacific Program, Univ. of Hawaii Cancer Ctr., Univ. of Hawaii at Manoa, Honolulu, HI, ²Div. of Cancer Res. and Training, Dept. of Internal Med., Charles Drew Univ. of Med. and Sci., David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract Body:

Background: Genome-wide association studies (GWAS) have reported dozens of genetic variants associated with risk of pancreatic cancer (PC), a deadly malignancy. However, a large majority of the identified variants lie in non-coding genomic regions and do not directly impact the coding sequence of genes, which retard the transformation of GWAS findings into clinical application. The assay for transposase-accessible chromatin using sequencing (ATAC-seq) could quantify DNA accessibility with the use of hyperactive mutant Tn5 Transposase that inserts sequencing adapters at the accessible chromatin regions, which theoretically enables investigation of transcription factor (TF) binding. Allele-specific Regulome-wide association study (RWAS) is a newly developed design to identify chromatin accessibility that is potentially associated with diseases. However, their potential link with PC remains elusive. **Methods:** The pan-cancer chromatin accessibility genetic prediction models were built using LASSO penalized regression (for variants in the cis-locus) and top1 (single best variant in the cis-locus) methods, by leveraging allelic, total, or combined signal. We evaluated associations between genetically predicted levels of chromatin accessibility and PC risk by investigating 8,280 cases and 6,728 controls included in the PanScan (I, II, and III) and PanC4 consortia. The correlations between ATAC-seq accessibility and gene expression across 373 samples were assessed to predict the links between the accessibility features and regulated genes. **Results:** After analyzing 561,208 developed pan-cancer RWAS models, 50 accessibility features were identified to be associated with PC risk at a false discovery rate (FDR) of <0.05. These include 24 at seven novel loci not reported in PC GWAS. Ten accessibility features (located in promoter, intron, exon, and distal genomic regions) were identified to be linked with regulated genes at FDR <0.01. Four linked genes were protein-coding genes, including *GSDMB*, *CHST5*, *LDHD*, and *PGAP3*. Of them, *GSDMB* and *PGAP3* had been reported in our previous transcriptomic-wide association study. Five other linked genes are categorized into lincRNA, miscRNA, antisense, or TEC protein-coding genes. **Conclusion:** Our study identified accessibility features in non-coding genomic regions associated with PC risk and predicted linked genes regulated by these features. Our findings provide new insights into the regulatory mechanisms of non-coding regions for pancreatic tumorigenesis.

Omics Technologies Posters - Thursday

PB3120. Revealing the sequence of neutralizing antibodies produced during infection using VyCAP B cell screening equipment coupled to an optimized single cell RNA sequencing protocol.

Authors:

K. Rubben, A-S. Vander Plaetsen, D. Deforce, F. Van Nieuwerburgh; Ghent Univ. - Lab. of Pharmaceutical Biotechnology, Ghent, Belgium

Abstract Body:

Since the sudden emergence and worldwide spread of the highly contagious SARS-CoV-2 almost three years ago, the rapid availability of new therapies has shown to be of utmost importance to lower morbidity and mortality levels. Besides the use of vaccines as a preventive measure, monoclonal antibodies (mAb) constitute a possible therapeutic approach against infections. Several methods for producing monoclonal antibodies already exist and have been used in the past. However, these methods all suffer from certain drawbacks inherent to the specific workflow that is used. Therefore, we are optimizing a novel workflow that aims to reveal the humoral B cell immune response during an infection in a fast and efficient way. The proposed workflow includes the use of a specifically designed filter unit to obtain single B cells in a microwell chip containing 6400 wells, a clamp unit to analyse their antibody production capacity on an antigen-coated membrane, and a puncher system to isolate the specific antibody-secreting B cells (ASC) of interest. These ASC are then lysed and the antibody mRNA sequence is determined by performing optimized reverse transcription (RT) and nested PCR protocols using human B cell primer mixes. Finally, these sequences can easily be determined by Sanger sequencing and cloned into a vector, allowing subsequent transfection of a suitable cell line. First, the VyCAP single B cell screening and isolation workflow was optimized to work with ASC from whole blood of patients, as the use of these cells provides challenges for cell viability and retainment of antibody production. Preliminary experimental testing in 24-well plates revealed that enriching CD38⁺ ASC using a negative and subsequent positive MACS selection step, incubating this cell fraction for 68 hours in a medium containing TLR 7/8-L and IFN- α , and detecting the produced antibodies by using both anti-IgA and anti-IgG secondary antibodies, maximized the chances of detecting viable SARS-CoV-2-specific ASC. Second, the cell lysis, RT and nested PCR protocols needed to be optimized to work with single cell input material. This was successfully done using an antibody-producing hybridoma B cell line. Future research will focus on determining the effect of the optimized conditions on ASC incubated in the more stressful microwell chip environment and applying the optimized RT and nested PCR protocols on single SARS-CoV-2-specific ASC. When all these optimizations are carried out successfully, this workflow could be used to reveal the B cell response during any infection and thereby contribute to the search for a suitable therapy against any infectious agent in the future.

Omics Technologies Posters - Wednesday

PB3121. Rigorous benchmarking of HLA callers for RNA sequencing data.

Authors:

R. Ayyala¹, D. Yu¹, S. Sadek², T. Tao³, R. Alomair⁴, S. Knyazev⁵, S. Mangul³; ¹Univ. of Southern California, Los Angeles, CA, ²California State Univ., Fullerton, Fullerton, CA, ³Univ. of Southern California, Sch. of Pharmacy, Los Angeles, CA, ⁴Univ. of California, Los Angeles, Los Angeles, CA, ⁵Univ. of California, Los Angeles, David Geffen Sch. of Med., Los Angeles, CA

Abstract Body:

Precise identification of alleles in the human leukocyte antigen (HLA) region of the genome is crucial for various clinical and research applications. HLA typing in the clinical laboratory setting is challenging due to its resource intensiveness and the high polymorphism of HLA residues within the population. To address this limitation, many computational tools have been developed to use widely accessible RNA-seq data to predict HLA types.

However, existing RNA-Seq-based benchmarking studies are not up to date, lacking to investigate newly released HLA callers. Previous studies also do not explore the effects of the IPD-IMGT/HLA reference versions, sequencing parameters (i.e., read length and coverage), and the ancestral diversity of the HLA region on prediction quality, while using large-scale and realistic gold standards.

As such, we rigorously compared the performance of 12 HLA callers on 445 RNA-seq samples across 6 cohorts in reference to their respective gold standard datasets. In each case, we produced evaluation metrics of accuracy, that is the percentage of correctly predicted alleles to determine the best performing tool. At the clinically relevant resolution (Four Digits), OptiType had the highest accuracy at 94% with seq2HLA following at a 92% accuracy. Moreover, all HLA caller outputs for Class 1 Genes were separated by HLA allele to determine the number of miscalled alleles. HLA Allele B was miscalled the most while HLA Allele A had the least amount of miscalls across all callers. In addition, CPU and memory metrics were collected for each tool, in which seq2HLA used the least amount of CPU and memory relative to all other tools. This study offers crucial information for researchers regarding appropriate choices of methods for an HLA analysis.

Omics Technologies Posters - Thursday

PB3122. rMATS-turbo: An efficient and flexible computational tool for alternative splicing analysis of large-scale RNA-seq data.

Authors:

J. Adams^{1,2}, Y. Wang^{1,3}, Z. Xie¹, E. Kutschera¹, K. Kadash-Edmondson¹, Y. Xing^{1,2}; ¹The Children's Hosp. of Philadelphia, Philadelphia, PA, ²Univ. of Pennsylvania, Philadelphia, PA, ³Univ. of California, Los Angeles, Los Angeles, CA

Abstract Body:

Pre-mRNA alternative splicing is a prevalent mechanism for diversifying eukaryotic transcriptomes and proteomes. Regulated alternative splicing plays a role in many biological processes, and dysregulated alternative splicing is a feature of many human diseases. Short-read RNA sequencing (RNA-seq) is now the standard approach for transcriptome-wide analysis of alternative splicing. Since 2011, our lab has developed and maintained rMATS, a computational tool for discovering and quantifying alternative splicing events from RNA-seq data. The rMATS software has been widely used by the research community. Here we describe the contemporary version of rMATS - called rMATS-turbo - a fast and scalable re-implementation that maintains the statistical framework and user interface of the original rMATS software, while incorporating a revamped computational workflow with substantial improvements in speed and data storage efficiency. The rMATS-turbo software scales up to massive RNA-seq datasets with tens of thousands of samples. To illustrate the utility of rMATS-turbo, we describe two representative application scenarios. Firstly, we describe a broadly applicable two-group comparison to identify differential alternative splicing events between two sample groups, including both annotated and novel alternative splicing events. Secondly, we describe a quantitative analysis of alternative splicing in a large-scale RNA-seq dataset (~1,000 samples), including the discovery of alternative splicing events associated with distinct cell states. We detail the workflow and features of rMATS-turbo that enable efficient parallel processing and analysis of large-scale RNA-seq datasets on a compute cluster. We anticipate that rMATS-turbo will be useful for studying alternative splicing in diverse biological systems.

Omics Technologies Posters - Wednesday

PB3123. RNA monsters generated by human mitochondrial RNA polymerase

Authors:

E. Greenwald¹, J. Park², N. Jain¹, I. Zheludev¹, K. Artiles¹, D-E. Jeong¹, W. Yin², A. Fire¹; ¹Stanford Univ., Palo Alto, CA, ²Univ. of Texas Med. Branch at Galveston, Galveston, TX

Abstract Body:

Human hepatitis delta virus and plant viroids are RNA pathogens that are copied by host DNA-dependent RNA polymerases (RNAPs) (Cunha et al., 2015. World J Virol.). RNA replication by transcription polymerases, classically perceived as DNA-dependent, could provide a means to copy and transmit RNA-based genetic material. Former studies found that the DNA-dependent RNA polymerase from bacteriophage T7 can regenerate certain RNAs, providing a model system for RNA replication by transcription polymerases (Jain et al., 2020. Science). Do similar transcription RNA polymerases also have RNA-templated replication activity? We performed in vitro reactions using human and yeast mitochondrial RNAP, which have structural similarity to T7 RNAP. Thus far, we have shown that human and yeast mitochondrial RNAP do yield RNA in in vitro no-template-added reactions. Sequencing of these reaction products shows strings of As interrupted by other bases, and these resulting sequences are not homologous to any known sequences. Further experiments are underway with a mix of DNAs as possible templates, with less As in the reaction, and with different sequencing methods to further understand the RNAs that mitochondrial RNAPs tend to make. The RNA-templated RNA replication and untemplated transcription activities by transcription polymerases challenge the textbook view of transcription. In the case of mitochondrial polymerase, it is intriguing that transcription by this enzyme could serve as a flexible sensor of both template sequence and biochemical environment. This provides a fundamental insight into the evolution in an RNA world that could indicate how RNA-based biology could respond to environmental conditions.

Omics Technologies Posters - Thursday

PB3124*. Robust mapping of cell states from multiomics data using implicit feature selection.

Authors:

H. Hu¹, Y. Choi¹, G. Quon²; ¹Univ. of California Davis, Davis, CA, ²Univ California Davis, Davis, CA

Abstract Body:

scRNAseq and scATACseq assays measure distinct aspects of gene regulation, and both are routinely used to infer cell types and states of individual cells. When the same cell types are profiled using both technologies, some cell types distinguishable in RNA space are not distinguishable in ATAC space, and vice versa. The introduction of multi-omics assays such as SHARE-seq that measure both data modalities (RNA, ATAC) in the same cell provide an opportunity to directly measure the extent to which the RNA and ATAC spaces can be mapped to each other, and therefore provide insight into the extent to which variation in open chromatin regions can explain variation in gene expression.

A critical step in mapping RNA and ATAC state spaces is feature selection: both the genes and the chromatin regions are typically subsetted based on variability before cell state mapping is performed. This is problematic because the high variable features may not be correlated across modalities and modality-specific cell type identifications can be nonaligned, leading to poor mapping.

Here we show that by training a deep neural network that simultaneously selects features and maps between RNA and ATAC state spaces, we substantially improve our ability to map cell state spaces. To do so, we present a novel supervised framework designed for jointly capturing the associated regions and genes by leveraging paired multi-omics data without pre feature selection. Our framework leads to improved prediction of gene expression from chromatin accessibility in 70-78% of the total genes, across data from diverse assays (SNARE-seq, SHARE-seq, 10x Multiome), and also when predicting chromatin accessibility from gene expression. We directly attribute this performance gain to the lack of explicit feature selection, compared to existing approaches. On the SNARE-seq cortex data for example, among the top 3000 genes that best predict ATAC state space, 753 genes are not selected by feature selection strategies employed by other approaches, illustrating how feature selection can throw away informative genes. Our framework also enables us to augment training data with larger uni-modal datasets available on the same cell types, leading to an improvement in accuracy of over 55% of all chromatin regions compared to when only multi-omic datasets are available.

Finally, we demonstrate the generalizability of our approach to studying multi-modal datasets involving data modalities such as RNA and single neuron electrophysiology. Our approach is therefore useful for establishing the extent to which mappings between e.g. RNA and ATAC cell state spaces can be established.

Omics Technologies Posters - Wednesday

PB3125. SARS-CoV-2 genomic surveillance in Rwanda: Introductions and local transmission of the B.1.617.2/Delta variant of concern.

Authors:

Y. Butera¹, M. Semakula², S. Hong³, N. Bollen⁴, S. Dellicour⁴, M. Artesi⁵, V. Bours⁶, K. Durkin⁵, L. Mutesa⁷, G. Baele⁴; ¹Ctr. for Human Genetics, Univ. of Rwanda, Kigali, Rwanda, ²Ctr. for Statistics, Hasselt Biostatistics and Statistical Bioinformatics Ctr., Diepenbeek, Limburg, Belgium, ³Dept. of Microbiol., Immunology and Transplantation, Rega Inst., KU Leuven, Leuven, Belgium, ⁴Dept. of Microbiol., Immunology and Transplantation, Rega Inst., KU Leuven, Leuven, Belgium, ⁵Lab. of Human Genetics, GIGA Res. Inst., Liège, Belgium, ⁶Lab. of Human Genetics, GIGA Res. Inst., Liège, Belgium, ⁷Univ. of Rwanda, Kigali, Kigali City, Rwanda

Abstract Body:

The emergence of the SARS-CoV-2 Delta variant of concern (lineage B.1.617.2) in late 2020 resulted in a new wave of infections in many countries across the world, where it often became the dominant lineage in a relatively short amount of time. We here report on a novel genomic surveillance effort in Rwanda in the time period from June to September 2021, leading to 201 SARS-CoV-2 genomes being generated, the majority of which were identified as the Delta variant of concern. We show that in Rwanda, the Delta variant almost completely replaced the previously dominant A.23.1 and B.1.351 (Beta) lineages in a matter of weeks, and led to a tripling of the total number of COVID-19 infections and COVID-19-related fatalities over the course of only three months. We estimate that Delta in Rwanda had an average growth rate advantage of 0.034 (95% CI 0.025-0.045) per day over A.23.1, and of 0.022 (95% CI 0.012-0.032) over B.1.351. Phylogenetic analysis reveals the presence of at least seven local Delta transmission clusters, with two of these clusters occurring close to the border with the Democratic Republic of the Congo, and another cluster close to the border with Tanzania. A smaller Delta cluster of infections also appeared close to the border with Uganda, illustrating the importance of monitoring cross-border traffic to limit the spread between Rwanda and its neighboring countries. We discuss our findings against a background of increased vaccination efforts in Rwanda, and also discuss a number of breakthrough infections identified during our study. Concluding, our study has added an important collection of data to the available genomes for the Eastern Africa region, with the number of Delta infections close to the border with neighboring countries highlighting the need to further strengthen genomic surveillance in the region to obtain a better understanding of the impact of border crossings on lowering the epidemic curve in Rwanda.

Omics Technologies Posters - Thursday

PB3126. scNanoGPS enables high throughput single cell nanopore sequencing of same cell mega-omics in human tumors

Authors:

C-K. Shiau; Northwestern Univ., Chicago, IL

Abstract Body:

Long read single cell nanopore RNA sequencing (scNanoRNAseq) is emerging as a powerful technology to simultaneously profile phenotypes and genotypes of same cells, which however are challenged by lacking robust computational tools and requiring parallel short reads to curate sequencing errors. To address these challenges, we developed a computational tool, scNanoGPS to deconvolute barcoded long reads into single cells and single molecules without short reads curation and calculate both phenotypes (gene expression, isoform) and genotypes (mutation, fusion) of same cells. We applied scNanoGPS onto 24,000 single cells of 4 tumors and 3 cell lines. Our results showed that scNanoGPS can robustly detect single cell mega-omics to delineate cell types and cell states as well as mutation clonality. In tumor samples, scNanoGPS dissected tumor microenvironment and aligned tumor developmental hierarchies onto evolutionary lineages. In summary, scNanoGPS enabled high-throughput single cell mega-omics analysis with single cell third generation sequencing technologies.

Omics Technologies Posters - Wednesday

PB3127. Searching for Somatic Variation in Rapid-onset Obesity with Hypothalamic dysfunction, Hypoventilation and Autonomic Dysregulation (ROHHAD)

Authors:

S. Barclay^{1,2}, C. M. Rand³, M. Khanbabaei^{1,2}, N. T. Bech-Hansen^{1,2}, D. E. Weese-Mayer^{3,4}, K. C. Kurek^{1,2}; ¹Univ. of Calgary, Calgary, AB, Canada, ²Alberta Children's Hosp. Res. Inst., Calgary, AB, Canada, ³Ann & Robert H. Lurie Children's Hosp. of Chicago, Dept. of Pediatrics, Div. of Autonomic Med. and Stanley Manne Children's Res. Inst., Chicago, IL, ⁴Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract Body:

Classically, the syndromes associated with somatic genetic variation have been those in which the tissues harbouring the pathogenic change are visibly altered from the tissues around them. More recently, this group has grown to include less 'visible' diseases, such as epilepsy and immune disorders. ROHHAD is a rare pediatric disorder in which healthy children between the ages of 1.5-7 years present with signs of hypothalamic dysfunction and dysregulation of the autonomic nervous system, that include rapid-onset obesity and potentially fatal central alveolar hypoventilation. ROHHAD is part of a group of disorders of respiratory control and autonomic nervous system dysregulation, some of which have genetic causes (i.e., CCHS, caused by *PHOX2B* variants). Extensive genetic investigations, including candidate gene, exome, and genome sequencing studies, have failed to identify a recurrent germline genetic explanation in any ROHHAD cohort. This fact, combined with the observations that a) about 40-50% of individuals with ROHHAD have tumours of neural crest origin, and b) our cohort contains two pairs of monozygotic twins discordant for ROHHAD, have led us to consider the possibility that ROHHAD pathogenesis may involve somatic changes. To investigate this hypothesis, we undertook whole genome sequencing, at an average of 100X depth, using blood, of the discordant monozygotic twin pairs. We identified only one discordant protein-altering variant in one of the twin pairs: an *FMR1* variant that is synonymous in the major isoforms of FMRP, but results in a missense change in the nuclear-localized isoforms ISO6 (c.1319C>T, p.(T440M)) and ISO12 (c.1256C>T, p.(T419M)). The variant was detected on 5/103 reads in the proband; 0/118 in the unaffected twin; 0/130 in the mother; and 0/50 in the father. We validated this finding using digital PCR, a variant detection method sensitive to 0.001%, which showed that the variant was present at 3% and 5% in a blood and tumour sample from the proband, respectively, and 0% in blood samples from the unaffected twin and parents. Whether this finding in a single ROHHAD proband has any relevance to the pathogenesis of ROHHAD is yet unknown. It has illustrated the potential of high-throughput sequencing to detect low level somatic variation, but points to the fact that increased depth of sequencing (even higher than 100X) would be required to have confidence that all variants at a frequency of 5% or lower will be detectable. We have recently had the privilege of receiving autopsy tissue donated by a family who lost a child to ROHHAD, and are in the process of investigating directly the tissues thought to be *affected* - the hypothalamus and brainstem.

Omics Technologies Posters - Thursday

PB3128. SeeNV: a pipeline ready tool for the integration and visualization of CNVs and their callers

Authors:

M. Bradshaw; Univ. of Colorado Boulder, Boulder, CO

Abstract Body:

Copy number variants (CNVs) can affect health and physiology by altering gene expression, manipulating epigenetic factors, and/or gene expression. CNV identification, or calling, is now common practice in genetic diagnostic laboratories. To maximize sensitivity, it is now an established best practice to use an ensemble of callers. However, the various CNV calling programs utilize different algorithms, parameters, and inputs. These differences can result in inconsistencies making it difficult to discern whether or not a call is a true positive, which necessitates manual curation by a clinician to determine which calls are both real and relevant.

To aid in this task of manual curation we present SeeNV, a tool to help balance the clinical need for high diagnostic yield without overwhelming clinicians with dozens of false positives. SeeNV provides means to simultaneously visualize and integrate multiple algorithms, parameter sets, lab specific reference cohorts and large public datasets. By comparing calls to those from the same lab, it can be determined if a call is real or an artifact of lab specific sample preparation and processing. Integration of large public datasets such as 1000 Genomes Project and varDB, make it possible to establish the population frequency, indicative of its relevance or deleterious effect. SeeNV provides a series of local and chromosomal visualizations. Local plots depict statistics such as read coverage and population frequency in the area immediately surrounding a call. Chromosomal scale plots help visualize the amount of noise present within a sample and how much noise is in the region containing the call.

SeeNV is already in use as part of a clinical pipeline at Children's Hospital Colorado; we have also generalized it with default parameters based on publicly available data so it can be used as a drop-in tool for labs with limited technical resources. The robust features comprising SeeNV are bundled into a simple command line tool with single step installation and a single command to run it with built in parallelization. SeeNV is freely available for download on GitHub:

<https://github.com/MSBradshaw/SeeNV>

PB3129. Sentieon DNAscope LongRead: a highly accurate, fast, and efficient pipeline for germline variant calling from PacBio HiFi reads.

Authors:

D. Freed¹, W. J. Rowell², A. M. Wenger², Z. Li¹; ¹Sentieon Inc, San Jose, CA, ²Pacific BioSci.s, Menlo Park, CA

Abstract Body:

PacBio HiFi sequencing leverages the random nature of errors in the underlying technology to generate highly accurate consensus reads that are both long and highly accurate, with read lengths greater than 10kb and average base accuracy exceeding 99.8%. Sentieon develops fast, efficient and accurate software for processing genomic data, including improved implementations of the GATK best practices pipelines for germline and somatic variant calling. To further improve germline variant calling accuracy beyond the GATK, Sentieon has developed DNAscope and has used DNAscope to successfully participate in and win awards in multiple precisionFDA (pFDA) challenges, including the original pFDA Truth Challenge and the pFDA Truth Challenge V2.

Here, we present DNAscope LongRead, a highly accurate pipeline for germline variant calling from PacBio HiFi reads that is an update and extension of our earlier DNAscope tool for germline variant calling from short reads. We benchmark DNAscope LongRead using samples from the pFDA Truth Challenge V2 and evaluated variant calling performance using the Genome in a Bottle v4.2.1 benchmark dataset. Compared to the pFDA Truth Challenge V2 winning submission, DNAscope LongRead reduces overall sequencing errors by 15%, with an average of 9,130 errors (mean F1-score of 0.9988) in the pFDA samples relative to the v4.2.1 benchmark.

DNAscope LongRead uses a machine learning model that was trained using samples sequenced using PacBio's chemistry 2.0 or earlier and evaluated against the Genome in a Bottle v4.2.1 benchmarks. To test the ability of DNAscope LongRead to generalize, we performed variant calling on a sample sequenced with PacBio's chemistry 2.2 on a Sequel II system. With this sample, DNAscope LongRead made 9,231 errors, similar to the accuracy obtained with earlier sequencing chemistries. Variant calling accuracy is also high across the Challenging Medically Relevant Genes benchmark, demonstrating the tool's ability to extend to more difficult benchmark regions. DNAscope LongRead was able to perform variant calling in under 5 hours on an Intel Xeon machine with 32 virtual CPUs for each sample tested and used less than 16GB of memory. These results demonstrate that DNAscope LongRead is a fast and accurate tool for calling germline variants from PacBio HiFi reads.

Omics Technologies Posters - Thursday

PB3130. Sentieon DNAscope: high accuracy small variant calling using machine learning.

Authors:

B. Gallagher; Sentieon Inc, San Jose, CA

Abstract Body:

Sentieon develops fast, efficient, and accurate software for processing genomic data, including improved implementations of the GATK best practices pipelines for germline and somatic variant calling. To further improve germline variant calling accuracy beyond the GATK, Sentieon has developed DNAscope and has used DNAscope to successfully participate in and win awards in multiple precisionFDA (pFDA) challenges, including the original pFDA Truth Challenge and the precisionFDA Truth Challenge V2. We present DNAscope, an accurate and efficient short-read germline small-variant caller. DNAscope combines the robust and well-established preprocessing and assembly mathematics of the GATK's HaplotypeCaller with a machine-learned genotyping model. Benchmarks of DNAscope and DNaseq (Sentieon's GATK-matching germline variant calling pipeline) demonstrate that DNAscope achieves superior SNP and insertion/deletion accuracy with reduced computational cost. DNAscope's machine-learning genotyping model is tuned for established and newly developed short read sequencing platforms including Illumina, MGI/BGI, Element Biosciences, and Ultima Genomics.

For a 30x HG002 sample sequenced on an Illumina platform DNAscope achieves an F1-score of 99.57% for SNPs and 99.46% for INDELS on the Genome in a Bottle v4.2.1 benchmark dataset. Notably, DNAscope reduces total errors by more than two-fold (from 87,607 to 34,634) relative to GATK. The high accuracy of DNAscope across multiple samples suggests that DNAscope's model is not overfit to the HG001 and HG005 samples used during model training. DNAscope models have been successfully trained for the Illumina, MGI, Element Bioscience and Ultima Genomics platforms, and produce state-of-the-art variant calling accuracy on each platform. DNAscope software can be run on x86 or ARM based architecture and can complete alignment and variant calling for a 30x WGS in less than 1 hour for less than \$2 on AWS.

Omics Technologies Posters - Wednesday

PB3131. Sequence-to-expression models of compact promoters for cell-type-specific promoter design

Authors:

A. Reddy, M. Herschl, A. Lu, A. Kumar, X. Geng, P. Hsu, S. Levine, N. Ioannidis; Univ. of California, Berkeley, Berkeley, CA

Abstract Body:

Advances in gene delivery technologies are enabling rapid progress in molecular medicines. Achieving the full potential of gene and cell therapies requires the precise expression of genetic cargo in desired cell types. However, current approaches are limited by the small number of experimentally demonstrated cell type-specific gene regulatory elements. It would be very useful to have promoter sequences of minimal length to enable facile delivery, capable of promoting expression in particular target cell types while silencing expression in other cell types.

Designing these promoters is difficult as it is infeasible to experimentally validate every possible sequence. Thus, we propose a data-driven machine learning-based approach to design promoters. Deep learning (DL) models can accurately predict gene expression using only the surrounding sequence by learning sequence features such as the presence and strength of transcription factor (TF) binding motifs. We can use these sequence-to-expression models to test sequences in-silico. However, DL models are prone to overfitting and produce unreliable results when tested using inputs that are very different from the training inputs. Model-based optimization (MBO) algorithms can combat these problems and reliably utilize these models to generate desirable promoters. Therefore, we are developing DL models of cell-type-specific expression from short promoter sequences that will be used together with state-of-the-art MBO algorithms to design promoters for gene therapy with improved cell-type specificity.

Most existing sequence-to-expression models predict expression using a large sequence input context to capture the effects of nearby cis-regulatory elements. However, it is challenging for compact gene therapy designs to incorporate distal regulatory elements, instead relying on TF binding within a short promoter sequence. Here, we train DL models to predict gene expression from short input sequences in a variety of cell types, using both MPRA and RNA-seq data for training. We evaluate multiple architectures and training strategies using the MPRA promoter sequence or short windows of endogenous gene promoters for the RNA-seq data. To demonstrate the use of these models in promoter optimization, we focus on three leukemia cell lines with the aim of designing promoters to target high expression in each cell line individually while minimizing expression in the other two. We are generating experimental data to validate the performance of our models and to train a second round of models optimized for these cell lines.

Omics Technologies Posters - Thursday

PB3132. Sequencing By Binding (SBB) demonstrates superior performance in low-pass whole-human-sequencing applications

Authors:

K-Y. Chen¹, A. Torkamani²; ¹The Scripps Res. Inst., La Jolla, CA, ²Scripps Res. Translational Inst., La Jolla, CA

Abstract Body:

Recently, PacBio introduced its sequencing by binding (SBB) chemistry, which provides an order-of-magnitude higher accuracy than the Illumina sequencing by synthesis (SBS) technology. In this study, the performance of Illumina SBS and PacBio SBB is compared on HG002 relative to the Genome in a Bottle benchmark for both high-coverage and low-coverage sequencing data. A HG002 WGS library was sequenced by PacBio SBB to 40x coverage. An SBS dataset for comparison was obtained from the Genome in a Bottle website. Deduplication and base quality score recalibration were conducted on SBS data. We then performed variant calling for single nucleotide variants (SNVs) and insertions and deletions (indels). Genotype imputation and variant evaluation are exercised for performance comparison. PacBio SBB achieved higher true-positive rate and lower false-negative rates in both SNVs and indels compared to SBS. Additionally, PacBio SBB provided a higher genotype concordance rate than SBS compared to benchmark SNVs and indels. Considering transition/transversion ratio (ti/tv) and heterozygous/non-reference homozygous ratio (het/hom ratio) as measurement of call quality, ti/tv and het/hom ratio generated by PacBio SBB were closer to the ones generated from benchmark calls. To access call quality, we evaluated variant calls in both platforms without imputation process across low-coverage sequencing data. For SNV calls, the results showed that SBB achieved a higher genotype concordance rate compared to SBS. In addition, after the imputation process, we found that SBB also offers higher imputation accuracy outcome across low-coverage sequencing data. PacBio SBB delivered high-quality outcomes in both high-coverage and low-coverage sequencing data compared to Illumina. These outcomes suggest that the performance of PacBio SBB exceeds well-established Illumina SBS platform and demonstrates its potential application in the field of genomic studies.

Omics Technologies Posters - Wednesday

PB3133. Sequencing By Binding (SBB) enables a lower limit of detection for Tuberculosis resistance genes *gyrA* and *katG*.

Authors:

C. Wike¹, C. Allender², N. Pezeshkian³, D. Nasko⁴, S. Pond¹, E. Engelthaler²; ¹Translational Genomics Res. Inst., Phoenix, AZ, ²Translational Genomics Res. Inst., Flagstaff, AZ, ³Pacific BioSci.s, Menlo Park, CA, ⁴Pacific, Menlo Park, CA

Abstract Body:

Tuberculosis (TB) remains a leading infectious disease due to many challenges associated with treating *Mycobacterium tuberculosis* (Mtb), including its ability to develop drug resistant mutations. Identifying the correct antibiotics to treat individuals with TB is critical and difficult to do without the ability to screen for certain drug resistance mutations in Mtb. Next generation sequencing (NGS) has enabled the detection of these genetic variants, specifically in genes *katG* and *gyrA*, which have been associated with reduced sensitivity to first-line and second-line treatments, respectively. However, these genes are encoded in GC-rich regions (~60-80%) that are challenging for current Sequencing By Synthesis (SBS) NGS techniques to sequence. We demonstrate that revolutionary sequencing-by-binding (SBB) chemistry can reliably sequence Mtb drug resistance mutations in *gyrA* and *katG* genes, despite their high GC content. Additionally, the improved accuracy of SBB enables a new lower limit of detection (0.001%) that is two orders of magnitude lower than current SBS sequencing platforms. Lower limits of detection along with rapid screening of resistance genes will enable earlier and more precise treatment of TB.

Omics Technologies Posters - Thursday

PB3134. *SigAlign* (Similarity-guided Align): A new, high-performance generalized pairwise alignment algorithm using simplified and intuitive regularization criteria

Authors:

K. Bahk, J. Sung; Genome Epidemiology & Hlth.Data Lab., Graduate Sch. of Publ. Hlth., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract Body:

BACKGROUND: Quantifying similarities between two nucleotide sequences, *a.k.a.* "pairwise alignment algorithm (PAA)," is a core but computationally expensive task in bioinformatics. A method to reasonably reduce the pairwise comparison is the key to this algorithm. Current PAA methods generally rely on the "affine-penalty function", which inevitably introduce multiple criteria that lack biological connections such as the "size of k-mers" or "X-drop value". Here, we propose a new alignment algorithm, "*SigAlign*" (Similarity-guided Align). We attempted to demonstrate that the new align algorithm is more reliable and faster than current standard methods, allowing flexible adjustment for the characteristics of data.**METHODS:** Multiple new methods constitute the *SigAlign* algorithm: first, automatically determine the optimal size of *k-mers*; second, search the exact matches or "seeds" using automatic and optimized methods in the reference; third, start outward PAA on both ends of the seeds until violating the new criteria. *SigAlign* uses two intuitive and simplified criteria to determine the extension/termination of PAA - 1) minimum alignment length (MAL) and 2) maximum penalty per length (MPpL). We compared the performance of our method with BWA-mem, Hisat2, and Bowtie2. We compared the throughput, alignment score and length using *Mycobacterium tuberculosis* and the human genome samples. We also performed a "recall test" to locate the exact match in the reference mixed with highly similar sequences (UHGG, unified human gastrointestinal genome), using simulated short-reads from the Illumina platforms.**RESULTS AND INTERPRETATIONS:** The proposed algorithm worked faster with higher alignment scores than all BWA-mem, Hisat2, and Bowtie2 at the same default penalty schemes with respective tools; up to 3.4, 1.2, and 9 times faster. The recall rate is near complete (~100%) for the *SigAlign*, whereas the rate of the other three tools ranged from 20 to 50%. We believe a new alignment algorithm based on simplified but adjustable criteria that bear biological connotations (MAL and MPpL). We expect the *SigAlign* would increase the alignment performance with the economy. The new method may need further validation on diverse, real-life tasks.

Omics Technologies Posters - Wednesday

PB3135. Simplified RNA-Seq Library Prep: Improved RNA sequencing results for FFPE and blood samples

Authors:

E. Putnam, S. Panja, S. Chung, B. Komorous, M. Ait Ichou; Quantabio, Beverly, MA

Abstract Body:

RNA-seq studies carried out using high-throughput sequencing of cDNA have provided tremendous insight into cellular transcript studies on a large and comprehensive scale. However, technical challenges such as laborious and lengthy workflows, affordability, compromised accuracy, read coverage biases and limited transcript diversity have impeded implementation of the technology in many labs. There are additional challenges when working with RNA derived from FFPE and blood, which are commonly used in precision medicine research. FFPE RNA is usually degraded and consists of small sized fragments. Blood RNA has high abundance of globin mRNA that could potentially mask the reads from regions of interest by saturating the sequencing runs.

Here we present a simple, affordable, high-performance solution for directional RNA-seq library preparation: the sparQ RNA-Seq HMR Kit. The kit integrates depletion of ribosomal and globin transcripts (human, mouse, and rat) and RNA fragmentation into a single step and tube. The proprietary, highly optimized enzymes and streamlined workflow generates high quality, directional, transcriptome NGS libraries from either intact or degraded RNA samples, with key improvements for FFPE and blood samples.

Utilizing RNA derived from FFPE and blood, we evaluated libraries prepared using sparQ RNA-Seq HMR Kit. The data gathered from the FFPE samples were compared to other RNA-seq kits. Comparison with 20 million sampled reads from each library demonstrated superior performance, even with limiting quantity: increased unique transcript identification, uniform 5' to 3' transcript coverage, efficient rRNA and globin mRNA removal, higher yield, and excellent data concordance.

The sparQ RNA-Seq HMR Kit with integrated ribo-globin depletion technology, enables faster time to result (5 hours), minimal hands-on time, and fewer pipetting steps, while generating high quality transcriptomic data for FFPE and blood samples.

Omics Technologies Posters - Thursday

PB3136. Simulating pathogenic and likely pathogenic variants for bioinformatics pipeline testing

Authors:

Q. Zeng, B. Huang, P. Hu, N. Russell, S. Letovsky, N. Leach, A. Kenyon; Labcorp, Westborough, MA

Abstract Body:

Next Generation Sequencing (NGS) is widely used to detect clinically significant variants in clinical samples. The analytical performance (sensitivity and specificity) of NGS tests is dependent on many factors, including the selection of an analysis pipeline, targeted genomic regions, variant types and length, library quality, sequencing technology, read length and quality, and coverage. It is critical to understand the impact of these factors in order to optimize testing performance.

The performance of NGS analysis pipelines can be assessed using different reference materials. First, a high-quality reference data set (e.g., Genome in a Bottle Consortium) provides a set of “gold standard” variants in a small number of well-characterized genomes. Second, some public repositories (e.g., Coriell Institute) have a large number of samples with well-characterized individual pathogenic variants. A third source is previously characterized clinical samples with reported pathogenic and likely pathogenic variants (PLP). All of these reference materials can be utilized to assess the sensitivity and specificity of the analysis pipeline, but they are limited in the number of PLP, and therefore, none provides a comprehensive picture of PLP detection across the genome.

Another approach is to supplement clinical samples and gold standard references with simulated samples. However, previous simulation studies have been limited in the number of simulated variants, mostly focusing on specific variant type(s) and variant length range. In this study, simulated samples are generated for all currently available ClinVar PLP, using a streamlined variant simulation framework developed in-house. We analyzed simulated samples with Illumina paired-end reads for over 110,000 PLP variants to assess the performance of our NGS testing analysis pipeline. Our analysis confirmed that the NGS pipeline has high sensitivity for the vast majority of the ClinVar PLP across the different variant types and length range throughout the genome. We also identified a number of challenging ClinVar PLP requiring customized pipeline settings, which further enhanced the performance of our NGS testing analysis pipeline. Our variant simulation framework for all current ClinVar PLP could be readily used by others to evaluate the performance of the NGS testing pipelines.

Omics Technologies Posters - Wednesday

PB3137*. Simultaneous dimensionality reduction and cell-type annotation of single-cell RNA-seq data using marker enriched uniform manifold approximation and projection.

Authors:

Sch. of Med., Stanford, CA, ⁶Dept. of Microbiol. and Immunology, Stanford Univ. Sch. of Med., Stanford, CA, ⁷Dept. of Pediatrics, Stanford Univ. Sch. of Med., Stanford, CA, ⁸Dept. of Statistics, Stanford Univ., Stanford, CA, ⁹Dept. of BioMed. Data Sci., Stanford Univ., Stanford, CA, ¹⁰Stanford Genome Technology Ctr., Stanford Univ., Stanford, CA

Abstract Body:

Background

Cell type identification is a key step in analyzing single-cell RNA-seq data. Existing methods typically take the cluster-then-annotate approach, wherein clustering is performed across cells using principal components that capture the dimensionality reduction of highly variable genes; and cell clusters are visualized through Uniform Manifold Approximation and Projection (UMAP). Cell type annotation is then performed for each cluster utilizing external marker gene information that represents highly expressed genes for each cell type. Thus, cell type annotation vs. dimensionality reduction are considered as independent problems and solved separately. This separation could potentially lead to poor annotation due to discrepancy between clustering and visualization subspaces.

Methods

We propose a novel method that unifies the problems of cell type annotation and dimensionality reduction/projection using marker enriched UMAP. Conventionally, UMAP constructs a cell-cell similarity graph and projects it to a lower dimensional space. In our approach, we directly incorporate marker gene information into UMAP by constructing and combining the following two graphs through weighting. One graph captures cell-cell similarity based on correlation patterns of marker gene expression, while the other graph encodes proximity of cells based on correlation patterns in the rest of highly variable genes. Cell type assignment is computed based on the UMAP projection using the weighted graph. We evaluate the performance of the proposed versus two existing methods, scType and Garnett, using public data for human colorectal cancer (CRC) and melanoma from NCBI Gene Expression Omnibus.

Results

The melanoma data consisted of 2887 cells from 19 melanoma tumors, curated into 6 cell types. The proposed method achieved high overall annotation accuracy (AC) of 0.90 (95% confidence interval [0.89-0.91]) outperforming both scType (AC 0.82; [0.80-0.83]) and Garnett (AC 0.35; [0.33-0.37]). In the largest group of T cells (2068 cells), the main source of misclassification by scType and Garnett occurred from mis-annotating 400 and 496 cells as 'unknown' due to conflicting clusters obtained independently from the annotation step; this reduced cell-type specific sensitivity to 0.76 and 0.15 (vs. 0.87 of the proposed method). Using the CRC data consisting of 364 malignant cells, the proposed method (AC 0.90; [0.86-0.93]) outperformed both scType (AC 0.59; [0.53-0.64]) and Garnett (AC 0.49; [0.44-0.55]).

Conclusion

We proposed a weighted-graph approach to incorporate marker genes into UMAP and demonstrated the potential for improving cell type annotation.

Omics Technologies Posters - Thursday

PB3138*. Single cell dissection of Alzheimer's disease and related dementias.

Authors:

A. Berg¹, B. James¹, N. Sun¹, K. Galani¹, D. Bennett², L-H. Tsai¹, M. Kellis¹; ¹MIT, Cambridge, MA, ²Rush Alzheimer's Disease Ctr., Chicago, IL

Abstract Body:

Alzheimer's Disease and Related Disorders (ADRD) are debilitating neurodegenerative disorders afflicting 47 million individuals globally. They include Alzheimer's Disease (AD), Frontotemporal Dementia (FTD), Lewy Body Disease (LBD), and Vascular Contributions to Cognitive Impairment and Dementia (VCID), which are highly heterogeneous, frequently co-occur, and share numerous clinical, pathological, and molecular manifestations, raising the question as to whether more etiologically-salient subdivisions exist. Previous attempts at cell-resolution molecular profiling and de novo subtyping were limited by the lack of single-cell, multi-omic datasets encompassing multiple ADRD subtypes. To address this challenge, we generated scRNA-seq and scATAC-seq data for 540,000 cells from the prefrontal cortex of 102 patients with AD, FTD, LBD, VCID, and neurotypical diagnoses. We used these data to derive cell type-specific functional descriptions of ADRD pathologies at the transcriptional, epigenomic, and TF-regulatory levels, including TF-regulon activation scores derived by SCENIC. Of all these levels, TF-regulons were particularly distinct between ADRDs and highly interpretable, revealing multiple shared and distinct GO-enrichments between the diseases. We trained a cell-type-specific logistic regression model for disease classification, showing consistently superior performance than gene expression or epigenomic information alone. We used the model coefficients to weight target genes in further biological enrichment analyses, and to deconvolve and identify shared and distinct cell-level regulatory patterns across the diseases, and as a basis for de novo subtyping across the ADRD spectrum. We also used flow, centrality, and community analyses of our TF-regulatory networks to reveal network-level cell-type-specific and disease-specific regulatory disruption. Lastly, we validated our biological enrichments and de novo ADRD subtypes using transcriptional, epigenomic, and phenotypic data. Overall, our cell-resolution profiling across ADRDs demonstrates a novel, algorithmically-amenable and biologically-informed dimensionality reduction technique for single-cell data analysis in complex traits, and reveals etiologically salient de novo subtypes in ADRD.

Omics Technologies Posters - Thursday

PB3139. Single cell RNA-seq analysis of Bone Marrow-derived Osteoblasts.

Authors:

L. Dillard¹, W. Rosenow¹, G. Calabrese¹, I. mesner¹, B. Al-Barghouthi¹, A. Abood¹, E. Farber¹, S. Onengut-Gumuscu¹, D. Brooks², M. Bouxsein², S. Tommasini³, M. Horowitz³, C. Rosen⁴, C. Farber¹; ¹Univ. of Virginia, Charlottesville, VA, ²Harvard Univ., Cambridge, MA, ³Yale Univ., New Haven, CT, ⁴Univ. of Maine, Orono, ME

Abstract Body:

Skeletal development and maintenance are controlled by numerous cell-types. Historically, genomic studies of bone cells have been challenging due to difficulties in isolating homogenous cell-types from marrow or bone. Recently, this has begun to change with the emergence of single-cell technologies. Here, we profile the transcriptomes of individual cultured bone marrow-derived stromal cells (BMSCs), a popular model of osteoblast differentiation and activity, from five Diversity Outbred (DO) mice using single-cell RNA-seq (scRNA-seq). The goals of the study were to explore technical challenges, evaluate heterogeneity, and determine if BMSCs could serve as a model for the generation of cell-type specific profiles of osteogenic cells derived from hundreds of mice in order to inform genetic studies. We demonstrate that dissociation of BMSCs from a heavily mineralized matrix has little effect on viability or their transcriptomic signature. Furthermore, we show that BMSCs cultured under osteogenic conditions are highly heterogeneous and consist of cells with characteristics of mesenchymal progenitors, pre-adipocytes, osteoblasts, osteocytes, and non-osteogenic immune cells. Importantly, these cells were representative and similar from a transcriptomic perspective to their *in vivo* counterparts. We also demonstrate the ability to multiplex cells and subsequently assign cells to their sample-of-origin using demultiplexing approaches based on genotypes inferred from coding SNPs. Exploring BMSCs from individual mice revealed that cell composition is dependent on characteristics of bone, especially bone marrow adipose content. Finally, we show that genes with higher expression in preadipocytes and osteocytes contribute more of the genetic signal identified by bone mineral density GWAS than the other cell-types profiled. Together, these data suggest that scRNA-seq of BMSCs has the ability to provide insight into the biology of multiple cells in the mesenchymal lineage. It also suggests that BMSCs may be an excellent model for the generation of cell-type specific profiles of homogenous bone cell-types in large mouse and human populations.

Omics Technologies Posters - Wednesday

PB3140. Single neuron whole genome sequencing for somatic CNVs using three different genome amplification methods

Authors:

C. Proukakis^{1,2}, E. Kalef-Ezra^{1,2}, D. Perez-Rodriguez¹, I. Bomann¹, M. Toffoli³, S. Behera⁴, S. Scholz⁵, Z. Zaunmuktane^{1,2}, F. Sedlazeck^{6,2}; ¹Univ. Coll. London, London, England, United Kingdom, ²Aligning Sci. Across Parkinson's (ASAP) Collaborative Res. Network, Chevy Chase, MD, ³Univ. Coll. London, London, United Kingdom, ⁴Baylor Coll. of Med., Houston, TX, ⁵NIH, Bethesda, MD, ⁶Baylor Coll. Med., Houston, TX

Abstract Body:

Somatic mutations occur in healthy and diseased brain. We have detected somatic CNVs of the alpha-synuclein gene (*SNCA*) using FISH in patients with synucleinopathies (Parkinson's disease and multiple system atrophy- MSA). Large CNVs can be detected by low coverage single-cell whole genome sequencing (scWGS) after whole genome amplification (WGA). We have already performed this as proof-of-principle in two MSA brains, with CNVs in ~30% of cells. We have now compared three WGA methods: Picoplex (Takara), a hybrid method, and two modifications of isothermal multiple displacement amplification (MDA): Primary template-directed amplification (PTA, BioSkryb) which uses chain-terminating nucleotides to avoid over-amplification, and droplet MDA (dMDA) in the X-drop device (Samplix) which amplifies genomic fragments in droplets. We amplified 55 single nuclei from the cortex of one MSA and one control brain followed by Illumina scWGS ~1x. The fraction of the genome covered at least once is higher in PTA than Picoplex, and lowest in dMDA. We analysed data using Ginkgo. At 500 kb bins, most cells amplified by Picoplex or PTA were suitable for CNV detection as the median absolute deviation (MAD) was <0.3, but none of the dMDA cells were successful (mean 0.19 for Picoplex, 0.20 for PTA, 0.53 for dMDA). Possible CNVs (gains) were reported in more MSA than control cells: Picoplex- 67% MSA, 17% control; PTA: 86% MSA, 43% control. We performed further analysis using Alfred for cells sequenced together. The error rate in MSA was highest in Picoplex (0.75%) against 0.49% in PTA and 0.37% in dMDA. For PTA, the error rate was lower both in control brain (0.37%) and NA12878 cells (0.34%), and for dMDA this was also lower in control brain (0.29%). The excess errors in MSA may represent DNA damage or somatic SNVs. The fraction of read pairs properly mapped in MSA was 91.4% in Picoplex, 89.4% in dMDA and 84.4% in PTA. Notably this was higher in PTA in control brain (87.8%) and highest in NA12878 cells (89.3%). dMDA also showed a higher fraction in control brain (91.9%). These results suggest that PTA leads to most chimeras. The lower fraction of properly mapped pairs in MSA using both PTA and dMDA could be due to somatic SVs. Nanopore sequencing of 6 MSA cells amplified by dMDA is being analysed. We provide comparative data from 3 WGA methods, with additional analysis of errors and chimeras, and long read sequencing, underway. The possible excess of errors and improperly mapped read pairs in MSA merits further investigation, and correlation with Illumina and Nanopore WGS from bulk tissue will also be performed. Additional scWGS will include a second MSA brain, and cells isolated by laser capture microdissection.

PB3141*. Single-cell allele-specific expression analysis reveals dynamic and cell-type-specific regulatory effects

Authors:

G. Qi¹, B. J. Strober², J. M. Popp¹, H. Ji¹, A. Battle¹; ¹Johns Hopkins Univ., Baltimore, MD, ²Harvard T.H. Chan Sch. of Publ. Hlth., Brookline, MA

Abstract Body:

Background. Allele specific expression (ASE), which quantifies the imbalance in gene expression between two parental alleles, is a powerful tool to study cis-regulatory effects. Such effects across conditions, e.g. experimental interventions, cell types, and developmental trajectories, can reveal differential ASE (D-ASE) indicating gene by context interactions. Recently, single-cell RNA sequencing (scRNA-seq) has allowed the measurement of ASE at the resolution of individual cells. Though statistical methods for identifying D-ASE using scRNA-seq are beginning to emerge, they have not properly addressed the correlation among cells due to repeated measurements per individual, or unknown phase information in the absence of genotype data. **Methods.** We develop DAESC, a statistical method for conducting D-ASE analysis using scRNA-seq data across multiple individuals. DAESC can be used for D-ASE with respect to any condition of interest, including cell-level conditions such as cell types or pseudotime, and sample-level conditions such as disease status. DAESC is comprised of a baseline model of beta-binomial regression with random effects accounting for correlation of cells from the same individual, and an extended mixture model to conduct implicit phasing. **Results.** We demonstrate through simulations that DAESC accurately captures D-ASE effects in a wide range of scenarios. The extended mixture model leads to substantially improved power under weak linkage disequilibrium between the exonic and regulatory SNPs. We use DAESC to analyze the single-cell ASE data from an endoderm differentiation experiment of 125 human induced pluripotent stem cell lines by Cuomo et al, which was designed to identify dynamic genetic effects on gene expression. DAESC identifies 622 genes (FDR<0.05) that show dynamic ASE along the developmental trajectory, and 72% are novel findings not reported by the original paper. Gene-set enrichment analysis shows significant enrichment in pathways related to the development of bone, nervous system, circulatory system, etc. A second application to a pancreatic islet dataset identifies several genes that show cell-type-specific D-ASE between type 2 diabetes patients and controls, indicating potentially dysregulated gene expression associated with the disease. **Conclusions.** We propose a powerful method for differential ASE analysis using scRNA-seq data. The method can be applied to a wide range of scenarios to study context-specific cis-regulatory effects, ultimately illuminating regulatory effects that may underlie processes including cellular differentiation and disease.

Omics Technologies Posters - Wednesday

PB3142. Single-cell dissection of ALS and frontotemporal dementia in the human motor and prefrontal cortices.

Authors:

S. Pineda^{1,2}, H. Lee¹, B. Fitzwalter¹, R. Linville¹, E. Cook³, D. Dickson³, V. Belzil³, M. Kellis^{1,2}, M. Heiman¹; ¹Massachusetts Inst. of Technology, Cambridge, MA, ²Broad Inst. of MIT and Harvard, Cambridge, MA, ³Mayo Clinic, Jacksonville, FL

Abstract Body:

Amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD) are devastating and fatal neurodegenerative diseases that share many clinical, pathological, and genetic signatures. However, the mechanistic basis of their shared and distinct circuitry remains unknown at the molecular level. To uncover cell type-specific transcriptional changes, underlying biological pathways, and putative upstream regulators, we conducted high-resolution single-cell profiling of transcriptional alterations in the primary motor and dorsolateral prefrontal cortices of 75 sporadic and *C9orf72*+ familial ALS and FTLD donor individuals and unaffected controls, providing the most comprehensive-to-date characterization of Brodmann areas 4 and 9, and yielding insights of unprecedented resolution into both ALS and FTLD. Our analysis revealed enhanced cross-region, and cross-phenotypic vulnerability of an extratelencephalic layer Vb population that includes the ALS and FTLD-implicated Betz cells and Von Economo neurons. We identified novel and highly-specific marker genes for these previously ill-defined populations and found that the majority of these are shared across brain regions and may comprise unique vulnerability factors. Analysis of differentially expressed genes (DEGs) showed that several ALS- and FTLD-associated genes were dysregulated across phenotypes and some with regional and cell type specificity. We observed that a number of high-ranking DEGs belonged to the class of TDP-43 binding targets, and that non-canonically disease-associated cells of the same type showed similar disease signatures across both phenotypes and brain regions. We also discovered disease-associated, but regionally-dependent, changes in gene expression and protein localization of several tight junction proteins and their regulators in vascular populations. Shared across cell types, we observed enrichment of pathway terms associated with oxidative stress, protein localization, and ribosomal dysfunction, and within excitatory neurons, an enrichment for terms associated with axonal growth, maintenance, and repair consistent with reports of axonal integrity deterioration. ALS-enriched pathways showed greater specificity for microtubule maintenance- and organization-associated processes, while FTLD dysregulated genes showed generally amplified enrichment for stress response-associated pathways. Overall, our study represents the largest and most accurate molecular atlas of these two human brain regions to date, and the first cell type-specific molecular characterization of ALS and FTLD in either.

Omics Technologies Posters - Thursday

PB3143*. Single-cell genome-wide association reveals a nonsynonymous variant in *ERAP1* confers increased susceptibility to influenza virus.

Authors:

B. Schott¹, L. Wang¹, X. Zhu¹, A. T. Harding¹, E. R. Ko¹, J. S. Bourgeois¹, E. J. Washington¹, T. W. Burke¹, J. Anderson¹, E. Bergstrom², Z. Gardener², S. Paterson², R. G. Brennan¹, C. Chiu², M. T. McClain¹, C. W. Woods¹, S. Gregory¹, N. S. Heaton¹, D. C. Ko¹; ¹Duke Univ., Durham, NC, ²Imperial Coll., London, United Kingdom

Abstract Body:

Diversity in the human genome is one factor that confers resistance and susceptibility to infectious diseases. This is observed most dramatically during pandemics, where individuals exhibit large differences in risk and clinical outcomes against a pathogen infecting large portions of the world's populations. Here, we developed scHi-HOST (single cell High-throughput Human in vitro Susceptibility Testing), a method for rapidly identifying genetic variants that confer resistance and susceptibility to pathogens. scHi-HOST leverages scRNA-seq (single-cell RNA-sequencing) to simultaneously assign genetic identity to individual cells in mixed infections of cell lines of European, African, and Asian origin, reveal associated genetic variants for viral entry and replication, and identify expression quantitative trait loci (eQTLs). Applying scHi-HOST to influenza A virus (IAV), we identified eQTLs at baseline and in genes that are induced by IAV infection. Integration of scHi-HOST with a human IAV challenge study (Prometheus) revealed that a missense variant in *ERAP1* (*Endoplasmic reticulum aminopeptidase 1*; rs27895) was associated with IAV burden in cells and human volunteers. Functional studies using RNA interference, ERAP1 inhibitor, and overexpression of alternative alleles demonstrated that ERAP1 is exploited by IAV to promote infection. Specifically, the nonsynonymous substitution, which results in a glycine to aspartate substitution at ERAP1 residue 348, would disrupt the substrate binding pocket of ERAP1, likely resulting in a significantly altered preference for substrates, poorer catalytic efficiency, or both. Finally, rs27895 exhibits substantial population differentiation, with the higher frequency of the minor T allele in two African populations likely contributing to the greater permissivity of cells from these populations to IAV infection. scHi-HOST is an important resource for understanding susceptibility to influenza and is a broadly applicable method for decoding human genetics of infectious disease.

PB3144. Single-cell multi-omics reveals gene regulation dynamics during mouse secondary palate development

Authors:

F. Yan¹, A. Suzuki^{2,3}, C. Iwaya^{2,3}, H. Yoshioka^{2,3}, G. Pei¹, X. Chen¹, M. Yu¹, L. Simon⁴, J. Iwata^{2,3}, Z. Zhao^{1,5}; ¹Ctr. for Precision Hlth., Sch. of BioMed. Informatics, The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, ²Dept. of Diagnostic and BioMed. Sci., Sch. of Dentistry, The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, ³Ctr. for Craniofacial Res., The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, ⁴Therapeutic Innovation Ctr., Baylor Coll. of Med., Houston, TX, ⁵Human Genetics Ctr., Sch. of Publ. Hlth., The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX

Abstract Body:

Background: Palatogenesis is a complex, dynamic, and highly orchestrated process, which relies on tight regulation of gene expression. Its disruption leads to cleft palate, the second common birth defect. **Methods:** To simultaneously resolve both gene expression and regulation dynamics and delineate palate development at the cellular level, we profiled single-cell transcriptomics and epigenomics from the same cells (n = 36,154) isolated from mouse palatal shelves at embryonic day (E) 12.5, E13.5, E14.0, and E14.5 using the 10x Chromium Single Cell Multiome platform. **Results:** Unsupervised dimension reduction and clustering analysis revealed eight major cell types defined by established marker genes, including cranial neural crest (CNC)-derived mesenchymal (*Prrx1*), epithelial (*Epcam*), endothelial (*Cldn5*), myeloid (*Lyz2*), glial (*Sox10*), neuronal (*Tubb3*), myogenic progenitors (*Myod1*), and myocytes (*Myf5*). Multiome on the same tissue allows reliable inference of critical transcription factors (TFs) by setting criteria on both modalities. Using a correlation-based approach, we identified 3,076 significant positively correlated peak-gene linkages (coefficient > 0, *adjusted p-value* < 0.05). Coupling differential gene expression analysis and motif enrichment analysis of these peaks, we pinpointed a list of TFs whose expression was enriched in the RNA measurements for a specific cell type, and whose motif accessibility was enriched in the ATAC measurements. For example, both the expression of *Foxo1* (*RNA.p-value* < 2.22×10^{-16}) and accessibility of Foxo1 binding motif MA0480.1 (*motif.p-value* = 4.91×10^{-18}) were enriched in endothelial cells. We then focused on CNC-derived mesenchymal cells. Integration of RNA velocity and pseudotime analysis revealed five trajectories, showing continuous differentiation of progenitors into different subtypes, including anterior and posterior palatal mesenchymal cells, dental mesenchymal cells, osteoblasts, and perimysial cells. The application of additional modeling showed high initial state probabilities in progenitor cells and terminal state probabilities in these subtypes, which validated inferred trajectories. We characterized a list of lineage-determining TFs that exhibited continuous progression along each trajectory, which was active at the early, middle, and late-stage of the trajectory, respectively. **Conclusion:** Collectively, our study uncovered gene-regulatory dynamics and built an atlas of gene expression and regulation of the developing mouse secondary palate. This multi-omic resource will serve as a comprehensive reference map and facilitate research on cleft palate.

Omics Technologies Posters - Thursday

PB3145. Single-cell RNA sequencing (scRNA-seq) of fresh, neuronal tissue using Pre-templated Instant Partitions (PIPseq) and comparison to alternative scRNAseq methods

Authors:

K. Kugler¹, A. May-Zhang¹, P. Frazel², S. Liddelow²; ¹Fluent BioSci., Watertown, MA, ²NYU, New York, NY

Abstract Body:

In neuroscience, scRNAseq has greatly improved our ability to identify, distinguish, and discover novel and rare cell types. However, even the largest individual scRNA-seq datasets only represent about 1% of the over 100 million cells in the adult mouse brain. PIPseq is a novel single-cell sequencing technology that makes scRNAseq accessible and affordable to all researchers and facilitates characterization and interrogation of larger and more numerous neuronal datasets. PIPseq has sample preparation improvements over other commercial systems by allowing samples to be “instantly partitioned” into single cell reaction vesicles without the use of microfluidics. PIPseq also has the advantage of convenient stable stopping points where sample collection can occur at one site and downstream processing can occur in a core lab or at Fluent BioSciences using our service model. Here, we compare the biological results and assess the performance of PIPseq versus 10x single cell RNAseq on neuronal tissue. We performed scRNAseq using both platforms using the same tissue sample (freshly dissected and dissociated postnatal day (P)30 mouse forebrain). PIPseq and 10x generated sequencing data was able to resolve all expected neuronal cell types. The proportion and variety of the common cell type markers derived from each scRNAseq method was comparable, with no drop-outs or biases observed. The differentially expressed genes from each technique were highly concordant and replicated what is commonly described in the literature and outlined in the Linnarsson Brain Atlas. These data highlight that PIPseq is a viable, reliable, and powerful method that can be used to perform scRNAseq analysis on fresh neuronal tissue in a single, simple reaction. Benefits to our simplified workflow include long shelf-life of capture cells (in PIPs), low cost, rapid generation of single cell suspensions, and scalability - with future capacity for sequencing millions of cells in a single sample.

Omics Technologies Posters - Wednesday

PB3146. Single-molecule, modified base sequencing to identify frequency and cause of rAAV vector breakpoints.

Authors:

J. Thompson¹, D. Selby¹, L. Soares¹, T. Hanscom¹, D. Browne², J. Walsh², M. Weiland², J. Korlach², D. Przybylski¹, J. Wright¹; ¹Homology Med.s, Bedford, MA, ²Pacific BioSci.s, Menlo Park, CA

Abstract Body:

There are approved gene therapies using recombinant adeno-associated virus (rAAV) as the vector for delivery of therapeutic genes, and the quality of the material is critical for safe and efficacious use. All AAV serotypes contain single-stranded DNA within each capsid that raises analytical challenges. Complementary genomic strands hybridize when capsids are lysed and standard sequencing library methods cause information from the individual genomes to be lost when inter-strand mismatches and gaps are repaired. This is especially important when gaps are repaired because that results in incomplete knowledge of whether genomes are partial or full-length. The presence of empty or partially full capsids is one factor that affects rAAV quality. We developed a novel NGS library preparation method that allows us to identify and quantitate gaps by distinguishing pre-existing DNA from DNA added during NGS library preparation. During the repair process common to NGS library methods, the standard nucleotides dCTP and dATP are replaced with the modified nucleotides 4Me-dCTP and 6Me-dATP so that any new DNA includes stretches of modified bases while the pre-existing ssDNA consists of natural, unmodified bases. Using the Sequel II system, the modified bases can be distinguished from unmodified bases, enabling breakpoint identification at high resolution. This method was used on a vector known to break during packaging, a phenomenon that can occur in AAV vectors of all serotypes. The exact location and frequencies of breaks allowed us to alter nearby sequences and reduce the frequency of breakage. The resultant new designs provide a higher quality AAV vector that is less susceptible to partial genomes. Partially filled capsids have been an ongoing regulatory agency concern and this approach provides information that standard methods do not. This use of modified bases for localizing DNA breaks enables improved vector designs and provides better characterization metrics for AAV vectors, resulting in higher quality gene therapy vectors. The same approach can be used in other systems where knowledge of pre-existing sequence and structure is important and may be lost when DNA is repaired.

Omics Technologies Posters - Thursday

PB3147. Single-nucleus profiling of the cerebellar cortex in essential tremor reveals Bergmann gliosis and oligodendrocyte myelin abnormalities as hallmarks of disease

Authors:

C-E. Castonguay¹, T. Bécrot¹, M. Medeiros¹, C. Liao¹, A. Rajput², P. Dion¹, G. Rouleau³; ¹McGill Univ., Montreal, QC, Canada, ²Univ. of Saskatchewan, Saskatoon, SK, Canada, ³Montreal Neurological Inst.-Hosp., Montreal, QC, Canada

Abstract Body:

Essential tremor (ET) is one of the most common movement disorder, affecting nearly 1% of the worldwide population. It presents itself as kinetic tremor affecting mostly the upper limbs but also other body parts such as the lower limbs and head. The disease has a significant impact on the daily lives of patients and can severely affect their autonomy. Previous genetic, transcriptomic, and histopathological studies of ET have highlighted the important contribution of the cerebellar cortex in the development of the disease. However, the molecular and cellular correlates of the disease within the cerebellar cortex are poorly understood. We sought to assess disease-related gene expression changes in all cell types of the cerebellar cortex using single-nucleus RNA sequencing of 16 ET and 16 control cerebellar samples in order to better understand the pathophysiological mechanisms underlying ET. Split-pool ligation-based transcriptome sequencing (SPLiT-seq) was used to obtain single-nucleus reads from frozen cerebellar samples. Cells were then clustered using Seurat and pseudo-bulk differential expression analysis for each cell type was done using DESeq2. We found that Bergmann glia, but not fibrous astrocytes, demonstrated differential expression of multiple genes related to astrogliosis (i.e., *ID4*, *NPL*, *SIPRI*). Pathway enrichment analysis identified terms related to glial cell differentiation (qval = 6.03E-04), astrocyte projection (qval = 5.24E-04) and the postsynaptic cell compartment (qval = 3.13E-04). In addition, differentially expressed genes in oligodendrocytes were enriched for structural constituents of myelin sheath (qval = 7.85E-03), concordant with previous associations between ET and axonal pathology. Consistent with these findings, deconvolution of bulk-RNA seq data from these 32 cerebellar cortex samples using Bisque demonstrated an increased proportion of Bergmann glia in ET samples (Z-score = 3.47, qval = 6.73E-03) as well as a significant decrease in the proportion of oligodendrocytes (Z-score = -3.05, qval = 2.93E-02). In support of previous histopathological observations, we found no difference in the proportions of Purkinje cells between cases and controls. Our study highlights potential cellular mechanisms implicating non-neuronal cells in ET, paving the way for more in-depth functional studies.

Omics Technologies Posters - Wednesday

PB3148. Single-stranded library preparation for cfDNA identifies unique fragment length signature in myelodysplastic syndrome with multi-lineage dysplasia and ring sideroblasts

Authors:

C. Schwartz¹, C. Naughton¹, J. Morgan¹, C. Troll¹, A. Ali², A. Raza², V. Rao¹, K. Harkins Kincaid¹, R. E. Green^{1,3}, C. Vaske¹; ¹Claret BioSci., Santa Cruz, CA, ²Columbia Univ. Med. Ctr., New York, NY, ³Univ. of California, Santa Cruz, Santa Cruz, CA

Abstract Body:

Fragmentomic analysis of cfDNA fragment lengths has been shown to reveal the epigenetic state of the source cells. Here we describe a novel signal based on cfDNA fragment lengths that likely reveals a novel epigenetic state in a subtype of myelodysplastic syndrome (MDS). The finding is made possible by using a single-stranded DNA sequencing preparation (*SRSLY*) that omits DNA end repair to preserve the true fragment length. We sequenced *SRSLY* libraries prepared from 1-5ng of cfDNA from healthy donors and MDS cases. We calculated the ratio of short to long cfDNA fragments across the genome, a feature that correlates with 3D nuclear compartment data derived from Hi-C experiments. A/B nuclear compartments are cell-specific and associated with open/closed chromatin, respectively. Deviations from expected open/closed chromatin states would reflect changes in the epigenomic landscape. Most MDS and normal samples show fragment length ratios concordant with the nuclear compartments from lymphoblastoid cell line GM12878. However, 75% (9/12) of the samples of subtype RS-MLD (multiple lineage dysplasia with ring sideroblasts) show consistent atypical fragment length ratios, with regions in the closed or B compartment showing a pattern resembling that of the open compartment. This signal is observable with as few as 5 million sequencing reads. We interpret this signal as an unexpected “opening” of chromatin in those genomic regions, which appear to be enriched in the B3 subcompartment. RS-MLD cfDNA also shows an atypical fragment length pattern within the open A compartment. The regions causing this deviation are enriched in the A2 subcompartment. In sum, the observed signals of genome reorganization suggest a different etiology for RS-MLD, possibly during maturation of erythrocytes, and could be a biomarker for erythrocytic disorders and treatment decisions.

Omics Technologies Posters - Thursday

PB3149*. SnapFISH: a computational pipeline to identify chromatin loops from DNA FISH data

Authors:

L. Lee¹, M. Hu¹, Y. Li²; ¹Cleveland Clinic, Cleveland, OH, ²Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract Body:

Super-resolution imaging technologies, such as chromatin tracing, DNA MERFISH, DNA seqFISH+, ORCA and OligoFISSEQ, provide powerful tools to measure chromatin spatial resolution at single cell resolution, enabling direct visualization of looping events between gene promoters and their cis-regulatory elements. However, computational methods to detect chromatin loops at high resolution from super-resolution imaging data are still lacking. Here, we describe Single-Nucleus Analysis Pipeline for DNA FISH data (SnapFISH), the first method that can identify chromatin loops from super-resolution imaging data. We first applied SnapFISH to 5Kb resolution chromatin tracing data at the 210Kb region in chromosome 3 containing the *Sox2* gene in mouse embryonic stem cells (mESCs), and found that SnapFISH can identify the loop between *Sox2* promoter and its confirmed super-enhancer ~100Kb downstream with as few as 75 cells. We further applied SnapFISH to 25Kb resolution DNA seqFISH+ data in all 19 autosomes in mESCs. SnapFISH demonstrated high sensitivity and accuracy in detecting chromatin loops, evaluated against chromatin loops detected by HiCCUPS from deeply sequenced bulk Hi-C data from mESCs. Finally, we re-analyzed the 25Kb resolution DNA seqFISH+ data collected from mouse brain cortex tissues, and detected cell-type-specific loops which are closely associated with cell-type-specific epigenetic marks and cell-type-specific gene expression. In sum, SnapFISH is the first computational method to identify chromatin loops from super-resolution imaging data, and has the potential to facilitate better characterization of cell-type-specific chromatin spatial organization, and improve our understanding of cell-type-specific gene regulation mechanisms.

Omics Technologies Posters - Thursday

PB3150*. Somatic genomic alterations in single neurons from brains with chronic traumatic encephalopathy (CTE)

Authors:

C. Ma^{1,2}, G. Dong^{1,2}, M. B. Miller^{1,2,3}, A. Y. Huang^{1,2,3}, A. C. McKee^{4,5}, E. A. Lee^{1,2,3}, C. A. Walsh^{1,2,3,6}; ¹Harvard Med. Sch., Boston, MA, ²Boston Children's Hosp., Boston, MA, ³Broad Inst. of MIT and Harvard, Cambridge, MA, ⁴Boston Univ. Sch. of Med., Boston, MA, ⁵VA Boston Hlth.care System, Boston, MA, ⁶Howard Hughes Med. Inst., Boston, MA

Abstract Body:

Chronic traumatic encephalopathy (CTE) is a neurodegenerative disease associated with repetitive head trauma. The genetic, molecular, and cellular mechanisms behind the development of CTE are less well understood than in other neurodegenerative diseases such as Alzheimer's disease (AD). The advent of single-cell sequencing technologies allows for the study of molecular perturbations at the individual cell or cell-population level as well as the analysis of contributions of non-germline somatic mutations to disease pathogenesis. Previous studies of single-cell whole genome sequencing (scWGS) on aging and neurodegenerative brains showed that somatic single-nucleotide variants (sSNVs) increase both with aging and in disease, but present with distinct patterns of mutational signatures, suggesting that genetic, environmental, or disease states might influence this accumulation.

In this study, we applied scWGS to neurons from the prefrontal cortex of CTE brains. Using PTA (Primary Template-directed Amplification), with LiRA (Linked-Read Analysis) and SCAN-SNV (Single Cell ANalysis of SNVs) bioinformatic pipelines to distinguish sSNVs from amplification artifacts, we compared the rates of sSNV accumulation in CTE and control brains. We found a significant increase of hundreds of sSNVs in CTE as compared with age-matched controls. Additionally, we identified specific mutational signatures more abundant in CTE than in controls, distinct from the composition of mutational signatures in AD, which gave us insight into potential causative agents of CTE. Since CTE is hypothesized to be caused by exposure to repetitive head trauma, its areas of pathological overlap with other neurodegenerative diseases, such as AD, make CTE a unique model for studying the effects of molecular pathways in neurodegeneration.

Omics Technologies Posters - Wednesday

PB3151. sparQ mRNA-Seq: Consistent and high-quality mRNA library preparation from both abundant and limiting samples.

Authors:

K. Conley, M. Aitichou, R. Heller, D. Schuster; Quantabio, Frederick, MD

Abstract Body:

Next-generation sequencing (NGS) of strand-specific RNA libraries has become established as one of the most comprehensive and informative methods for transcriptome profiling for molecular analysis of disease states and biological traits, allowing for the identification of both known and novel RNA structural features and isoforms and for the accurate quantification of transcripts from both orientations. Removal of uninformative highly abundant RNAs is a critical step in achieving a focused library containing biologically relevant sequences for insights and actionable results. Ribosomal RNA depletion methods are useful for preparing libraries that contain both exonic and biologically relevant non-coding RNAs sequences and can overcome 3'-bias in degraded RNA preparations. However, these methods are often costly, time consuming, and limited by species-specific homology constraints. mRNA-seq, which exploits selection of polyadenylated RNA in addition to utilizing directional library preparation, also eliminates highly abundant and uninformative RNA sequences, and is applicable to poly(A)+ RNA from any species. However, this method is typically limited to samples capable of providing relatively large quantities of total RNA. Focused sequence analysis of less abundant mRNA quantities requires both an efficient mRNA enrichment module as well as highly optimized enzymatic reactions.

Here we present the sparQ mRNA-Seq kit that enables efficient preparation of stranded mRNA-seq libraries for Illumina NGS systems in less than 4.5 h. This workflow reduces hands-on time and delivers reliable mRNA-seq libraries from as little as 5 ng to 1 µg of total RNA with high quality reads from reference total RNA. Evaluation of library yields, mapped reads, transcript coverage uniformity, and (individual/total) gene count qualified sparQ mRNA-Seq as the most sensitive of mRNA-seq workflows compared to other leading mRNA-Seq kits. We demonstrate application of this technology to include the study of samples with limiting amounts of RNA by combining efficient isolation of mRNA with a streamlined workflow for preparing mRNA-seq libraries that delivers consistent exonic read coverage across varying RNA input amounts and reduced bias in GC-rich transcripts.

Omics Technologies Posters - Thursday

PB3152. STOC: A Simple Tool Of Compression

Authors:

R. Klein; Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Modern genomic technologies are producing an avalanche of data that needs to be stored and analyzed. Efficient use of these data requires balancing the need to compress them to save on storage costs while maintaining them in a format that can easily be read as-is and randomly accessed for analyses without the need for storing the uncompressed data. The underlying data used by downstream genomics analysis tools typically is represented as a text file. Many programs that work with genetic variation data can read the files when they are compressed with the standard gzip compression program. However, gzip-compressed files do not support random access; the file must be uncompressed in-memory and scanned to identify regions of interest. To get around this limitation, various bespoke compression approaches are used, though these approaches require specialized software. Simultaneous with the growth of genomics data, numerous technologies have been developed to work with large data sets in a scalable fashion. Many of these technologies focus on data parallelism, where the same operation is performed simultaneously on each record of the data. These technologies work optimally when separate processes can work on separate parts of the compressed file at the same time, which is not possible out of the box with standard genomics file formats. Here, I propose a Simple Tool for Compression (STOC), designed to be use as part of a larger genomics data lake. The concept of this file format is simple: the first N columns of a file are stored uncompressed, as these are used for searching purposes. The remaining columns are then compressed into a single string, represented as base64 text. This then allows the data to be manipulated using standard genomics or data analytic programs, before the underlying data is uncompressed for the final computations. As STOC is especially useful in working with imputed genotype data with low minor allele frequencies, as can be found from TopMed imputation, I designed it to automatically extract and recompress the results from the TopMed imputation server. The resulting files are VCF-compliant and variant-level filtering can be performed with standard VCF-aware software. To illustrate its utility, I ran it on TopMed imputation results for a set of 3972 men. While the original bgzip-compressed TopMed data took 152GB of disk space, using STOC and bzip2 compression took slightly less space (142GB). This approach may be especially useful for datasets that will be repeatedly analyzed over subsets of the genome.

Omics Technologies Posters - Wednesday

PB3153. STRT-N: A newly optimised single-cell RNA sequencing method.

Authors:

N. Boskovic^{1,2}, G. Yazgeldi³, S. Ezer^{3,4}, S. Katayama^{1,3,4}, M. H. Tervaniemi^{3,4}, T. Skoog¹, K. Krjutskov^{5,6}, J. Kere^{1,3}; ¹Dept. of BioSci.s and Nutrition, Karolinska Inst.t, Stockholm, Sweden, ²Dept. of Obstetrics and Gynecology, Univ. of Helsinki, Helsinki, Finland, ³Folkhälsan Res. Ctr., Helsinki, Finland, ⁴Stem Cells and Metabolism Res. Program, Univ. of Helsinki, Helsinki, Finland, ⁵Competence Ctr. of Hlth.Technologies, Tartu, Estonia, ⁶Dept. of Obstetrics and Gynecology, Inst. of Clinical Med., Univ. of Tartu, Tartu, Estonia

Abstract Body:

Background:Single-cell RNA sequencing (scRNA-seq) has revolutionised the field of transcriptomics since its introduction. The protocols for scRNA-seq have progressed from one cell to the possibility of sequencing thousands of cells. However, the early methods that could use only a very limited number of samples have become obsolete with the progress of the scRNA-seq methods, creating a new need for a method that can be used for a small number of samples. Therefore, we have looked back in earlier protocols and optimised one for use with the current sequencing platforms. **Methods:** Single-cell Tagged Reverse Transcription (STRT) was previously adjusted to work on bulk RNA, globin rich tissue samples, and new sequencing technologies, but had become suboptimal for scRNA-seq. For optimisation, we tested 10 different template switching oligos (TSO), 3 different reverse transcriptase enzymes, 3 enzymes for cDNA synthesis, and additional clean-up steps. **Results:** We found that the sensitivity of the method is greatly dependent on the reverse transcriptase enzyme as well as the cDNA amplification enzyme when working with very small RNA input (10 pg). Additional clean-up step before cDNA amplification was needed to prevent by-products (primer dimers, excess TSO, and oligo dT primer) overtaking the reaction. **Conclusion:**The newly optimised STRT-N RNA-seq method is highly sensitive and can detect as low as 10 pg of RNA input. The sequencing library consists of 48 barcoded cDNA samples and is highly useful for studies with limited availability of samples such as mammalian embryos.

PB3154. Structural and copy number variant detection, filtering, annotation, and classification by optical genome mapping in constitutional disorders.

Authors:

B. Clifford, J. Hauenstein, H. Barseghyan, A. Pang, A. Chaubey, A. Hastie; Bionano Genomics, San Diego, CA

Abstract Body:

In contrast to methods like karyotyping, chromosomal microarray (CMA), fluorescence in situ hybridization (FISH) or sequencing, optical genome mapping (OGM) is sufficiently versatile to identify all classes of structural variants from large-scale fusions to intragenic deletions in an easy to master technical and analytical workflow. OGM can comprehensively identify structural variants (SVs), copy number variants (CNVs), aneuploidies, absence of heterozygosity (AOH), and triploidy with high sensitivity and specificity. Here, we demonstrate a comprehensive and lab-ready workflow for whole genome OGM data analysis, alignment, and annotation using GRCh38, variant evaluation, and classification.

For constitutional disorders, OGM data is collected and analyzed by Bionano Access software. Maps are assembled based on direct fluorescent labeling of a six base pair sequence motif, with sample data aligned to GRCh38 to resolve variants and annotate against a common reference. SVs are further queried for overlap against a database of assay matched phenotypically healthy controls. To generate a prioritized list, we apply a workflow to filter based on size (≥ 1.5 kbp), near-absence in controls database ($\leq 1\%$ presence) and overlap with a gene. The resulting curated variant list presents an average of ~20-30 variants for further classification.

Each variant is assessed in a genome browser, showing properties such as size and putative impact to genes in a variant classifier visualization. Multiple analysts may work together to independently classify the variants. Lastly, a supervisor can reconcile analyst records to adjudicate classifications, record any large-scale genomic irregularities, and download a complete research report. Support for OGM data analysis is currently being developed for NxClinical variant classification software to enable automated ACMG scoring, additional databases and knowledgebases and ability to overlay NGS and CMA data. OGM data is well suited to identify a breadth of variants relevant to constitutional disorder research. The analytical approach annotates thousands of genome-wide variants accurately, and the filtering workflow discussed here directs focus to the most promising dozens. The subsequent classification and reporting tools provide utility for communicating their significance.

PB3155. Structuring information via an immune-focused ontology enables the construction of a high-quality knowledge graph for the study of autoimmune diseases

Authors:

V. Q. Truong^{1,2,3,4,5}, J. D. Romano^{1,3}, A. R. Greenplate^{1,4,5,6}, S. M. Dudek^{1,3,7}, E. Wherry^{1,5,4,6}, M. D. Ritchie^{1,3,7,8}, ¹Univ. of Pennsylvania, Philadelphia, PA, ²Genomics & Computational Biology PhD Program, Philadelphia, PA, ³Inst. for BioMed. Informatics, Philadelphia, PA, ⁴Immune Hlth.Project, Philadelphia, PA, ⁵Inst. for Immunology, Philadelphia, PA, ⁶Dept. of Pharmacology & Translational Therapeutics, Philadelphia, PA, ⁷BioMed. and Translational Informatics Lab., Philadelphia, PA, ⁸Dept. of Genetics, Philadelphia, PA

Abstract Body:

Autoimmune diseases are a highly heterogeneous family of diseases which occur due to immune dysfunction causing systemic attacks against the body's own tissues. Approximately 4.5% of people worldwide are impacted by at least one autoimmune disorder, but global incidence of autoimmune disease is rising while our comprehensive understanding remains static. Recent discoveries of linked genes provide a clue for commonalities in co-occurring disorders, but tremendous work remains to uncover new links between disorders with suspected likelihoods. The study of autoimmunity is further complicated by the complexity of the immune system as a hierarchical network of interacting biomolecular components spanning multiple levels of biology (genes, proteins, pathways, immune cells, and more). The disorganization and separation of immunological knowledge across disparate repositories is a major hurdle preventing the discovery of possible biomarkers and disease mechanisms. Thus, biomedical informatics is well-suited to unify heterogeneous data into a queryable information network known as a knowledge graph (KG) where entities are stored as nodes, while edges represent the relationships connecting them. KGs offer a powerful and efficient solution for connecting heterogeneous knowledge, but recent biomedical implementations were constructed in a non-standardized process, contained outdated information, lacked structure, and/or did not capture autoimmunity well. These challenges led us to i) integrate and structure immune-related information into a queryable knowledge graph, and ii) validate an ontology-based model which turns implicit understanding into explicit reasoning. First, we identified several sources of curated immunological and biological knowledge from ImmunoGlobe, Hetionet, Pathway Commons, DisGeNet, and more. Next, we developed a specialized ontology to define the semantic meaning of entities (nodes) and relationships (edges) in our KG. Finally, we integrated information about genes, proteins, pathways, cell types, and diseases into a KG containing 8 node types, 14 relationship types, and more than 1000 immune-specific interactions. The KG quality was assessed according to established metrics: accuracy, trustworthiness, timeliness, availability, completeness, and consistency. Coupled together, our immune-focused ontology and knowledge graph enables the discovery of links between nodes, which represent pre-existing, unfilled, or new knowledge. Our work provides a path forward to explore data beyond single data-types and embrace a meta-dimensional framework for modeling strategies and applications in autoimmunity.

Omics Technologies Posters - Thursday

PB3156. SVPred: An integrated framework for Structural Variant Discovery

Authors:

V. Sarwal¹, S. Sankararaman¹, E. Eskin¹, S. Mangul²; ¹UCLA, Los Angeles, CA, ²Univ. of Southern California, LOS ANGELES, CA

Abstract Body:

SVPred: An integrated framework for structural variant discovery

Background: Structural variation (SV), refers to insertions, deletions, inversions, and duplications in human genomes. SV's plays a fundamental role in genome evolution and can underlie inherited or acquired diseases such as cancer. Comprehensive discovery of SV's from whole-genome sequencing data uses several approaches including read-pair, split-read, and read-depth. With advances in whole genome sequencing (WGS) technologies, a plethora of SV detection methods has been developed. However, dissecting SVs from WGS data presents a substantial number of challenges, with the majority of SV detection methods suffering from a high false-positive rate, and no existing method able to detect a full range of SV's present in a sample accurately.

Results: Here, we report an integrated structural variant calling framework, SVPred that combines the outputs of individual callers using a newly devised filtering and merging algorithm. Previous studies have shown the performance of SV callers to be significantly affected by the variant length. SVPred utilizes this difference by dividing the outputs of individual callers into bins based on the variant length, and combining the best-performing tools per bin. SVPred executes various combinations of Pindel, MistrVar, indelMINER, Manta, GRIDSS, BreakDancer, LUMPY, DELLY, CREST, RDXplorer, PopDel, GASV, and GenomeSTRiP to generate SV events. We evaluated the performance of SVPred on data with varying organisms and coverage. We ran SVPred on the public benchmark data for the Ashkenazi Jewish Trio son (NA24385/HG002) from the Genome-in-a-Bottle (GIAB) consortium, along with 7 strains of the mouse genome. SVPred has the highest F1 score measured across both mouse and human genomes. In addition, many of the variants predicted by SVPred were highly consistent with the experimentally validated truth set.

Conclusions: We present SVPred, a novel variant calling integrated framework to obtain a genome-wide landscape of SV's in a highly accurate manner. Using both mouse and human WGS data analysis, we show that SVPred provides an accurate SV calling framework and can serve as the gold standard for SV calling for the research community.

Omics Technologies Posters - Wednesday

PB3157. Systematic evaluation of transcriptome sequencing applied to real-world rare disease cohorts: Insights and limitations

Authors:

S. Silverstein^{1,2,3,4}, J. Fu¹, S. Donkervoort², P. Uapinyoying^{2,5}, B. N. Pusey¹, K. R. Ganapathy⁴, S. Gorokhova^{6,7,2}, T. Cassini⁸, T. DeLong², V. Ganesh⁹, B. Weisburd⁹, A. R. Foley², C. J. Tifft^{1,10}, M. Malicdan¹, Undiagnosed Diseases Network, W. Gahl¹, C. G. Bonnemann², P. Mohammadi⁴, D. R. Adams^{1,10}; ¹Undiagnosed Diseases Program, NIH, Bethesda, MD, ²Neuromuscular and Neurogenetic Disorders of Childhood Section, NINDS, Bethesda, MD, ³Rutgers New Jersey Med. Sch., Newark, NJ, ⁴Dept. of Integrative Structural and Computational Biology, The Scripps Res. Inst., La Jolla, CA, ⁵Ctr. for Genetic Med. Res., Children's Res. Inst., Children's Natl. Hosp., Washington, DC, ⁶Aix Marseille Univ, INSERM, MMG, U 1251, Marseille, France, ⁷Dept. of Med. Genetics, Timone Children's Hosp., APHM, Marseille, France, ⁸Med. Genetics & Genomic Med. Training Program, Natl. Human Genome Res. Inst., NIH, Bethesda, MD, ⁹The Broad Inst. of MIT and Harvard, Cambridge, MA, ¹⁰Office of the Clinical Director, NHGRI, NIH, Bethesda, MD

Abstract Body:

Rare diseases are estimated to affect 1 in 10 individuals. For those evaluated with exome and genome sequencing, typical diagnosis rates average 30%; incorporating transcriptomic sequencing additionally improves molecular diagnosis by 8-36% of previously undiagnosed cases. RNA studies can be used to augment genome analysis by detecting single allele transcription, interpreting potential splice modifiers leading to aberrant splicing, and identifying outlier transcription levels. Published computational tools are available to systematically evaluate these events. The DROP Pipeline, as an example, incorporates three component tools: OUTRIDER (expression outliers), FRASER (splicing outliers) and MAE (allelic imbalance).

We used DROP to analyze RNASeq data from 140 rare disease patients in two cohorts, including the NIH Undiagnosed Diseases Program (74 fibroblast samples, 75% undiagnosed) and the NINDS Neuromuscular and Neurogenetic Diseases of Childhood section (66 muscle samples, 57% undiagnosed). Each cohort contained known true positive genetic diagnoses that were shown to impair gene expression, and therefore could be detectable by the DROP analyses. We ran all DROP modules with both default and alternative parameters to assess the sensitivity and to detect new aberrant events for unsolved cases. We followed up the identified outlier genes for the undiagnosed cases by manual inspection of sequencing reads in IGV.

We found that the DROP pipeline correctly identified 3/27 (11%) known molecular diagnoses in the muscle cohort and 2/11 (18%) in the fibroblast cohort. This corresponds to an overall performance of 13% (95% CI 4.4%-28.1%), which is lower than previously reported values. Out of all candidate outliers, OUTRIDER produced one new diagnosis of *NBAS* deficiency for a patient with an atypical clinical phenotype in the fibroblast cohort. We present a detailed analysis of the results of each module, followed by a discussion of benefits and limitations of this approach.

Our analysis provides insight into optimizing the design of systematic approaches and strategies for rare disease genomics diagnostic pipelines and sets expectations of diagnostic benefit in "genome negative" cohorts. We recommend development of standardized protocols for sample and data collection when applying transcriptome analysis to clinical questions arising from individual patients.

Omics Technologies Posters - Thursday

PB3158*. Tagmented, Indexed, and Pooled followed by ChIP Sequencing (TIP-ChIP) to generate high-throughput multi-target ChIP-Seq Results

Authors:

J. Cayford, S. Traynor, **S. Ngoc Tran**, J. Poole; Active Motif, Carlsbad, CA

Abstract Body:

Epigenomic profiling approaches have become standard practice in understanding the molecular basis underlying clinically relevant disease states. The adoption of epigenetic analysis in translational medicine has been slow due to a complex workflow. Specific barriers include limited tissue availability, the laborious nature of chromatin generation, and the amount of cellular material needed for a single chromatin immunoprecipitation (ChIP) reaction. These issues are further compounded by the fact that single-plex reactions provide insufficient information to fully understand the epigenetic landscape of disease states. To address these issues, we have built upon previous concepts such as it-ChIP, mint-ChIP, ATAC-Seq, and many others which have improved the workflow and allowed for methods of probing the epigenetic landscape in cells. Here we introduce Tagmented, Indexed, and Pooled ChIP-Seq (TIP-ChIP). TIP-ChIP was developed to rapidly complete ChIP-Seq on 96 samples for multiple epigenetic and transcription factor marks. To maintain the current gold standards in the field, formaldehyde-fixed cells are tagmented with Tn5 to incorporate unique barcodes into each sample. After tagmentation and chromatin solubilization with a brief sonication, the samples are pooled and prepped for a standard ChIP-Seq reaction. The power of the technique lies in the ability to remove a fraction of the pooled sample and complete a single IP reaction with a small number of cell equivalents of all 96 starting samples which allow for numerous epigenetic marks to be in a multiplexed fashion. If four epigenetic targets were to be selected, it would be possible to complete the equivalent of 384 ChIP-Seq experiments over a three-day period, drastically improving the ability to test large cohorts of samples.

As clinical and translational research moves to incorporate epigenomics in the pursuit of personalized medicine, the innovation of rapid generation of ChIP-Seq data with fixed samples will enable many more samples to be tested in a rapid manner. Combined with a quicker workflow, higher throughput, and cheaper sequencing allows for this technique to be utilized by a wider audience than previously possible.

Omics Technologies Posters - Wednesday

PB3159. Targeted sequencing of a 1 Mb carrier screening panel using molecular inversion probes.

Authors:

J. Amaral, P. Saunders, A. Patel, J. Vieira, G. Porreca, E. Boyden; Molecular Loop BioSci.s, Inc, Woburn, MA

Abstract Body:

Common methods of target capture for next generation sequencing (NGS) include hybridization capture, which suffers from a complicated and labor-intensive workflow, and PCR capture, which is typically less onerous but prone to poor uniformity and allele dropout. We have developed and optimized an alternative method based on molecular inversion probes (MIPs) that combines robust data quality, enabled by dense bi-stranded MIP tiling that ensures high coverage uniformity and resistance to allele dropout, with a highly scalable and easily automatable protocol that may be conducted using either a single-day or overnight workflow. Historically MIP capture panels have commonly targeted relatively small regions with modest numbers of probes; to demonstrate that neither target size nor probe number is technologically limited, we developed and evaluated a full gene expanded carrier screening (ECS) panel that captures over 1 Mb of coding exons, splice sites, and 5' UTRs for 339 genes, using more than 43,000 MIPs with an average of 5 MIPs per target base. The superior performance of this panel shows that even full exome capture may be feasible, which would greatly improve on the simplicity and scalability of current methods without compromising data quality.

Omics Technologies Posters - Thursday

PB3160. Targeted sequencing of native telomeres reveals patterns of telomere length and subtelomere methylation at single chromosome resolution in human cells

Authors:

S. Hickey¹, A. Drong², P. Rughani¹, C. Tyer¹, X. Dai², J. Baulaurier¹, S. Juul²; ¹Oxford Nanopore Technologies Inc, San Francisco, CA, ²Oxford Nanopore Technologies Inc, New York, NY

Abstract Body:

Background: Telomeres are critical for genomic stability during replication, and the mechanisms for telomere maintenance are important in cancer progression and aging. The investigation of telomerase (TERT) -dependent and -independent mechanisms, such as Alternative Lengthening of Telomeres (ALT), is limited by the repetitive and homologous nature of telomeric regions within individual chromosome arms. Single-molecule long-read nanopore sequencing of native telomeres allows direct measurement of telomere length and alignment to specific chromosome ends, as well as differential methylation profiling and variant calling in human cells. **Methods:** We developed a novel approach for direct telomere targeted sequencing, without amplification, using a 3' overhang telomere hybridization probe coupled to nanopore sequencing adapters. The resulting full-length telomeric reads were basecalled using a custom telomere basecalling model trained using *Bonito*, filtered and aligned to the telomere-to-telomere human reference CHM13v2.0. Next, we used the methylation-calling tool *Remora* to characterize raw-read CpG methylation and ran *Jellyfish* to identify variants of the canonical TTAGGG human telomeric repeat. **Results:** We specifically determined the telomere lengths of individual chromosomes in multiple human cancer cell lines, at single chromosome resolution. The approach yielded a 30-fold increase of mapped telomeric reads compared to whole genome sequencing. Cancer cells with TERT and ALT mechanisms, as well as tumor/normal matched cells, can be distinguished based on their telomere length profiles and distributions. Additionally, differential methylation was observed at CpG islands within the subtelomeric regions at specific chromosome arms. Lastly, telomeric repeat variant calling revealed an increase in non-canonical telomeric variants in cancer relative to normal cells. **Conclusion:** Here we demonstrate a robust, single molecule sequencing method for characterizing telomeres, including length measurements, CpG methylation, and variant information. Single-molecule, chromosome-specific telomere characterization gives a clearer overview of telomere biology and provides information for potential biomarker discovery and clinical interventions.

Omics Technologies Posters - Wednesday

PB3161. Targeted transcriptome sequencing enables exponential scaling of combinatorial barcoding.

Authors:

V. Tran¹, P. Matulich¹, E. Papalexi², R. Koehler¹, C. Roco¹, A. Rosenberg¹; ¹Parse BioSci.s, Seattle, WA, ²Parse BioSci.s Inc., Seattle, WA

Abstract Body:

In the thirteen years since its inception, single-cell RNA-sequencing (scRNA-seq) has rapidly spread across multiple fields of research, leading to many new discoveries. As technologies have matured, the number of cells that can be processed in a single experiment has seen exponential growth, with workflows now assaying up to one million cells in an individual experiment. While high throughput sequencing methods have facilitated the discovery and characterization of various cell types, sequencing costs can be prohibitively high for routine use. Many applications of scRNA-seq are focused on cell type identification, gene regulatory networks, or biomarker discovery. These applications often do not require surveying the entire transcriptome, but rather require the interrogation of specific sets of well-characterized genes. In these cases, sequencing the entire transcriptome is unnecessary and adds substantial sequencing costs to the project. To increase throughput and minimize sequencing costs, the development of targeted gene enrichment methods is required. Building on Evercode™ Whole Transcriptome's technology of split-pool combinatorial barcoding, we applied a method to enrich a subset of genes in the final single cell sequencing libraries. To illustrate the power of our technology, we enriched a whole transcriptome library of 1 million peripheral blood mononuclear cells (PBMCs) using gene panels that targeted immune cell markers and pathways. The percent of reads on target increased from as low as 1.6% in the whole transcriptome libraries to 70% in the targeted libraries. The unenriched whole transcriptome library of these 1 million cells were sequenced on a NovaSeq using an S4 flow cell. In contrast, a gene panel library enriching approximately 1,000 genes was sequenced with NextSeq 550 using a High Output flow cell (generating ~500 mean reads/cell). Despite a nearly ten-fold reduction in sequencing reads, the resulting clustering yielded very high concordance of cell type identities when unenriched and enriched libraries were compared. This modular enrichment strategy allows researchers to use either custom or preexisting gene enrichment panels with any gene subset of interest. This approach enables researchers to simultaneously reduce sequencing costs while drastically scaling up the number of cells and samples across experiments.

Omics Technologies Posters - Thursday

PB3162. Tempo: an unsupervised Bayesian algorithm for circadian phase inference in single-cell transcriptomics

Authors:

B. Auerbach¹, G. A. FitzGerald¹, M. Li²; ¹Univ. of Pennsylvania, Philadelphia, PA, ²Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

The circadian clock is a 24-hour cellular timekeeping mechanism that temporally regulates human physiology. Answering several fundamental questions in circadian biology will require joint measures of single-cell circadian phases and transcriptomes. However, no widespread experimental approaches exist for this purpose. While computational approaches exist to infer cell phase directly from single-cell RNA-sequencing (scRNA-seq) data, existing methods yield poor circadian phase estimates, and do not quantify estimation uncertainty, which is essential for interpretation of results from highly sparse scRNA-seq data. To address these unmet needs, we developed Tempo, a Bayesian variational inference approach that incorporates domain knowledge of the clock and quantifies phase estimation uncertainty. Through simulations and analyses of real data, we demonstrate that Tempo yields more accurate estimates of circadian phase than existing methods and provides well-calibrated uncertainty quantifications. We further demonstrate that these properties generalize to the cell cycle. Tempo will facilitate large-scale studies of single-cell circadian transcription.

Omics Technologies Posters - Wednesday

PB3163. Temporal motif discovery in biological interaction networks

Authors:

A. Jazayeri; Washington Univ. in St. Louis, St. Louis, MO

Abstract Body:

Consideration of the time aspect is essential in monitoring cellular signaling and processes, identifying functional regions within signaling genes, and investigating transcription regulation and phenotypic evolution. With the revolution in high-throughput sequencing technologies in recent years, collecting and analyzing the temporal biological structure and expression data have attracted increasing attention. On the other hand, one of the fundamental analysis and mining tools used for biological network analysis and interactomics is motif discovery. This problem, also known as frequent subgraph mining, aims to identify interaction patterns observed more frequently in the original network than in the randomized version of the same network. However, consideration of the temporality in frequent pattern mining and motif discovery increases the computational complexities associated with graph and subgraph isomorphism problems. Therefore, the typical approach adopted by the algorithms proposed for motif discovery in temporal networks is to transform the temporal networks into a series of networks where each network represents an aggregated version of interactions recorded over the inter-network intervals. In this study, we show that even though this type of representation reduces the computational complexities, it negatively impacts the expressiveness of the network data and, consequently, the derived insight from detected frequent patterns. Therefore, we develop a novel lossless model for temporal network representation. By developing novel definitions for graph and subgraph isomorphism for temporal networks, we create a series of algorithms for identifying motifs in a data set of heterogeneous temporal networks. We applied the proposed algorithms to different simulated data sets of interactomes representing gene-gene interactions from mice models' and human tissues' biological expression data. The results show that the patterns detected by the proposed algorithms are significantly different from patterns detected by the common approaches proposed in the literature for motif discovery, whether the networks are considered static, or a sequential representation of the networks is adopted.

Omics Technologies Posters - Thursday

PB3164. The impact of ageing on the transcriptome profile of human germline and somatic cells

Authors:

M. Pham, L. Chappell, Y. Hooks, M. Stratton, R. Rahbari; Wellcome Sanger Inst., Cambridge, United Kingdom

Abstract Body:

Male germline cells have been reported to acquire considerably fewer mutations compared to the somatic cells. A few possible explanations for this phenomenon have been proposed, including a lower rate of stem cell turnover and an increase in transcription-coupled repair. However, evidence purported to support these hypotheses remains inconclusive. Thus, our study focuses on other potential processes influencing mutations, particularly transcriptional alterations in the human testes, to interrogate how the germline cells might be protected from mutations during ageing.

We applied a laser capture microdissection (LCM) approach to collect the germline cells from seminiferous tubules of 16 normal testes, and the somatic cells from colonic crypts of eight normal colons (as an example of somatic counterparts) from the same donors (age range 21-71). A total of 192 small pools of whole transcriptome data were generated from those LCM patches. This data enables us to investigate the gene expression changes, especially those related to the DNA repair genes, as well as the effect of ageing on transcriptome across the two tissues. Additionally, we generated single-cell whole transcriptome data from ~2000 germline cells from the above donors using a novel single-cell sorting method, which allows isolation of whole cells from frozen tissues. At least four cell populations during spermatogenesis, including spermatogonial stem cells, primary spermatocytes, secondary spermatocytes and spermatids, could be isolated with this method. We then used this single-cell RNA data to demultiplex LCM transcriptome data, reconstruct developmental trajectories in testicular tissues and infer the effect of ageing on repair pathways in male germline cells. Ultimately, our detailed molecular study of age-related transcriptional changes provides mechanistic insights into how the germline cells are protected during ageing.

Omics Technologies Posters - Wednesday

PB3165. The impact of insert length on variant calling quality in whole genome sequencing.

Authors:

B. Lajoie, A. Altomare, K. Blease, R. Kelley, E. Miller, J. Moreno, C. Thompson, J. Zhao, S. Kruglyak; Element BioSci.s, San Diego, CA

Abstract Body:

Accurate variant calling is critical for whole genome sequencing applications, including rare disease and oncology. The availability of high-quality truth sets provided by NIST has enabled various benchmarking efforts across both sequencing platforms and NGS algorithms. Based on these benchmarking results, we have an understanding of the most accurate variant calling methods, the impact of greater read length, and the properties of the remaining difficult regions. However, we do not yet have a careful examination of the impact that varying insert length distributions have on accuracy. This is in part because amplifying long inserts is challenging for certain sequencing chemistries.

Our hypothesis is that longer inserts, like longer reads, could improve alignment in certain genomic regions, thus improving overall variant calling accuracy. The intuition is that a short insert may match several repetitive locations in the genome, whereas a longer insert may have at least one end outside of the repetitive region, thus providing an anchor for the alignment.

We began with a simulation study to determine the appropriate conditions to try experimentally. The open source NEAT simulation framework (<https://github.com/ncsa/NEAT>) was first used to generate inserts with typical mean insert length of ~350 bp. Benchmarking of the simulated reads produced SNP and Indel metrics similar to what we observed from benchmarking public sequencing data from the Precision FDA Truth Challenges. We then synthetically varied the insert length distributions and repeated the benchmarking. As we increased the insert length, the total number of variant calling errors decreased, particularly in the false negative category for positions that span the “difficult regions.” This supported our initial hypothesis.

Next, we generated sequencing libraries with mean insert sizes ranging from 350 bp to 1000 bp. We then benchmarked alignment and variant calling quality as a function of insert length. Consistent with the simulation, we saw a higher fraction of reads aligned at high mapping quality and lower number of total variant calling errors as a function of insert length. We conclude that some of the benefits of longer reads can be attained through the use of longer inserts.

Omics Technologies Posters - Thursday

PB3166. Tissue specific transcript and protein isoforms in the human neural retina

Authors:

T. Riepe¹, M. Stemerding¹, R. Salz¹, E. de Vrieze¹, J. Gloerich¹, B. Ferrari², S. Ferrari², S. Roosing¹, F. P. M. Cremers¹, P. A. C. Hoen¹; ¹Radboudumc, Nijmegen, Netherlands, ²Fondazione Banca degli Occhi del Veneto, Venice, Italy

Abstract Body:

The retina is the light sensitive tissue at the back of the eye. It converts light into electric stimuli that can be interpreted by the brain. Like the brain, the retina is known to be enriched for alternative splicing. However, our knowledge about the transcript and protein isoforms expressed in the retina is not complete. Genetic defects in genes that code for proteins involved in normal retina function can cause inherited retinal diseases (IRDs). IRDs affect about 1 in 2,000 individuals worldwide and cause vision loss. It is estimated that approximately 1/3 of causative variants in IRD-associated genes disrupt splicing. Several previous studies revealed retina-specific splicing factors and isoforms. A more complete atlas of the retina transcriptome and proteome will contribute to the identification of IRD-associated variants, disease mechanisms and treatment options. In this study, we analyzed three human post-mortem neural retina samples with PacBio long read RNA-sequencing and mass-spectrometry-based proteomics to create an atlas of retina transcript and protein isoforms. We identified more than 125,000 unique isoforms, which resulted in more than 55,000 Open Reading Frames (ORFs). More than half of the isoforms were classified as novel, and more than two-third of the identified transcript isoforms from IRD-associated genes were novel. Both novel exons and exon skipping events were found in IRD-associated genes. Using a PacBio GENCODE hybrid database, more than 15,000 peptides from more than 2,500 proteins were identified. 20 of these peptides were novel peptides that confirm a novel transcript isoform. One interesting novel peptide mapped to an intron retention event in *ATP1A3*, which is a candidate gene for autosomal dominant cone-rod dystrophy. There are several reasons why we detect many more retina-specific transcripts than peptides. First, proteomics coverage is still limited and chances to detect a peptide that maps uniquely to a novel transcript are low. Second, a lot of transcript variation affects noncoding regions, without any effect on the ORF, but with possible consequences for translational efficiency and protein expression levels. Third, not all novel ORFs are translated into stable proteins. To conclude, the retina cell atlas provides novel insights into the retina transcriptome and proteome and can be used as reference for future IRD research. Moreover, it demonstrates the need to study tissue specific transcriptomes and proteomes.

Omics Technologies Posters - Wednesday

PB3167. Transcriptome analyses of congenital heart disease tissue from participants with Trisomy 21.

Abstract Body:

Introduction: Trisomy 21 (T21), a prevalent human genetic syndrome occurring in 1:600 live births, is characterized by congenital heart defects (CHD), craniofacial dysmorphologies, neurocognitive, pulmonary, endocrine abnormalities, and increased risks for comorbidities. Despite a definitive genetic cause, the molecular mechanisms by which T21 perturbs development and homeostasis of human tissues remains poorly defined.

Hypothesis: We hypothesized altered cardiac gene expression in T21 might provide clues to the pathogenesis of its clinical manifestations.

Methods: We performed RNA sequencing (RNAseq) of CHD cardiac tissue from 49 T21 and 226 euploid (eCHD) patients aged 0-19.8 years and compared genome-wide transcript expression between groups. T21 individuals were equally likely to be male (47% vs 57%, P=0.19) but younger (mean 1.4 vs 3.1 years, P=0.02) than eCHD individuals. Septal defects were the most common types of CHD (65 eCHD and 38 T21), and atrioventricular canals were present in more T21 patients (24 T21 vs. 10 eCHD, OR 20.7, p<2.2E-16). The most common tissue samples was right atrium (83 eCHD and 37 T21). Using single nuclear RNA sequencing (snRNAseq) on an independent set of ten T21, 13 eCHD and 12 healthy adult hearts we assessed expression within cell lineages.

Results: In addition to chr21 genes, T21 increased *SOST* (chr17) expression 11-fold above eCHD tissues (P=1.2E-8). *SOST* and *ZNF467* (chr7), a *SOST* transcriptional activator, were co-expressed (r=0.32; P=1.7E-7). In endothelial cells, *SOST* levels were 12-fold higher in T21 than euploid cells (P=2.7E-27) and were correlated with ch21 *DSCAM* (Down syndrome cell adhesion molecule; r=0.77, P=1.9E-05).

Conclusion: Wnt signaling is critical for atrioventricular canal, craniofacial and long bone development, maintenance of bone mass, and endothelial regulation of pulmonary vascular homeostasis. Consequently, chronically increased tissue *SOST* expression that inhibits Wnt activities might promote prototypic T21 manifestations: atrioventricular septation defects, diminutive craniofacial bones, shortened stature, low bone mineral density and increased risks for osteoporosis and pulmonary hypertension. These findings imply therapeutic potential of anti-sclerostin antibodies for multiple T21 phenotypes.

Omics Technologies Posters - Thursday

PB3168. Transcriptome sequencing of RNA isolated from small volumes of blood stabilized in Tempus solution: a technical assessment of different extraction methods and DNase treatment

Authors:

S. Tomei, H. Manjunath, F. Vempalli, L. Mathew, L. Liu, L. Wang, G. Wang, K. Wang, O. Soloviov, S. Lorenz, M. Kalikiri; Sidra Med. and Res. Ctr., Doha, Qatar

Abstract Body:

Transcriptome profiling of human whole blood is used to discover biomarkers of diseases and to assess phenotypic traits. RNA sequencing technologies offer many advantages for transcriptomic profiling over other technologies, including the ability to detect novel transcripts, a wide dynamic range of transcript detection, high specificity and sensitivity and the ability to detect low-abundance transcripts. Recently, finger-stick blood collection systems have allowed a less invasive and quicker collection of peripheral blood that does not necessarily require medical infrastructures. This sampling of small volumes of blood offers practical advantages, allowing large-scale projects. The quality of gene expression data is strictly dependent on the steps used for the sample collection, extraction, preparation and sequencing. Here we have: i. compared the manual and automated RNA extraction of small volumes of blood using the Tempus Spin RNA isolation kit (ThermoFisher Scientific, USA) and the MagMAX™ for Stabilized Blood RNA Isolation Kit (ThermoFisher Scientific, USA), respectively; and ii. assessed the effect of TURBO DNA Free treatment on the transcriptomic data of RNA isolated from small volumes of blood. RNA Libraries were prepped using the QuantSeq 3' FWD mRNA-Seq Library Prep Kit (Lexogen). Library QC was performed on the LabChip GXII and quantified using KAPA Library quantification kit by qPCR. Libraries were pooled and sequenced on the Illumina HiSeq4000 system. The data QC was performed as recommended by Illumina. Reads were mapped to the human genome GRCh38.p13 (Genome Reference Consortium Human Build 38), INSDC Assembly GCA_000001405.28, Dec 2013) using STAR_2.6.1d aligner, and featureCounts v2.0.0 was used to generate the raw counts. We used DESeq2 (v1.32.0) to normalize read counts with standard settings. Normalized data was transformed using variance-stabilizing transform (VST) and removed batch effect using limma::removeBatchEffect from Lima package (v3.48.2). Heatmaps, correlation matrices and PCA plots were generated as relevant. Transcriptomic profiles were overall consistent, however the samples isolated manually displayed a higher variability in the transcriptomic data as compared to the other samples. The TURBO DNA Free treatment affected the RNA samples negatively, decreasing the RNA yield and reducing the quality and reproducibility of the transcriptomic data. We conclude that automated extraction systems should be preferred over manual extraction systems for data consistency, and that the TURBO DNA Free treatment should be avoided when working on RNA samples isolated manually from small volumes of blood.

Omics Technologies Posters - Wednesday

PB3169. Transcriptome signature of sodium intake in and links to cardiovascular traits

Authors:

A. Gaye; NHGRI, Bethesda, MD

Abstract Body:

Background: In average, Americans consume more than 3,400 milligrams of sodium per day, an amount much higher than recommendations in the US 2015-2020 Dietary Guidelines. Studies have shown that dietary intake high in sodium, fat and sucrose are strongly related to an increased risk for cardiovascular disease (CVD). However, the molecular mechanisms by which these nutrient impacts CVD are not fully understood. The aim of this analysis is to conduct an unbiased transcriptome analysis in African Americans (AA), a population with disproportionate burden of CVD. **Methods:** The analysis is a cross-sectional study of whole blood transcriptome mRNA sequencing (mRNA-seq) of 472 AA from the MHGRID and GENE-FORECAST studies. Random Forests (RF) was used to define a transcriptome profile empirically related to salt intake, and evaluate the relationships between that profile and other diet variable (fat, sucrose and calories) and cardiovascular traits including hypertension status (HTN), systolic and diastolic blood pressure (SBP and DBP) and kidney function (eGFR). Weighted Gene Co-expression Network Analysis (WGCNA) was subsequently conducted to identify clusters of co-expressed genes within the transcriptome profile defined by RF. **Results:** From the 13,359 protein coding transcripts that passed QC filters, RF defined a transcriptome profile of 816 mRNA that classified subjects with high vs low sodium intake with an area under the curve (AUC) of 0.82. That transcriptome profile classified fat, sucrose, calorie intake and the cardiovascular traits with AUC=76 (fat), AUC=67 (sucrose), AUC=0.77 (calorie), AUC=0.72 (HTN), AUC=0.71 (SBP), AUC=0.67 (DBP), AUC=0.71 (eGFR). WGCNA analysis identified 3 network modules that include genes such as ALMS1, RAP1, CXCR4, TRAF3, and IL16 involved in pathways that regulate vascular tone, flow, remodeling and sustained high blood pressure. **Conclusions:** This study employed machine learning predictive models to examine the blood transcriptome and define molecular signatures of mRNA transcripts associated with sodium intake and cardiovascular traits, in one of the largest mRNA-seq sample set of AA to date. The findings provide new insights into biomarkers and molecular pathways that may mediate the effects of sodium, fat and sucrose on cardiovascular health.

Omics Technologies Posters - Thursday

PB3170. Transcriptomic analysis of circulating endothelial colony-forming cells in patients with sickle cell anemia and ischemic stroke.

Authors:

J. Nicoliello Pereira de Castro, S. Matilde da Silva Costa, A. Lima Camargo, M. Tomie Ito, B. Batista de Souza, V. de Haidar e Bertozzo, T. Adalton Rosa Rodrigues, R. Casagrande Saez, M. Castro Ozelo, F. Ferreira Costa, M. Barbosa de Melo; UNICAMP, Campinas, Brazil

Abstract Body:

Background: Cerebrovascular alterations such as ischemic stroke (IS) are common and severe complications of Sickle Cell Anemia (SCA), being fatal in 15% of cases. The complex pathophysiology encompasses an interaction of hemolysis, thromboinflammation, endothelial activation and vasoconstriction that culminate in vaso-occlusion prior to ischemic accidents. In this context, the vascular endothelium has a pivotal role in this cascade of events. Objectives: To evaluate the differential gene expression profile in Endothelial Colony Forming Cells (ECFCs) from SCA patients with IS compared to SCA patients without IS and investigate the relevant biological pathways in ischemic stroke. Methods: RNA samples from ECFCs of SCA patients with IS (N=4) and SCA patients without IS (N=4) were sequenced by RNA-Seq. Normalization and differential gene expression analysis were performed by the *edgeR* package in R. Gene Ontology (GO) analysis for Biological Process category of the Differentially Expressed Genes (DEGs) was performed using *DAVID* tool. Next, we applied *stringApp* plugin in Cytoscape tool to construct protein-protein interaction network (PPI) of genes present in enriched GO terms, and *cytoHubba* plugin to identify the most hub-genes of the network. Results: We found 2,469 DEGs: 1,836 superexpressed and 633 DEGs underexpressed. There were 23 significantly enriched GO terms, such as defense response, inflammatory response, immune response and taxis. We identified 1,519 protein-coding genes in the main PPI network, with 1,556 interactions. The top 5 hub-genes were: *AKT1* (AKT serine/threonine kinase 1, Log₂FC = 2.57), *HRAS* (HRas proto-oncogene, GTPase, Log₂FC= 3.71), *PIK3R1* (Phosphoinositide-3-kinase regulatory subunit 1, Log₂FC = -2.13), *CDC20* (Cell division cycle 20, Log₂FC = 2.62), *MAPK11* (Mitogen-activated protein kinase 11, Log₂FC = 2.71). These protein-coding genes are predominantly present in signaling cascades of cell proliferation, inflammation and angiogenesis. *AKT1*, the most relevant protein in our network, is a serine/threonine kinase of the Akt pathway, activated in several physiological and pathological mechanisms. In this context, this protein has already been identified as a potential interaction target for pharmacological compounds of ischemic stroke treatment. Conclusions: Next-generation sequencing technologies are strategic tools for uncovering the complexity of several diseases and their complications. Thus, RNA-Seq analysis is a relevant approach that may enable the discovery of new molecular pathways of biological importance for IS in SCA.

Omics Technologies Posters - Wednesday

PB3171. Transcriptomic analysis reveals long-term effect of SARS-CoV-2 infection on host genetic regulation

Authors:

W. Zhu¹, H-H. Chen², H. Polikowsky¹, D. Shaw¹, L. Petty¹, D. Kim³, X. Zhang⁴, M. Yaser⁵, P. Sharma⁶, K. Young⁷, J. McCormick⁸, S. Fisher-Hoch⁸, K. North⁷, C. Huff⁹, J. Below¹⁰; ¹Vanderbilt Univ., Nashville, TN, ²Vanderbilt Univ. Med. Ctr., Nashville, TN, ³UNC-Chapel Hill, Chapel Hill, NC, ⁴Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ⁵Univ. of North Carolina Chapel Hill, Chapel Hill, NC, ⁶Univ. of North Carolina, Chapel Hill, NC, ⁷Univ North Carolina, Chapel Hill, NC, ⁸The Univ. of Texas, Houston, TX, ⁹The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX, ¹⁰Vanderbilt Univ Med Ctr., Nashville, TN

Abstract Body:

Background: COVID-19, caused by severe acute respiratory syndrome virus (SARS-CoV-2), is highly infectious and has led to a worldwide pandemic since 2019. Over 500 million cases and 6 million deaths have been reported globally as of today. Although 80% of cases only experience mild to moderate symptoms, approximately 5% patients developed critical symptoms. Moreover, beyond the typical recovery timespan, ~2.3% patients suffered from lingering symptoms of COVID-19 for weeks to years. This Post Acute Coronavirus Syndrome (or so-called “Long COVID”) is a multisystem disorder including a wide range of symptoms, commonly affecting the respiratory, cardiovascular, and hematopoietic systems. **Methods:** To investigate acute and long-term impacts of COVID-19 on transcriptomic regulation, we sequenced whole blood RNA samples isolated both before and after SARS-CoV-2 infection for 215 COVID-19 cases confirmed with presence of antibody against the nucleocapsid (to differentiate antibodies present due to vaccination from natural infection), and 188 sex-, age- and interval-matched healthy controls (antigen-negative) in Cameron County Hispanic Cohort. Another 220 single timepoint RNA samples acquired from matched COVID-19 cases and controls were also included in our analysis. We applied linear mixed-effects models adjusted for sex, age, and PEER factors to compare changes of gene expression over time between individuals with incident COVID-19 and controls. **Results:** Our analysis identified 9 genes whose change in expression is significantly associated with incident COVID-19 after multiple testing correction ($p < 2.86 \times 10^{-6}$): *ABCA4*, *ANGPTL6*, *ARHGEF10*, *KLF15*, *LINC00431*, *LOC101928514*, *MSLN*, *OLFM4* and *RPL3L*. Further analysis restricted to symptomatic infections revealed another 14 significant genes: *RNF5P1*, *OVCH1.AS1*, *LOC100506159*, *LILRB5*, *KRT79*, *IQSEC3*, *CPA5*, *CTXN2*, *CRLF2*, *SIGLEC12*, *CNTNAP3P2*, *CCL23*, *HBB* and *ZNF890P*. Prior evidence links several genes to immune processes or COVID-19 symptoms. Based on functional annotation by DAVID, *CCL23*, *LILRB5* and are involved in immunoregulatory and inflammatory processes. Our *RPL3L* finding validates a recent report from re-analysis of a cross-sectional differential expression study of COVID-19 (Vastrad 2020). *HBB*, a gene known to cause sickle cell disease, is significantly associated with pneumonia susceptibility (Chen 2021). **Conclusion:** In summary, our study profiled transcriptomic changes associated with SARS-CoV-2 infection and symptomology, identifying long-term effects of COVID-19 on the expression profile of 23 genes. These results provide compelling insight into COVID-19 pathophysiology.

Omics Technologies Posters - Wednesday

PB3172. Ultrasensitive Duplex Sequencing for Diverse Applications on the Singular Genomics G4 Platform.

Authors:

E. Schmidt, **D. Fitzgerald**, P. Van, M. J. Hipp, C. C. Valentine, J. Salk, J. Higgins; TwinStrand BioSci.s, Seattle, WA

Abstract Body:

Duplex Sequencing (DS) is an extremely accurate DNA sequencing technology which has broad applications across life science and medicine where detection of low frequency mutations is critical. The method relies on double-stranded consensus-making to achieve an error rate below one-in-ten-million. Nearly all DS studies to date have been carried out on Illumina sequencers. The Singular Genomics G4 platform is a newly available instrument with novel chemistry designed to deliver ~2x faster sequencing results. To assess relative platform performance, we benchmarked several TwinStrand DuplexSeq Assays on the Singular G4 platform vs. the Illumina NovaSeq 6000. To evaluate data yield over a range of inputs, libraries were seeded with 50-1000ng of high-quality human DNA and enriched with a small (2.4kb) control panel. Resulting peak DS depths ranged from 2,300-47,000 (G4) and 2,800-57,000 (NovaSeq), with the slight differences likely due to variation in experimental conditions. To evaluate the sensitivity and specificity of mutant detection across a range of VAFs, we prepared synthetic low frequency mixtures of DNA from cell lines carrying seven different cancer-associated *TP53* mutations (SNV & indels) spiked into DNA derived from a healthy donor (expected VAFs from 6E-3 to 9E-5). Spike-in mixes, as well as pure healthy donor DNA, were sequenced to an average DS depth of >50,000x across all exons of *TP53*. The measured mutant frequencies down to the lowest level spike-in matched that which was expected within variation predicted from Poisson sampling statistics on both platforms. Zero mutant counts at spike-in sites were identified in negative controls; thus the analytical performance of the assay was 100% sensitivity and 100% specific for detecting clones to below one-in-ten-thousand. To evaluate performance for measuring ultra-low frequency mutations, 200 ng of DNA from blood of a healthy donor was used to prepare libraries using TwinStrand's DuplexSeq Human Mutagenesis Assay (48 kb panel). A total of 70 unique mutant nucleotides out of 452,802,985 total duplex nucleotides (mutant frequency 1.03E-7 +/- 2.5E-8) and 51 mutant nucleotides out of 485,440,864 (mutant frequency 1.55E-7 +/- 3.2E-8) were respectively identified in the Illumina and Singular libraries. No statistically significant differences in overall mutant frequency or spectrum were observed between the platforms. In conclusion, three independent forms of analytical testing of TwinStrand Duplex Sequencing across extremes of DNA input, rare cancer clone detection, and ultra-sensitive mutagenesis applications yielded nearly identical performance on the Singular and Illumina platforms.

Omics Technologies Posters - Thursday

PB3173. Ultra-sensitive TCR/BCR clonotyping and immunophenotyping.

Authors:

A. Chenchik¹, M. Makhanov¹, T. Liu¹, D. Hu¹, K. Ghias¹, P. Diehl², L. Kobzik¹; ¹Cellecta, Inc., Mountain View, CA, ²Cellecta, Mountain View, CA

Abstract Body:

TCR and BCR repertoire profiling holds great potential for understanding disease mechanisms and for the development of new therapeutics in infectious disease, autoimmunity, and immuno-oncology. This potential could be greatly improved by combining information about receptor clonotypes with immunophenotypes of T and B cells. To facilitate these studies, we developed a novel technology for combined profiling of all human TCR and BCR variable regions and phenotypic characterization of immune cells. The developed TCR/BCR immunophenotyping method involves multiplex RT-PCR amplification and sequencing of CDR3 regions of TCR and BCR genes and a set of the most informative T- and B-cell phenotyping genes. Bioinformatic analysis of NGS data allows profiling of TCR/BCR clonotypes, and identification of major immune cell subtypes and their activation status. Preliminary studies indicate the assay has unparalleled throughput, sensitivity, and improved cost-effectiveness for high-throughput immunity biomarker discovery applications.

Omics Technologies Posters - Wednesday

PB3174. Undergraduate research assistant

Authors:

M. Williams¹, Y. Zhang¹, E. Perillo², E. Parsaee¹, G. Tremel², J. Jung², P. Chen¹, J. Flint¹, J. R. Ecker³, J. Beechem², C. Luo¹; ¹UCLA, Los Angeles, CA, ²NanoString Technologies, Seattle, WA, ³Salk Inst./HHMI, La Jolla, CA

Abstract Body:

Single-cell technologies have revolutionized the characterization of heterogeneous human tissues allowing unbiased census of constituent cell types and their transcriptomic and epigenomics signatures. However, the mapping of molecular signatures onto three-dimensional tissue structure remains highly challenging since most single-cell methods can only analyze disassociated cells or nuclei. We have developed photonic-indexing sequencing (pi-seq) strategies for in situ spatial barcoding with single-cell and subcellular resolution. The pi-seq strategy writes high complexity barcodes into the tissue using sequential ligation of DNA indices with the ligation reaction controlled by high-resolution patterned illumination. The rapid but lower-resolution mode of pi-seq enables spatial genomics with a ~200 µm resolution using a regular epi-fluorescence microscope and no other specialized equipment or reagent. The high-resolution mode of pi-seq uses 2-photon scanning microscopy to barcode single cells with exceptional spatial specificity. Compared to other spatial genomic platforms, pi-seq can be readily scaled to large tissue areas and allows the selection of cell-of-interest using immunofluorescent labeling as guides. The sequencing library generated by pi-seq is fully compatible with commercial short-read sequencing platforms.

Chromatin accessibility and cytosine modifications are well-established epigenomics marks playing critical roles in transcription regulation in normal and disease tissues. We have integrated pi-seq with well-established single-cell open chromatin profiling technique ATAC-seq, and single-cell methylome technique snmC-seq2 to develop methods for the spatial profiling of chromatin accessibility (pi-ATAC-seq) and methylcytosine (pi-mC-seq). These spatial epigenomic approaches have been applied to mouse brain slices to investigate the spatial diversity and organization of brain cell types, using the extensive scATAC-seq and snmC-seq2 profiles generated by the BRAIN initiative as the reference.

Omics Technologies Posters - Thursday

PB3175. Untargeted metabolomics profiling in patients with and without epilepsy.

Authors:

K. Oja^{1,2}, M. Ilisson², K. Reinson^{2,1}, K. Muru^{2,1}, T. Reimand^{2,1}, T. Esko¹, T. Haller¹, J. Kronberg¹, M. Wojcik^{3,4}, G. Michelotti⁵, A. O'Donnell-Luria⁶, S. Pajusalu^{2,1}, K. Ounap^{1,2}; ¹Univ. of Tartu, Tartu, Estonia, ²Tartu Univ. Hosp., Tartu, Estonia, ³Broad Inst. of MIT and Harvard, Boston, MA, ⁴Boston Children's Hosp., Boston, MA, ⁵Metabolon, Morrisville, NC, ⁶Boston Childrens Hosp. / Broad Inst. / HMS, Somerville, MA

Abstract Body:

Epilepsy is a central nervous system disorder with abnormal brain activity. Our understanding of its pathophysiology is still growing. In recent years, research has become more focused on finding biomarkers that would help with differential diagnosis and provide opportunities for the development of new anti-epileptic drugs. Metabolomics is a promising approach to understanding the pathophysiology of epilepsy. We devised a hypothesis free study comparing the metabolic profiles of persons with and without epilepsy. Untargeted metabolomics analysis was performed in two cohorts using ultra performance liquid chromatography (UPLC) instruments paired with mass spectrometry (UPLC/MS). First cohort consisted of 31 pediatric patients with suspicion of a genetic disorder from Tartu University Hospital, who remained unsolved after trio exome sequencing. The second cohort consisted of 824 adult participants from the Estonian Biobank, for whom untargeted metabolomics analysis data was available. We performed Welch's t-tests separately in the two cohorts to compare groups with and without epilepsy. P-values were adjusted to multiple testing using the Benjamini-Hochberg procedure. Epilepsy was present in eleven pediatric patients and in 37 Biobank participants according to their medical health records. The two cohorts had very different general characteristics (the median age was respectively 9 and 71 years). Most pediatric patients also had developmental delay (25/31), intellectual disability (21/31) and brain structural anomalies (17/31). The most relevant comorbidities in the Biobank cohort were disorders of lipoprotein metabolism and other lipidemias (288/824). Still, changes in lipid pathways were seen in both cohorts. In the pediatric cohort 18 significantly differing metabolites were detected (corrected p-value <0.05). These included sixteen different glycerophosphatidylcholines (GPC), dimethylglycine and eicosanedioate (C20-DC). In the Biobank cohort nine significantly altered metabolites were found, these were mainly triacylglycerides, which are also precursors in the GPC synthesis pathway, and one phosphatidylethanolamine. Although the two cohorts revealed different significantly altered metabolites, they both had changes mainly in the phospholipid pathways. Further research is required in order to understand, whether these changes could be used as biomarkers. Funding: Estonian Research Council grants PRG471, PSG774.

Omics Technologies Posters - Wednesday

PB3176. Using an NGS readout for high-throughput proteome-wide analysis in large population health studies.

Authors:

C. Lawley¹, L. Wik², N. Nordberg², J. Broberg², J. Björkesten², E. Assarsson², S. Henriksson², I. Grundberg², C. Westerberg², E. Liljeroth², A. Falck², M. Lundberg², L. Folksersen³, A. Malarstig⁴; ¹Olink, San Francisco, CA, ²Olink, Uppsala, Sweden, ³Nucleus Genomics, Ltd, New York, NY, ⁴Karolinska Inst., Stockholm, Sweden

Abstract Body:

Understanding the dynamics of the human proteome is crucial for identifying biomarkers to be used as measurable indicators for disease severity and progression, patient stratification, and drug development. The Proximity Extension Assay (PEA) is a technology that translates protein information into actionable insights across large samples sizes in both healthy and disease samples. The high-throughput nature of the assay is enabled by linking protein-specific antibodies to DNA-encoded tags that can be read out on a next generation sequencer. We have combined the PEA technology described above with automated sample preparation and a high-throughput sequencing readout for parallel measurement of ~3,000 proteins for up to 384 samples at a time, generating over 1 million data points per run. Characterizing the proteome alongside genetic and clinical data enables a pQTL framework to not only validate known clinical targets and identify new clinical targets but to also suggest repurposing opportunities of clinical candidates for new indications. Here we will summarize results where proteomics is impacting large population health studies (e.g., UK Biobank, SCALLOP) to advance precision and personalized medicine.

Omics Technologies Posters - Thursday

PB3177. Using combinatorial barcoding to simultaneously profile the transcriptome and immune repertoire of 1 million T cells.

Authors:

E. Papalexi, P. Matulich, V. Tran, G. S. Kim, D. Diaz, C. Roco, A. Rosenberg; Parse BioSci.s Inc., Seattle, WA

Abstract Body:

T cells are able to recognize and eliminate a wide variety of immunologic threats while maintaining self-tolerance. Pathogen recognition and clearance is ensured by a process called V(D)J recombination, during which a T cell obtains a unique set of V, D and J gene segments for all the chains (α and β or γ and δ) that make up its T cell receptor (TCR). Each recombined TCR detects a specific disease-associated antigen peptide, which triggers the appropriate adaptive immune response.

Understanding the relationship between TCR sequences and T cell activation during disease pathogenesis and progression can assist in the development of next-generation therapeutics with more favorable and sustainable outcomes. Recent advances in single-cell sequencing allowed for simultaneous profiling of TCRs and full transcriptomes leading to the characterization of key T cell populations with pathogen recognition and disease clearance capabilities. Despite their success, these methods rely on microfluidics devices or plate-based protocols with limited sensitivity and throughput (1,000s-10,000s of cells) making the study of disease-relevant T cells time consuming and costly.

To overcome these limitations, we have extended Parse's combinatorial barcoding technology (originally based on Split Pool Ligation-based Transcriptome sequencing or SPLiT-seq) to simultaneously characterize the TCRs alongside the full transcriptomes of up to 1 million T cells. Using this approach, we were able to recover paired TCR sequences in more than 75% of individual T cells together with their corresponding transcriptomes. We find that clonotype assignments are highly accurate with low rates of misassigned chains. We further obtained an accurate estimate of TCR repertoire diversity in 5 healthy donors and identified signatures that correspond to viral infection.

In summary, we report on the extension of our highly flexible and scalable combinatorial barcoding technology to allow researchers to profile up to 1 million of T cells in a single experiment and investigate their functional responses during infection, cancer, autoimmunity, or therapeutic interventions.

Omics Technologies Posters - Wednesday

PB3178. Using single cell CRISPR/dCas9-based regulatory element screening to dissect complex genetic loci.

Authors:

L. Bounds¹, A. Barrera¹, P. Giusti-Rodriguez², T. E. Reddy¹, Y. Li³, M. I. Love⁴, P. F. Sullivan³, A. A. Allen⁵, G. E. Crawford¹, C. A. Gersbach¹; ¹Duke Univ., Durham, NC, ²Univ. of Florida Coll. of Med., Gainesville, FL, ³Univ North Carolina, Chapel Hill, NC, ⁴UNC-Chapel Hill, Chapel Hill, NC, ⁵Duke Univ, Durham, NC

Abstract Body:

The Major Histocompatibility (MHC) Locus is the most SNP-dense region in the human genome and has been linked with >100 polygenic disorders. However, it remains unknown which variants affect gene expression. To dissect cis-regulation within the locus, we performed noncoding CRISPR/dCas9-based regulatory element screening with single-cell RNA-sequencing readout and identified putative regulatory element (pRE)-gene pairs in three diverse cell types: human induced pluripotent stem cells (hiPSCs), hiPSC-derived neural progenitor cells (hNPCs), and the K562 cell line.

We designed a sgRNA library targeting 581 elements with 150 TSS-targeting positive controls and 1,273 nontargeting negative controls (12,723 sgRNAs). We engineered hiPSCs, hNPCs, and K562 cells to express the repressor dCas9-KRAB, and hiPSCs and hNPCs to express the activator dCas9-p300. We transduced each cell line with the sgRNA library at a multiplicity of infection greater than one and profiled 1.2 million single cell transcriptomes seven to nine days post-transduction.

We performed differential expression testing between all cells with a given sgRNA versus all cells in which a different sgRNA was observed and recovered >170 significant pRE-gene links in each cell type. 16.3% of elements demonstrated regulatory function in all cell types when perturbed with dCas9-KRAB. Of these regions, 45 pREs regulate the same gene, and the change in gene expression was correlated across cell types. pRE-gene links present in all cell types versus cell-type specific links span shorter chromosomal distances and lead to greater changes in gene expression upon perturbation.

In all three cell types, we identified pREs that responded to perturbation but did not overlap a DHS in the corresponding cell type. In dCas9-KRAB NPCs, significant pREs that overlapped a DHS had greater accessibility than the NS pREs that overlapped a DHS. In the activation screen, there was no significant difference in the signal between the significant and NS pREs that overlap DHSs. We also observe pREs that do not overlap DHSs. There is no significant difference in accessibility of these regions and the “closed” pRE-gene links have a greater median pair distance versus those in accessible regions. We find similar trends in the other cell types. Taken together, our results highlight the importance of performing both repression and activation experiments as local chromatin context may influence the perturbation modality.

Finally, we demonstrate that hybridization-based targeted enrichment of the gene expression libraries increases on-target reads >160-fold and achieves >90% sequencing saturation with ~5,000 reads per cell.

Omics Technologies Posters - Thursday

PB3179. Using single nuclei multiomics and spatial transcriptomics to identify drivers of early pulmonary fibrosis

Authors:

A. Vannan¹, C. Taylor², M-I. Chung¹, L. Peter¹, M. Salisbury², T. Blackwell², J. Kropski², N. Banovich¹; ¹Translational Genomics Res. Inst., Phoenix, AZ, ²Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract Body:

Pulmonary fibrosis (PF) is a heterogeneous clinical syndrome that represents the end-stage of chronic interstitial lung diseases (ILD). The most common (20%) and severe form of PF is idiopathic pulmonary fibrosis (IPF), which typically leads to respiratory failure within 5 years of diagnosis. While current therapies for IPF can slow disease progression, they have not been shown to improve survival or quality of life. The limited progress developing effective disease-modifying therapeutics has been due in part to an incomplete understanding of the sequence and coordination of molecular programs that drive disease pathogenesis. The advent of single cell genomics has revolutionized our understanding of the molecular and cellular mechanisms underlying PF. We and others have recently identified multiple previously unrecognized cell types/states that appear almost exclusively in individuals with PF and demonstrated cell-type specific dysregulation of gene expression in PF-lungs. While impactful, these studies have been limited to individuals with end stage disease, as samples were obtained from explant lungs removed during a transplant, and a comprehensive understanding of pathogenic molecular mechanisms across the natural history of PF is lacking. To investigate this, we have leveraged a unique cohort comprised of unaffected family members of familial pulmonary fibrosis patients. In this high-risk cohort, individuals underwent chest CT and bronchoscopy with transbronchial lung biopsy at the time of study enrollment, and have been followed for 5-10 years with serial imaging. We observe four trajectories within this cohort 1) no lung abnormalities, 2) newly arising lung abnormalities 3) stable lung abnormalities, 4) lung abnormalities progressing to symptomatic PF. To assess the molecular and cellular changes associated with early lung abnormalities and assess differences between these trajectories we performed single nuclei multiomics (RNA and ATAC) as well as spatial transcriptomics using the Vizgen MERSCOPE on tissues from three individuals within each category. We have identified patterns of dysregulation in both gene regulation and cellular composition that are distinct from the observed changes in late stage disease. Using the spatial transcriptomics data we have assessed these patterns in-situ and identified patterns of expression correlated with structural changes within the lung. Together, these data provide unique insights into the molecular mechanisms that drive the early pathogenesis of pulmonary fibrosis.

Omics Technologies Posters - Wednesday

PB3180. Utilization of Agena massARRAY to improve quality assessment of saliva samples for clinical genome sequencing

Authors:

C. Ho¹, L. Liao¹, P. Tong¹, N. Hammond¹, W. Qiao²; ¹Stanford Hlth.Care, Palo Alto, CA, ²Stanford Univ., Palo Alto, CA

Abstract Body:

Whole-genome sequencing (WGS) is becoming an increasingly powerful diagnostic tool for identifying genomic aberrations in patients. Given the inherent high cost of genome sequencing, a stringent quality assessment of each sample is typically performed in clinical laboratories to reduce clinical testing failures due to mislabeling and/or unintended specimen swaps. Moreover, the increasing use of saliva specimens for germline genetic testing necessitates additional specimen quality monitoring, given its variable bacterial content. Although DNA extracted from saliva is generally considered to be of comparable quality to that derived from blood, recent studies have shown that non-human contaminating DNA in human saliva can interfere with whole genome sequencing results. As such, it is necessary and important to evaluate the quality of human DNA extracted from each saliva sample and adjust the library input amount accordingly for downstream clinical genome sequencing. Therefore, our laboratory developed and validated a DNA fingerprinting assay using the commercially available MassARRAY genotyping kit, which interrogates 44 single nucleotide polymorphisms, three gender markers, and five sample integrity quality control (QC) markers. The clinical sensitivity, specificity, and accuracy of the fingerprinting assay were all >99.9%, with 95% confidence interval for clinical accuracy being 94.2-100%, supporting its use in clinical testing. In addition, potential bacterial contamination levels among patient saliva samples were estimated based on the ratio of amplifiable copies for human DNA to total DNA. 42 clinical and reference material samples were included in the DNA fingerprinting assay validation and an additional 24 saliva samples were used specifically to determine the percentage of human DNA in each sample, which subsequently were compared to the corresponding clinical genome sequencing ($\geq 40X$) mapped reads percentage to define the appropriate QC metric. Importantly, a linear relationship was observed between amplifiable copy values and mapped read percentage, which was leveraged to inform saliva WGS library loading. An improved weighting strategy based on the required mapped reads percentage that would pass genome sequencing QC metrics was subsequently established and implemented for clinical WGS library loading of saliva samples, and >95% sequencing QC passing rate to obtain 40X genome coverage was achieved. These results support the use of the massARRAY fingerprinting assay, coupled with our novel DNA quality assessment/management strategy, to effectively reduce clinical genome sequencing testing failures for saliva samples.

Omics Technologies Posters - Thursday

PB3181. Utilization of multi-omic, multiplexed cell atlases and benchmark analysis demonstrates purity of product in the manufacture of induced pluripotent stem cell derived natural killer cells

Authors:

M. Denholtz, A. Fernandez-Perez, K. Palomares, S. Kothapally Hanok, C. Chen, J. Yao, J. Hernandez, Z. Fazal, Y. Sui, B. Bober, B. Rezner, R. Bjordahl, T. Lee, D. Robbins, B. Valamehr; Fate Therapeutics Inc, San Diego, CA

Abstract Body:

Despite the promise of autologous cellular immunotherapies, the complexities of manufacturing, including the required single-patient manufacturing runs, extended patient treatment time, heterogeneity related to cellular engineering, and the overall high-cost of manufacturing, present substantial challenges to their broad clinical adaptation. To circumvent these challenges, our novel platform utilizes genetically engineered, clonal master human induced pluripotent stem cells (iPSCs) lines to derive allogeneic T (iT) and natural killer (iNK) cell based cellular immunotherapies. These master iPSC lines undergo directed differentiation to generate a nearly unlimited supply of a specialized, homogeneously engineered product, creating a true “off-the-shelf” cellular immunotherapy. The manufacture of iPSCs-derived cellular immunotherapy products includes a proprietary and complex multistep differentiation process to generate iNK cells. This process is designed to mimic *in vivo* hematopoietic development and yields exceptionally pure, homogenous cell products. To fully characterize this unique manufacture process which includes the generation of various cell types during the intermediate stages of the differentiation process, we developed a combined experimental and analytical pipeline to characterize the intermediate cell types in our iNK cell differentiation process, and to nominate validated flow cytometry markers for analytical development. Utilizing public multi-omic single cell atlas data sets we used benchmark analysis utilizing knowledge transfer algorithms to identify, characterize, and quantify distinct cell types present at the various stages of our differentiation process. Key intermediate cell types were further characterized via generation of internal, multiplexed, multi-modal cell atlases, thus allowing for the direct comparison of the transcriptional and cell surface protein repertoires of the intermediate cell types and final product. Utilizing this in-depth characterization pipeline, we confirmed the high level of homogeneity of the assessed iNK cell products (greater than 95 percent), defined key intermediate hematopoietic cell types in our differentiation process, and identified shared and engineering-specific differentiation pathways.

Omics Technologies Posters - Wednesday

PB3182. Utilizing paraformaldehyde fixation to expand opportunities for single-cell RNA-sequencing.

Authors:

B. Meta¹, D. Corney¹, Y. Han¹, Y. Qiu¹, J. Lozach², P. Vishwanath¹, M. Stephens¹, H. Latif¹, G. Zhou¹; ¹Azenta, South Plainfield, NJ, ²Rosalind Bio, San Diego, CA

Abstract Body:

Traditional approaches to performing transcriptional profiling have relied heavily on bulk RNA-seq which, while straight-forward and cost-effective, eliminates all evidence of heterogeneity that may have been present within a complex and diverse tissue. For this reason, high-throughput droplet- and microfluidic-based approaches for performing single-cell RNA-seq (scRNA-seq) have become powerful techniques to answer important questions in a wide range of fields. However, a significant bottleneck to widespread and routine usage has been the specialized and involved sample preparation requirements prior to performing scRNA-seq. Typically, tissues must be dissociated and processed immediately, which makes it difficult to batch and transport samples off-site, or cryopreserved, which is associated with challenges related to poor cellular viability upon sample thawing.

To further broaden the ability for researchers to deploy scRNA-seq, we describe our experience deploying a pre-commercial workflow developed by 10x Genomics to resolve these sample management and logistics challenges. On-site paraformaldehyde (PFA) fixation at the point of specimen collection allows samples to be collected, fixed, and transported to off-site laboratories for downstream processing. To demonstrate the workflow, various sample types were collected and either immediately fixed or cryopreserved for paired analysis by either probe-based transcriptome-wide gene expression profiling or using current single-cell 3' end counting. In all cases, fixed and cryopreserved cells demonstrated comparable clustering, gene and UMI detection, and gene expression metrics. Furthermore, inference of PBMC cell type identity determined by gene expression signatures showed comparable frequencies across both cryopreserved and fixed samples. Finally, downstream data analysis and visualization was performed in the Rosalind analytics platform, thereby enabling straightforward and collaborative interpretation with the ability to incorporate data obtained from other modalities for multiomic analysis. Taken together, this new approach expands the ability to perform single-cell transcriptome-wide analysis of gene expression at high sensitivity on challenging sample types and sample collection locations.

Omics Technologies Posters - Thursday

PB3183. Utilizing REVEAL SingleCell for single cell spatial transcriptomics data storage, analysis, and visualization

Authors:

C. Bragdon, S. Sarangi, U. Mudgal, Z. Pitluk, K. Sharma; Paradigm4, Waltham, MA

Abstract Body:

Single cell 'omics methods such as RNA-seq, CITE-seq, and ATAC-seq are valuable techniques for generating molecular profiles of cell type distributions and understanding regulatory networks in tissue samples. However, due to the required dissociation of cells in these techniques, there is loss of spatial information that might otherwise inform important questions about tissue organization such as disease microenvironment in Alzheimer's disease, inflammation centers, and tumor microenvironment in cancers. Spatial transcriptomics (ST) has become the key method to measure gene activity in a tissue sample and preserve the spatial information. While ST currently needs to improve read depth, transcriptome coverage, and there is a tradeoff between throughput and cell level resolution, the technique is a powerful tool that improves mechanistic and functional understanding of disease processes to build and test novel hypotheses. The growth in ST datasets and technologies, and integration with other single cell 'omics is creating the need for efficient storage and querying of multi-omics single cell and imaging data easily across multiple samples. In this poster, we present features of the REVEAL SingleCell analytical platform that support working with ST data and allow development and testing of novel use cases. We demonstrate loading of Visium ST data through the R-API using 10x, Seurat, or h5 objects signifying interoperability and ease of use. Rapid data retrieval of expression values as well as image metadata from ST datasets is also achieved through the R-API allowing efficient integration with downstream analysis workflows. Next, we present timings for scalable analytics such as computation of z-scores and identification of top expressed genes across Visium ST 'spots' in a sample. We also demonstrate creating and analyzing integrated ST datasets (iSets) from multiple samples, simulating creating bespoke ST atlases. Finally, we present a potential use case with REVEAL SingleCell that allows a user to select images associated with ST samples followed by selection of regions and querying gene expression.

Omics Technologies Posters - Wednesday

PB3184. Visualize RNA biomarkers to spatially interrogate complex tissues using the RNAscope™ HiPlex v2 in situ hybridization assay

Authors:

A. Dikshit, S. Basak, C-W. Chang, K. Collins; Advanced Cell Diagnostics, Newark, CA

Abstract Body:

Precise characterization of cell types in complex tissues is essential to determine their functional significance. Targeted gene expression analysis enables profiling of diverse cell types found in heterogeneous tissues such as the tumor and brain. The tumor microenvironment (TME) is comprised of tumor cells, immune cells, stromal cells, and extracellular matrix. Interrogating spatial interactions and activation states of immune cells in the TME is crucial for implementing successful therapies. Similarly, establishing gene expression profiles is critical for better understanding the pathology underlying many CNS disorders. This study demonstrates the use of highly specific RNAscope HiPlex v2 in situ hybridization (ISH) assay for detecting target gene expression in fresh frozen brain and FFPE tumor samples. The RNAscope HiPlex v2 assay has the capability of iteratively multiplexing up to 48 targets in fixed and fresh frozen samples and up to 12 targets in formalin fixed paraffin embedded (FFPE) tissues. The novel FFPE reagent effectively reduces background autofluorescence, improving the signal to noise ratio. We have leveraged this technology to investigate spatial expression of 12 oncology and immunology target gene as well as 12 targets implicated in the pain modulation in the brain. In the tumor tissues, we visualized T cell infiltration and identified T cell subsets within tumors using *CD3*, *CD8*, *PD1* and *IFNG* markers. Cytotoxic T cell phenotype and activated T cell phenotype were quantified using HALO image analysis. We further identified subsets of pro- and anti-inflammatory macrophages by *CD68* and *CD163* expression and detected chemokines and cytokines such as *CXCL10* and *CCL22*. Quantitative analysis indicated higher degree of macrophage and tumor associated macrophage (TAM) infiltration in the lung tumor compared to the cervical tumor. In the mouse brain, differential expression of opioid receptors, *Oprm1*, *Oprd1* and *Oprk1* was observed in different regions of the brain, implying region-specific function. Neuropeptide Y known to be involved in pain perception and transmission was observed to localize in the astrocytes and microglia of the nucleus accumbens. Using a highly sensitive multiplexed RNAscope HiPlex v2 ISH assay, we have demonstrated a technique to spatially resolve 12 targets in FFPE human tumor and frozen mouse brain tissues. The FFPE reagent efficiently quenched background autofluorescence in the FFPE tissues. This technology is highly valuable for investigating spatial interactions and can provide insights into the biological crosstalk among various cell types in complex and heterogeneous tissues.

Omics Technologies Posters - Thursday

PB3185. WES, with its limitations, continues to provide an attractive mode for genomic data collection

Authors:

S. Rockowitz, C. French, W. Shao, A. Sharma, P. Sliz; Boston Children's Hosp., Boston, MA

Abstract Body:

The transition from whole exome sequencing (WES) to whole genome sequencing (WGS) has opened opportunities for new types of analysis and may increase diagnostic yields, yet, the deployment of WGS over WES presents several challenges including: regime of sample collection, cost and data management. At BCH, we developed a hybrid WES/WGS sample collection system where we have collected WES and/or WGS samples from 6,188 individuals from 2,645 families (1,990 with WES only, 203 with WGS only, 452 with WES and WGS). As we collected both sets of data, we systematically evaluated the operationalization from sample collection to diagnosis and re-analyses. Lack of a streamlined process for the collection of remote CLIA WGS blood samples led cohorts to prioritize the collection of buccal swabs for WES. Preliminary analysis of these data indicates that when WGS was collected, diagnosis rates were increased over WES across numerous cohorts. Further, automated re-analyses workflows held additional diagnostic promise for initially undiagnosed cases.

Omics Technologies Posters - Wednesday

PB3186. Whole genome sequencing of low input tagmentation-based libraries results in high quality somatic variant calling comparable to ligation-based PCR-free libraries.

Authors:

E. Rice¹, L. Jiang¹, X. Zhang¹, C. Alba¹, G. Sukumar¹, M. D. Wilkerson², C. L. Dalgard²; ¹Henry M. Jackson Fndn., Bethesda, MD, ²Uniformed Services Univ. of the Hlth.Sci., Bethesda, MD

Abstract Body:

Whole genome sequencing (WGS) of tumor tissue may indicate novel treatment paradigms through molecular classification of human cancers. While surgically obtained tumor samples may yield DNA below the microgram input required by established ligation-based PCR-free library preparation workflows, the lower, 100 to 300 nanogram inputs of novel PCR-free tagmentation-based methodologies may broaden the WGS applications of such samples. Comparative analysis of tagmentation- to ligation-based workflows along with benchmarking to a high-confidence reference is prudent to ensure maintenance of high-quality calls for future translational and clinical applications. To address this validation, replicates of tagmentation- and ligation-based sequencing libraries were generated for the HCC1395 breast cancer-derived tumor cell line and its matched germline normal lymphoblastoid cell line previously characterized by the SEQC2 Somatic Mutation Working Group. WGS was performed on the Illumina NovaSeq 6000 to a targeted sequencing depth of 30x for germline and 90x for tumor, and variant calling was performed. Sequencing quality control metrics, germline variant calls, and somatic mutation calls were compared to assess technical performance, concordance, precision, and sensitivity across methods. Tagmentation- and ligation-based libraries both achieved above threshold Q30 percent, above target mean coverage, greater than 90% aligned reads, and highly similar average insert size. Germline variant calls analyzed pairwise displayed 99.98% concordance between workflows. Germline variants showed greater than 98% precision and sensitivity using ligation-based variants as a reference. For somatic mutation calling using method-specific pairs, 88% precision and 81% sensitivity in exonic regions was observed against a ligation-based baseline. Against the SEQC2 reference call set, ligation- and tagmentation-based method SNP calls resulted in 93% and 89% precision and 73% and 74% sensitivity, respectively. A high fraction of false negative calls from the SEQC2 high/medium confidence space was associated with low tumor variant allele frequency (TVAF) of <0.1. Applying a cutoff of >0.1 TVAF for SEQC2 calls only increased ligation- and tagmentation-based method sensitivity to 82% and 81%, respectively, underscoring a highly similar outcome for both workflows. In summary, high concordance with ligation-based methodology, and similar precision and sensitivity compared to reference data provides confidence for tagmentation as a suitable method for attaining high quality somatic mutation calls from minimal starting material.

Omics Technologies Posters - Thursday

PB3187. Why long-read sequencing is poised to become key to clinical genetics: an episodic ataxia study.

Authors:

S. Audet^{1,2}, V. Triassi^{1,3}, C. Michaud^{1,2}, E. Bareke¹, V. Ferraro^{4,2}, L. Touma^{4,2}, A. Duquette^{4,2}, M. Tétreault^{1,2}; ¹CRCHUM, Montreal, QC, Canada, ²Dept. of NeuroSci.s, Univ. of Montreal, Montreal, QC, Canada, ³Dept. of Bioinformatics, Univ. of Montreal, Montreal, QC, Canada, ⁴Dept. of Neurology, CHUM, Montreal, QC, Canada

Abstract Body:

Despite a rapid evolution of technologies available in clinical settings, such as next generation sequencing (NGS) which has had a major impact on the identification of pathogenic variants, many patients remain without a molecular diagnosis. For rare neurological disorders, standard diagnostic approaches generally achieve a success rate of 20-50%. One of the major obstacles faced with NGS is the complexity of interpreting variants of unknown significance (VUS). Hence, the many applications of long-read sequencing (LRS) are highly compelling to efficiently bridge the identification of variants and the interpretation of their impact. Indeed, allowing the capture of full-length gene transcripts in a quantitative manner generates a great amount of functional information which could facilitate VUS interpretation in several manners.

Our lab conducted a pilot study for which the aim was divided in two parts: 1) evaluating the performance of a multi-omics approach on the diagnostic yield of complex ataxia cases and 2) defining how powerful LRS is for the validation of candidate VUS. The hypothesis was that diagnosis would be reached for more than half of the cohort, and that LRS would be a major contributor to the validation steps of our investigation.

A cohort of eight patients with complex episodic ataxias were recruited following a thorough yet unsuccessful clinical investigation to define the cause of their disease. DNA, RNA and proteins were extracted from peripheral blood mononuclear cells, enabling the combination of whole-genome and RNA-sequencing, as well as validation experiments. LRS was performed using Nanopore technologies. The multi-omics approach has allowed the identification of excellent candidates in each patient, four of which have been functionally validated through LRS (4/8; 50%). The interesting part of the result is the diverging contexts in which long-reads were used to evaluate the impact of the variants: to demonstrate the trans configuration of two *SPG7* variants, to prove the alternative splicing and transcriptome shift of *ELOVL4* and *PMPCB* in two separate patients, and to precisely quantify the number of *ATXN2* repeats in another case. The tool's versatility was unsurprisingly a major factor in its capacity to contribute to the functional validation.

These results highlight the potential of multi-omics and LRS in the context of clinical genetics.

Additionally, they should have a direct impact on patients through the psychological relief linked to an official molecular diagnosis, a better understanding of the pathology, and better care management.

Finally, these findings may hopefully lead to novel therapeutic targets in the future.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday
PB3188. A comprehensive analysis of the reusability of public omics data across 2.8 million research publications

Authors:

M. Vahed¹, N. Darci-Maher², K. Peng¹, J. Brito¹, A. Rajesh¹, A. Smith¹, R. Thompson³, A. Nellore⁴, J. Jacobs⁵, D. Duong⁶, E. Eskin⁷, S. Mangul⁸; ¹Univ. of Southern California, Los Angeles, CA, ²Univ. of California, Los Angeles (UCLA), Oakland, CA, ³Oregon Hlth.& Sci. Univ., Portland, OR, ⁴Univ. of Pennsylvania, Philadelphia, PA, ⁵QIAGEN Digital Insights, Redwood City, CA, ⁶Univ. of California Los Angeles, Culver City, CA, ⁷Univ California los Angeles, Los Angeles, CA, ⁸Univ. of Southern California, Sch. of Pharmacy, Los Angeles, CA

Abstract Body:

There is growing evidence that data sharing enables important discoveries across various biomedical disciplines. When data is shared on centralized repositories in easy-to-use formats, other researchers can examine and re-analyze the data, challenge existing interpretations, and test new theories. Additionally, secondary analysis is economically sustainable and can be used in countries with limited resources. Advancements in high-throughput omics technologies have reshaped modern biomedical research. However, once a research team publishes critical findings derived from an omics dataset, secondary analysis can play a crucial role in enabling and verifying the reproducibility and generalizability of published results. On the other hand, there is a lack of knowledge of how widely and what types of genomic data are reused and how it contributes to novel biological discoveries. We have performed a data-driven examination of reuse patterns of the reusability of public omics data across 2,882,007 open-access biomedical publications (published between 2001 and 2020; across 13,753 journals). Our search included two omics data repositories, NCBI Sequence Read Archive (SRA) and NCBI Gene Expression Omnibus (GEO). We searched for SRA or GEO accession IDs inside the publications using regular expressions. We tested the accuracy of this assumption using a subset of datasets for which investigators manually linked their dataset records with PubMed identifiers and found it to be accurate. Using the proposed protocol, we were able to identify 88,429 publications with SRA or GEO identifiers and compare the number of studies performing primary analysis versus the number of studies performing secondary analysis. We found out publications mentioning GEO have a higher proportion of secondary analysis than those saying SRA, and the balance of publications mentioning GEO with performing secondary analysis has increased over time, from roughly 20% in 2004 to approximately 60% in 2019. Of the publications citing SRA, this rate has remained around 30% from 2009 to 2019. Considering the data in units of datasets and the number of times they are reused, we found that except for a few initiatives, omics data is poorly reused, and over 59% of the data in GEO, and over 70% of the data in SRA, is not reused even once. Datasets in GEO have been reused 4.27 times, while datasets in SRA have been reused 1.89 times. Our study establishes the current state and trends of secondary analysis of omics data and suggests that an easy-to-use format is needed to enable omics data reusability.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3189. A comprehensive database of Long-chain fatty acid oxidation disorder gene variants.

Authors:

H. Richbourg¹, V. Rangel Miller¹, S. Daugherty¹, O. K. Japalaghi¹, D. Marsden¹, H. McLaughlin², A. Willcock³, N. Miller⁴; ¹Ultragenyx Pharmaceutical, Novato, CA, ²Invitae, South Lyon, MI, ³Invitae Corp., San Francisco, CA, ⁴Ultragenyx, Brisbane, CA

Abstract Body:

Long-chain fatty acid oxidation disorders (LC-FAOD) are rare autosomal recessive conditions caused by defects in genes encoding mitochondrial enzymes that convert long-chain fatty acids into energy. Patients with LC-FAOD may have characteristic elevations in plasma acylcarnitine profiles, identified through newborn screening follow-up and by testing patients with ongoing clinical signs and symptoms. We developed a comprehensive database of variants in the 6 genes associated with LC-FAOD (*ACADVL* [VCLAD], *CPT1A* [CPT1], *CPT2* [CPT2], *HADHA* [LCHAD or TFP], *HADHB* [TFP], and *SLC25A20* [CACT]) by integrating data from three sources: a systematic review of all published medical literature, a sponsored LC-FAOD gene panel testing program, and Ultragenyx clinical programs. Variants were annotated with molecular diagnoses, newborn screening test results, detailed clinical and biochemical phenotypes, and ACMG variant interpretations. As of 5 May 2022, the LC-FAOD gene variant database reports 3830 variants from 2970 patients (809 female, 930 male, 1231 unknown) with one or more LC-FAOD gene variants. These represent 957 unique variants: 682 (71%) pathogenic (P) or likely pathogenic (LP), 246 (26%) variants of uncertain significance (VUS), 1 (0.1%) benign, 7 (1%) likely benign, and 17 (2%) with conflicting information. Single nucleotide variants (658, 69%) are the most common type followed by small deletions (132, 14%), small insertions (40, 4%), deletions (>100bp) (9, 1%), indels (12, 1%), and insertions (1, 0.1%); the remaining 105 variants (11%) document a protein-level change with no cDNA information available. 2185 patients had a positive LC-FAOD molecular diagnosis (at least 2 P/LP variants) distributed as follows: *ACADVL*, 901/42%; *CPT2*, 501/23%; *HADHA*, 461/21%; *HADHB*, 202/9%; *SLC25A20*, 65/3%; *CPT1A*, 55/3%. 18 additional patients are reported as LC-FAOD double heterozygotes (P/LP or VUS) with 18 unique gene variant combinations, most commonly including *ACADVL* (15) and/or *HADHA* (8). 119 patients with a *CPT2* diagnosis also had ≥ 1 of 3 known thermolabile variants in this gene: c.1055T>G, c.1102G>A, c.1939A>G. This comprehensive database of LC-FAOD gene variants will be available on a searchable, interactive website and will continue to compile data on variants identified in ongoing clinical studies, genetic testing programs, and literature searches. Centralized resources like the LC-FAOD genes database are critically important in rare diseases where clinical information on variants is scarce and VUS are frequent and insufficient to support a molecular confirmation of diagnosis.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3190. A comprehensive Japanese genetic variation database TogoVar.

Authors:

T. Katayama¹, N. Mitsuhashi¹, M. Kawashima², L. Toyo-oka³, Y. Moriya¹, S. Kawashima⁴, T. Takagi³; ¹Database Ctr. for Life Sci., Kashiwa, Chiba, Japan, ²Japan Sci. and Technology Agency, Chiyoda-ku, Japan, ³Toyama Univ. of Intl. Studies, Toyama, Japan, ⁴Database Ctr. for Life Sci., Chiba, Japan

Abstract Body:

TogoVar (<https://togovar.biosciencedbc.jp>) is a database that offers integrated Japanese allele frequency information derived from the Japanese Genotype-phenotype Archive, the GEM Japan Whole Genome Aggregation Panel, the ToMMo 8.3KJPN Allele Frequency Panel, and the Human Genetic Variation Database. As the sample size of the Japanese population in the international variant database is still limited and Japanese genome information is scattered in distributed databases with controlled access, it is essential for Japanese human genetics research to provide a public dataset that accumulates Japanese allele frequencies from these data sources. This year we have constantly enhanced the amount of data in collaboration with the cohort and sequencing projects in Japan that resulted in over 100 million variants. To aid the interpretation of these variants, TogoVar also integrates additional information: (1) allele frequencies from the gnomAD database so that researchers can make a comparison of allele frequencies with a specific ethnicity, (2) annotations of variants including molecular consequence and variant effects calculated by the Ensembl Variant Effect Predictor, (3) pathogenicity information provided by the ClinVar database, and (4) relevant literature information from LitVar and PubTator tools. For fully utilizing the integrated information, we have implemented the advanced query interface that enables researchers to combine conditions of variant types, consequences, clinical significances, and allele frequencies in each dataset with the logical AND/OR operators. The query results will be navigated to a variant report page as well as newly introduced gene and disease report pages that provide a summary of variants relevant to a specific gene and a disease. Lastly, from the perspective of the system architecture, TogoVar provides two unique features: (1) tables and charts in TogoVar are provided as a set of reusable modular elements that can be embedded in any web application as a WebComponents module, and (2) the integrated data is internally standardized as a knowledge graph so that developers can make advanced graph queries for analysis. Here we report new advancements and the future directions of the TogoVar database.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3191. A globally representative panel of human genomes: Resource and tutorials to support analyses of diverse populations

Authors:

M. Yohannes^{1,2}, Z. Koenig^{1,2}, J. Goodrich^{1,2}, M. Wilson^{1,2}, G. Tiao¹, A. Kim^{1,2}, L. Nkambule^{1,2}, X. Zhao^{2,1,3}, S. Hao^{2,1}, N. Sahakian¹, M. Talkowski^{2,1,3}, H. Brand^{2,1}, K. Karczewski^{1,2}, M. Daly^{2,1,4}, E. Atkinson^{5,1,2}, A. Martin^{2,1}; ¹The Broad Inst. of MIT and Harvard, Cambridge, MA, ²Massachusetts Gen. Hosp., Boston, MA, ³Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, ⁴Inst. for Molecular Med. Finland, Helsinki, Finland, ⁵Baylor Coll. of Med., Houston, TX

Abstract Body:

Due to a lack of resources supporting their analysis, diverse populations are often excluded from genomic studies. The 1000 Genomes Project (1kGP) and Human Genome Diversity Project (HGDP) are among the most valuable genomic resources because of the breadth of global diversity they capture as well as their open sharing policies that allow release of unrestricted individual-level data. Recently, these two resources were sequenced to high coverage, but have yet to be well harmonized. To alleviate the disparity in resources, we are releasing a joint-called reference panel of more than 155 million high-quality variants obtained from harmonizing a deeply sequenced set of over 4,000 whole genomes from 1kGP and HGDP. Additionally, we are providing detailed tutorials for conducting many of the most common quality control steps and analyses with these data in a scalable compute setting.

These tutorials outline steps for conducting quality control, ancestry analyses, and joint calling with additional datasets. They were developed from best practice analysis scripts so researchers of any level can run through each step to develop an understanding of the data and how to work with it using state-of-the-art processing pipelines. They are currently available on Github

(https://github.com/atgu/hgdp_tgp/tree/master/tutorials) and utilize the Hail Python library, an open source scalable tool for genomics that intuitively interfaces cloud computing and genetic analyses.

In sum, the release of these tutorials along with the reference panel aims to aid researchers in learning cloud based tools in addition to introducing methods for working with diverse ancestry datasets. Public release of this resource will foster representative genomic studies to fully capture the breadth of global genetic variation.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3192*. A novel reference architecture for multi-party federation: enabling joint analysis of large-scale clinical-genomic data across distributed Trusted Research Environments.

Authors:

C. Davison¹, I. Knarston¹, I. Peral¹, B. Goncalves¹, S. Keshari Sahu¹, R. Zochling¹, E. Kyriakou¹, T. Seeger¹, N. Raine¹, R. Fennessy², C. Bacchelli¹, P. Moss³, M. Chatzou Dunford¹, P. Prieto Barja¹, M. Avery², S. Nik-Zainal²; ¹Lifebit Biotech Ltd, London, United Kingdom, ²Univ. of Cambridge, Cambridge, United Kingdom, ³Genomics England, London, United Kingdom

Abstract Body:

Enabling researchers access to the vast amounts of linked clinical and genomic data available is crucial to answering the world's most pertinent research questions. Current real-world genomic and clinical data is predominantly siloed to protect data privacy due to strict regulatory frameworks. Siloed data sets are notoriously difficult for researchers to access and analyse. Establishing a secure computing environment that holds data, often called Trusted Research Environments (TREs), enables researchers to access that data for analysis while securing sensitive, identifiable patient data. However, joint analysis of multiple TREs is impossible within this current model, and data cannot be moved to a centralised repository without compromising data security. Multi-party federation solves this problem, allowing researchers to access and analyse data from multiple TREs enabling more data to be analysed simultaneously, leading to an increased potential for novel discoveries with some estimates that 10x the data leads to 100x the findings. The DARE UK-backed multi-party trusted research environment federation consortium, which includes the University of Cambridge, NIHR Cambridge Biomedical Research Centre, Genomics England, Eastern AHSN, Cambridge University Health Partners and Lifebit, is developing a novel reference architecture to define how federated analysis can be performed on large-scale clinical-genomic data across distributed TREs. This novel demonstration of a multi-party federation will securely bridge the TREs of a UK leading research institute, NIHR Cambridge BRC and a public-sector clinical research endeavour, Genomics England. Lifebit has deployed its TRE platform, CloudOS, across these large scale data resources and is developing novel Application Programming Interface technology to enable TRE communication, in addition to a scalable airlock system for secure export into and out of the TRE. All novel technology for this project will be fully open-source and developed in alignment with Global Alliance for Genomics and Health (GA4GH) standards. Lifebit's cloud-based platform will allow in situ analysis to be run on each TRE individually and then aggregate the results from both TREs to be generated in a 'safe-haven'. This groundbreaking study and use case will contribute novel insights for future multi-party federated analysis - demonstrating best practice reference architecture, the necessary open-source technology and data governance recommendations standard for how TREs can communicate to allow joint analysis.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3193. A Private, universal registry for patient engagement in biomedical research - Xia-Gibbs Syndrome as a model.

Authors:

A. Hansen¹, E. Little¹, D. Belliston¹, M. Murugan², J. Hu², C. Hansen¹, R. Gibbs²; ¹Geneial, Houston, TX, ²Baylor Coll. Med., Houston, TX

Abstract Body:

Many isolated collections of data from affected individuals have been established as disease-agnostic ‘biobanks’ or indication-specific ‘registries’. However, for orphan genetic disorders, despite best intentions to aggregate data, individual biobanks and registries often fail to achieve a critical mass of data necessary to attract commercial interest, leaving patient communities with a lack of resources to accelerate research and development. A critical mass could be achieved by pooling data from disparate biobanks, or by augmenting registries with additional samples found in biobanks, but competitive interests across data managers and the sensitivity of biomedical data have combined to create an environment where **health-privacy and data ownership concerns universally limit access to—and value of—these data resources.**

To address these concerns, we are developing a platform for data interoperability, pooling, and exchange that safeguards patient privacy and data ownership. **Using the Xia-Gibbs Syndrome Registry as a model, we have demonstrated proof-of-concept for a privacy-preserving disease registry search layer** that operates directly on encrypted data without the need for decryption at the point of analysis, enabling data aggregation and analysis to be securely outsourced to a third party unable to view raw data or analysis results. We tested these features against over 200 registry fields for over 150 participants and reported the baseline, unoptimized performance of each operation, measuring performance across a range of registry sizes to understand computational scalability, demonstrating a worst-case scenario of a linear relationship between registry size and computational cost.

In parallel, we have developed a HIPAA-compliant variant annotation service and ‘universal’ registry platform with a modular, hierarchical framework for structured phenotypic data management that supports both registry-specific field customization and cross-registry analysis. With further development these tools will enable privacy- and ownership-preserving targeted sample matchmaking and cohort creation across a network of independent, standardized, interoperable data repositories. **Ultimately, this will increase privacy protections for research participants and data owners while simultaneously increasing data availability and effective sample size for researchers through a decentralized, interoperable platform.**

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3194. A reference panel composed of Alzheimer's Disease enriched single-nucleotide and structure variants for structure variants discovery on SNP array data.

Authors:

P-L. Cheng, H. Wang, W-P. Lee; Pathology and Lab. Med., Philadelphia, PA

Abstract Body:

Compared to whole-genome sequence (WGS), SNP array is cost-effective and indeed has more data available for Alzheimer's Disease (AD) research. However, due to technology limitations, SNP array is limited to capture complete genomic information and is unlikely to support structure variant (SV) discovery which has been proven as a contributor to the genetic basis of human disease. Imputation, which is the process of inferring unobserved genotypes in a sample, may mitigate the challenge, but current reference panels contain either none or a limited number of SVs.

As the quality of a reference panel may be affected by sample size, target variant density, and genetic relationship of samples, a pure SV only panel is infeasible. Thus, we took SNPs and SVs detected on 16,905 WGS data from the Alzheimer's Disease Sequencing Project (ADSP), and composed a reference panel by employing SHAPEIT4 and MINIMAC3, which could use to impute other datasets by MINIMAC4.

To explore the feasibility, we used two regions of known SNPs and SVs in the same linkage disequilibrium (LD) block and examine imputation results. The first region is in MAPT gene where rs8070723 and a 238bp deletion are in the same LD block, while the second one is located at NCK2 where rs143080277 and a 5510bp deletion are in the same LD block. We created a panel for each region for the deletion and SNVs in +/- 100kbp. Then, we assess the results by imputing an independent SNP array dataset with ~1600 samples. The result showed concordant genotypes of SNPs and the deletions. It suggests the feasibility of including SVs and SVs for a reference panel building. We expanded the experiment to build a reference panel genome widely. The project could further clarify the relationship between SVs and SNPs, enable SV discovery in numerous array data of AD, and facilitate finding novel genetic associations of AD.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3195. A systematic assessment of the completeness of TCR databases across *Mus musculus* strains.

Authors:

Y. He, Y-N. Huang, Y. Patel, C. Ronkowski, S. Mangul; Univ. of Southern California, Sch. of Pharmacy, Titus Family Dept. of Clinical Pharmacy, Los Angeles, CA

Abstract Body:

Immunogenetics databases facilitate the study of genetic polymorphisms in the immune system and the analysis, diagnosis, and treatment of diseases. It allows researchers to tap into the evolution of TCR diversity to study numerous diseases, such as cancers, autoimmune diseases, inflammation, and infectious diseases. In laboratory settings, lab mice (*Mus musculus*) account for the majority of non-human vertebrate data and are vital for in-vivo and in-silico studies. However, many studies neglect certain strains used to build mouse models. Disparities exist on how immunogenetics databases represent diverse mouse strains. In this study, we examined the completeness of the IMGT database, a comprehensive database for mouse TCR genes, representing diverse lab mice strains. To conduct the assessment, we analyzed the TCR-sequences of 100 mice samples from the Sequence Read Archive (SRA) using the BCR and TCR analysis toolkit, MiXCR. MiXCR aligns the sample TCR-Seq reads to the IMGT database across diverse mice strains. From the output of MiXCR, we will be able to analyze the mismatches in the VDJ genes and unmapped TCR reads of the diverse mice strains. The proposed methods allow us to evaluate the completeness of the IMGT database representing diverse mice strains by counting the number of mismatches and unmapped reads. Mismatches include substitutions, deletions, and insertions in the VDJ genes of the mice samples compared to the reference. Our evaluation of the completeness of immunogenetics databases representing diverse mice strain types would reveal the strains of lab mice which are underrepresented in the IMGT database. The results can highlight the disparities in the completeness of TCR databases across mice strains and guide further efforts aimed to complete such databases.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday
PB3196. ALS/FTD Compute: an open, centralized repository of genomic data for ALS/FTD research

Authors:

B. Traynor¹, C. Dalgard², P. Keagle³, J. Glass⁴, J. E. Landers³; ¹Natl. Inst Aging, Bethesda, MD, ²USUHS - TAGC, Bethesda, MD, ³Univ. of Massachusetts Med. Sch., Worcester, MA, ⁴Emory Univ., Atlanta, GA

Abstract Body:

BackgroundThe discovery of genes responsible for amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) has revolutionized our understanding of these related diseases and changed the clinical approach to patients diagnosed with this spectrum of fatal neurodegenerative conditions. It also has provided targets for drug development and targeted gene therapy efforts to slow progression. *ALS/FTD Compute* was established to maintain the momentum of gene discovery in these disorders by unifying existing whole-genome sequencing efforts of ALS and FTD patients into a central repository. **Methods**Using the AnVIL cloud environment, we established the *ALS/FTD Compute* as an open central repository. This platform consolidates data from multiple patient and control subject sequencing efforts on a single cloud provider. This effort will facilitate data harmonization improving the quality of the data available for analysis. The ultimate goal is to lower the costs associated with genomic analysis in the ALS/FTD space while democratizing access to this harmonized cohort. **Results**Major sequencing efforts are currently participating in *ALS/FTD Compute*. These include Answer ALS, Genomic Translation for ALS Care GTAC, New York Genome Center ALS Consortium, National Institutes of Health, and Project Mine USA, illustrating the collaborative spirit among the various groups and their recognition of the value of this efficient model of collaboration. To date, whole-genome sequence data for 10,000 samples have been uploaded to *ALS/FTD Compute*. An additional ~35,000 control samples will be included in our harmonization efforts. A cloud environment eliminates the prohibitive costs of large-scale data movement and provides the infrastructure to perform complex genomic analyses. Additionally, the AnVIL platform is built upon well-established components that facilitate various workflows, including Terra, Gen3, Jupyter, Galaxy, Bioconductor, and the Dockstore. AnVIL actively collaborates with other genomic data resources by adopting the FAIR (Findable, Accessible, Interoperable, Reusable) principles. **Conclusions***ALS/FTD Compute* sets the stage for the next iteration of gene discovery in ALS and FTD by adopting an efficient, open and inclusive platform. Our platform demonstrates the utility and efficiencies of the central repository approach in rare neurological diseases.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3197. An improved platform for sharing genomic information of underrepresented populations: BIPMed 2.0

Authors:

I. Lopes-Cendes^{1,2}, T. C. de Oliveira^{1,2}, W. de Souza^{1,2}, C. S. Rocha^{1,2}, B. S. Carvalho^{1,2}; ¹Univ. of Campinas (UNICAMP), Campinas, Brazil, ²Brazilian Inst. of NeuroSci. and Neurotechnology (BRAINN), Campinas, Brazil

Abstract Body:

Introduction: The Brazilian Initiative on Precision Medicine (BIPMed), established in 2015, provided the first platform for sharing genomic and health-related information of admixed populations in Latin America (www.bipmed.org). Over the past two years, we performed a major overhaul in the BIPMed genomic platform so that it can continue serving the medical and research community worldwide. **Materials and Methods:** We have performed several modifications to the BIPMed genomic platform, including implementing CRAM and VCF file formats. Also, we are making the BIPMed genomic data publically available in two reference genomes, hg19 and hg38. Furthermore, we have developed a new tool to import variants from VCF files to the BraVe application programming interface (API) based on the GA4GH Genomics API. **Results:** Currently, the platform has seven databases, including genomic and genetic information from about 900 individuals. Two of these databases are from the 'reference' Brazilian population, containing datasets of admixed individuals ascertained based on place of birth and not on disease phenotypes. Five are disease-specific databases, including diverse phenotypes ranging from cancer to neurological disorders. The two reference databases are composed of unique SNPs identified using whole-exome sequence and SNP arrays. Genetic variation within the databases can now be searched using three online tools (BEACON - GA4GH -, LovD - Leiden University - and the BraVe application, which has been developed in-house). Using this new implementation, we found that data processing in the web interface is considerably faster and fixes some critical issues regarding missing information in the variants file. **Conclusion:** Keeping public genomic databases running demands time and effort, requiring computational solutions for hosting, displaying, searching, and interacting with the datasets. Furthermore, the web interface should provide a good experience to suit users with different scientific backgrounds. By releasing BIPMed 2.0, we are keeping with our mission of supporting the implementation of precision medicine in Brazil. Funding: FAPESP, SP, Brazil.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3198*. Assessing the completeness of immunogenetics databases across diverse populations

Authors:

Y. Huang¹, Y. Meng¹, N. Patel², J. Mehta², B. Hua², M. Fayzullina², H. Alachkar¹, S. Mangul¹; ¹Dept. of Clinical Pharmacy, Sch. of Pharmacy, Univ. of Southern California, Los Angeles, CA, ²Dept. of Pharmaceutical Sci., Sch. of Pharmacy, Univ. of Southern California, Los Angeles, CA

Abstract Body:

Although the advanced development of bioinformatics tools has driven the popularity of AIRR sequencing (AIRR-Seq) studies and has promoted the scientific community to profile human AIRR efficiently, it has been previously disclosed that most of the study participants in the AIRR-Seq studies were of European ancestry, which lacks samples representing the underrepresented populations. Expanding the knowledge of the underrepresented populations in the field of AIRR studies will enhance the understanding of the phenotypic differences in immune cell receptor repertoires and elucidate the different responses to immune-related diseases across diverse populations. In the study, we examined the completeness of the international ImMunoGeneTics information system® database (IMGT database) for representing diverse populations. By leveraging the bioinformatics software, MiXCR, we will be able to comprehensively examine the mismatches in different ancestry group samples' read in the VDJ gene and evaluate the completeness of the IMGT database across diverse ancestry groups. MiXCR aligns and compares the TCR-Seq reads to the IMGT database. In our preliminary results, we analyzed ten European samples and ten Asian samples from Sequence Read Archive (SRA) and counted the number of substitutions, insertions, and deletions in the V and J genes of the T cell receptor sequences (TCR-Seq) from the output of MiXCR and counted the number of the unmapped reads of the samples. We compared the number of mismatches of the samples across diverse ancestry groups and discovered that the samples of European ancestry had fewer mismatches (Mean number of mismatches is 0.77) in the V genes than samples of Asian ancestry (Mean number of mismatches is 4.59) and a similar trend of mismatches are observed in the J genes among the European and Asian group. The result indicates that the IMGT database is more completely representing European ancestry compared to Asian ancestry. We are currently expanding the analysis to the publicly available datasets on the SRA and aim to run MiXCR across all TCR-Seq samples with available ancestry labels from SRA. Unveiling the completeness of the IMGT database representing diverse populations could highlight the need to improve ancestry diversity in those underrepresented populations and guide future immunogenomics studies to improve ancestry availability and distribution.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3200. Blockchain and Artificial Intelligence-Enabled Stratified Trial System (BESTS) - A patient driven data sharing platform that leverages genomic and health data to accelerate clinical trial recruitment for precision therapies

Authors:

L. Brady¹, G. Coyne², K. Power¹, Z. McCrea¹, O. Teltsh¹, D. Murphy², W. Northey², M. White¹, E. Gilbert¹, M. Grealley¹, R. Ileras³, C. Doherty^{4,5}, N. Delanty^{6,1}, M. Meagher², K. Marshall⁷, O. Rigby², G. L. Cavalleri¹; ¹Royal Coll. of Surgeons in Ireland, Dublin, Ireland, ²Akkure, Dublin, Ireland, ³Microsoft, New York, NY, ⁴Trinity Coll., Dublin, Ireland, ⁵St. James's Hosp., Dublin, Ireland, ⁶Beaumont Hosp., Dublin, Ireland, ⁷Microsoft, Dublin, Ireland

Abstract Body:

Background: Precision medicine requires the integration of clinical and genetic data to better understand disease, tailor treatment strategies and deliver improved patient outcomes. To facilitate the development of increasing targeted therapies, clinical trials will also need to become more personalized and stratified. However, recruitment continues to be a significant barrier for trial sponsors, clinical research teams and patients. This challenge can be met by connecting and stratifying patients to trials via their clinical and genomic data. Here we present BESTS- a cloud based platform developed for collaborative use by patients, healthcare providers (HCPs) and clinical research organisations. It allows patients to be intelligently matched to, and make their health data available for use in genomically-stratified clinical trials, while retaining complete control and ownership of that data. *Methods:* Twenty five participants representing potential users of BESTS engaged in a series of qualitative research methods including delphi interviews and ethnographic fieldwork to inform platform design and build. Applying a data privacy impact assessment approach, a dynamic consent module with an appropriate governance and rule-based permissions structure enabled by blockchain technology, was designed. A genomics module was developed to allow patients upload pre-existing genetic data or generate new data by accessing sequencing through the platform. A genomics working pipeline that facilitates automatic reanalysis was built based on GATK4 algorithms and deployed on Cromwell with Jupyter Notebook. An R script was added to create a shortlist of variants for ACMG classification. A proof of concept of the full pipeline was performed using whole genome and whole exome data. *Results:* Value propositions for patients included greater control around use of their data, personalised trial matching, contributing to research that benefits wider population and access to genetic sequencing. Value propositions for HCPs included identification of patients for trials, potential to demonstrate suitability as trial site, integration with electronic health records and access to characterised patient population. An early prototype of platform was developed and genomics pipeline deployed demonstrating successful delivery of appropriate output files. *Conclusion:* Embedding user centred design in the development of BESTS enables its realworld effectiveness and application. Access to genomic and phenome data through BESTS provides for high resolution recruitment to clinical trials, facilitating faster introduction of treatments into patient care pathways.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3201. Breast cancer related genes: a genome-first approach of the Geisinger and UK Biobank cohorts

Authors:

S. Kim^{1,2}, J. Kim¹, J. Haley³, M. Ramos¹, S. Rao³, B. Graubard¹, DiscoverEHR collaboration, H. Katki¹, D. Carey³, D. Stewart¹; ¹Natl. Cancer Inst., Rockville, MD, ²Johns Hopkins Med. Inst., Baltimore, MD, ³Geisinger, Danville, PA

Abstract Body:

Background: Breast cancer is the most common cancer in women and approximately 5-10% of patients harbor a germline pathogenic variant in a tumor-susceptibility gene. For low-to-moderate penetrance breast cancer genes, there is uncertainty about their prevalence, penetrance, and phenotype (other associated tumors). We undertook a genome-first approach to characterize these features in a set of 15 genes associated with breast cancer risk. **Methods:** Using the genome first approach from Geisinger (n=175,449) and UK Biobank (n=200,600), we investigated 15 genes (*ATM, BARD1, BRCA1, BRCA1, CHD1, CHEK2, MSH6, NF1, PALB2, PIK3CA, PTEN, RAD51C, RAD51D, RECQL and TP53*) previously reported to be associated with breast cancer risk. In both cohorts, pathogenic/likely pathogenic (P/LP) variants in 15 genes were annotated using ClinVar and InterVar. For each individual harboring a P/LP variant, history of breast cancer and other cancers was determined using the Electronic Health Records (EHR) and relevant registries; family history of cancer was also determined. Odds ratios (using matched non-carrier controls) were calculated to assess the risk of breast cancer of individuals with a P/LP variant. **Results:** In Geisinger, 7,229/175,449 individuals (4.1%) harbored at least one P/LP variant in one of the 15 genes; in the UK Biobank, 3,978/200,600 individuals (2.0%) harbored at least one P/LP variant in one of the 15 genes. Of these individuals, 504/7,229 (7.0%) in Geisinger and 389/3,978 (10.0%) in UK Biobank were diagnosed with breast cancer. Of these, 11/7,229 (0.2%) and 4/3,978 (0.1%) were male in Geisinger and UK Biobank, respectively. In UK Biobank, the risk of breast cancer was significantly increased in the individuals with P/LP variants in *BARD1, BRCA1, BRCA2, CHEK2, PALB2 and RAD51D* with the p-value <0.0001. In Geisinger, the risk of breast cancer was increased in *ATM, BRCA1, BRCA2, NF1, PALB2, and TP53* (P<0.05). In the UK Biobank among the patients with breast cancer, 1,501/3,978 (37.7%) had a family history of breast cancer (in the mother or siblings). **Conclusions:** Our results of the genome-first approach showed that P/LP variants in *BARD1, BRCA1, BRCA2, CHECK2, PALB2, RAD51D, NF1 and TP53* were associated with increased risk of breast cancer. We anticipate that the information on the other cancers related to these genes and the family history of cancers will help to plan on cancer screening and genetic counseling for the family.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday
PB3202. Brotman Baty Institute Clinical Variant Database (BBI-CVD).

Authors:

A. Folta¹, L. Santos², A. Sedeno Cortes¹, M. Horike-Pyne¹, M. Dubard-Gault², F. Hisama¹, A. Stergachis¹; ¹Univ. of Washington, Seattle, WA, ²Fred Hutchinson Cancer Ctr., Seattle, WA

Abstract Body:

Precision genomics has the potential to revolutionize clinical medicine by improving diagnosis and treatment of patients with common and rare disorders. However, clinical and genetic data for patients with rare disorders exist in silos, which limits the utility of extant variant databases, and inhibits collaboration between clinicians seeing patients with rare disorders and researchers studying the causative genes. To help overcome this, we have developed the Brotman Baty Institute Clinical Variant Database (BBI-CVD), which is a REDCap database of clinical germline genetic variant information from patients with rare genetic disorders seen at a tertiary academic medical center. This database captures demographic data, genetic testing indications, and genetic testing results for patients with rare genetic disorders cared for at the UW and/or Fred Hutchinson Cancer Center clinics. This database is available to researchers hoping to obtain detailed clinical information on individuals with a particular genetic variant, and we have developed a tiered system of data accessibility. Specifically, overview information regarding all the variants in our database is displayed through a web-based data explorer. Deidentified genetic and non-genetic diagnostic testing reports on participants within the BBI-CVD is available to any researcher upon request. Finally, researchers with separate IRB-approved protocols may request access to additional database information to identify individuals suitable for clinical trials that target specific genetic variants. While this database is primarily for the use of researchers, it also tracks important information for clinicians like indication frequency per gene, which will help clinicians monitor the use of genetic testing through the institution with the potential to change genetic testing guidelines. We will present preliminary data on the several hundred patients entered to date to demonstrate the utility of our database and its potential to advance precision genomics research. Overall, we hope that the BBI-CVD will serve as a bridge between clinicians and researchers working to resolve the many variants of uncertain significance, and enable development of new functional assays, diagnostic, and therapeutic approaches to rare diseases.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3203. Burden of Mendelian disorders in a large middle eastern biobank.

Authors:

W. Aamer¹, A. Al-Maraghi¹, N. Syed², A. Al-kurbi¹, G. D. Gandhi¹, O. Al-Saei¹, K. Al-Malki¹, S. Abbasi¹, N. Agrebi³, F. Abbaszadeh⁴, A. Akil¹, R. Badii⁴, N. Krishnamoorthy¹, B. Lo^{3,5}, The Qatar Genome Program Research Consortium, Y. Mokrab^{1,6}, K. Fakhro^{1,6,5}; ¹Lab. of Genomic Med., Sidra Med., Doha, Qatar, ²Applied Bioinformatics Core, Sidra Med., Doha, Qatar, ³Lab. of Immunoregulation, Sidra Med., Doha, Qatar, ⁴Diagnostic Genomic Div., Hamad Med. Corp., Doha, Qatar, ⁵Coll. of Hlth.and Life Sci., Hamad Bin Khalifa Univ., Doha, Qatar, ⁶Weill Cornell Med.-Qatar, Doha, Qatar

Abstract Body:

Genome sequencing has enabled the discovery of hundreds of Mendelian genes that are implicated in various phenotypes and diseases. Recently with the advance of large biobank cohorts, the interrogation of the mutational burden in seemingly healthy individuals has provided useful insight complementing small-scale family studies. Here, we interrogated 6,045 genomes from Qatar Biobank with over 60 associated qualitative/quantitative traits and assess Mendelian disease burden in this representative Middle Eastern population. By examining known pathogenic variants from Clinvar in 2,442 Mendelian genes, we identified 17 carriers with phenotypes or clinical history consistent with the pathogenic burden documented in the literature. We also identified novel pathogenic variants in known Mendelian genes including 3 putative disease-causing alleles with extreme quantitative traits. We performed rare-variant burden testing in Mendelian genes identifying 18 genes with high mutational load, six of which are related to a diabetes panel. This increased load is consistent with the high incidence of diabetes in Qatar and the region and suggests potential actionable options specific for these mutations. Novel pathogenic variants discovered in this cohort will be valuable for future research with relevance to the wider population in the region and worldwide and serve as useful resource for public health strategies for tackling genetic disease.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3204. Clinical Variants for Brain Gene Curation: A Powerful and Under-Utilized Resource.

Authors:

M. Chopra¹, J. Savatt², T. Bingaman², M. E. Good², M. Wangler³, K. German⁴, M. Wasserstein⁵, S. Walkley⁵, S. Molholm⁵, A. Gropman⁶, C. Arnerson⁷, L. Dewalt⁷, S. Shankar⁸, S. Mahida¹, V. Lanzotti⁹, J. Constantino¹⁴, Brain Gene Registry Consortium (Intellectual Disability and Research Centers); ¹Boston Children's Hosp., Boston, MA, ²Geisinger, Danville, PA, ³Baylor Coll. Med., Houston, TX, ⁴Univ. of Washington, Seattle, WA, ⁵Albert Einstein Coll. of Med., Bronx, NY, ⁶Children's Natl. Hosp., Washington, DC, ⁷Univ. of Wisconsin, Madison, WI, ⁸UC Davis, Sacramento, CA, ⁹Washington Univ., Washington, MO, ¹⁰UCLA, Los Angeles, CA, ¹¹Children's Hosp. of Philadelphia, Philadelphia, PA, ¹²Boston Children's Hosp, Boston, MA, ¹³Univ North Carolina, Chapel Hill, NC, ¹⁴Washington Univ., Saint Louis, MO

Abstract Body:

Establishing gene-disease validity and delineating new neurodevelopmental disorders (NDDs) rely on publicly accessible variant and phenotypic data. Variants identified during routine clinical care have the potential to contribute novel data to inform gene curation and phenotypic spectrum but are often siloed in medical records or internal databases. Although laboratories are encouraged to share variants with public databases, workflows are variable and accompanying phenotypic information is often incomplete. Case reports are prone to bias towards severity, and those beyond the initial report are less likely to be published. Such barriers result in the under-utilization of clinically ascertained genetic and health data. The National Brain Gene Registry (BGR) is an initiative harnessing clinically ascertained variants together with standardised neurobehavioral phenotyping and electronic health record (EHR) data to understand the role of genes implicated in NDDs. To evaluate our hypothesis that clinically ascertained variants are under-represented in publicly available resources, we selected 55 genes, focusing on those not previously curated for intellectual disability/autism by ClinGen (n=30), and those for which additional evidence could potentially change the existing classification (n=16). Eight BGR clinical sites searched for variants (VUS or above by ACMG criteria) in these genes using laboratory databases, EHRs and internal clinical databases. Variants were evaluated for presence in 7 disease databases - ClinVar, DenovoDB, Vericata, ADAMI DBD, LitVar, Decipher and HGMD. The search yielded 471 unique variants in 54 genes. Overall, 273 (58%) variants were absent in ClinVar, and 253 (54%) were absent from all databases, demonstrating the potential for this initiative to contribute novel data to the public knowledgebase. Furthermore, access to case-level data may impact variant classification. For the 198 variants present in ClinVar, 39 (20%) had aggregate ClinVar classifications of “conflicting” and 58 (29%) had aggregate classifications of “VUS.” In these instances, BGR participant phenotype and/or inheritance information could resolve discrepancies and shift to more definitive classifications. There were 40 variants (36%) with an aggregate ClinVar classification that conflicted with the BGR site-provided classification; this information could potentially be relayed to participants and result in a change in diagnostic course. The co-registration of genetic variant, phenotype and EHR data has the power to inform gene curation, the phenotypic spectrum of new and emerging Mendelian NDDs, and variant pathogenicity.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3205. Colorado Biobank Portal is a cloud platform for the interactive exploration of genome-wide association studies results

Authors:

N. Pozdeyev¹, N. Rafaels¹, S. Chavan¹, T. Phang¹, M. Lin¹, D. Mayer¹, I. M. Brooks¹, L. K. Wiley¹, R. Mathias², K. Barnes¹, C. R. Gignoux¹; ¹Univ. of Colorado Anschutz Med. Campus, Aurora, CO, ²Johns Hopkins Univ, Baltimore, MD

Abstract Body:

The number of genome-wide association studies (GWAS) is growing rapidly, increasing the need for interactive and functional web tools to explore large-scale GWAS summary statistics data. We developed Colorado Biobank Portal (CBP, <http://hdc-sandbox-bioengine.uw.r.appspot.com/>), a web portal that provides access to GWAS results for 1258 phenotypes for ~34K participants in the Colorado Center for Personalized Medicine (CCPM) Biobank. Phenotypes were defined with phecodes, and GWAS analyses were performed using REGENIE whole genome regression modeling software. To increase computational efficiency and reduce cost, up to 10 phenotypes clustered by data missingness were analyzed in a single run. CBP stores statistical analyses results, Ensembl Variant Effect Predictor annotation, information on exon, transcript and gene structures, gene aliases, and rsID identifiers in a Google BigQuery database. Each variant is assigned a unique integer coordinate spanning across all chromosomes. The database was partitioned by integer coordinate to allow for efficient data query and retrieval. The application's data access layer was programmed in the Python Flask web framework. Visualization templates were written in HTML, CSS, and JavaScript and were borrowed from the Global Biobank Engine open source code (<https://github.com/rivas-lab/GlobalBiobankEngine>) or newly created. The CBP is deployed on the Google App Engine managed platform. Innovations of the CBP include: 1) Scalable design enabling rapid and inexpensive access to ~53 billion GWAS summary statistics. 2) Support for both "horizontal" (by variant, region, transcript, or gene) and "vertical" (by phenotype) data requests. 3) Real-time phenome-wide association analysis for any of the 49.4 million genetic variants. 4) Low cost and maintenance-free serverless deployment. 5) Convenient user access and management with the help of the Google Identity platform. The CBP is free to use by the researchers at the University of Colorado and by collaborators from outside academic institutions sponsored by CCPM faculty. This technology can be used by other Biobanks worldwide and is being further developed to support new types of analyses such as genetic ancestry and polygenic risk score estimates.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3206. CombVar: A pipeline to combine variant impact from prioritizers, integrators, and annotations

Authors:

A. Nato¹, V. Magalhães Borges¹, R. Mingroni-Netto², A. V. R. Horimoto³; ¹Dept. of BioMed. Sci., Joan C. Edwards Sch. of Med., Marshall Univ., Huntington, WV, ²Dept. of Genetics and Evolutionary Biology, Univ. of Sao Paulo, Sao Paulo, SP, Brazil, ³Dept. of Biostatistics, Univ. of Washington, Seattle, WA

Abstract Body:

Variant annotation and prioritization are strategies known to facilitate the identification of genetic variants that have higher contributory effect to a disease. However, numerous variant prioritizers, integrators, and annotations exist, such that it may be challenging to specifically select which one to use for a particular dataset. Here, we develop CombVar, a pipeline written in R that employs an algorithm to combine variant information from multiple annotation sources as well as variant prioritizers and integrators. For the preliminary version of this pipeline, we included: (1) variant prioritizers and integrators (i.e., VAAST Variant Prioritizer (VVP), Ensembl Variant Effect Predictor (VEP), UCSC Variant Annotation Integrator (VAI), Combined Annotation Dependent Depletion (CADD), and Machine Learning Var (MLVar)) and (2) variant annotation databases (i.e., ANNOVAR, SIFT, PolyPhen-2, and Mutation Taster). CombVar provides salient information about variants being analyzed, including: (1) general annotation (e.g., alternative sequence, type of mutation, location, gene, transcript, and frequency), (2) classification based on ACMG/AMP guidelines, and (3) factors overlapping with the variant (e.g., epigenetic elements). For each variant, CombVar estimates an overall score λ , which ranges from 0 to 10 (with 10 being the highest), based on the impact of the variant, making it useful in evaluating its degree of pathogenicity from different sources. Users will be able to choose the prioritizer(s) and/or annotation(s) and the corresponding weights specific for their analysis. Using CombVar, we analyzed 20 associated genetic variants with suggestive/significant level of significance in our in-house essential hypertension dataset. For this test, equal weight was used for all sources. The scores ranged from 0.17 to 4.22. The top 3 genetic variants with the greatest probable impact on the phenotype are: rs1805087 ($\lambda= 4.22$), rs79656879 ($\lambda= 2.34$), and rs12602540 ($\lambda= 2.08$).

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday
PB3207. Concordance in variant calls from short-read sequencing data of admixed individuals using different reference genomes

Authors:

T. de Oliveira, W. Souza, B. Carvalho, I. Lopes-Cendes; Univ. of Campinas, Campinas, Brazil

Abstract Body:

Introduction: The recent completion of the human genome (CHM13) by the T2T consortium has identified the missing 8% of the human genome contained in the references GRCh37 and CRCh38. The present work compares the impact of using the different human genome assemblies as a reference for variant identification in exome data generated from admixed Brazilian individuals. **Materials and Methods:** We analyzed 318 exomes from the Brazilian Initiative of Precision Medicine (bipmed.org). Raw sequences were aligned to GRCh37, CRCh38, and CHM13 using BWA-MEM. Local realignment and variant calling were performed with the GATK best practices workflow. We used the PLINK software to perform several filtering strategies, including thresholds in missing genotypes and samples, relatedness, and heterozygosity deviation. Variant lift-over and comparisons among the variant datasets were performed using the liftover tool. Concordant and discordant variants were compared using vcfeval. Identification of discordant reference patches (DISCREPs) and enrichment analysis for genomic features were performed as described in <https://github.com/hurleyLi/discreps>. **Results:** We identified similar numbers of filtered variants (~175,000) when using the three reference assemblies. However, approximately 7.6% of the variants were discordant when comparing calls using the different assemblies. Furthermore, around 60% of these discordant variants were uniquely identified in the CHM13 assembly. Also, we found DISCREPs in 0.6% of the tested genomic 10kb-windows, and these were enriched for variants in the comparisons between GRCh37 and CHM13-GRCh37 and when comparing GRCh38 and CHM13- GRCh38 (rate $q < 0.01$). Furthermore, we found that DISCREPs were also enriched in alternate haplotypes called with the GRCh38 assembly and in single tandem repeats found with the GRCh37. **Conclusion:** Our results indicate that discrepancies in variant calls are seen predominantly in regions known to contain repeat sequences. Also, these differences do not seem to be due to problems in the assemblies of the previous reference genomes. This is an ongoing project, and we plan to perform additional annotations using the CHM13 reference, including the verification of gene enrichments which will help us better quantify the impacts of the changing reference genomes on common and rare variants. We believe that our results are relevant for improving genetic diagnosis practices in admixed individuals.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3208. Distance-based panel generation optimizes gene selection for targeted gene panel design

Authors:

O. Isakov^{1,2,3}, S. Ben Shachar^{1,3,4}; ¹Clalit Res. Inst., Innovation Div., Clalit Hlth.Services, Tel Aviv, Israel, ²Raphael Recanati Genetic Inst., Rabin Med. Ctr.-Beilinson Hosp., Petach Tikva, Israel, ³The Ivan and Francesca Berkowitz Family Living Lab. Collaboration, at Harvard Med. Sch. and Clalit Res. Inst., Boston, MA, ⁴Sackler Faculty of Med., Tel Aviv, Israel

Abstract Body:

Background: Targeted gene panel sequencing is used to limit the search for causative genetic variants to genes associated with a certain phenotype. Collaborative tools, such as PanelApp, facilitate gene panels design based on expert review and include mostly genes with a strong association to the phenotype. This approach limits the sensitivity of the panel to identify causative variants in genes with weaker phenotypic association. Available commercial panels differ significantly from one another and some include genes without a clear association to the phenotype. Taken together, designing or selecting the most appropriate gene panel for a given phenotype is often challenging.

Aim: Review the gene content in panels for various phenotypes from different vendors world-wide and compare them with curated gene panels. Develop a method to improve gene panel design based on the collective wisdom represented by the publicly available gene panels.

Methods: Publicly available gene panel data was downloaded from the Genetic Testing Registry (GTR) and the PanelApp web server. Panels corresponding to 20 different phenotypes were selected for analysis. Naive-search panels were generated by unifying all the genes in all the panels identified by a naive text based phenotype search. Inter-panel gene content distance was calculated using the Jaccard index.

Distance based panels were generated by collecting all the genes found in panels similar to a prespecified PanelApp panel and scoring them according to the distance of their original panel from the PanelApp panel. For each gene in each panel, a literature search was run in order to elucidate the number of publications associating it with the phenotype. Performance metrics were then calculated for each panel based on the cumulative identified gene-phenotype associations.

Results: A total of 6053 panels from 225 different vendors were found in the GTR. For the selected phenotypes, a naive search identified, on average, 25.6 panels per phenotype (IQR [16.75,29.5]). High inter-panel discrepancy was noted for most phenotypes, with almost half of the genes (45.9%) IQR[35.6%,68.4%] found in less than 10% of the collected panels. Compared to the naive search panel, the distance based panel achieved a higher PPV while maintaining comparable sensitivity (difference = 0.05, 95% CI [0.01, 0.10]). Compared to the curated PanelApp panels, the distance based panels demonstrated a higher F1 score (difference = 0.08, 95% CI [0.04, 0.11]).

Conclusion: Panels generated using a distance based method maintain accurate gene content compared to curated panels while enabling a more comprehensive inclusion of phenotypically relevant genes.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3209. Dynamically querying thousands of genomes to identify genetically matched cohorts with Intel® Optane™ Persistent Memory.

Authors:

K. Schneider¹, M. Chowdhury¹, M. Tepper², J. Khan², S. Dongaonkar², C. Gignoux³, R. Layer⁴; ¹Univ. of Colorado Boulder, Boulder, CO, ²Intel Labs, Hillsboro, OR, ³Univ of Colorado Denver, Anschutz Med. Campus, Aurora, CO, ⁴Univ. of Colorado, Boulder, CO

Abstract Body:

Reproduction, migration, and random mutation events over hundreds of millennia have contributed to incredible genetic diversity across the human population. The nuance of this genetic diversity contributes to challenges for computation methods in precision medicine. For example, calculating polygenic risk scores (PRSs) is an effective way to identify an individual's risk of disease onset. This calculation requires a comparative analysis against the individual, a large cohort of individuals who present with some diseases, and a large cohort who do not. However, PRSs have little application across distinct genetic background (i.e. PRSs calculated across cohorts of European ancestry will not accurately describe risk for individuals of African descent). To mitigate this limitation, current methods use pre-defined cohorts of ancestry (e.g. European, African, Puerto Rican, etc.) to compute respective ancestry-based PRSs. These pre-defined cohorts still do not capture the complete diversity of the human population, and do not address the complexity of population-wide data being introduced by emerging datasets (e.g. H3Africa, PRS Diversity Consortium, IGNITE, eMERGE, etc.). To address these problems, it is necessary to identify cohorts of genetically similar individuals among a large population, disparate from pre-defined ancestry, with speed and accuracy. We propose a method to dynamically identify cohorts of genetically matched individuals by (1) performing highly accurate similarity searches for full-population, genome-wide analyses; and (2) enable precision queries for new samples. Our method adopts a similarity search method which leverages the Intel® Optane™ Persistent Memory system. We included custom encoding for phased genotypes on genetic variation data; and designed novel query algorithms to allow for quick whole-genome cohort identification for incoming samples. Our method improves upon current methods in both accuracy and speed of search, and introduces the novelty of dynamic searching for new patients. Adoption of this method will be a first step in precision medicine pipelines to more accurately describe how genetic variation between individuals contributes to the risk, onset, and progression of many known human diseases.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3210. Early development of a locus specific database for *GUSB*, the gene associated with Mucopolysaccharidosis type VII: hints of a higher predicted prevalence.

Authors:

S. Daugherty¹, V. Rangel Miller¹, D. Garica¹, R. Giugliani², O. K. Japalaghi¹, D. Marsden¹, H. McLaughlin³, A. Willcock⁴, M. Hegde⁵, N. Miller¹; ¹Ultragenyx Pharmaceutical, Novato, CA, ²HCPA/UFRGS, Porto Alegre, Brazil, ³Invitae, South Lyon, MI, ⁴Invitae Corp., San Francisco, CA, ⁵PerkinElmer, Lilburn, GA

Abstract Body:

Accurate interpretation of rare genetic variants is essential for diagnosis and, in ultra-rare disease, is confounded by variants of uncertain significance (VUS). Mucopolysaccharidosis type VII (MPS VII) is an ultra-rare, autosomal recessive, lysosomal storage disease caused by β -glucuronidase (*GUSB*) enzyme deficiency. MPS VII may present early with nonimmune hydrops fetalis (NIHF), which can lead to death in utero or early infancy, or may present later with skeletal dysplasia, dysmorphology and cardio-pulmonary signs. MPS VII is estimated to occur in 0.02-0.027/100,000 newborns with an overall prevalence of 0.07/million, but we hypothesize this number underestimates true frequency due to unrecognized atypical disease and perinatal lethal cases.

We integrated data from public databases and Ultragenyx clinical and sponsored genetic testing programs through March 2022 to develop a *GUSB* gene database. Prevalence estimates were calculated using allele frequency data from gnomAD and a published Bayesian estimation method for analyzing ultra-rare disease frequency. A total of 231 unique *GUSB* variants were collected and 189 were associated with an ACMG classification criteria: pathogenic (P) or likely pathogenic (LP) 61 (33%), VUS 118 (62%), benign 10 (5%). 90 (39%) of these variants were not present in ClinVar, including 34 published variants from HGMD. To predict prevalence of MPS VII based on these data, we first analyzed all P and LP variants. The Bayesian estimation gave a prevalence of 1.49/million (95% CI= 1-2/million) or ~1/670,000. Given the high rate of VUS, we next included all VUS variants with a Combined Annotation Dependent Depletion (CADD) phred score >20, adding 27 VUS to the analysis, which increased the Bayesian estimation of prevalence to 9.11/million (95% CI = 7.5 -10.7/million) or ~1/110,000. This dataset revealed the high frequency of *GUSB* variants classified as VUS, underscoring the importance of parallel biochemical and molecular diagnosis of MPS VII. Our prevalence estimates suggest a higher potential prevalence of MPS VII and future studies are warranted to understand whether perinatal lethality, lack of diagnosis of atypical MPS VII, or both depress the predicted population frequency. We plan to expand the *GUSB* dataset with additional global evidence to further refine the prediction. Data-sharing efforts are critical to support accurate and consistent variant interpretation in ultra-rare disease, particularly for newborn screening (NBS) as MPS VII is screened for in multiple NBS pilots around the world.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3211. Efficient querying of genomic reference databases with *gget*

Authors:

L. Luebbert, L. Pachter; California Inst. of Technology, Pasadena, CA

Abstract Body:

A recurring challenge in interpreting genomic data is the assessment of results in the context of existing reference databases. Currently, there is no tool implementing automated, easy programmatic access to curated reference information stored in a diverse collection of large, public genomic databases. *gget* is a free and open-source command-line tool and Python package that enables efficient querying of genomic reference databases, such as Ensembl. *gget* consists of a collection of separate but interoperable modules, each designed to facilitate one type of database querying required for genomic data analysis in a single line of code. The manual and source code are available at <https://github.com/pachterlab/gget>.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3212. Efficient reinterpretation of rare disease cases using Exomiser

Authors:

L. Vestito¹, Genomics England Research Consortium, Monarch Initiative, J. Jacobsen¹, P. Robinson², D. Smedley¹; ¹Queen Mary Univ. of London, London, United Kingdom, ²The Jackson Lab. for Genomic Med., Farmington, CT

Abstract Body:

High-throughput and lower-cost sequencing have enabled the integration of whole-exome and whole-genome sequencing (WES/WGS) in clinical practice and the advent of large sequencing projects, like the UK's 100,000 Genomes Project. These extraordinary advances enabled the discovery of hundreds of novel gene-disease associations per year, published in peer reviewed journals. However, despite this impressive discovery rate, a substantial fraction of patients (75-80%) remain currently undiagnosed following WES/WGS. To address this, a periodic reinterpretation of the genetic data for undiagnosed individuals has been proven to increase the diagnostic yield by 10-15% and has the potential to bridge the gap between the dynamic scientific knowledge and clinical practice for patient benefit. A new diagnosis can lead to tailored therapeutic management, more accurate genetic counselling and better prognosis. Exomiser, a phenotype-driven tool to annotate, filter and prioritise likely causative variants, integrates numerous data sources and leverages information on variant frequency, predicted pathogenicity and semantic similarity between the Human Phenotype Ontology (HPO) terms describing patient's phenotype and the phenotypic annotations of human diseases (OMIM/Orphanet), orthologs in mice (MGI/IMPC) or zebrafish (ZFIN) model organisms, and phenotypes of protein-protein associated neighbours (STRING). We tested and compared the ability of seven releases of the Exomiser database from Feb 2019 until Feb 2022 to detect 37 real patient diagnoses from the 100,000 Genomes Project, in one of the 556 disease-gene associations that first appeared in OMIM since Feb 2019. We investigated in detail the distribution of Exomiser variant, phenotype, human phenotype and combined scores over time and settled on a threshold of variant score ≥ 0.8 and an increase in human phenotype score ≥ 0.2 between Exomiser releases as the optimal way to detect candidates based on novel emerging evidences published in clinically-relevant databases such OMIM, Orphanet or ClinVar. These thresholds highlighted 54 variants of interest in the 37 solved cases, with 31 being the correct diagnosis, representing impressive recall (84%) and precision (57%). Over time, Exomiser also successfully re-classifies these variants from variants of unknown significance (VUS) to pathogenic (P) or likely pathogenic (LP) in 34/37 of the cases, following an automated ACMG/AMP variant classification pipeline.

In conclusion, our data show the ability of Exomiser to highlight and re-classify novel candidates for diagnosis over time in light of novel emerging evidence of gene-disease associations.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3213. Genomic database query tracking to understand the prevalence of rare diseases: *ASAH1* in the VarSome database

Authors:

N. Confer¹, K. Crosby¹, A. Joyner², S. Solyom¹; ¹Aceragen, Durham, NC, ²Saphetor, Lausanne, Switzerland

Abstract Body:

Pathogenic variants in *ASAH1* cause acid ceramidase deficiency with a spectrum of phenotypes including Farber disease and spinal muscular atrophy with progressive myoclonic epilepsy (SMA-PME). *ASAH1*-related conditions are considered ultra-rare with fewer than 250 cases reported in the medical literature, but the prevalence is likely under-reported. VarSome is a community-driven search engine of human genome variant data that allows clinical and research professionals to search more than 130 harmonized datasets within a single interface. VarSome data searches are utilized in over 150 countries by hundreds of thousands of users to perform genome-wide variant evaluations by ACMG guidelines. In this study we used the VarSome database to aggregate *ASAH1* queries over the past two years to quantify the total number of variants, unique users and countries represented. These data were compared to historical literature to improve the prevalence estimation for Farber disease and SMA-PME, globally and by country. Since the first case of Farber disease in 1952, approximately 200 additional cases of Farber and 50 cases of SMA-PME have been published. These cases are from 32 countries with Egypt (14% of cases), the United States (13%), Iran (9%), France (9%) and Italy (8%) being the most represented. A recent review article lists 73 total published pathogenic/likely pathogenic (P/LP) variants in the *ASAH1* gene. For comparison, from May 2020 to May 2022, there were 787 distinct queries in the VarSome database for variants in the *ASAH1* gene. These queries were submitted by 717 unique users in 61 different countries, with Iran (16% of queries), Turkey (11%), Spain (8%), India (6%), and Russia (5%) being the most represented. There were 250 unique variants represented in these queries, with 69 P/LP (28%), 48 benign/likely benign (19%), and 133 variants of uncertain significance (53%). The number of countries and unique users represented in VarSome queries over the previous 2 years suggests the prevalence of *ASAH1*-related conditions is underestimated. This use of a large consolidated variant database to estimate prevalence for rare diseases may be superior to traditional literature-based approaches, while also essential to the conducting of natural history studies and successful enrollment of patients in clinical trials. These findings further support that published cases often under-represent the prevalence and geographic distribution of a rare disease.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3214. Global landscape of primary omics data generation and its secondary analysis across 193 countries and territories

Authors:

Q. Peng¹, N. Darci-Maher², Y. Patel¹, M. Vahed¹, A. Rathore³, G. Sharma³, S. Mangul¹; ¹Univ. of Southern California, Los Angeles, CA, ²Univ. of California, Los Angeles (UCLA), Los Angeles, CA, ³Inst. of Bioinformatics and Applied Biotechnology (IBAB), Bengaluru, India

Abstract Body:

Traditionally, novel scientific discoveries were a privilege of researchers who generated data, and no further analyses were conducted after the generation of original data. However, as we entered the era of omics, researchers have gradually attached more importance to re-analysis of existing open-access data. Instead of generating new data in the lab, some researchers tend to analyze existing data for new hypotheses in the form of a new research question or an alternative perspective on the original question. This process, known as secondary analysis, may enable novel discoveries across a variety of disciplines, including computational biology and medicine. Also, the secondary analysis excludes the cost of data-generating, therefore, helping in economic sustainability, making it a suitable research technique for countries with limited resources. Despite numerous advantages of secondary analysis of omics data, the scale of the secondary analysis across various countries of omics data is currently unexplored. Also, it remains unidentified whether secondary analysis was adopted more in developing countries or remains the privilege of developed countries. To address these emerging questions, we have performed a comprehensive analysis of omics datasets submitted via open-access, their sources, and the reusability of public omic datasets based on 4.2 million open-access publications published between 2001 and 2021. Among these publications, 148,239 papers containing SRA or GEO accession numbers were classified as studies generating data or performing secondary analysis. The selected papers were further classified as primary analysis or secondary analysis papers. The classification was done by comparing the publication date of a given dataset to the publication date of each paper including the dataset. The earliest-published publication was marked as primary analysis, and the rest of the publications (if they existed) were marked as secondary analysis. The countries where the data was generated and/or data analysis was performed were identified. The affiliated country of the last author was considered the country for the respective dataset. These data uncovered the scales and features of secondary analysis across 193 countries and territories. In this study, we also discussed factors limiting secondary analysis in countries with limited resources were discussed. Lastly, we identified challenges associated with secondary analysis and needs in bioinformatics training.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3215. Growing a research ecosystem in the cloud: Early insights from the All of Us Research Program.

Authors:

C. Lunt¹, K. Mayo², H. Master²; ¹NIH, Bethesda, MD, ²Vanderbilt, Nashville, TN

Abstract Body:

Background: The NIH *All of Us* Research Program makes phenotypic and genomic data available for more than 350,000 participants on a cloud-based research platform, the Researcher Workbench (RW). Approved researchers conduct projects in collaborative workspaces. To promote transparency, information about each workspace's research purpose and team are publicly available. De-identified, row-level phenotypic data has been available since May 2020, and the program released a new "controlled tier" of data in March 2022, containing the first nearly 100,000 whole genome sequences from *All of Us* participants. Here, we demonstrate how workspace usage and description data can be used to characterize the current *All of Us* research ecosystem. Specifically, we describe the current researcher community and examine emerging trends and research topics.

Methods: Researcher demographic information and workspace data were collected during researcher account and workspace creation and analyzed to inform RW utilization and collaboration. Additionally, Natural Language Processing was used to evaluate the emerging research topics from workspace descriptions.

Results: As of June 2022, the *All of Us* researcher community is composed of more than 2,000 researchers across different career stages and settings. Over 83% describe themselves as students, trainees, or early career investigators. These researchers represent 354 institutions from more than 45 states. More than 1,500 workspaces use "registered tier" data, and span a broad range of topics including education and methods development. Most research is centered on disease, and our analysis suggests that diabetes, cancer, and cardiovascular disease are the 3 most analyzed topics. Furthermore, researchers have created more than 400 controlled tier workspaces. Given the availability of diverse genomic data in this tier, a significant number of projects are focused on understanding health and disease in minority populations.

Conclusion: Cloud-based analysis platforms like the RW enable real-time characterization of growing research communities. Our findings suggest that this resource may help develop a biomedical research workforce hungry to advance our understanding of health in underserved populations.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday
PB3216. HLA-SPREAD: a natural language processing based resource for curating HLA association from PubMed abstracts

Authors:

D. Dholakia; CSIR-IGIB, Delhi, India

Abstract Body:

Extreme complexity in the Human Leukocyte Antigens (HLA) system and its nomenclature makes it difficult to interpret and integrate relevant information for HLA associations with diseases, Adverse Drug Reactions (ADR) and Transplantation. PubMed search displays ~ 146,000 studies on HLA reported from diverse locations. Currently, IPD-IMGT/HLA (Robinson et al., Nucleic Acids Research 48:D948-D955, 2019) database houses data on 28,320 HLA alleles. We developed an automated pipeline with a unified graphical user interface HLA-SPREAD that provides a structured information on SNPs, Populations, REsources, ADRs and Diseases information. Information on HLA was extracted from ~ 28 million PubMed abstracts extracted using Natural Language Processing (NLP). Python scripts were used to mine and curate information on diseases, filter false positives and categorize to 24 tree hierarchical groups and named Entity Recognition (NER) algorithms followed by semantic analysis to infer HLA association(s). This resource from 109 countries and 40 ethnic groups provides interesting insights on: markers associated with allelic/haplotypic association in autoimmune, cancer, viral and skin diseases, transplantation outcome and ADRs for hypersensitivity. Summary information on clinically relevant biomarkers related to HLA disease associations with mapped susceptible/risk alleles are readily retrievable from HLA-SPREAD. The resource is available at URL <http://hla-spread.igib.res.in/>. This resource is first of its kind that can help uncover novel patterns in HLA gene-disease associations.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday
PB3217*. How UK Biobank is democratising access to large-scale genomic and phenotypic data for discovery science

Authors:

B. Lacey¹, N. Allen², M. Effingham³, M. Pancholi³, L. Carson³, L. Burkitt-Gray³, R. Collins¹; ¹UK Biobank, Univ. of Oxford, Oxford, United Kingdom, ²UK Biobank, Univ. of Oxford, OXFORD, United Kingdom, ³UK Biobank, Stockport, United Kingdom

Abstract Body:

UK Biobank is scientifically unparalleled as a biomedical research study and is now arguably the world's most important health research resource. With its unique combination of scale, depth, maturity and accessibility, the resource is enabling researchers worldwide to make scientific discoveries that improve human health. UK Biobank has collected (and continues to collect) detailed data on genetics, biomarkers and lifestyle factors from half a million people across the UK, whose health has been followed up for about 15 years through linkage to electronic health records.

UK Biobank has integrated large-scale genomic data (in 500,000 participants) with deep phenotyping data (including lifestyle factors, physical measures, accelerometry and multi-modal imaging), coupled with long-term longitudinal health records. The ability to leverage significant funding from public-private partnerships to perform cohort-wide whole-exome and whole-genome sequencing (with genome-wide genotyping and imputation already available) has made UK Biobank one of the world's most important resource for identifying rare genetic variants that are particularly valuable for drug discovery. The addition of large-scale proteomic data is creating an even more powerful resource for the identification of protein quantitative trait loci for protein biomarkers of thousands of phenotypic traits; together with large-scale metabolomics, transcriptomics and whole-body imaging data, UK Biobank will enable a better understanding of disease biology and will support innovative drug development for more effective therapies.

To accommodate the rapid growth of the resource and to enable more researchers across the world to access these data without limitations of transferring, collating, storing, and accessing data at this scale, UK Biobank launched an innovative cloud-based Research Analysis Platform (RAP) in 2021, democratising access to large scale compute and novel technologies. The availability of financial research credits for early-career researchers and those from low and middle-income countries is further democratising access to this unique resource. The RAP also serves to foster greater collaboration between researchers around the world by allowing users to analyse multiple data types together and to benefit from the returned data from other researchers within the cloud-based platform.

Ready access for researchers around the world to the combination of in-depth genomic, other -omic, imaging, lifestyle and health information from half a million UK participants is enabling novel research that is advancing discovery science and improving human health.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday
PB3218. Identification and characterization of genomic variations from population scale whole genome sequencing in south India.

Authors:

B. Kahali; Ctr. for Brain Res., Indian Inst. of Sci., Bangalore, India

Abstract Body:

Representation of Indians in human genetic studies has been limited so far. Therefore, population-specific reference genome datasets as well as genome-wide association studies in Indian population are warranted. India's population of 1.3 billion comprising >4,500 well defined ethnic groups could have numerous distinct genetic variations resulting from the rich genetic and social diversity of the country, multiple waves of migration into the country over the past thousands of years, and unique socio-cultural practices followed by extant population groups. Here, we present a comprehensive analysis of SNPs and InDels in about 650 individuals from the TATA Longitudinal Study of Aging (TLSA) and Srinivaspura Aging Neurosenescence and Cognition (SANSCOG) population-based cohorts, including data from more than twenty population groups across South India. We identify and characterize about 30 million SNPs and 4.5 million InDels from deep (40X) coverage short-read whole genome sequencing data. The rare variants hugely outnumber the common variants, and about two-thirds of our identified SNPs and InDels are present in <1% individuals in our dataset. 3% of our identified variations are present in coding regions. Out of 12,000 frameshift causing variations, 4300 are rare in our study. We find that on an average each individual can carry 20 variants that are intolerant to protein coding loss of function changes. We elucidate the population structure and disease associations inferred from these genetic variants. We also report the performance of these genetic variants in imputation, to facilitate genetic studies in Indian populations across Asia and worldwide. This work will help pilot the detection and characterization of genetic variations in understudied population based and disease cohort studies and help address the underrepresentation of genetic variant discovery from non-European, especially South Asian populations. Finally, this dataset will be a resource for designing, and interpreting large scale association and functional genomic studies in Indian population that could pave the way for devising better diagnosis and treatment strategies for a substantial proportion of world population.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday
PB3219. Identifying Variants of Interest in Samples with Whole Genome Sequencing Data using Kids First Variant WorkBench

Authors:

Y. Guo¹, J. Costanza², A. Resnick¹, V. Ferretti², Kids First Data Resource Center; ¹The Children's Hosp. of Philadelphia, Philadelphia, PA, ²Ctr. Hosp.ier Univ.ire Sainte-Justine, Montréal, QC, Canada

Abstract Body:

Kids First Data Resource Center developed Kids First Data Resource Portal (KFDRP; <https://portal.kidsfirstdrc.org/>), which is a centralized data platform for both Kids First and collaborative cohorts. The recently released KFDRP component named Variant WorkBench (VWB) enables users to query, mangle, analyze and visualize germline genomic variants. We demonstrate the feasibility of analyzing germline Whole Genome Sequencing (WGS) data using VWB for customized families whose vcf files are provided by the user. The VWB uses Zeppelin notebooks for scripting and the current effort has four steps which are all written in notebook paragraphs. The first step is database initialization, loading variant annotations in the public domain, such as Cancer Hotspots, ClinVar, COSMIC, dbNSFP, gnomAD, TOPMed, as well as gene-phenotype links provided by OMIM, HPO, Orphanet, and the Deciphering Developmental Disorders Project. Then as the second step, we use Glow, an open-source toolkit for working with genomic data at biobank-scale and beyond, to read in the vcf file (either single- or multi-sample) then store the vcf file as a dataframe. In the third step, we join the newly generated dataframe with tables initialized in the first step to annotate the variants, and label variants with inheritance patterns according to the observed genotypes stored in the dataframe. Lastly, we flag a list of variants satisfying the user's predefined criteria such as minor allele frequency thresholds in general population, variant deleteriousness assessment scores, and gene-disease correlations, then export this list into an external file in the Cavatica system, enabling further review. As an example, we selected a family trio of a boy with kidney and urinary tract defects and healthy parents, input a three-sample vcf file into VWB, ran the notebook and discovered a missense variant in *TRAP1* which is homozygous in the proband and heterozygous in both parents. This variant is reported before as pathogenic in a cohort with Congenital Anomalies of the Kidney and Urinary Tract, indicating the ability of using VWB to identify variants linked to genetic disorders.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3220. Indiana Biobank: a resource of linked electronic health records, omics data, genetic data, and biospecimens for the research community.

Authors:

D. Lai¹, T-H. Schwantes-An¹, A. Roberts², M. Abreu¹, J. Lee¹, M. Zhang¹, B. Patz¹, T. Foroud¹; ¹Indiana Univ. Sch. of Med., Indianapolis, IN, ²Regenstrief Inst., Indianapolis, IN

Abstract Body:

Indiana Biobank (<https://indianabiobank.org/>) is a state-wide collaborative effort that combines state-of-the-art centralized biobanking and linked electronic health records (HER). Each participant's de-identified EHR are available via the Indiana Network for Patient Care (INPC) supported by the Regenstrief Institute at Indiana University School of Medicine. Currently, Indiana Biobank has DNA from over 50,000 broadly consented participants and actively adds over 100 new participants each week. More than 9,000 samples have been genome-wide genotyped and more than 6,000 samples have been whole exome sequenced; the rest of the samples will be genotyped and sequenced in the near future. Additionally, transcriptomics, metabolomics, and HLA haplotype data are available in subsets of participants. The EHR includes basic demographic information, diagnoses based on ICD9/10 codes, hospitalization information, laboratory test results, and prescription drug information obtained from patients at each visit, all de-identified by the Regenstrief Institute. Furthermore, information extracted from the physicians' note using natural language processing are also available, which is especially important for rare diseases not indexed by ICD codes. Recently, COVID-19 testing, vaccination, and hospitalization data from over 27,000 participants (including 4,700 with genotype data) were added. For samples that have been genotyped, 42.71% are male; 76.44% are white; and 21.87% are black. The average age at enrollment and last visit are 53.51 (SD=15.36; range: 1.77-96.68) and 58.43 (SD=15.33; range: 4.66-101.80), respectively. The majority of Indiana Biobank participants are unrelated. Based on ICD9/10 codes, >506 diseases have >100 cases and these data can be included in meta-analyses or for replication of previous genome-wide association studies (GWAS) findings. We have calculated >2,100 polygenic risk scores (PRS) from The Polygenic Score Catalog. Phenome-wide GWAS (PheGWAS) and genetic correlation studies are ongoing. With appropriate approvals, summary information (GWAS, PRS, and genetic correlations, etc.) will be made available to academic investigators via an online searchable platform. The Indiana Biobank is a growing resource for the research community that combines EHR, omics, and genetic data to improve patient care.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3221. JBrowse 2: a modular genome browser for visualizing synteny and structural variants

Authors:

I. Holmes¹, C. Diesh¹, R. Buels¹, G. Stevens¹, T. Martinez¹, S. Dider¹, C. Bridge², S. Cain², R. Haw², L. Stein³; ¹Univ. of California, Berkeley, CA, ²Ontario Inst. for Cancer Res., Toronto, ON, Canada, ³Ontario Institute for Cancer Res., Toronto, ON, Canada

Abstract Body:

Genome browsers are useful tools for research in human genetics, able to display and integrate biological information such as long and short read sequencing data, variant calls, and annotations. While traditional linear genome browsers have demonstrated broad utility for many applications, there is an increasing need for visualizing complex structural variants (SVs) beyond the linear view. To meet these challenges, we created JBrowse 2: an extensible open-source platform for visualizing and integrating genomic data. JBrowse 2 is a modular general purpose genome browser that can display linear, circular, synteny, and other types of views. To facilitate academic collaboration and innovation, JBrowse 2 has been designed with a pluggable interface that permits the development of features tailored to the specific needs of an individual or organization.

Unique to JBrowse 2 are its specialized structural variant views. JBrowse 2 can display discontinuous regions side-by-side or vertically stacked. Large or inter-chromosomal structural variants can be visualized with the read evidence (split long reads or paired end reads) shown with connected lines. Users can also visualize de novo assembled contigs or individual long reads aligned to a reference either with a synteny-style view or a dotplot view, each clearly showing inversions, deletions, and insertions. Whole-genome overviews of coverage (or other quantitative data) reveal copy number variation and large-scale duplications.

JBrowse 2 can be run on a web page, as a desktop application, inside Jupyter notebooks, from R sessions, or via the command line. A plugin framework enables developers to create new data adapters, track types, and view types. We have also integrated JBrowse 2 with R and Python ecosystems with JBrowseR, installable from CRAN, and dash_jbrowse, a widget that can embed JBrowse 2 in Jupyter notebooks.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3222. Lifebit delivers a federated Trusted Research Environment to allow researchers seamless access to 35,000 whole genomes in a novel COVID-19 cohort.

Authors:

N. Raine¹, M. Chatzou Dunford¹, P. Prieto Barja¹, C. Bacchelli¹, B. Goncalves¹, D. Silva¹, C. Chatzipantsiou¹, I. Peral Alvarez¹, D. Ardley¹, C. Davison¹, I. Knarston¹, T. Seeger¹, P. Moss²; ¹Lifebit Biotech Ltd, London, United Kingdom, ²Genomics England, London, United Kingdom

Abstract Body:

The COVID-19 pandemic has caused immeasurable global harm. However, the pandemic has also seen unprecedented collaboration and data sharing efforts worldwide. Genomics has played a central role in the COVID-19 response. Not least the fact that millions of whole genomes of SARS-CoV-2 have been uploaded to the international Global Initiative on Sharing Avian Influenza Data (GISAID) database to be shared globally. This near-real-time sequencing was the first time this technology was applied to rapidly inform public-health decisions and showed the world the power of genomics and global collaboration. However, COVID-19 remains a prominent public health issue with considerable impact beyond deaths and hospitalisations. One meta-analysis revealed that 56.9% of people infected with SARS-CoV-2 had at least one long-covid symptom at a median follow-up of 6-months. Genomics research could prove an invaluable resource to continue to track the evolution of SARS-CoV-2 and provide insights into patient response to infection, elucidating critical mechanisms of disease severity, potentially resulting in novel treatment options. To tackle these challenges, researchers require patients' linked genomic and health data. This data is being generated worldwide in multiple clinical trials; however, due to the sensitive nature of the data, it becomes siloed within hospitals and health services and proves difficult to access for research. To address this challenge and answer these key research questions, Genomics England (GEL), in partnership with the GenOMICC consortium, accomplished whole genome sequencing of 35,000 COVID-19 patients, 20,000 intensive care patients collected from 230+ hospitals across the UK and 15,000 people with mild symptoms. GEL selected Lifebit CloudOS as its new secure research platform or 'Trusted Research Environment' to enable rapid, secure access and analysis to this cohort. With a fully federated architecture, CloudOS has allowed GEL to securely retain this sensitive patient dataset within their own cloud environment, while CloudOS is deployed as a virtual abstraction layer. Federation allows approved researchers anywhere in the world to seamlessly access this large dataset of real-world data and perform analysis within the CloudOS platform. Analysis of this dataset has the potential to understand COVID-19 better, leading to discoveries of genetic factors relating to disease severity. Lifebit's federated CloudOS is a validated high-performance solution for population-level health data management. It addresses the problem of data sharing and collaboration with these datasets, which contains highly valuable but sensitive data.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3223. MANE Select and beyond: expanding the joint NCBI and EMBL-EBI transcript set

Authors:

J. Loveland¹, S. Pujar², A. Astashyn², R. Bennett¹, A. Berry¹, E. Cox², C. Davidson¹, O. Ermolaeva², C. Farrell², R. Fatima¹, T. Goldfarb², J. Gonzalez¹, D. Haddad², M. Hardy¹, T. Hunt¹, J. Jackson², V. Joarda², M. Kay¹, V. Kodali², K. McGarvey², J. Mudge¹, M. Murphy², S. Rangwala², F. Thibaud-Nissen², A. Vatsan², C. Wallin², D. Webb², A. Frankish¹, F. Cunningham¹, T. Murphy²; ¹EMBL-EBI, Hinxton, United Kingdom, ²NCBI/NLM/NIH, Bethesda, MD

Abstract Body:

Comprehensive gene annotation is essential for understanding the impact of clinically relevant variants. Historically there has not been a standard for clinical reporting which complicates the process of consistent interpretation and reporting. To address this, the Matched Annotation from NCBI and EMBL-EBI (MANE) collaboration between Ensembl/GENCODE and RefSeq has defined a high-value set of transcripts and corresponding proteins for use as a universal standard for variant reporting (Nature 2022;604(7905):310-315). Each MANE transcript represents an exact match between the exonic sequence of an Ensembl/GENCODE transcript and its counterpart in RefSeq, such that the identifiers can be used synonymously. The MANE Select set identifies a representative transcript for each human protein-coding gene with the MANE Plus Clinical set providing additional transcripts at loci where the Select alone is not sufficient to report all currently known clinical variants. MANE release 1.0 has MANE Select transcripts for 99.7% of human protein-coding genes, including all ACMG SF v3.03 genes. MANE transcripts are accessible from major genome browsers and key resources. Widespread adoption will increase consistency of reporting, facilitate exchange of data regardless of annotation source, and help streamline clinical interpretation. The MANE collaboration will continue, aiming to 1) reach 100% coverage of protein-coding genes on the human reference genome GRCh38, including those on patches and alternative loci; 2) capture novel pathogenic clinical variation in MANE Plus Clinical transcripts; 3) expand to include additional functionally important transcripts with exonic features absent from MANE Select and MANE Plus Clinical; and 4) incorporate a small set of transcripts from clinically relevant non-coding genes. MANE annotation is anticipated to be very stable, with proposed changes announced at <https://ftp.ncbi.nlm.nih.gov/refseq/MANE/> in advance of public release. We welcome input from the community to ensure that all aspects of the MANE collaboration provide maximum benefit to users. Please contact us at mane-help@ebi.ac.uk or MANE-help@ncbi.nlm.nih.gov. This work is supported by: Wellcome Trust-WT200990/Z/16/Z; EMBL-Core-Funds; NIH-U41HG007234. This work was supported in part by the National Center for Biotechnology Information of the National Library of Medicine (NLM), National Institutes of Health (NIH).

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday
PB3224. Metadata retrieval from sequence databases with *ffq*

Authors:

A. Galvez Merchan, A. Boeshaghi, L. Pachter; Caltech, Pasadena, CA

Abstract Body:

We present a command-line tool, called *ffq*, for querying user-generated data and metadata from sequence databases. Given an accession or a paper's DOI, *ffq* fetches metadata and links to raw data in JSON format at a rate of 10s per sample. *ffq*'s modularity and simplicity makes it extensible to any genomic database exposing its data for programmatic access. This enables the re-analysis of existing published data from numerous existing and future databases alongside novel experiments. *ffq* is open source, and the code can be found here: <https://github.com/pachterlab/ffq>

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3225. MetaMatchMaker: An artificial Intelligence tool for data discovery and meta-data harmonization

Authors:

G. Page¹, H. Pan², A. Blatecky³, K. Burdekin³, R. Chew³, I. Glaze³, C. Hamilton³, R. Henao⁴, C. Ives³, M. Mandal⁵, T. Reeve³, D. Williams⁶, X. Wu³, E. Earley³; ¹RTI Intl., Atlanta, GA, ²RTI Intl., RTP, NC, ³RTI Intl., Durham, NC, ⁴InfinML, Durham, NC, ⁵RTI Intl., Research Triangle Park, NC, ⁶RTI Intl., Research Triangle, NC

Abstract Body:

High quality data is a fundamental need in genomics, data sciences and the development of Artificial intelligence (AI) systems. The quality, nature, experimental design, and quantity of data determines the utility, performance, fairness, robustness, and scalability of the genetics analysis and AI models. However, data cleaning is often the least incentivized aspect of studies, viewed as ‘operational’ relative to the higher profile work of building novel models and algorithms. According to a 2018 Kaggle survey of data scientists, 50-65% of the time of a data study is devoted to data work including finding, gathering, harmonizing, and cleaning data. This is in part due to the highly manual nature of these steps, but this does not need to be the case. We have developed **MetaMatchMaker (M3)**, a suite of cutting-edge AI approaches and tools to reduce the time and costs of finding and integrating genomic, molecular, and clinical data for analysis. At its core, M3 is an advanced pretrained learning model (PLM) created using a natural language processing (NLP) neural network we call M3 neural network (M3:NN). With this approach we take advantage of the recent advancements in NLP entity matching to predict similarities between complex human language terms. **M3:NN** has been trained on data generated by data harmonizers with decades of experience abstracting and mapping terms between studies. Training data was drawn from ~30k unique, manually mapped study concepts between the PHENX toolkit and study terms within dbGAP (June, 2018). Subsequent model training included terms from BioLINCC and FITBIR. M3:NN supports two common use cases - data discovery and data linking. **M3:Find** is a data discovery tool (available at www.MetaMatchMaker.com) which lets users find publicly available data by matching user-supplied terms to study variables across numerous public databases and tools including dbGaP, BioLINCC, PhenX, and FITBIR. The M3:NN model predicts content similarity between terms based on the training data. **M3:Link** allows users to link meta data study terms between two or more studies, allowing for more rapid data integration across cohorts. This tool is also useful for building common data elements across multiple studies. M3:Link has been evaluated using dbGAP data submitted after July 1, 2018 to link 70,945 dbGAP variables from to the 9,148 PhenX variables at a score > 0.99 links to a correct variable 79% of the time and incorrectly 21% of the time. Use of MetaMatchMaker can reduce the time and budget for harmonizing complex datasets by simplifying the process of linking variables and meta data.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3226. MGeND: Integrated database of clinical and genomic information to encourage precision medicine in Japan

Authors:

M. Kamada¹, Y. Kawai², K. Tokunaga³, Y. Okuno¹; ¹Kyoto Univ., Kyoto, Japan, ²Natl. Ctr. for Global Hlth.and Med., Shinjuku-ku, Japan, ³Natl. Ctr. for Global Hlth.and Med., Tokyo, Japan

Abstract Body:

In order to improve the accuracy of genomic medicine, it is necessary to accumulate genomic data with clinical interpretations that consider the diversity of genomes. To this end, we have been developing and operating the Medical Genomics Japan Database (MGeND), an integrated database of genomic and clinical information discovered in the East Asian population. We have been updating the database contents upon continuous submissions of data. The database previously provided variant information only for the genome assemblies specified by the registrant. We newly produced liftover of all variants between GRCh37 and GRCh38, and the mapped data were published on MGeND for download. In addition, we have improved the response time for downloads that took a long waiting time when the combination of items to be downloaded are specified. Currently, to resolve inconsistency of disease names, mapping between registered disease names in MGeND with the MONDO and NANDO disease ontologies is underway, where NANDO targets intractable disease Nanbyo in Japanese. Since MGeND deals with multiple public databases, it requires flexibility in the updating procedure. Therefore, we are refactoring the system to allow partial updates of corresponding information by introducing the Semantic Web framework. This enhancement enabled us to maintain data in the Resource Description Framework (RDF) so that we are able to represent complex data in a standardized data model. We have also introduced the TogoStanza framework that allows database developers to embed the information in our database as visualization modules in various applications, including other Japanese variant databases such as TogoVar. This presentation will introduce the system update and our efforts to develop a new system.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday
PB3227. National Center Biobank Network (NCBN) and genomic information for NCBN bioresources.

Authors:

K. Tokunaga¹, Y. Omae¹, Y. Kawai², E. Noiri¹, K. Kitajima¹, S. Hideyuki¹, Y-i. Goto¹; ¹Natl. Ctr. Biobank Network, Tokyo, Japan, ²Natl. Ctr. for Global Hlth.and Med., Tokyo, Japan

Abstract Body:

The six national centers (6NCs) for advanced and specialized medicine in Japan conduct basic and clinical research on major diseases that have a significant impact on national health. Disease-specific bioresources and information collected by each NC are stored in a separate biobank. The National Center Biobank Network (NCBN) coordinates the biobanks and researchers of the 6NCs via an open access database (Catalogue Database: http://www2.ncbiobank.org/Index_en) for efficient provision of registered biological resources and data for use in research communities. The NCBN resources are characterized by their high quality and rich medical information and are available for life science research and for the development of novel testing methodologies (biomarkers), new treatments, and drugs for future healthcare in the scope of personalized medicine, through a deeper understanding of disease pathogenesis. In addition to the bioresource and medical information, whole genome sequencing analysis for 9,850 NCBN samples has been conducted since 2020. These can be utilized as control subjects in research into cancer and rare diseases in the Japanese population and their variant frequency information will be registered to NBDC Human Database and Medical Genomics Japan Variant Database (MGeND) after publication. The total number of obtained genome-wide data for NCBN bioresources is increasing for many diseases through whole genome sequencing analysis or SNP array analysis and it is now possible to search the Catalogue database for bioresources with genomic information. NCBN is creating a system that can provide both bioresources and genomic data to users.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3228. NCBI dbGaP FHIR API Provides Access to Thousands of Studies to Improve Data Integration and Interrogability for Biomedical Research

Authors:

L. Phan¹, E. Moyer¹, J. Bloom¹, L. Hao¹, M. Kimura¹, M. Feolo¹, P. Lynch², H. Xie², Y. Sedinkin², L. Amos², C. McDonald², L. Ziyabari¹, V. Lyoshin¹, K. Kaur¹, R. Russette¹, B. Kattman¹; ¹NIH, NLM/NCBI, Bethesda, MD, ²NIH, NLM/Lister Hill Natl. Ctr. for BioMed. Communications, Bethesda, MD

Abstract Body:

NCBI has developed an FHIR data-model-based API for fast, selective, secure, and reliable access to patient-level research study-related controlled data. The initial delivery of this API can pull data from dbGaP.

The Database of Genotypes and Phenotypes (dbGaP) was developed to archive and distribute the results of studies that have investigated the interaction of genotype and phenotype in humans. It contains thousands of studies, >350K phenotypic variables, and ~2.5 billion observations from millions of subjects. Once a dbGaP study is processed and approved for release, it is made available through dbGaP FHIR API (GFA). The FHIR format can accelerate the use of clinical data for research. FHIR is a standardized way of transmitting health data from one health information system to another through an application programming interface (API). It is also compatible with analytic resources used in biomedical research, such as R and Python. The format is being widely promoted and adopted for use in clinical care. GFA provides two levels of access:

Open - provides study and variable metadata and summary (available to anyone with no restrictions). Users can search using multiple criteria including studies title, sponsor (IC), type (prospective, longitudinal, cohort, case-control), keyword, condition, and many others.

Controlled - provides individual-level genotype and phenotype data that have been de-identified (i.e., no personal identifiers, such as name, etc.) The new GFA can be used to download phenotype data from several large population cohort studies in dbGaP.

We will demonstrate GFA to assist researchers access diverse and large datasets. Users could then develop third-party applications to extract clinical data from the API to enable new discoveries and improved health.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3229*. NIA Genetics of Alzheimer's Disease Data Storage Site (NIAGADS): 2022 Update.

Authors:

H. Issen¹, A. Kuzma¹, O. Valladares¹, E. Greenfest-Allen¹, P. Gangadharan¹, Z. Katanic¹, A. Wilk¹, Y. Zhao¹, L. Qu¹, M. Kirsch¹, M. Moon¹, A. Lerro Rose¹, J. Manuel¹, L. Armus¹, N. Saravanan¹, P. Keskinen¹, J. Cifello¹, O. Pathak¹, S-Y. Chou², W-P. Lee¹, Y. Leung¹, A. Naj¹, C. Stoeckert Jr.¹, G. Schellenberg¹, L-S. Wang¹; ¹Univ. of Pennsylvania, Philadelphia, PA, ²Lehigh Univ., Bethlehem, PA

Abstract Body:

Background: NIAGADS is a national genomics data repository that facilitates access of genotypic and sequencing data to qualified investigators for the study of the genetics of Alzheimer's disease (AD) and related neurological diseases. Collaborations with large consortia and centers such as the Alzheimer's Disease Genetics Consortium (ADGC), Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium, the Alzheimer's Disease Sequencing Project (ADSP), and the Genome Center for Alzheimer's Disease (GCAD) allow NIAGADS to lead the effort in managing large AD datasets that can be easily accessed and fully utilized by the research community.

Methods: NIAGADS is supported by National Institute on Aging (NIA) under a cooperative agreement. All data derived from NIA funded AD genetics studies are expected to be deposited in NIAGADS or another NIA approved site. NIAGADS manages a Data Sharing Service (DSS) that facilitates the deposition and sharing of genomic data and association results with approved users in the neurodegenerative research community. In addition, researchers are able to freely use the NIAGADS Alzheimer's Genomics Database (www.niagads.org/genomics/) to search annotation resources that link published AD studies to AD-relevant sequence features and genome-wide annotations.

Results: As of June 2022, NIAGADS houses 88 datasets comprised of >144,000 samples including GWAS, sequencing, gene expression, annotations, deep phenotypes, and summary statistics. Qualified investigators can retrieve ADSP sequencing data with ease and flexibility through the NIAGADS DSS. To date, the ADSP and other contributing studies have completed whole exome sequencing (WES) of 20,503 samples and whole genome sequencing (WGS) of 16,905 samples. Raw WES and WGS files, quality controlled VCF files, and phenotype data files are available via qualified access. The next round of sequencing currently underway will generate around 18,000 additional genomes to be released in the second half of 2022.

Conclusion: NIAGADS is a rich resource for AD researchers, with the goal of facilitating advances in Alzheimer's genetics research. By housing datasets from many projects and institutions, NIAGADS enables AD researchers to meet their research goals more efficiently. Datasets, guidelines, and features are available on our website at <https://www.niagads.org>.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3230. North Carolina Macular Dystrophy (NCMD/MCDR1): Analysis of our entire database, a model disease of non-coding mutations.

Authors:

K. Small¹, M. Leys², P. S. Bernstein³, A. Scott⁴, E. M. Stone⁵, F. S. Shaya⁶; ¹Molecular Insight Res. Fndn., GLENDALE, CA, ²West Virginia Univ. Eye Inst., Morgantown, WV, ³Univ. of Utah Hlth. Moran Eye Ctr., Salt Lake City, UT, ⁴John Hopkins Wilmar Eye Inst., Belair, MD, ⁵Univ Iowa Hosps & Clinics, Iowa City, IA, ⁶Macula and Retina Inst., Glendale, CA

Abstract Body:

Purpose: We published the initial findings of 5 mutations in 12 NCMD families with 141 subjects. The purpose of this study is to clinically and molecularly study our entire NCMD database to determine if our initial findings continue to be substantiated. **Methods:** Ophthalmic examinations and whole genome sequencing (WGS) and/or targeted DNA Sanger sequencing was performed on our entire dataset of 53 families with 318 subjects. Junction PCR and Sanger sequencing was used to confirm point mutations and characterize duplications involving the MCDR1/MCDR3/*PRDM13* locus. **Results:** Of the total 318 subjects evaluated to date, 185 were found to be affected having DNA sequence changes consistent with MCDR1 on chromosome 6 or MCDR3 on chromosome 5. In addition to our 12 initial families, we report the findings of an additional 41 families with 75 subjects affected and 32 unaffected. Eight of these new families, 35 subjects, were found to have the original “V1” Chr6:99593030G>T mutation, in a non-coding region of the DNASE1 site upstream of *PRDM13*. Eleven families, 36 subjects, had the “V2” mutation Chr6:99593111G>C in the same DNASE1 site. One Asian family with 2 subjects had our previously reported Asian “V3” Chr6:99593164C>T mutation in the same DNASE1 site. Two new single nucleotide variants (SNVs) have recently been reported by us from our dataset, Ch6:99599064A>G in four members of one Czech family and Chr6:99959303G>C in four members of a Mexican family. A new tandem duplication Chr6:99560265-99616492 involving the same DNASE1 site, was recently reported by us in a Turkish family. **Conclusions:** North Carolina Macular Dystrophy (NCMD) is more prevalent than typically thought with a worldwide distribution making the name of this disease a gross misnomer. Continued identification of subjects and families and their mutations supports our initial discovery of mutations. A total of 8 of 13 worldwide NCMD mutations have been found by our group. All of the mutations (SNVs and duplications) appear to involve DNASE1 sites in non-coding regions. The mutations on chromosome 6 continue to appear to alter the expression of the retinal transcription factor *PRDM13* while the chromosome 5 mutations may affect the *IRX1* expression as we originally reported.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3231. Participant-provided case-level data from GenomeConnect can impact variant classification

Authors:

A. Morgan¹, E. Riggs², J. Savatt³, D. Azzariti⁴, C. Martin¹, H. Rehm⁵; ¹Geisinger, Danville, PA, ²Geisinger Hlth.System, Huntsville, AL, ³Geisinger, Lewisburg, PA, ⁴Broad Inst., Cambridge, MA, ⁵Massachusetts Gen. Hosp., Boston, MA

Abstract Body:

Variant classifications may evolve over time with the emergence of new evidence. GenomeConnect, the ClinGen patient registry, enables sharing of de-identified variants, phenotype, and inheritance with ClinVar; other information, such as co-occurring variants, are available within the registry. Such data can impact variant classification. Here, we report on an assessment of variants shared by participants and their potential to inform other laboratories' variant classifications. Of the 2285 unique variants submitted to ClinVar by GenomeConnect, 213 (9.3%) had conflicting interpretations. Of these, 53 (24.9%) had a likely pathogenic/pathogenic (LP/P) classification on the participant's report. We focused on participant variants with case-level data that may inform other laboratory's classifications. These included 1) variants in autosomal dominant (AD) or X-linked genes that were found to be de novo in the GenomeConnect participant (potentially adding PM6 or PS2 to laboratories' classifications) or 2) variants in autosomal recessive (AR) genes co-occurring with a second LP/P variant in trans (potentially adding PM3). Variants unlikely to contribute to the classification (e.g., weak evidence types) were removed. We identified 12 unique variants where participant-contributed data could help be used to inform classification by another ClinVar submitting laboratory with VUS classification in the database. These included 6 de novo variants in AD genes and 6 variants in AR genes with another LP/P variant in trans. ClinVar submissions for these 12 variants had conflicting classifications (LP/P and VUS) from multiple submitters. For the 6 variants in AD genes, no laboratory submitter cited de novo inheritance as part of their classification. Two of the 6 variants in an AR gene did not note co-occurrence of a second variant in trans in ClinVar; such data are available in GenomeConnect. GenomeConnect participants also provided phenotypic details beyond what was included in the ClinVar laboratory submissions for all variants. These data highlight participant-provided individual-level data can provide additional evidence to help resolve discrepancies in variant classification. As a next step, the submitting laboratories for the 12 variants in conflict will be contacted by GenomeConnect to explore whether our participant-provided data could change their classification and resolve the discrepancy in ClinVar. This initial small-scale pilot and future work using GenomeConnect participant data could assist in future work on data sharing to inform discrepancy resolution, which can allow patients to receive updated and more accurate genetic test results.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3232. Partly Cloudy: analysis of blood lipids across All of Us and UK Biobank demonstrates the promise and limitations of cross-biobank analyses in the cloud

Authors:

M. Selvaraj¹, N. Deflaux², H. Condon³, K. Mayo³, M. Basford³, M. Effingham⁴, D. Glazer⁵, P. Natarajan¹, A. Bick³; ¹Massachusetts Gen. Hosp., Boston, MA, ²Verily Life Sci., Seattle, WA, ³Vanderbilt Univ., Nashville, TN, ⁴UK Biobank, Stockport, United Kingdom, ⁵Google, Mountain View, CA

Abstract Body:

Background: The rapid growth of genomic data precipitates a new research paradigm where data is stored centrally in Trusted Research Environments (TREs) such as the All of Us Researcher Workbench (AoU RWB) and the UK Biobank Researcher Analysis Platform (UKB RAP). Here we characterize the advantages and drawbacks of TREs in facilitating cross-analysis, as demonstrated by genome wide association study (GWAS) of blood lipids.

Methods: We conducted GWAS using lipid phenotypes (HDL-C; LDL-C, TC, TG) on UKB 200K whole exomes sequence (WES) and AoU 98K whole genome sequence (WGS) datasets (filtered to UKB exome capture region) in both siloed and pooled fashion on the UKB RAP and AoU RWB. In the siloed analysis, we carried out the GWAS on each cohort separately and meta-analyzed the results. In the pooled analysis, we combined datasets and carried out GWAS once for all samples. We compared the results from siloed and pooled analysis to each other and against a published multi-ancestry lipid study in the NHLBI TOPMed cohort.

Results: We curated lipid measurements for 37,754 AoU participants with WGS data and 190,982 UKB participants with WES data. Single variant GWAS was carried out with ~1.6M and ~2.1M variants from AoU and UKB cohorts respectively. After applying the AoU data dissemination policy which restricts dissemination of data on fewer than 20 participants (eg AC<40), we retained 30% and 23% of variants in AoU and UKB for further analysis. We meta-analyzed ~500K variants and identified 454 and 445 genome wide significant variants in siloed and pooled analysis, respectively. Overall there was strong correlation with known lipid loci ($R^2 \sim 92-97\%$) from both meta-analysis and pooled methods. Importantly, 84 variants were unique to siloed analysis and 75 variants were unique to pooled analysis. Examining these, we noted a significant increase in the proportion of variants predominantly from non-european ancestry individuals in the pooled analysis compared to siloed ($p=0.01$). We also show that pooled analysis required ~half as many computational steps as meta-analysis.

Conclusion: We demonstrate that results from siloed and pooled approaches to trans-biobank genetic analysis are similar but not identical. We found that pooled analysis is notably less complicated and has important implications for studying genetic variants in diverse individuals. These findings have important technical and policy implications for biobank TREs.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3233. Path to independence: Overview of challenges and opportunities of computational data-driven research in biology

Authors:

T. Ramesh¹, K. Chhugani¹, V. Jönsson², S. Mangul³; ¹Univ. of Southern California, Los Angeles, CA, ²Univ. of California, Santa Cruz, Santa Cruz, CA, ³Univ. of Southern California, Sch. of Pharmacy, Los Angeles, CA

Abstract Body:

Over the past decade, the rapid advancement of high-throughput technologies has reshaped modern biomedical research by vastly extending the diversity, richness, and availability of data and methods across various domains. Computational data driven, or dry lab, research focuses on developing and applying computational models and methods across various types of omics datasets. The researchers also perform secondary analysis- mine and reanalyze publicly available large scale open datasets to make novel biological discoveries. Here we have discussed the pitfalls, the opportunities and the significance of computational data driven research. With increasing importance to computational driven research in recent times, the paradigm shift in attitudes towards the computational research is also discussed -there is more receptiveness of the field by the biomedical community over the years, through increasing computational projects thriving in the leading consortium integration studies and publishing of the research in high caliber journals. Yet, there are fewer funding and powerful roles in the funding panels are assigned to computational researchers, suggesting the appreciation to the field is still not as significant. Computational research is pervasive and plays a multi-disciplinary role in almost every field and is not limited to biology, philosophy, sociology etc. In biology, the computational applications largely focus on genomics and translational bioinformatics which open doors to clinicians and wet lab experimentalists to come up with new diagnostics, therapeutics, or insights to the disease. Computational driven research is unique as it enables researchers to be creative and provide the freedom to discover novel diseases, invent new methods and tools or improve the existing ones to enhance data analysis. By establishing more meaningful collaborations between dry and wet lab research, the findings of computational data driven research becomes more interdisciplinary and crucial by validating the results from dry lab in wet lab. Transitioning into the future, many accomplished scientists believe that effective technical, research, and communication skills are key in thriving in the field of computational research. Computational research has a unique potential of being the bridge between the large amounts of data collected by wet labs and understanding this data. With effective collaborations with clinicians, and wet lab experimentalists, computational research is likely to flourish greatly and reach a remarkable level in the biomedical field in the future notably, in the fields of disease prevention, therapeutics and treatment decisions.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3234. PhenX presents Bone and Joint updates and expansion of Social Determinants of Health

Authors:

M. Krzyzanowski¹, M. Nelms¹, D. Williams¹, L. Cox¹, J. Schoden¹, C. Ives¹, A. Brandow², P. Carroll³, D. Felson⁴, K. Norris⁵, M. G. Cockburn⁶, W. Huggins¹, D. Maiese¹, L. Gridley¹, P. West¹, X. Wu¹, M. Mandal¹, H. Pan¹, N. Jones⁷, V. Marshall⁷, T. HENDERSHOT¹, C. Hamilton¹; ¹RTI Intl., Research Triangle Park, NC, ²Med. Coll. of Wisconsin, Milwaukee, WI, ³Johns Hopkins Univ., Baltimore, MD, ⁴Boston Univ. Sch. of Med., Boston, MA, ⁵Div. of Gen. Internal Med. and Hlth.Services Res., Univ. of California Los Angeles, Los Angeles, CA, ⁶Univ. of Southern California, Los Angeles, CA, ⁷Natl. Inst. of Minority Hlth.Disparities, Bethesda, MD

Abstract Body:

The PhenX (**Phenotypes and eXposures**) Toolkit (<https://www.phenxtoolkit.org>) is a web-based catalog of recommended measurement protocols and associated bioinformatics tools to assist with study design and facilitate cross-study data integration and analyses. PhenX protocols are recommended by domain experts using a consensus-based process that includes community input. The PhenX Toolkit currently includes measurement protocols from 29 research domains (e.g., Demographics and Diabetes) and six collections that add depth to the Toolkit (e.g., Social Determinants of Health) and has over 4,200 registered users. An established resource that continues to expand content for investigators, the PhenX Toolkit includes expansion of the Social Determinants of Health (SDoH) Research collection, updates to the Bone and Joint domain, and a new Sickle Cell Disease (SCD) Pain specialty collection. As part of the National Institute of Minority Health Disparities research framework and vision, the PhenX Toolkit received funding to expand the existing SDoH Research collection. New protocols were recommended by SDoH-X Working Group members, focused on topics including water access, housing insecurity, accommodations for mental or physical disabilities and incarceration history. These new protocols will enhance the existing individual and structural SDoH protocols already in the Toolkit. Supported by the National Heart, Lung, and Blood Institute (NHLBI) through co-funding to the “PhenX Toolkit-Expansion and Sustainability” (U41) project Y3-Y5, the Bone and Joint Working Group recommended new protocols to assess bone turnover and mineral content, fracture, pain, gout, arthritis, and fibromyalgia. The SCD Pain Working Group, identified a set of 24 protocols that encompass the burden of pain on an individual’s day-to-day life, the magnitude of pain experienced by an individual, the location of the pain experienced, the extent to which the pain interferes with the person’s daily life, the individual’s overall physical mobility, the specific subjective sensations associated with pain, and the coping strategies employed by the individual. We will present the final protocols recommended by the Working Groups with review and approval by the Sickle Cell Disease Research and Scientific Panel and the PhenX Steering Committee.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3236. PreSiBO: Database system for genome guided and data driven drug repurposing.

Authors:

D. Priyadarshi, N. Sahelijo, G. Jun; Boston Univ., Boston, MA

Abstract Body:

Precision medicine aims to develop patient driven treatment solutions using genetic profiles and corresponding drug options. Since clinical manifestation of Alzheimer's disease (AD) is complex in both neuropathology and underlying disease mechanisms, there is an urgent need to develop a tool enabling precision medicine in AD. We, therefore, developed an integrated database system after profiling predictor, signature, biomarker, and outcome (PreSiBO) features of genome-guided patient subgroups.

Methodology: To aid precision medicine in AD, we collected, collated and curated omics, protein interaction, and existing drugs data and connected these by leveraging their inherent hierarchical structure. The data included:

- 1) Predictors - genome-wide association study (GWAS) summary statistics, network based polygenic risk scores,
- 2) Signatures - transcriptome, methylome, lipidome, and proteome profiles,
- 3) Biomarkers - cerebrospinal fluid and MRI, PET imaging,
- 4) Outcomes - Clinical/neuropathological.

We created *PreSiBO subgroups* for precision medicine that profile subjects using genetic risk scores for biologically connected gene networks derived from the curated omics data. Gene-to-drug and protein-protein interaction data were incorporated into the database to identify existing FDA approved drugs within a gene-network for a targeted PreSiBO subgroup.

Implementation: PreSiBO was implemented using a MySQL based relational database system deployed on Amazon Web Services (AWS) for quick retrieval of these logically linked datasets. A custom web interface dashboard was also developed using R Shiny for easy search and navigation of the datasets in the database. We will, further, scale the system and implement machine learning algorithms to detect priority targets that have best matched approved drugs for drug repurposing, in each PreSiBO subgroup.

Conclusion: In summary, PreSiBO system has allowed us to better organize the diverse but logically connected precision medicine data to holistically understand genetic profiles for data driven drug repurposing in AD.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday
PB3237. Rare Disease Phenotyping: What is Next?

Authors:

D. Adams¹, C. Esteves², E. Burke³, M. Malicdan¹, W. Gahl⁴, A. McCray², Undiagnosed Diseases Network; ¹NIH, Bethesda, MD, ²Harvard Med. Sch., Boston, MA, ³NIH - NHGRI, Bethesda, MD, ⁴NHGRI (NIH), Bethesda, MD

Abstract Body:

Clinical phenotype has long been a critical component of both clinical care and research for patients with rare inherited diseases. The era of genomic sequencing, and particularly consequent reverse phenotyping, have increased the pace of evolution in disease definition. For newly described and ultra-rare disorders, phenotype can be a critical component for establishing coherent cohorts. The launch of the Human Phenotype Ontology (HPO) in 2007, and subsequently Matchmaker Exchange (ME) and GeneMatcher (GM) in 2013, heralded fundamental changes in how rare phenotypes are documented and shared. Each of these tools continues to be used broadly in the rare disease research community. Azzariti and Hamosh reported in 2020 that MME encompassed “150,000 cases from more than 11,000 contributors in 88 countries”. In the Undiagnosed Diseases Network, 1775 cases have been posted to the PhenomeCentral (PC) ME node, generating 746 matching inquiries. Importantly, most matches are triggered by gene name rather than phenotypic similarity. HPO continues to be updated with new terms, with the last posted release occurring in April of 2022. However, coding of some phenotype classes remains challenging, e.g., neurodevelopmental, neuroradiological and laboratory measurement. Computational tools that incorporate HPO matching typically use terms without metadata. Therefore, important information about severity, periodicity, age of onset and other factors are not utilized. Despite a significant published literature addressing the generation of HPO terms from text, robust open-source tools in active development are lacking. The challenges of obtaining funding to develop and maintain tools for documenting HPO terms has driven most projects in to an expensive commercial realm that comprises a barrier to use for smaller and less-resourced projects.

We present a summary of our experience with phenotype recording and subsequent utilization. We then propose a list of phenotype-related goals for the rare disease community, funders and users alike, to consider for the future development of this critical rare disease research infrastructure.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3238. Regeneron Genetics Center (RGC) Cohort Identification Application

Authors:

D. Sharma¹, M. Cantor¹, S. Malhotra¹, S. Gokhale¹, G. Mitra¹, J. Staples², M. Nafde¹; ¹Regeneron Pharmaceuticals, Tarrytown, NY, ²Regeneron Genetic Ctr., Tarrytown, NY

Abstract Body:

Integrating high-throughput exome sequencing and diverse phenotypic data is at the core of therapeutic target research and identification. The Regeneron Genetics Center has developed an interactive application that allows scientists to efficiently explore and visualize the phenotypic data for generating clinical cohorts for Genome-Wide Association (GWAS) analysis. The application represents massive clinical phenotypic datasets from various collaborations worldwide, representing over a million participants. The data is derived from multiple sources, such as electronic health records, registries, and patient surveys which makes this application unique since most platforms (e.g., i2b2) focus only on data from a single source or source type. The data is standardized and harmonized through mapping to standardized vocabulary concepts within RGC's internally developed Master Ontology, permitting the uniform representation of clinical concepts across data sources. The phenotype browser application makes it highly efficient to query the structured data via vocabulary concepts, thus, allowing for quick and flexible self-service selection of patients that share common clinical characteristics across multiple studies and expanding the scope of target discovery. The application has been deployed widely within RGC for clinical data exploration and supports drag and drop clinical cohort queries, cohort visualization and comparison, and interoperability with other enterprise applications through interaction with the backend relational databases through a browser-based user interface. For example, for the use case for generating a composite Breast cancer phenotype, a user can search for neoplasm of breast ICD-10 CM concept (C50 and its children concepts) within internal Master Ontology and find relevant data across all RGC's collaborations. Similarly, to locate Hemoglobin A1c (HbA1c) data, a user can search for HbA1c LOINC parts concept code (LP16413-4). Using the drag and drop functionality, all patients that are cases for breast cancer and have HbA1c > 7.5% can be added to the query for generating a composite phenotype. The application also allows for a graphical view of the query results by age, gender, race, and ethnicity. Users can in real-time edit the query, and get the updated results. The application's short-term plans include extending the cohort builder functionality to include longitudinal phenotype data and integrating deep learning models to identify more patients that meet the cohort inclusion criteria.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday
PB3239. Role of Python APIs, Big data and Cloud computing in understanding the Genetic basis of a Disease

Authors:

S. Murthy; Self Employed/ Freelancing, Hyderabad, India

Abstract Body:

Background: Datasets on signaling events appear central to investigators in understanding the genetic basis of a disease. Recently, there has been much focus on the use of emerging information technology (IT) tools in this regard. Say, for example, API (application programming interface) is one such area. APIs connect to multiple EHRs (electronic health records), labs, pharmacies, and patient portals and finally provide commercial firms access to general health data. Here, database development and storage of information using cloud technology is an important subarea to emphasize. However, there is poor literature with regard to the application of this IT-based platform particularly using python (a programming language) APIs or python based web APIs as useful tools in understanding the cross-talk between signals and genes. **Aim:** The aim of this project is to carry out a literature review on how python API and cloud computing are efficient in exploring and synthesizing the datasets/big data in understanding the genetic- disease specific signalling events. **Methods:** A web-based literature search was carried out. Electronic databases like PubMed were accessed between January 1, 2012, and May 31, 2022. The keywords used were ‘role of APIs in medicine’, ‘role of APIs in genetics’, ‘signals in host-pathogen interaction’, ‘APIs in health and genetics’, ‘the significance of APIs in healthcare industry’, ‘python in genetic disease management’, ‘big data in genetic disease management’, ‘big data in genetic disease management, and ‘cloud computing in genetic disease management, respectively, to recognize studies that apply the role of python in clinical settings in this area. **Results:** The database search result revealed only a limited number (below ten) of articles. **Conclusion:** The gaps in data may imply that an IT-driven understanding of signal machinery requires attention. Molecular signals may possess a strong link with the host’s unique genetic make-up and can be instrumental in influencing a particular disease cycle. So, datasets linking a disease, distinct signals, and the gene need to be created and stored in huge cloud servers. Such strategy when integrated with python APIs (API integration) may not only uncover undiscovered correlations, hidden patterns, and other insights through inspecting large-scale multiple sets of data but also facilitate systems to exchange the sources of data. This makes the data more accessible and understanding with further exploratory insights on database schemas for the healthcare community.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3240. STR Truth Set for Evaluating Genome-wide STR Calls

Authors:

B. Weisburd, N. Kurtas, V. Jalili, H. Brand, G. Tiao, H. L. Rehm; Broad Inst. of MIT and Harvard/Massachusetts Gen. Hosp., Cambridge, MA

Abstract Body:

Short tandem repeats (STRs) are scattered throughout the human genome. Recent advances in tools such as GangSTR and ExpansionHunter have made it possible to survey the full range of STR variation using whole genome sequencing data (WGS). However, the lack of a high-confidence genome-wide STR truth set makes it difficult to determine 1) which STR caller(s) to use for genome-wide analyses; 2) what set of STR loci to genotype; and 3) the accuracy of results. Current approaches to addressing these issues involve simulating STR expansions, Mendelian-violations analyses, and/or using standard long-read sequencing data as truth. However, simulated data doesn't sufficiently capture the complexities of WGS, Mendelian-violations analyses can inform about specificity but not sensitivity, and long read variant calls or diploid assemblies are anecdotally inaccurate for STR loci as described in [Dashnow 2021] and [Chiu 2021].

Here, we report a genome-wide STR truth set based on the Synthetic Diploid Benchmark [Li 2018]. It contains 178,909 STR variants found in the CHM1-CHM13 sample. To derive this truth set, we filtered the 4.1 million variants in the original synthetic diploid benchmark to insertions and deletions whose variant sequence + flanking reference sequence consist of at least 3 repeats of some shorter motif (excluding homopolymers). For example, if the original truth set contains a variant that denotes a deletion of CAGCAG from a reference context of 5 CAGs, we add it to the STR truth set as a contraction of 2 CAG repeats. We find this to be a good source of truth because it is based on haploid long-read assemblies which are more accurate than diploid assemblies. Additionally, since CHM13 is the basis of the new telomere-to-telomere (T2T) reference genome, we can further validate STR expansions by lifting them over to T2T, checking that at least one allele matches the T2T reference, and then lifting them back to GRCh38 to see if they map to their original GRCh38 locations. The fact that 98.3% of identified STR variants pass this QC process, and that we find nearly equal numbers of STR expansions (89,460) and contractions (89,449) highlights the quality of this truth set.

We then evaluate the accuracy of both short- and long-read STR callers on the 99.6% of truth set STR loci where the motif inside the variant is also found in the surrounding reference context. We additionally evaluate 178,246 other STR loci from the reference genome as true negatives. Among other findings, we see that ExpansionHunter and GangSTR have similar accuracy of ~70% when we define accuracy as $(TP+TN)/(\text{total \# of loci})$.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3241. Study design using the PhenX COVID-19 Collection and Variable Compare Tool

Authors:

D. Williams, M. Krzyzanowski, L. Cox, M. L. Engle, I. Glaze, W. Huggins, C. Ives, D. Maiese, T. Reeve, T. HENDERSHOT, C. Hamilton; RTI Intl., Research Triangle Park, NC

Abstract Body:

The PhenX (**Phen**otypes and **eX**posures) Toolkit (<https://www.phenxtoolkit.org>) is a web-based catalog of recommended measurement protocols and associated bioinformatics tools to assist with study design and facilitate cross-study data integration and analyses. PhenX protocols are recommended by domain experts using a consensus-based process which includes research community input. The PhenX Toolkit currently includes measurement protocols from 29 research domains (e.g., Demographics and Diabetes) and six collections that add depth to the Toolkit (e.g., Social Determinants of Health) and has measures included in 523 National Institutes of Health Funding Opportunity Announcements. The Toolkit released a COVID-19 Research Collection and is continuing to build tools for COVID-19 research. The COVID-19 Research Collection has six specialty collections to address research areas of concern to the community: Behaviors and Risks; Ethnicity, Race and Demographics; History, Treatment and Outcomes; Information Resources; Psychosocial and Mental Health; and Socioeconomic. Investigators are encouraged to use protocols from these collections when planning or designing a new study. Because health disparities were identified as an area of particular concern, the Social Determinants of Health Core collection is recommended to complement the COVID collections. Expansion of the existing COVID collection to include Long COVID protocols is in progress. The PhenX COVID-19 Variable Compare Tool (VCT) was developed to allow researchers to explore the protocols and variables in the COVID-19 Research Collection and the full instruments included in the PhenX COVID-19 Library. VCT features include a Keyword Search at the variable level, Side-by-Side comparisons of similar variables from two questionnaires, and visual representations of 3+ questionnaires via a heatmap. The Keyword Search allows researchers to address specific research topics by finding individual response items from questionnaires. For example, an investigator could search for “depression” to see which variables and response items relate to participants’ experience with depression as related to COVID-19. The Side-by-Side Comparison feature presents the degree of similarity between two questionnaires at the variable level. The heatmap visual representation gives a large-scale comparison between questionnaires and their number of similar variables. These tools can be employed to identify protocols that can be more easily harmonized with data from published COVID-19 research using the same questionnaires.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3242. The Alzheimer's Disease Sequencing Project - Follow Up Study ADSP-FUS: APOE genotype status and demographic characteristics across datasets

Authors:

P. Mena¹, A. Zaman¹, K. faber², L. Adams³, J. Inciute¹, P. Whitehead¹, T. Foroud⁴, D. Reyes-Dumeyer⁵, A. Kuzma⁶, H. Issen⁷, A. Naj⁷, E. Martin⁸, C. Dalgard⁹, G. Schellenberg¹⁰, L-S. Wang¹¹, R. Mayeux¹², B. Vardarajan¹², J. Vance¹, M. Cuccaro¹³, B. Kunkle¹, M. Pericak-Vance⁸; ¹Univ. of Miami, Miami, FL, ²Indiana Univ., Indianapolis, IN, ³Univ Miami, Miami, FL, ⁴Indiana Univ Sch Med, Indianapolis, IN, ⁵Columbia Univ., New York City, NY, ⁶Univ Pennsylvania, Philadelphia, PA, ⁷Univ. of Pennsylvania, Philadelphia, PA, ⁸Univ. of Miami Miller Sch. of Med., Miami, FL, ⁹USUHS - TAGC, Bethesda, MD, ¹⁰Univ Pennsylvania Sch Med, Philadelphia, PA, ¹¹Univ. of Pennsylvania, Pennsylvania, PA, ¹²Columbia Univ, New York, NY, ¹³John P. Hussman Inst. for Human Genomics, Miami, FL

Abstract Body:

Background: The ADSP-FUS is a National Institute on Aging (NIA) initiative focused on identifying genetic risk and protective variants for Alzheimer Disease (AD) by expanding the ADSP beyond non-Hispanic Whites of European Ancestry (NHW-EA) populations. Given the lack of diversity in the ADSP, the ADSP-FUS was designed to whole genome sequence (WGS) existing ethnically diverse and unique cohorts. The upcoming phase for ADSP-FUS, ADSP- FUS 2.0: The Diverse Population Initiative, focuses on inclusion of Hispanic/Latino (HL), non-Hispanic Black with African Ancestry (NHB-AA), and Asian populations. **Methods:** ADSP-FUS cohorts consist of studies of AD, dementia, and age-related conditions. Clinical classifications are assigned based on standard criteria and derived from clinical measures and history, as well as additional neuropathologic data. In addition to production of WGS, genome-wide array and *APOE* genotyping is acquired or performed for all ADSP-FUS samples. **Results:** The ADSP-FUS currently consists of 38 cohorts comprised of ~40,000 individuals, with plans to sequence > 100,000 individuals from diverse ancestries. Genotyping, sequencing, and clinical adjudication has been performed on 19,305 participants (cases N=6,679, median age=75; controls N=11,155, median age=72; ADRD N=1,471, median age=72). Median age varies greatly within individual cohorts: oldest for cases is 81.8+7.9, youngest cases is 56.1+3.3; oldest for controls is 85.3+8.0, youngest is 66.5+6.7. More than 60% of participants are female and are evenly distributed across cases (62%), controls (65%), and ADRD (62%). As expected the most prevalent *APOE* genotype is *APOE* 3/3 (% by cases/controls for 2/2=0.2,0.7; 2/3=4.2, 9.8; 2/4=2.7, 2.8; 3/3=37.3, 53.5; 3/4=43.5, 29.7; 4/4=12.1, 3.5). These proportions vary greatly within ethnicities, with the highest for *APOE* 4/4 observed in Amerindian participants (22%) and the lowest in NHW-EA participants (7.5%). Median Braak stage for AD cases is higher (4.9+1.2) than controls (2.1+1.3) and ADRD participants (2.8+1.0). **Discussion:** The results provide an overview of features of ADSP-FUS cohorts. The continued growth of the ADSP-FUS is central to the ADSP. As the ADSP-FUS expands in size and diversity, this genomic resource, available via NIAGADS, will be integrated with ADSP programs focused on phenotype harmonization, association analyses, functional genomics, and machine learning. In concert with these programs, the ADSP-FUS will accelerate the identification and understanding of potential genetic risk and protective variants for AD across all populations with the target of developing new treatments that are globally effective.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3243. The BaseJumper™ research platform for single cell multiomic analysis and interactive visualization

Authors:

V. Weigman, V. Amin, I. Salas Gonzalez, T. Tate, C. Culler; BioSkryb Genomics, Durham, NC

Abstract Body:

Translating the molecular alterations, especially those from a single cell, can be a powerful tool to understand underlying mechanisms of disease and somatic mosaicism. Along with managing the vast data volume from sequencing technologies, the complexity of these changes requires a multi-dimensional approach to first compute and identify the variance found within the cells of a study and then display these effects concomitantly. The platform was designed for researchers across computational skill levels, placing more energy on the ability ask direct questions of across the multiple forms within their dataset. We present a secure, cloud-based bioinformatics and visualization platform that can be run from any laboratory computer on a standard web browser. Samples can be pulled from across repositories: local and cloud, to create analysis projects that can be wholly contained within an institution or shared across collaborators for distributed analysis considerations. Available pipelines provided within the platform enable simple (SNV/insertion/deletion) and complex (structural/copy number/highly polymorphic) variant detection in addition to cell identification, cell state and pathway status from gene expression. Pipelines have been benchmarked across single cells of NIST standards like NA12878 achieving a ~94% accuracy and ~99% precision for variant identification. Context for variation across cells is provided through annotation to several known repositories for genetic variation (gnomAD, ExAC, 1000 genomics) and clinical relevance (COSMIC, ClinVar). These can be directly queried for prevalence or in addition to other filtering strategies, where schema can be saved and toggled within and across research groups. This filtering across the whole genome dataset (hundreds of thousands to tens of millions of variants) occurs in just a few seconds. Leveraging cellular or sample phenotypes, different methods can be directly applied to datasets to run association studies, and important genotypes presented, without the need for pulling extra compute. Native to the platform is the ability to toggle these associative markers across transcript and genome-level of paired datasets. Output from one analysis can be used to guide visualization or narrow focus of another data type. Visualization applications can take datasets across genomic and transcriptomic results and can be manipulated based on expert interpretation of the researcher to maximize biological leverage. Compiling all of this within a browser maximizes accessibility of data so you can perform analyses anywhere inspiration takes you.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3244*. The cellxgene suite is an online analytical platform and the largest repository of standardized single-cell data.

Authors:

B. Aebermann¹, P. Garcia-Nieto², S. Chambers¹, T. Harley¹, B. Raymor¹, M. Lombardo¹, K. Liang¹, M. Czerwinski¹, S. Badajoz¹, C. Megill¹, T. Smith¹, M. Dunitz¹, D. Hegeman¹, A. Mani¹, T. Huang¹, K. Katsuya¹, E. Bezzi¹, B. Martin¹, A. Tolopko¹, A. Infeld¹, M. Urisko¹, J. Cool¹, A. Carr¹; ¹CZI, Redwood City, CA, ²Chan Zuckerberg Initiative, Redwood City, CA

Abstract Body:

Cellxgene (cellxgene.cziscience.com) is a free-to-use online data portal hosting a growing corpus of more than 350 single-cell datasets with over 24 million unique cells from human and mouse. The portal hosts single-cell data from modalities that include gene expression, chromatin accessibility, DNA methylation, and spatial transcriptomics. All data are standardized to include raw and normalized counts, and annotated using an ontological shared vocabulary for cell and gene metadata.

Data are easily searchable and can be downloaded in multiple formats via web or by programmatic API calls. Additionally we deploy UI-based analytical tools for exploration of single datasets that do not require download. We will showcase the main tools hosted in the portal. First, the cellxgene explorer which displays an interactive 2-dimensional representation of cells in a dataset and allows users to color cells by gene activity or metadata (e.g. cell type, disease, technical features, etc.), subset and analyze subgroups of cells, perform differential gene expression and create scatter plots of gene expression. Second, scExpression which allows querying the expression of any gene across all human and mouse cell types available in the concatenated data from the portal.

Cellxgene is intended for community use and contributions. By supporting multiple modalities and data generated by labs around the world, the cellxgene suite of tools and data aims to maximize rapid use of data. To date, we support data from over dozens of labs and consortia such as the Tabula projects, LungMap, BICCN, Allen Institute for Brain Science, KPMP and the Human Cell Atlas. New contributions are welcome, the cellxgene team actively supports curation of data, and we work to ensure that self-curation is easy.

We are continuously improving the usability of cellxgene and adding new features tailored to the needs of cell and computational biologists. Groups interested in submitting their own data can contact the cellxgene team at cellxgene@chanzuckerberg.com to explore whether your data would be a good fit for the cellxgene resource.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3245. The ClinGen Allele Registry, Linked Data Hub, and Evidence Repository Support Curation Efforts Through Registration of Variants, Aggregation of Supporting Evidence, and Publication of Pathogenicity Classifications

Authors:

K. Riehle¹, A. R. Jackson¹, N. Shah¹, A. Zuniga¹, T. Farris¹, A. Kodochygov¹, K. Yu¹, M. Wright², C. Preston², K. Dalton², M. Mandell², G. Cheung², D. Ritter¹, L. Babb³, K. Ferriter³, E. Milosavljevic¹, Clinical Genome Resource; ¹Baylor Coll. of Med., Houston, TX, ²Stanford Univ. Sch. of Med., Stanford, CA, ³Broad Inst. of MIT and Harvard, Cambridge, MA, ⁴Children's Hosp. of Philadelphia, Philadelphia, PA, ⁵Children's Hosp. Los Angeles, Los Angeles, CA, ⁶UC Santa Cruz, Santa Cruz, CA, ⁷Walter & Eliza Hall Inst. of Med. Res., Parkville, Australia, ⁸Natl. Library of Med., Bethesda, MD, ⁹Washington Univ. Sch. of Med., St. Louis, MO, ¹⁰Texas Children's Hosp., Houston, TX

Abstract Body:

To support ClinGen curation efforts and also provide services for research and clinical genome interpretation, we developed a suite of web accessible services, including the ClinGen Allele Registry (CAR) for variant registration and naming, the Linked Data Hub (LDH) for aggregation of supporting evidence associated with variant pathogenicity assessments, and the Evidence Repository (ERepo) for publishing variants and evidence curated through the Variant Curation Interface (VCI). The VCI accepts a registered CAR canonical allele identifier (CA ID) as input in which aggregated supporting information (per variant) is queried and procured from the LDH. Upon completion of variant classification “publication” in the VCI, the structured data is transmitted through the ClinGen Data Exchange to the ERepo in SEPIO format (GA4GH) and is accessible by the public. The CAR, LDH, and ERepo are open access and accessible via both User Interfaces (UIs) and programmatically via the Application Programming Interfaces (APIs). Both the UIs and APIs are accessible at clinicalgenome.org/tools and are described in more detail below. The ClinGen Allele Registry contains over 2.57B canonical alleles and 300k CNVs registered from individual investigators, public external databases, and contributors from research and clinical communities. In order to support further growth of the CAR database, we have released a major update to support 64-bit identifiers, thus allowing UI-based registration of individual and small batches of variants and API-based bulk registration at a speed of between 100 to 100,000 variants per second (tinyurl.com/car-guide). The ClinGen Linked Data Hub supports Open, Linked Data principles by leveraging infrastructure to store structured documents linked to one another, to aggregate variant annotations excerpted from external databases and literature. Additionally, the LDH tracks provenance information, which is vital for supporting current and previous curations that may require reassessment. We are actively soliciting content contributions from additional external databases (e.g., BRCA Exchange, CIViC, hypothes.is, MaveDB, MSeqDR, tmVar/LitVar and others) in the implementation and testing of a “self-service” approach that will empower data owners towards contributing fresh variant data to inform curation and for any other use by the research and clinical communities. The ClinGen Evidence Repository, the designated distribution point for FDA-recognized ClinGen pathogenicity classifications, currently contains curations for over 3,600 curated variants from 19 Variant Curation Expert Panels categorized by 45 separate conditions.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3246. The importance of assessment of gene-disease association in the clinical practice.

Authors:

P. Bauer, E. Zonic, M. Ferreira, N. Ordonez, D. Saravanakumar, L. Almeida, I. Fernandes, N. Gulati, R. Higgins, R. Al-Ali, C. Pereira, O. Paknia, U. Hladnik, J. Pinto Basto, A. Bertoli-Avella; Centogene GmbH, Rostock, Germany

Abstract Body:

Background/Objectives:

One of the major challenges for diagnostic laboratories is the evaluation of potentially relevant variants within genes that are not yet conclusively associated to a genetic disease but have been identified in patients. With this study, we aimed to explore the gene-disease association evidence for 56 different genes and the significance of a large bio/databank for the classification process.

Methods:

The ClinGen Clinical Validity Framework for evaluation of gene-disease associations was applied. All but one of the 56 assessed genes had no publicly available gene-disease assessment in the ClinGen database, and 38 genes had no registered OMIM® phenotype. CENTOGENE's bio/databank with exome/genome data from previously tested individuals, in addition to data available in the literature or public databases were used for gene classification. According to the framework, Definitive, Strong, Moderate, Limited, or No Known Disease Relationship were assigned.

Results:

A Strong level of evidence has been reached for 21.1% of the genes, Moderate for 28.1%, Limited for 49.1%, and No Known Disease Relationship for 1.7% of the genes. A higher total number of points has been reached for 85.7% of the genes when using our bio/databank compared with using only externally obtainable data, allowing to increase the final level of classification in 19.6% of the genes.

Conclusion:

Our results demonstrate the importance of careful assessment of gene clinical validity data, along with the use of genetic data repositories. Implementation of ClinGen standardized scoring system for assessment of gene-disease association is relatively easy to apply and relevant in a clinical diagnostic setting. Diagnostic laboratories should implement such systems and contribute to closing the knowledge gap in genetic diagnostics.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3247. The International Mouse Phenotyping Consortium: A unique resource underpinning the study of human disease

Authors:

T. Groza¹, V. Muñoz-Fuentes¹, R. Wilson¹, H. Haseli Mashhadi¹, F. Lopez Gomez¹, O. Gunes¹, P. Cacheiro², A. Frost³, B. Vardal³, A. McCoy³, T. Cheng³, P. Keskivali-Bond³, L. Santos⁴, S. Wells³, D. Smedley², A-M. Mallon⁴, H. Parkinson¹; ¹EMBL - European Bioinformatics Inst., Hinxton, United Kingdom, ²Queen Mary Univ. of London, London, United Kingdom, ³Mary Lyon Ctr. at MRC Harwell, Didcot, United Kingdom, ⁴The Turing Inst., London, United Kingdom

Abstract Body:

The International Mouse Phenotyping Consortium (IMPC) is a world-wide initiative started in 2011 that links genes to function using single-gene knockout mice to inform mammalian gene function and human disease. Currently, more than 9,000 lines have been produced, many of which represent poorly understood genes. The IMPC data is produced via a systematic phenotyping pipeline, spanning across organismal physiological systems and comprising more than 250 phenotypic parameters collected on embryos, young adult and aged mice.

IMPC is a one-of-a-kind effort supporting the identification of new mouse models of rare and common human diseases, new gene functions and the development of novel methodological approaches that form the basis of new gene-disease associations. Moreover, it underpins successful experiments effectively uncovering pleiotropy, of particular importance when elucidating the genetic causes of syndromic disorders, as well as wide-ranging sexual dimorphism.

The IMPC data exists in a complex ecosystem of projects and ever growing databases which are evolving to deliver systematic analyses of cellular, organism level and population analyses. Data are curated, integrated and analysed and are made available to the public through data releases and a Web portal at mousephenotype.org. The latest release (April 2022) consists of over 80M data points and over 93,000 statistically significant phenotype hits mapped to human diseases. Interoperability with human disease and phenotype resources is achieved via widely-adopted community ontologies, such as the Human Phenotype Ontology. This enables, for example, the integration of the IMPC data directly into the interpretation of clinical genomes for National Health Service patients in the UK and in US based sequencing programs such as the Undiagnosed Disease Programme and Network.

From a clinical perspective, to date, IMPC has identified over 1700 disease models that can be used for mechanistic or therapeutic studies, where clinical phenotypes associated with known disease-gene associations are recapitulated in the mouse. In addition, thousands of novel, potential disease-gene associations have been detected that can inform on the candidacy of variants detected in patient sequencing studies. In addition to the significant impact made so far in large-scale functional studies, as complex disease analyses move from association studies to causative or 'effector' gene analyses, the functional data provided by IMPC is critical to understand the phenotypic consequences of variants, to understand which genes are essential and which contribute to diseases enabling downstream functional follow up.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3248. The NINDS Human Genetics Resource Center: 20 Years of Impact

Authors:

X. Jian¹, L. Scheinfeldt¹, S. Heil¹, A. Green¹, A. Amberson¹, S. Sander-Effron¹, R. Zhang²; ¹Coriell Inst Med. Res., Camden, NJ, ²Natl. Inst. for Neurological Disorders and Stroke-NIH, Bethesda, MD

Abstract Body:

The National Institute of Neurological Disorders and Stroke (NINDS) Human Genetics Resource Center was established in 2002 by the NINDS as a public biorepository of DNA and lymphoblastoid cell lines to facilitate the identification of genetic risk factors for neurological disorders. Each biospecimen is annotated with standardized de-identified clinical and demographic data. Since the establishment of the NINDS Repository, specimens from over 42,000 unique individuals have been successfully banked at the Coriell Institute for Medical Research and can be accessed through an online catalog (<https://www.coriell.org/1/NINDS>), and over 66,000 catalog samples have been distributed to researchers around the world. The collection includes samples from individuals diagnosed with cerebrovascular diseases (N>12,800), Parkinsonism (N>5,600), motor neuron diseases (N>2,500), Epilepsy (N>6,100), Tourette syndrome (N>4,200), Dystonia (N>3,700), and neurologically normal controls (N>7,500). To date, NINDS Repository samples have been used in over 600 peer-reviewed scientific publications, including genome-wide association studies, whole-exome sequencing studies, and structural variation studies, and these studies have been cited over 66,000 times. The genomic data collected by these studies have been deposited in the Database of Genotypes and Phenotypes (dbGaP), a NIH/NLM sponsored restricted-access data repository for studies investigating the contributions of genetic variation to phenotypic variation and disease (<https://www.ncbi.nlm.nih.gov/gap/>). The NINDS Repository catalog includes a resource page devoted to the annotation of genomic data collected from NINDS Repository samples that are available in dbGaP (<https://www.coriell.org/1/NINDS/NINDS-Samples-in-dbGaP>). Cumulatively, data from 11 dbGaP accessions are cross-referenced to over 7,000 unique NINDS Repository subject samples. Genomic data collections include genome-wide single nucleotide polymorphisms (n=6,229), genome-wide copy number variants (n=895), and whole exome sequencing (n=2,113). This public NINDS Repository collection of biospecimens, clinical and demographic data, and dbGaP annotation has made a significant research impact over the past 20 years and continues to offer extensive resources for use in new genetic and genomic studies of neurological disorders and human disease more generally.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday PB3249*. The One-Sided Matchmaking Platform (OSMP) - Accelerating genomic matchmaking and gene discovery through robust data sharing

Authors:

M. Osmond¹, M. Price¹, T. Hartley¹, C. Klamann², H. Le², J. Xu², K. Mo², H. Driver¹, M. Brudno², O. Buske³, K. Boycott¹; ¹Children's Hosp. of Eastern Ontario, Ottawa, ON, Canada, ²Univ. of Toronto, Toronto, ON, Canada, ³Phenotips, Toronto, ON, Canada

Abstract Body:

Gene discovery (associating a gene with a disease for the first time) is essential for continuing to solve undiagnosed rare diseases (RDs). A key piece of evidence for gene discovery is to identify at least one unrelated individual with overlapping phenotype and rare variant(s) in the same gene (called 'matchmaking'). Considering the scarcity of any given RD, finding similarly-affected individuals requires sharing data across borders. However, RD data is often siloed due to privacy concerns, presenting a major barrier to matchmaking efforts.

Recent initiatives such as the Matchmaker Exchange (MME), a federated network of RD databases, have enabled sharing of RD data between institutions for the purposes of matchmaking. Current matchmaking protocols such as the MME use a "two-sided" approach, where users flag candidate genes for individuals with undiagnosed RDs and potential matches are returned only when two parties flag the same gene. This excludes participation from large cohorts that do not have the resources to flag candidates themselves. Further, many cases in the MME do not provide information on phenotype or mode of inheritance up front, which results in lengthy email exchanges between users to determine if cases are a true match. Not only are two-sided approaches labour intensive, but in our experience, have false positive ratios as high as 85%.

To further expand and improve matchmaking approaches, we have developed the One-Sided Matchmaking Platform (OSMP). This web-based portal supports "one-sided" matchmaking, in which variants in novel candidate genes are identified directly from the genome-wide sequencing data within RD databases. An OSMP user may query a gene of interest across participating databases. Using application programming interfaces (APIs), the OSMP returns rare variants in the gene, along with participant-level phenotypic (HPO terms) and genotypic (zygosity, inheritance, variant quality) information. The portal's user-friendly design allows the queriers to filter and sort variant/participant information to rule matches in or out, reducing the need for time-consuming email correspondence. A pilot querying the last 6 months of new gene-disease associations in OMIM is being conducted using OSMP to explore its ability to improve the false positive ratio and identify matches of interest in the RD databases Genomics4RD (Canada) and Genomic Answers for Kids (United States). We anticipate that through robust data sharing practices, the OSMP will provide a more accessible and efficient solution to genomic matchmaking for RD researchers, and foster future connections with additional international repositories.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3250. The Osteogenesis Imperfecta Variant Database: current state

Authors:

S. Stolk¹, L. Zhytnik^{1,2}, T. van Welzenis³, M. Eekhoff¹, L. Wisse¹, A. Maugeri¹, R. Dagleish⁴, G. Pals¹, D. Micha¹; ¹Amsterdam UMC, Amsterdam, Netherlands, ²Dept. of Traumatology and Orthopedics, Inst. of Clinical Med., The Univ. of Tartu, Tartu, Estonia, ³Osteogenesis Imperfecta Federation Europe, Denemarken, Netherlands, ⁴Dept. of Genetics and Genome Biology, Univ. of Leicester,, Leicester, United Kingdom

Abstract Body:

ObjectiveThe Osteogenesis Imperfecta Variant Database (OIVD) contains comprehensive information on variants, their pathogenicity, and patients' phenotypes. Submission of newly found variants to OIVD will further enhance its significance for the OI community. The database was created around 1984 and is widely consulted for OI gene diagnoses and numerous research projects. In 2008 the database migrated to the Leiden Open Variation Database (LOVD), supported initially by the EC GEN2PHEN project. The current OIVD includes variants for 25 genes for OI and overlapping disorders. The database is recognized as a powerful tool for genetic diagnosis, prediction of disease progression, genotype-phenotype correlations, and translational and clinical research. Recently, the main curation of the database was transferred to Amsterdam UMC. We encourage variant submission to OIVD to ensure consolidation and harmonization in OI variant interpretation. **Methods**Variants, published in journals, should be submitted to OIVD. Anybody can become a submitter (https://databases.lovd.nl/shared/docs/LOVD3_submit.pdf). Variant reporting follows current standards (mandatory transcript identifier and use of the HGVS variant nomenclature guidelines), pathogenicity assessment uses the ACMG guidelines, and correct OI clinical types are reported. These measures apply to variants submitted both directly to LOVD-OI and to those from the literature added by the curators. All data are checked and verified by the curators of the database. All OI variant information can be found at <https://lovd.nl/OI-genes>. **Results**OIVD contains approximately 3250 unique OI variants in 6290 patients, with a complete coverage of variants till 2018. Completing and updating the database with published variants (2019-current) is being reinitiated by Amsterdam UMC. Currently, missing OI variants from 2019-2020, are being submitted, including 930 variants from the AGDx. **Conclusion**OIVD is the most comprehensive database of OI genetic variants and patient phenotypic data but few updates have been made since 2018. We strongly encourage our colleagues to submit their (un)published variants and the database is open for submissions. **Funding and acknowledgements**We would like to acknowledge following organizations: Department of Human Genetics, Amsterdam UMC; Leiden University Medical Centre; Osteogenesis Imperfecta Federation Europe (OIFE), The Ehlers-Danlos Society; OI Society Australia. The authors declare no conflicts of interest.

Ethical approvalNot applicable

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3251. TT-Mars: structural variants assessment based on haplotype-resolved assemblies

Authors:

J. Yang, M. Chaisson; Univ. of Southern California, Los Angeles, CA

Abstract Body:

Structural variant (SV) benchmarking is a critical for method development and evaluating the accuracy of genetic variation studies. Typically this has been performed by comparing against a curated SV callset. However this approach is not satisfactory when there are multiple valid representations of the same variant. This drawback is exacerbated in repetitive regions that not only are highly variable, but are also where new sensitive SV discovery methods using long reads find the most variation. We have developed an alternative approach for validating variation, TT-Mars, that scores variant calls based on the sequence implied by the SV rather than the call itself. TT-Mars compares implied genome content to high-quality haplotype-resolved genome assemblies generated from long-read sequencing. In our initial study, we demonstrated about 20.9% additional SVs from short read, and 50.9% from long read data could be validated by TT-Mars, compared to the state of the art, gold-standard based method, Truvari. Here, we present an update to TT-Mars to evaluate calls produced as a result of pangenome graph construction, and whole-genome alignments of de novo assemblies constructed from Oxford Nanopore (ONT) data. Both of these approaches require the flexibility to validate “fragmented” SV calls: multiple nearby calls that in aggregate represent the true call, but individually may not be valid. We find that for graph genomes, when phase data are available, about 4,600 aggregate calls may be validated, and for ONT data about 1,000 aggregate calls are validated.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3252. Using RGD to analyze genes associated with obesity.

Authors:

M. Vedi, J. R. Smith, G. Thomas Hayman, M. L. Kaldunski, S-J. Wang, S. J.F. Laulederkind, M. Hill, W. Demos, M. Tutaj, A. Gibson, L. Lamers, H. S. Nalabolu, K. Thorat, J. Thota, M. A. Tutaj, J. L. De Pons, M. R. Dwinell, A. E. Kwitek; Med. Coll. of Wisconsin, Milwaukee, WI

Abstract Body:

RGD (<http://rgd.mcw.edu>) provides a rich core of human genomic and phenotypic data with an infrastructure of standardized ontologies, disease portals, and many bioinformatics tools to allow users to explore and make disease-related connections among these datasets. These tools and data are integrated with nine other species used as models for human disease (rat, mouse, pig, chinchilla, dog, bonobo, 13-lined ground squirrel, vervet, and naked mole-rat) for translational research.

Obesity is a complex disease and a worldwide health concern due to its implication as a critical risk factor in multiple conditions, including stroke, dementia and COVID-19. As an example workflow, we used RGD's Multi-Ontology Enrichment Tool (MOET) to do an enrichment analysis of the top 200 differentially expressed genes in a gene expression profile dataset of peripheral blood mononuclear cells among normal weight and moderately obese subjects obtained from GEO (GSE69039). The top terms in biological process and pathway ontologies were cellular response to stress and regulatory pathway. The top term in the gene-chemical interactions (ChEBI) ontology was an antirheumatic drug which is interestingly associated with weight loss. To further analyze these genes, users can easily navigate from MOET to the other RGD tools such as Variant Visualizer to investigate clinical variants and GViewer for a genome-wide view of the genes.

RGD provides researchers with the Obesity & Metabolic Syndrome Disease Portal as one of fifteen Disease Portals that offer data for genes, QTLs and rat strains associated with the disease. As another example, we generated a list of human genes common between obesity and stroke using the Obesity & Metabolic Syndrome Disease Portal and Object List Generator and Analyzer (OLGA). This list was used as input for the Variant Visualizer, which found the *LDLR* gene to include many predicted damaging variants and was also linked to Hypercholesterolemia. Additional information about the *LDLR* gene can be found on the RGD gene report page, including disease annotations, clinical variants with associated conditions, and links to the gene report pages of other RGD species. The rat *Ldlr* gene report page shows the multiple *Ldlr* rat strain genetic models available for obesity and obesity-related conditions research. For example, the SD-*Ldlr*^{em1Sage} strain page shows obesity-related disease and mammalian phenotype annotations and PhenoMiner (quantitative phenotype) data. In conclusion, RGD aims to build functionality to support widespread use and assist researchers in finding and utilizing the data and models they need to explore to further gene-to-disease research.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3253*. Variant reclassification based on the allele frequency information from exome sequencing data of 20,455 patients enriched with under-represented populations.

Authors:

K. Kwon, H. Han, G. Seo, H. Lee; 3billion, Seoul, Korea, Republic of

Abstract Body:

Accurate variant classification is essential for making a molecular diagnosis, and therefore, multiple lines of evidence are carefully considered for determining variant pathogenicity. One of the most important lines of evidence used for diagnosing rare Mendelian disorders is the variant allele frequency (AF) information. Filtering out variants based on AF is the most effective way of narrowing down the number of variants that need interpretation, as it removes a substantial number of variants that are too common to be disease-causing. There are several publicly available databases (DB) such as gnomAD that provide AF information from large populations. Many of these large DBs tend to be dominated by few populations though and therefore it is less effective when filtering out variants for individuals from underrepresented populations. Accordingly, many variants remain of uncertain significance (VUS) and even incorrectly classified as pathogenic or likely pathogenic (P/LP) because of its absence in these public DBs. Here, we investigated if a subset of ClinVar P/LP variants and VUS can be downgraded to likely benign (LB) based on AF information from our internal exome sequencing data of 20,455 patients that are not part of any publicly available DBs. From a total of 1.1 billion variants identified in the exome of 20,455 patients, we extracted 399 ClinVar P/LP/VUS variants in clear autosomal dominant genes. These variants were not observed in gnomAD but observed in more than 2 individuals in our DB, while not being reported as disease-causing variants because of inconsistent phenotype. To account for incomplete penetrance and variable expressivity, AF of the most common ClinVar P variant of each gene was obtained from gnomAD and used as a threshold. There were 384 variants with an internal AF greater than this threshold and therefore could be considered LB. Seven of these variants were classified as P/LP in ClinVar, although none of them had ClinVar review status above 1 star. As expected, these 384 variants were mostly found in the “East Asian” (39%) and “others” (30%, non-major) population, suggesting that lack of AF information is the most likely reason for over-classifying the variants. It is not uncommon to find a variant not observed in gnomAD to be very common in a specific population within our dataset consisting of 58% Asians (40% East Asians, 15% South Asians, 3% other Asians). This study highlights the significance of using matched population data to filter variants and the importance of spearheading the effort of sequencing more underrepresented populations.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3254. VariantMatcher a tool to enable connections amongst individuals with interest in a specific variant

Authors:

R. Paulo Martin¹, E. Rodrigues¹, S. Griffith¹, C. Antonescu¹, L. Vail¹, J. Posey², Z. Coban-Akdemir², S. Jhangiani^{2,3}, K. Doheny¹, J. Lupski^{2,3,4,5}, D. Valle¹, A. Hamosh¹, N. Sobreira¹; ¹McKusick-Nathans Dept. of Genetic Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ²Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, ³Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX, ⁴Dept. of Pediatrics, Baylor Coll. of Med., Houston, TX, ⁵Texas Children's Hosp., Houston, TX

Abstract Body:

VariantMatcher (<https://variantmatcher.org>) was developed to connect individuals around the globe with an interest in a specific variant. It enables sharing of variant-level and phenotypic data from participants in research projects for discovery of disease-causing variants and genes. VariantMatcher contains rare (MAF < 1% in gnomAD) nonsynonymous SNVs identified in 6,235 VCF files (896,847 unique variants) of affected and unaffected individuals sequenced as part of multiple projects and their detailed phenotypic information. Users must register and be approved by site administrators. Users may upload up to 10 genomic coordinates per day and are notified of any match. The query format is "chr:coordinate refAllele > altAllele". Queries using hg18 or hg38 are lifted over to hg19 prior matching. Phenotypic features can be added and shared in the email notifying the match, but the match is based on the genomic location. When a match occurs, both parties are notified by simultaneous emails. If a match is not made, the queried coordinates can be stored for future matching. VariantMatcher is also connected to the Beacon Network through the Beacon protocol. If a user querying the Beacon Network is informed that the variant is found in VariantMatcher, VariantMatcher registration is required to obtain additional information regarding the variant. As of June 1, 2022, VariantMatcher had 767 submitters from 47 countries; 5,630 variants were queried and 87 variants matched to 982 individuals. The 87 variants affected 82 genes. 64 of these genes are known disease-causing genes. 15 variants in these genes were classified as pathogenic or likely pathogenic in ClinVar, 28 were classified as variant of uncertain significance and 10 were classified as benign or likely benign. To date, no variant match was confirmed as a phenotype match but most of the matches helped to rule out the variant queried as the cause of the phenotype being investigated. Additional query capabilities are planned in upcoming releases, including: indels; variants by zygosity state; specific variant with phenotypic feature(s); and specific group of variants/gene (e.g., individuals with nonsense variants in gene X). In addition, VariantMatcher will implement the standards and protocols from Data Connect API (GA4GH) to connect VariantMatcher with other variant-level databases such as Franklin and MyGene2/Geno2MP. By connecting different variant-level databases and individuals, we expect to improve the variant classification process in both research and clinical settings and also to increase the discovery rate of novel disease-causing variants by increasing the specificity of matches.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday

PB3255. VuTR: Visualising the consequences of high-impact 5' UTR variants

Authors:

E. Dsouza¹, J. Martin-Talbot¹, D. MacArthur², N. Whiffin¹; ¹Univ. of Oxford, Oxford, United Kingdom, ²Ctr. for Population Genomics, Sydney, Australia

Abstract Body:

5'untranslated regions (5' UTRs) are directly upstream of the protein-coding sequence and have important roles in regulating RNA stability, localization, and rate of mRNA translation. Variants within 5' UTRs that disrupt these regulatory processes have been implicated in genetic disorders, however, annotating and interpreting any individual variant of interest is difficult. Approximately 30% of likely pathogenic variants in the ClinVar database potentially act through perturbing upstream open reading frames (uORFs), which are short translated elements in the 5' UTRs that negatively regulate downstream protein translation. Here we present, VuTR, to enable the exploration of annotated variants in 5'UTRs and their impact on uORFs. For any transcript defined by the Matched Annotation from NCBI and EMBL-EBI (MANE) project, the application displays its native 5' uORF architecture overlaid over its genomic sequence along with the likelihood that each uORF is translated given the surrounding Kozak consensus context and harnessing experimental data on translational efficiency. VuTR displays the effect of all 5' UTR variants from the ClinVar and gnomAD databases using annotations from the Ensembl Variant Effect Predictor (VEP) plugin, UTRannotator. Additionally, users are able to query and visualise the impact of any 5' UTR SNV or indel (up to 3bps) of interest. VuTR facilitates annotation and interpretation of variants in 5'UTR regions by both clinical scientists and researchers. In the future, the application will be expanded to include additional regulatory elements. VuTR is available through an easily accessible and open web application build on python3, Flask and nginx (<http://49.12.238.72:8080/>). Its source code and pipeline are released on a GPLv2 License and can be accessed through our GitHub repository (<https://github.com/Computational-Rare-Disease-Genomics-WHG/VuTR>).

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Thursday

PB3256. Web Tools and Resources for Generating and Accessing ACMG Criteria Specifications for Variant Classification by ClinGen Variant Curation Expert Panels

Authors:

N. Shah¹, A. Jackson¹, T. Farris¹, D. Azzariti², M. DiStefano^{2,3}, S. Harrison^{4,2}, M. Mandell⁵, C. Preston⁵, J. Goldstein⁶, M. Wright⁵, T. Klein⁷, S. Plon^{8,9,10}, A. Milosavljevic¹; ¹Baylor Coll. of Med., Houston, TX, ²Broad Inst. of MIT and Harvard, Cambridge, MA, ³Precision Hlth.Program, Geisinger, Danville, PA, ⁴Ambry Genetics, Salt Lake City, UT, ⁵Dept. of BioMed. Data Sci., Stanford Univ. Sch. of Med., Stanford, CA, ⁶Dept. of Genetics, Univ. of North Carolina, Chapel Hill, NC, ⁷Dept.s of BioMed. Data Sci. & Med., Stanford Univ. Sch. of Med., Stanford, CA, ⁸Molecular and Human Genetics Dept., Baylor Coll. Med., Houston, TX, ⁹Pediatrics-Oncology, Baylor Coll. of Med., Houston, TX, ¹⁰Cancer Genomics Clinical and Res. Programs, Texas Children's Hosp., Houston, TX

Abstract Body:

The ClinGen Sequence Variant Interpretation (SVI) Working Group provides general recommendations for using ACMG/AMP criteria codes to enhance consistency in usage and transparency of variant classification rationales. In addition to following these general recommendations, ClinGen Variant Curation Expert Panels (VCEPs) define and apply their own gene-disease specific recommendations for each of these ACMG evidence codes. We here present multiple web-accessible tools that facilitate generation and dissemination of these specifications in both human- and machine-readable formats. ClinGen Criteria Specification (CSpec) Registry database contains 22 criteria specification documents, defined by 20 VCEPs for more than 50 genes. The CSpec Registry UI (<https://cspec.genome.network>), is a user-friendly web interface for browsing, filtering, and searching criteria specifications by gene and disease. The CSpec data messaging service publishes SVI approved specifications to the ClinGen Data Exchange thereby notifying other ClinGen Curation Tools, like the Variant Curation Interface (VCI), of the approval and release of these specifications. This enables CSpec integration into the VCI curation and ClinGen workflows, as well as provides direct access to the up-to-date specifications by the curators as they classify variants. In addition, the CSpec Editor allows VCEP coordinators and other members to create, update, and release approved specifications for public sharing. The CSpec Registry REST-API service (<https://cspec.genome.network/srvc>) provides programmatic access to the structured content in JSON and JSON-LD formats so that other resources, including those external to ClinGen, can integrate ClinGen approved evidence code specifications into their variant classification and genome interpretation processes. By allowing both programmatic and web user interfaces for developing and releasing the criteria specifications, these tools elevate the transparency and consistency of variant curation processes across ClinGen while empowering research and clinical communities globally. In addition, these resources will be instrumental in supporting our ongoing efforts to automate batch variant curation. Programmatic access further empowers automation of variant classification beyond ClinGen.

Genetic, Genomic, and Epigenomic Annotations, Databases and Resources Posters - Wednesday
PB3257*. Web-CSEA: Web-based Cell-type-Specific Enrichment Analysis of Genes

Authors:

Y. Dai¹, R. Hu¹, A. Liu², K. Cho¹, A. Manuel¹, X. Li¹, X. Dong³, P. Jia², Z. Zhao⁴; ¹UTHlth.at Houston, Houston, TX, ²UTHlth., Houston, TX, ³Brigham & Women's Hosp, Cambridge, MA, ⁴Univ Texas HSC Houston, Houston, TX

Abstract Body:

Background: Human complex traits and common diseases show tissue- and cell-type- specificity. Recently, single-cell RNA sequencing (scRNA-seq) technology has successfully depicted cellular heterogeneity in human tissue, providing an unprecedented opportunity to understand the context-specific expression of complex trait-associated genes in human tissue-cell types (TCs). There is a pressing need for advanced computational methods and web services that could characterize the signature genes of human cell types and, reversely, assess the cell types that a particular gene set may be enriched. **Methods:** We curated a total of 111 scRNA-seq panels of human tissues and 1,355 TCs from 61 different general tissues across 11 human organ systems and developmental stages. We adapted our previous decoding tissue-specificity (*deTS*) algorithm to train and measure the enrichment for each tissue-cell type (TC). To overcome the potential bias from the number of signature genes between different TCs, we further calculated a permutation-test p-value with ~20,000 previously calculated p-values derived from genetic trait-associated gene sets of diverse human diseases and traits, which naturally contains moderate TC-specificity. **Results:** We present the first web-based application to quickly assess the cell-type-specificity of genes, named Web-based Cell-type Specific Enrichment Analysis of Genes (WebCSEA, available at <https://bioinfo.uth.edu/webcsea/>). We provide extensive visualization functions such as interactive heatmap, and interactive and static jitter plots to display the cell-type specificity across 1,355 human TCs by human organ system, developmental stage, and top-ranked tissues and cell types. We benchmark the performance of our WebCSEA by using a few ground truth gene lists from cell-type signature genes, disease risk genes with unknown onset tissues, and cell-type-specific pathways. Users could use WebCSEA to explore the TC-specificity of focal gene lists in different scenarios, including 1) cellular context for candidate genes of complex disease, 2) validation for tissue-specific and cell type-specific signatures, 3) differentially expressed genes from bulk transcriptome/epigenome, 4) validation of developmental stage-specific genes, and 5) tissue-cell-type specific gene ontology/KEGG pathway. **Conclusion:** WebCSEA is a user-friendly interactive platform that provides a comprehensive exploration of the TC-specificity of genes among human major TC map. Just like the gene-set enrichment analysis, we expect WebCSEA to serve the broad users in both research and clinical community to explore the biological context of human genes.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3258. 8 Billion Polygenic Risk Score distributions: building unique reference populations based on genetic ancestry to increase the performance of PRS

Authors:

G. Busby, A. Bolli, J. Kintzle, P. Di Domenico, G. Bottà; Allelica, New York, NY

Abstract Body:

The clinical utility of PRS depends on a clear assessment of their predictive performance in the population in which they are intended to be used. Typically, this is achieved by estimating the association (i.e. effect size) of a PRS with disease in a range of different Testing populations. Predicting risk in a new Target individual involves identifying the most appropriate reference distribution from these Testing populations, placing the Target individual within this distribution, and computing the relative increase or decrease in disease risk after applying the appropriate population-specific effect size. Current approaches assume that Target individuals belong to one of a fixed number of a priori defined reference populations. These are typically categorized by (sub-)continental ancestry or ethnicity labels (European, African American etc). While appealing, such categorization enforces boundaries between human populations that are both artificial and potentially misleading. Human genetic diversity is continuous and genetic ancestry is a description of history more than geography.

We present a novel approach to defining a PRS reference distribution that selects the unique set of reference individuals who are most genetically similar to a Target individual without having to assign them to a pre-defined group. The reference individuals are selected from a balanced and deep dataset of individuals from diverse genetic ancestries. Using a combined genetic and clinical dataset of almost 500,000 individuals across the spectrum of global genetic diversity, we test the ability of multiple ancestry-specific PRS to predict risk of breast and prostate cancer in a range of individuals. We construct unique reference distributions using a multivariate approach to identify genetically similar individuals. Comparisons of the performance of these distributions show a significant increase in the accuracy of PRS compared with approaches that place individuals into a limited set of predefined reference populations. Our study shows the potential for large, diverse genetics datasets to power the clinical use of PRS by providing a framework for building personalized PRS reference distributions for the accurate prediction of risk in all 8 billion people on earth.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3259. A Cox proportional hazards whole genome sequencing study of ischemic stroke risk in a Brazilian sickle cell population

Authors:

E. Earley¹, F. Fang², E. Sabino³, C. Dinardo⁴, S. Kelly⁵, B. Custer⁵, G. Page⁶, NHLBI Recipient Epidemiology Donor Evaluation Study (REDS-III) International Component - Brazil; ¹RTI Intl., Durham, NC, ²RTI Intl., Lexington, MA, ³Univ. de São Paulo, São Paulo, Brazil, ⁴Inst. de Med. Tropical, Univ. of São Paulo, São Paulo, Brazil, ⁵Vitalant Res. Inst., San Francisco, CA, ⁶RTI Intl., Atlanta, GA

Abstract Body:

Ischemic stroke is a major complication of sickle cell disease (SCD) and without preventive care affects 11% of children with SCD before the age of 20. Ischemic stroke is more common in children, whereas hemorrhagic stroke is more common in SCD patients who are 20-30 year-olds. Previous genetic studies of stroke in SCD have been either un-replicated or conflicting. To address this gap, we have conducted a genome-wide association study (GWAS) of ischemic stroke within SCD with three novel features: 1) the largest cohort to date at N=1,333 HbSS homozygotes; 2) early-life risk association with a cox proportional hazards model; 3) whole genome sequencing data.

Medical records were abstracted including a history of stroke using standardized definitions across 6 Brazilian sites in Brazil. Cox Proportional Hazards model was run with stroke as the outcome on 1,333 homozygous HbSS individuals (178 Ischemic strokes) using whole genome sequence (MAF > 1%; minimum depth 10x) within the NHLBI Trans-Omics for Precision Medicine (TOPMed), and the top 10 principal components were used as covariates to control for population stratification. Alleles were coded as dosages (0, 1, or 2) across 14M sites.

14 genomic regions were associated with early ischemic stroke at genome wide significance ($P < 5 \times 10^{-8}$). This included variants near two genes which have been previously linked to pediatric or early onset stroke in non-SCD cohorts: *ADAMTS2* (rs147625068, $P = 3.70 \times 10^{-9}$) and *CDK18* (rs12144136, $P = 2.38 \times 10^{-9}$). Individuals in our study harboring multiple risk alleles exhibited increasing rates of stroke at earlier timepoints ($P < 0.001$, Gehan-Wilcoxon). Significant gene enrichment was observed in multiple tissue classes, including upregulated genes in the coronary (8 genes, $P = 0.0005$, FDR), tibial (9, $P = 0.03$, FDR) and aorta arteries (7, $P = 0.03$, FDR), as well as downregulated genes in the spleen (7, $P = 0.005$), pancreas (13 genes, $P = 0.02$), esophagus mucosa (8, $P = 0.03$), hypothalamus (10, $P = 0.03$), and substantia nigra (11, $P = 0.03$). We also observed enrichment within the GWAS Catalog disease category white matter lesion progression (*CNNM2*, *NT5C2*, $P = 0.01$) and the combined phenotype of coronary artery disease or large artery stroke (*CNNM2*, *NT5C2*, $P = 0.04$).

In conclusion, we have conducted the largest GWAS of ischemic stroke in SCD to date. Results have replicated known associations with pediatric and early stroke (<65 years) for genes *ADAMTS2* and *CDK18*, respectively. Pathway analysis suggests gene dysregulation in the arteries (coronary, tibial, and aorta), spleen, pancreas, esophagus mucosa, hypothalamus, and substantia nigra.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3260. A fast Bayesian screen to identify pleiotropic loci and describe pleiotropic profiles.

Authors:

S. Huo¹, L. Wang², S. Lindström², P. Kraft¹; ¹Harvard Univ., Boston, MA, ²Univ. of Washington, Seattle, WA

Abstract Body:

Pleiotropy occurs when a genetic variant is associated with more than one trait. Multi-trait test statistics have been proposed that leverage pleiotropy to increase power in identifying trait-associated loci. However, most of these methods only test the global null that none of the tested traits are associated with a variant but do not provide any information regarding whether the variant is associated with more than one trait, or with which traits the variant is associated. In this paper, we propose a new fast screening framework based on the Bayesian support region to overcome these restrictions. Our approach accounts for correlation among test statistics due to sample overlap and leverages cross-trait heritability. Computation scales linearly in the number of traits. We compare our approach to widely used alternatives (including the likelihood-ratio test, Bonferroni correction for the number of traits, and ASSET, among others) via simulation. Our approach shows both high sensitivity and high specificity and outperforms the alternatives under most scenarios. For example, our approach can correctly detect up to 67.8% more pleiotropic SNPs than Bonferroni correction. We applied our approach to GWAS summary statistics from 12 different cancers and identified 82 independent regions exhibiting pleiotropy, including *TERT*, *ABO*, and the HLA region, each associated with three cancers. We hope that this new method can facilitate biological discoveries in the future.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3261. A fast variational inference approach for powerful genome-wide association of quantitative traits.

Authors:

H. Loya^{1,2}, G. Kalantzis¹, A. Pazokitoroudi³, S. Sankararaman^{3,4,5}, P. Palamara^{1,2}; ¹Dept. of Statistics, Univ. of Oxford, Oxford, United Kingdom, ²Wellcome Ctr. for Human Genetics, Univ. of Oxford, Oxford, United Kingdom, ³Dept. of Computer Sci., UCLA, Los Angeles, CA, ⁴Dept. of Human Genetics, David Geffen Sch. of Med., UCLA, Los Angeles, CA, ⁵Dept. of Computational Med., David Geffen Sch. of Med., UCLA, Los Angeles, CA

Abstract Body:

The rapid growth of modern biobanks is creating new opportunities for large-scale genome-wide association studies (GWAS) and the analysis of complex traits. The computational cost of performing GWAS in millions of samples, however, often leads to a trade-off between computational efficiency and statistical power, reducing the benefits of data collection efforts. We developed a method, called Quickdraws, that achieves increased association power without sacrificing efficiency. Quickdraws uses a non-infinitesimal model based on a mean-field spike-and-slab prior on phenotypic effects, which is efficiently optimized using stochastic variational inference, GPU matrix operations, and code vectorization for parallel trait analysis.

We tested the statistical power and robustness of Quickdraws and other available GWAS methods by simulating data sets of 50k UK Biobank samples including up to 10% of related individuals, as well as 50 quantitative traits with 2% polygenicity, 40% heritability, and population stratification. Quickdraws, BOLT-LMM-MoG, and FastGWA were robust to relatedness and stratification, while linear regression was inflated in the presence of relatedness and Regenie was inflated when only very close relatives were included. We evaluated association power using average χ^2 test statistics at simulated causal SNPs. Quickdraws and BOLT-LMM-MoG yielded similar average χ^2 statistics (7.38, SE = 0.25 and 7.43, SE = 0.25, respectively), significantly higher ($p < 10^{-25}$) than Regenie (7.06, SE = 0.22), FastGWA (6.76, SE = 0.22), and linear regression (6.72, SE = 0.22).

We applied Quickdraws and other methods to 50 quantitative blood-related traits in 404k self-reported UK Biobank White British samples. We performed variant clumping (Plink p-value threshold = 5×10^{-9} , r^2 threshold = 0.01) to extract sets of approximately independent variants. Consistent with simulations, Quickdraws and BOLT-LMM-MoG detected more associations than other methods ($N_{\text{Quickdraws}} = 14,801$, $N_{\text{BOLT-LMM-MoG}} = 14,796$, $N_{\text{BOLT-LMM-Inf}} = 13,713$, $N_{\text{Regenie}} = 14,149$, $N_{\text{FastGWA}} = 11,287$). We compared computational costs by fitting 458k model SNPs and performing association for 7.4 million imputed SNPs. Quickdraws was 43x faster than BOLT-LMM-MoG and 20% faster than Regenie v3 ($T_{\text{Quickdraws}} = 10.6\text{h fitting} + 22\text{h association testing}$, $T_{\text{BOLT-LMM-MoG}} = 1,150\text{h} + 255\text{h}$, $T_{\text{Regenie}} = 4.7\text{h} + 36.2\text{h}$).

These results highlight the promise of leveraging modern machine learning techniques such as stochastic variational inference and GPU-based acceleration to develop scalable GWAS association methods without sacrificing statistical robustness or power.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3262. A framework to improve the interpretation and prediction of variant effect sizes using non-linear functional models

Authors:

S. Cheng^{1,2}, S. Gazal^{1,2}; ¹Dept. of Population and Publ. Hlth.Sci., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA, ²Ctr. for Genetic Epidemiology, Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA

Abstract Body:

Modeling the relationship between the effect sizes of common variants and their functional annotations is critical to accurately characterize the functional genetic architecture of human diseases and complex traits. Existing functional models rely on linear relationships between variants squared effect sizes (or per-variant heritability) and their functional annotations; this linear relationship is methodologically constrained by the fact that we are observing marginal effect sizes from genome-wide association studies (GWAS), and that true effect sizes are unobserved. However, linear models constrained our interpretation of functional architectures, and it is thus unclear if a non-linear structure would improve model prediction. Here, we aim to improve interpretation and prediction of existing functional models by using machine learning approaches.

We developed a framework that 1) leverage the fine-mapping method SuSie (Wang et al. 2020 Journal of the Royal Statistical Society) to estimate the true allele effect sizes of each common variant, and 2) model per-variant heritability directly on these estimated effects (rather than marginal effects) using 96 functional annotations from the baseline-LD model (Gazal et al. 2017 Nat Genet). First, using in 16 independent traits of the UK Biobank, we observed that a simple linear regression on SuSie effects provide similar functional enrichment than the state-of-the-art method S-LDSC (Finucane et al. 2015 Nat Genet) that estimate enrichment directly on marginal effect sizes ($r = 0.93$ across 40 functional annotations), validating the approach and allowing further investigation of non-linear models. Second, we ran decision trees and deep neural networks using a different set of hyper parameters on these 16 traits, and observed that these approaches outperform the linear model when looking at the mean squared error (MSE), and that they are robust to overfitting when using a leave-one-chromosome-out (LOCO) approach. We compared functional enrichment obtained with these approaches and S-LDSC to validate current S-LDSC estimates. Finally, we ran decision trees with only 3 layers on 16 UK Biobank traits, and observed a more interpretable functional architecture of human disease and complex traits.

To summarize, we have developed and validated a framework using non-linear models to investigate functional architectures of human diseases and complex traits. These new predictions could be leveraged to improve priors of fine-mapping and/or polygenic risk score analyses.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3263. A gene-based association test of interactions for maternal-fetal genotypes identifies genes associated with non-syndromic congenital heart defects.

Authors:

M. Huang¹, C. Lyu², N. Liu¹, W. N. Nembhard³, C. A. Hobbs⁴, M. Li¹, The National Birth Defect Prevention Study; ¹Indiana Univ., Bloomington, IN, ²New York Univ. Grossman Sch. of Med., New York, NY, ³Univ. of Arkansas for Med. Sci., Little Rock, AR, ⁴Rady Children's Inst. for Genomic Med., San Diego, CA

Abstract Body:

The risk of congenital heart defects (CHDs) may be influenced by maternal genes, fetal genes, and their interactions. Existing methods commonly test the effect of maternal and fetal variants one-at-a-time, and may have reduced statistical power to detect genetic variants with low minor allele frequencies. In this article, we propose a gene-based association test of interactions for maternal-fetal genotypes (GATI-MFG). GATI-MFG is a region-based method that can integrate the effect of multiple variants within a gene or genomic region, and thus, may detect the associations of rare variants with improved power. It also evaluates the joint effect of maternal and fetal genotypes while allowing for their interactions. In simulation studies, GATI-MFG had improved statistical power over alternative methods, such as the single-locus test and functional data analysis under various disease scenarios. We further applied the method to a two-phase genome-wide association study of CHDs using 947 CHD case mother-infant pairs and 1,306 control mother-infant pairs from the National Birth Defects Prevention Study. After Bonferroni adjustment for 23,035 genes, two genes on chromosome 17, *TMEM107* (p-value=1.64e-06) and *CTCI* (p-value=2.0e-06), were identified for significant association with CHD risk. Gene *TMEM107* encodes a ciliary transition zone protein which regulates ciliogenesis and ciliary protein composition. Previous studies have shown that *TMEM107* is associated with heterotaxy. Gene *CTCI* plays an essential role in protecting telomere from degradation. Previous studies have suggested that telomere length is associated with heart development, function, and disease. Our findings are consistent with existing literature supporting the association between *CTCI* and CHDs.

PB3264. A generalized framework to decorrelate family or population structure that can easily incorporate epistasis, GxE interaction or multiple-variant analysis in GWAS and NGS studies

Authors:

D. Li, D. McGovern; Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract Body:

Background: Linear mixed models (LMMs) have been widely used in Genome-wide Association Studies (GWAS) or Next Generation sequencing studies (NGS) to account for population or family structures. Still, most of the proposed algorithms are limited to single-variant analysis and there are intensive needs for novel algorithms to accommodate analyses such as epistasis, GxE interaction or multiple-variant analyses.

Methods: Instead of directly incorporate the Genetic Relation Matrix (GRM) as a random term in the LMM, we utilized an extension of generalized least square (GLS) as a way to “decorrelate” the genetic structure. In brief, a reverse of the Choleski Decomposition of the GRM was multiplied to the original genetic matrix G and phenotype vector Y , which generates the transformed G' and Y' .

It can be proved that with this transformation, direct regression of Y' on G' will yield a Best Linear Unbiased Prediction (BLUP) of the coefficient β . With this approach, all the methods developed for epistasis, GxE interaction or multi-variant analysis can be applied to the decorrelated G' and Y' .

A simulation was performed to evaluate the performance of the proposed GLS approach across different scenarios. Performance was compared to no adjustment for genetic structures (lm_{crude}) under the null hypothesis across different scenarios including single-variant, epistasis, GxE interaction as well multiple causal variants. Performance was also compared to the LMM based approach, when the corresponding algorithm is available (single variant, epistasis, GxE).

With the multi-variant association a SKAT-CommonRare based association was performed in the transformed G' and Y' . In this case the performance of the GLS was not compared to LMM as currently there is no LMM based SKAT algorithm available.

Results: Under the null hypothesis, the proposed GLS approach retained nominal type I error rate across all the scenarios. For example, when the genetic structure was from trio families, with a p-value threshold of 0.05, type I error rate is 0.048 for GLS and 0.092 for the lm_{crude} in the multi-variant analyses.

Under the alternative hypothesis, the proposed GLS approach has comparable power compared to the LMM based analysis. For example, in the single-variant analysis, when there are both family and population structures, the power is 0.865 for GLS and 0.857 for LMM.

Conclusion: With the proposed GLS approach, investigators can easily apply different algorithms with independent hypothesis to GWAS or NGS datasets with complex genetic structures.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3265*. A genetic correlation disease-disease network (gcDDN) for the improved identification of novel phenotype relationships

Authors:

V. Sriram, J. Woerner, Y. Nam, D. Kim; Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Many complex disorders share associations with multiple phenotypes. However, our understanding of these disease connections is still severely limited, and it is unclear how much of a role is played by genetics. A disease-disease network (DDN), a graph where nodes represent diseases, can help to identify related disorders. By applying cross-trait linkage disequilibrium score regression to the data generated from a biobank-scaled phenome-wide association study (PheWAS), we can generate a corresponding genetic correlation DDN (gcDDN), where edges represent genetic associations between phenotypes. We hypothesize that a gcDDN can help to better identify novel disease co-occurrences as well as highlight potential genetic contributors to these disease connections, particularly compared to conventional PheWAS-derived DDNs, where edges simply represent the number of phenotype-associated variants that pass a specified significance threshold and are shared across nodes. We constructed a gcDDN for 487 phenotypes that had at least 1000 cases from UK Biobank (UKBB) PheWAS summary data. To demonstrate the gcDDN's clinical significance, we focused on myocardial infarction (MI), a polygenic disease with high heritability, as our index phenotype of interest. Graph-based semi-supervised learning was applied to generate scores of predicted disease co-occurrence between MI and its neighboring phenotypes in the gcDDN. These predictions were validated against ground truth disease co-occurrences derived from UKBB in-patient data. We find that the gcDDN identifies disease connections with MI evinced in the in-patient data more accurately than a conventional DDN, with a 22.8% increase in the area under the receiver operating curve (AUC) from 0.632 to 0.776. This result suggests that a gcDDN can effectively identify relationships between diseases for complex, heritable phenotypes, indicating its relevance in further explorations of personalized medicine and disease comorbidity. Remaining work involves the assessment of gcDDN for additional phenotypes as well as an interpretation of the specific genetic variants that contribute to connections in the network.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3266. A genome-wide search for parent-of-origin effects in 4,505 unrelated individuals identifies the *8q21.3* locus as a novel genetic regulator of Factor V plasma levels.

Authors:

B. Gendre¹, A. Martinez-Perez², M. Kleber³, A. Van Hylckama Vlieg⁴, A. Boland³, N. Saut⁵, J-C. Souto⁶, M. Germain⁷, G. Delgado⁸, J. Deleuze³, M. Winfried⁸, M. Sabater-Lleal⁶, F. Rosendaal⁴, J-M. Soria⁶, P-E. Morange³, D-A. tregouet⁷; ¹Univ. of Bordeaux, Bordeaux, France, ²Hosp Sant Pau, Barcelona, Barcelona, Spain, ³Leiden Univ., Med. Ctr., Leiden, Netherlands, ⁵CRB-HV, Aix-Marseille Univ., Marseille, France, ⁶Res. Inst. Hosp. Sant Pau, Barcelona, Spain, ⁷INSERM, Bordeaux, France, ⁸V Med. Clinic, Univ. of Heidelberg, Mannheim, Germany

Abstract Body:

Factor V (FV) is a key molecular player in the coagulation cascade. FV plasma levels have been associated with several human diseases, including thrombosis, bleeding and diabetic complications. Two genes have been robustly found to contribute in the inter-individual variability of plasma FV levels: structural *F5* gene and *PLXDC2*. Because the later has been observed to be an imprinted gene in some rodent model, we investigated if parent-of-origin effects (POE), a specific epigenetic mechanism linked to imprinting, could participate in the genetic regulation of FV plasma levels. For this, we deployed the QUICKTEST program dedicated to the detection of POE in GWAS datasets of unrelated individuals. QUICKTEST is based on the Brown-Forsythe statistical methodology and suggests the presence of POE at a given polymorphism when the phenotypic variance observed in heterozygotes is significantly higher than that observed in homozygotes. QUICKTEST was applied to 4 independent GWAS studies (LURIC, MARTHA, MEGA and RETROVE) totaling 4,505 participants of European ancestry with measured FV plasma levels. The regression coefficients characterizing the difference of phenotypic variances and obtained in the 4 cohorts were then meta-analyzed using a fixed effect model.

We observed a genome-wide significant association at *SLC7A13/PSKH2* locus, on *chr8q21.3*, where the lead variant, *rs75463553*, associated with a POE regression coefficient of 0.128 ± 0.022 ($p = 8.4 \cdot 10^{-9}$). This effect was very homogeneous across the 4 contributing studies: 0.098 ± 0.033 , 0.181 ± 0.049 , 0.147 ± 0.050 , 0.115 ± 0.055 in LURIC, MARTHA, MEGA and RETROVE, respectively. Of note, the *rs75463553* did not show any association with mean FV plasma levels in the 4,505 individuals ($p = 0.49$). No evidence for POE was detected at the *PLXDC2* locus (minimum p-value = $6.1 \cdot 10^{-3}$). Of importance, other mechanisms than POE, such as haplotype effects, gene x gene or gene x environment interactions, could produce significant QUICKTEST results. Preliminary haplotype and epistasis analyses remained inconclusive and family studies are now underway to confirm that the *chr8q21.3* locus contributes to the genetic regulation of FV plasma levels through POE. The association of the identified locus with methylation marks is also ongoing.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3267. A locus near *ICOS* modifies risk for *Mycobacterium avium* complex airway infection in people with cystic fibrosis.

Authors:

W. Gordon¹, A. Faino², A. Stilp¹, E. Blue^{1,3}, K. Buckingham¹, M. Rosenfeld^{2,1}, P. Qu², J. Collaco⁴, R. Pace⁵, G. Cutting⁴, M. Knowles⁵, M. Bamshad^{1,3,2}, R. Gibson^{2,1}, Cystic Fibrosis Genome Project; ¹Univ. of Washington, Seattle, WA, ²Seattle Children's Res. Inst., Seattle, WA, ³Brotman Baty Inst. for Precision Med., Seattle, WA, ⁴Johns Hopkins Univ., Baltimore, MD, ⁵Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract Body:

Nontuberculous mycobacteria (NTM) is an increasingly common lung disease in people with cystic fibrosis (PwCF) associated with substantial comorbidities and mortality. The two most common NTM complexes in PwCF are *Mycobacterium avium* complex (MAC) and *Mycobacterium abscessus* complex (MABSC). Most incident NTM infections in PwCF do not progress to NTM lung disease and microbiological criteria for NTM disease require ≥ 2 NTM+ sputum cultures. Here we focus on NTM lung infection as an antecedent to NTM lung disease.

To find genetic modifiers of risk for MAC and MABSC infections in PwCF we identified 3,321 pancreatic insufficient PwCF of European ancestry with NTM sputum cultures in the U.S. Cystic Fibrosis Foundation Patient Registry. Controls were defined as PwCF with no NTM+ sputum cultures and ≥ 2 years of NTM culture data. We defined 2 infection outcomes of interest— ≥ 1 (“incident”) or ≥ 2 (“repeated”) positive cultures—for both MAC and MABSC, totaling 4 outcomes. Among the 3,321 PwCF, 1,830 met our uninfected control criteria. For both infection outcomes, we found that MAC infection was more common (353 had ≥ 1 MAC+ cultures, 143 had ≥ 2 MAC+ cultures) than MABSC infection (257 had ≥ 1 MABSC+ cultures, 120 had ≥ 2 MABSC+ cultures).

We conducted a genome-wide association study on whole genome sequencing data (hg38) from the Cystic Fibrosis Genome Project. Cases for each of the 4 outcomes were compared with the shared control set. Relatedness estimates and principal components (PCs) were calculated using PC-Relate and PC-AiR. We fit a generalized linear mixed model with a binomial family using the GMMAT approach, adjusting for sex, birth cohort, PCs 1 and 2, and genetic relatedness as a random effect. Assuming an additive effect, we performed score tests for variants with a minor allele count > 10 and missingness $< 2\%$.

Genomic inflation was absent ($1.00 \leq \lambda \leq 1.01$). An association signal near *ICOS* was observed in both the tests of ≥ 1 MAC+ cultures (chr2:204111791, $p=2.12 \times 10^{-7}$, minor allele frequency (MAF)=0.03) and ≥ 2 MAC+ cultures (chr2:204109873, $p=2.05 \times 10^{-9}$, MAF=0.02). A less significant signal was seen in this region for tests of ≥ 1 MABSC+ cultures (chr2:204076672, $p=1.13 \times 10^{-5}$, MAF=0.02) and ≥ 2 MABSC+ cultures (chr2:204111791, $p=1.12 \times 10^{-3}$, MAF=0.02).

ICOS encodes the inducible T cell costimulator protein. Reduced expression of *ICOS* has been associated with NTM lung disease in people without cystic fibrosis, and our results indicate that in PwCF variants near *ICOS* modify risk for NTM infection. Together, these observations suggest that within the lung *ICOS* plays roles in susceptibility to NTM infection and disease.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3268. A machine-learning approach for disease prediction improves GWAS and polygenic scores

Authors:

L. Eick, M. Cordioli, S. Jukarainen, Z. Yang, FinnGen, A. Ganna; Inst. for Molecular Med. Finland, FIMM, Helsinki, Finland

Abstract Body:

Background/Objectives:

GWAS assume there is a correct classification of subjects into cases and controls. Nonetheless, misclassification is expected, especially in biobanks that rely on administrative health data. Accounting for misclassification and for diseases liability can improve GWAS discovery and development of more predictive polygenic scores.

Methods:

To address these limitations, we implemented a gradient boosted classifier (XGBoost) that we used to predict 6 diseases (type 2 diabetes, ischemic stroke, coronary heart disease (CHD), Alzheimer, Dementia and Breast cancer) by integrating information on 3828 diagnoses, 499 medications, 25 socio-economic variables and other health information. Instead of binary disease labels, the model outputs a continuous liability measure which was used to perform GWAS. The analyses were conducted on N=317,687 individuals from the FinnGen study.

Results:

We predicted disease prevalence with an AUC between 90% (type 2 diabetes) and 97% (Alzheimer's disease). First, we perform a GWAS of the predicted liability values. Results recapitulate a case/control GWAS and in some instances identify new loci (e.g. 3 loci in stroke). Second, we performed a GWAS of disease liability only in the control group. To see if the model was capable of assigning high liability values to those who may be at high risk of developing the disease. The results of the liability GWAS in controls were highly genetically correlated with the case-control GWAS (e.g. $r_g=0.88$, $P\text{-value}=3.7e-7, 6.3e-14$ for stroke and CHD). We also identify established loci, for example APOE among alzheimer controls ($rs429358$, $P\text{-value}=1.97e-29$)

We used MTAG to combine the results from the case-control GWAS with the disease liability GWAS among controls. These combined results improved prediction ability of polygenic scores when tested in UK Biobank, for some but not all traits (e.g. $AUC=0.537$ to $AUC=0.546$, $P\text{-value difference}=2e-16$ for stroke).

Conclusion:

Our method extends the capabilities of GWAS by recovering signals from the control group. The possibility to go beyond a case-control model for GWAS analyses opens new venues to the development of more predictive polygenic scores. However, interpretation of new biological results from this approach remains challenging.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3269. A multi-omics risk score approach to identify individual risk for incident type 2 diabetes

Authors:

H. Ng¹, M. Loh^{1,2,3}, D. Tay¹, L. Lakshmanan¹, F. Tai¹, X. Guan¹, R. van Dam^{4,5}, X. Sim⁶, J. Chambers^{1,7}; ¹Nanyang Technological Univ., Singapore, Singapore, ²Imperial Coll. London, London, United Kingdom, ³Natl. Skin Ctr., Singapore, Singapore, ⁴Natl. Univ. of Singapore, Singapore, Singapore, ⁵Havard Univ., Boston, MA, ⁶Natl. Univ Singapore, Singapore, Singapore, ⁷Imperial Coll. London, London, United Kingdom

Abstract Body:

Introduction: Type-2 diabetes (T2D) is one of the leading causes of mortality and morbidity globally. Environment factors such as diet and physical inactivity as well as genetics are recognized as important factors that contribute to T2D risk, with polygenic risk score (PRS) gaining popularity as a method to estimate an individual's risk of developing T2D. In addition, other omics data such as epigenetic and metabolomics have shown promising results in recent years. However, these omics studies have been carried out predominantly amongst people of European ancestry. To improve risk score prediction, we took a multi-omics approach by combining genetic data (PRS) with DNA methylation data and metabolomics data [methylation risk score (MRS) and metabolomic risk score (MetRS) respectively] and assess the performance of the risk scores with respect to incident T2D prediction. In particular, we investigated the performance of our risk scores in a multi-ethnic South East Asian populations, whereby data are currently lacking globally.

Method: The PRS and MetRS were developed from summary statistic derived from published studies while the MRS was developed from in-house unpublished DNA methylation data measured on Illumina 450K and EPIC array, using baseline samples (4,349 East Asians, Malays and South Asians from United Kingdom and Singapore) collected before onset of T2D. The performance of the multi-omics risk scores were then evaluated in an independent series of 1,819 South Asians (900 incident T2D; 919 controls) with genetic (GSA array), methylation (EPIC array) and metabolomics data (H-NMR, Nightingale).

Results: In a univariate model, relative risks of PRS and MRS were 1.37 [95% confidence interval (CI): 1.24-1.51, P = 2.01E-10] and 1.58 [95% CI:1.43-1.75, P=1.07E-18] per 1 standard deviation increase in risk score respectively. When included in a multivariate model including traditional risk factors such as body mass index (BMI), HbA1c and fasting glucose, in additional to age and gender, the PRS and MRS still remained highly and independently significant, with relative risks of 1.27 [95% CI: 1.14-1.43; P= 3.43E-05] and 1.33 [95% CI: 1.18-1.49; P= 3.16E-06] respectively. The analysis of MetRS is currently ongoing.

Summary: In addition to the traditional risk factors and the more commonly used PRS, molecular risk scores from other omics data such as epigenetics could improve prediction of T2D, thereby optimising stratification of resources for disease surveillance and education to targeted individuals with higher risk for disease, leading to improved disease prevention and treatment.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3270*. A network based approach for fine-scale population structure inference in genetic datasets

Authors:

R. Shemirani¹, S. Cullina¹, C. Gignoux², N. Zaitlen³, G. Belbin⁴, E. Kenny⁵; ¹Icahn Sch. of Med. at Mt. Sinai, New York, NY, ²Univ. of Colorado Anschutz Med. Campus, Aurora, CO, ³UCLA, Los Angeles, CA, ⁴Gencove Inc., New York, NY, ⁵Icahn Sch. of Med. at Mt Sinai, New York, NY

Abstract Body:

Background: The Genetic Relatedness Matrix and Principal Components (PCs) of the genotype data play a prominent role as proxies for population structure in statistical genetics applications such as association studies. They assist with model calibration and correcting for confounding factors including environmental signals not captured in genetic datasets. Inadequacies of these methods in delineating recent fine-scale structure could result in spurious findings. Here, we use segments of the genome inherited from a common ancestor identical-by-descent (IBD) to create a network of samples with shared recent ancestry. We demonstrate that the graphical properties of such networks carry additional structural information that augments the information derived from PCs. **Methods:** First, we propose a novel approach to generate IBD networks by dissecting IBD segments into contemporary groups to preserve temporal structure. Secondly, we introduce a method to extract fine-scale structural data from these networks in the form of spectral representations of nodes as the laplacian eigenvectors. Finally, we demonstrate that these representations carry signals derived from recent population structure via observing the proportion of variance in traits explained by them. **Results:** In the UK Biobank dataset, our method generates 6 networks with ~19 billion edges connecting 350,110 samples with British ancestry. Using easting and northing birth coordinates as examples of traits with solely environmental origins, our spectral representations yield an increase of 66.7%[66.5-66.8] and 27.9%[27.6-28.0] in the proportion of variance explained when compared to the first 40 PCs, respectively. This demonstrates the ability of our method in extracting signals of recent structure, which also results in a 43.8%[43.1-44.6] and 177.3%[156.7-209.7] increase in the proportion of variance explained in the overall health conditions and HDL Cholesterol levels in individuals, respectively. Combining the spectral representation with the PCs results in an increase of 97.3%[55.6-104.3] in proportion of variation explained for the body-mass index, suggesting that these representations can complement PCs in genetic studies. **Conclusions:** Our method could supplement the current approaches and improve the power of genetic studies by accounting for recent fine-scale population structure, especially in diverse and admixed cohorts where PCs provide inadequate environmental data to address confounding issues. We plan to investigate the efficacy of our method in overcoming the biases that stem from unbalanced datasets in the of calibration Polygenic Risk Scores in such cohorts.

PB3271*. A novel approach identified eight gene x alcohol or gene x smoking interactions that contribute to serum lipids

Authors:

X. Zhu¹, Y. Yang², N. Lorincz-Comi¹, G. Li¹, A. Bentley³, P. de Vries⁴; ¹Case Western Reserve Univ., Cleveland, OH, ²case western reserve Univ., Cleveland, OH, ³NIH, Bethesda, MD, ⁴UTHlth.at Houston, Houston, TX

Abstract Body:

Introduction: Gene-environment (GxE) interactions have been suggested to contribute significantly to the phenotypic variation of complex traits. However, detection of GxE interactions has been challenging even in large sample sizes, as demonstrated in multiple large GxE interaction studies in the CHARGE consortium. **Methods:** We performed a novel analysis to detect gene×smoking and gene×alcohol interactions on serum lipids using trans-ethnic summary statistics from large genome wide association studies of lipid levels: 1) the Global Lipids Genetics Consortium study (GLGC, (Graham et al., 2021, N=1.65M); 2) Studies of GxE interactions of smoking and alcohol from the CHARGE consortium (Bentley et al 2019, de Vries et al. 2019, N=134K). We compared the genetic effect estimated in GLGC with the main effect estimated in the GxE interaction model from CHARGE in a way similar to Mendelian Randomization (MR) analysis, i.e, selecting lipids associated variants as the instruments and considering the genetic effects from CHARGE as exposure effects and that from GLGC as outcome effects. We then searched the genome for significant departures from the causal line ($P < 5E-8$) to identify genetic variants that either have a GxE interaction effect or an effect on the trait that is mediated by the environmental factor. To exclude variants with mediation effects through the environmental factor, we excluded all loci associated with smoking status or alcohol drinking ($P < 5E-7$ in Liu et al, 2019, Jiang et al 2021). We further examined the identified variants by using the interaction test directly and corrected for multiple testing using Bonferroni corrections. **Results:** Through MR analysis, we identified 3, 6 and 4 genome-wide significant independent loci for high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), and triglycerides (TG) with alcohol, and 3, 5 and 5 loci for LDL-C, HDL-C and TG and smoking, respectively. By filtering out the variants using the interaction test, we identified the following gene x alcohol interactions: *APOE* and *LDLR* for LDL-C, *GALNT2* and *CETP* for HDL-C, and *APOE*, *ZPR1* and *RPL30P9 (LPL)* for TG. We identified gene x smoking interactions for *APOE* with LDL-C, *CETP* with HDL-C, and *APOE*, *ZPR1*, *RPL30P9 (LPL)* and *TRIB1* with TG, respectively. **Conclusion:** We identified 8 gene-smoking or gene-alcohol interactions that contribute to serum lipids traits. All the genes/loci have been reported to be associated with lipids levels, but their interaction effects have not been confirmed. Our approach can be useful in efficiently detecting interactions by combining large GWAS with or without incorporating interactions.

PB3272. A novel computational deconvolution method to estimate sample-level cell-type-specific gene expression profile

Authors:

K. Kang, M. Kellis; Massachusetts Inst. of Technology, Cambridge, MA

Abstract Body:

The relatively high cost of single cell sequencing may render large cohort studies resorting to bulk RNAseq, however, heterogeneity in tissues hampers efforts to probe the role of each cell type. Hence, in bulk data analysis, deconvolution is a key step to extract cell-type-specific information. Nevertheless, most such tools focus on estimating cell type fractions. Only a few are able to infer cell-type-specific gene expression profiles (ctsGEP) among which barely one or two aim at estimating ctsGEP for each individual. Yet, the technical challenges demand more sophisticated approaches for better estimates which are invaluable for various downstream analyses, such as cell-type-specific differential expression inference and eQTL calling, to list but a few.

To this end, we developed a deconvolution method to estimate both sample-level ctsGEPs and the cell-type proportions simultaneously using bulk RNAseq. We modeled the observed expression data using multinomial distributions whose parameters reflect the unknown ctsGEP and sample-specific proportions. Our model incorporated prior information from single cell data and we used a Dirichlet distribution to control the degree of confidence in the priors. Integrating these components, we built a Bayesian model that fully captures the stochastic nature of bulk data. We employed an MCMC procedure for parameter estimation. Importantly, the hyperparameters of the hierarchical model, which is critical in posterior inference, were also being optimized in a principled way.

We benchmarked our method using mixtures of varied but known composition. Specifically, we generated 48 in silico mixture samples using human brain single cell data from 48 individuals. We performed deconvolution using a reference single cell profile from a different study as a prior and evaluated its performance by comparing the estimated sample-level ctsGEPs with the ground truth. We assessed the accuracy of ctsGEP for each individual; and, more importantly, the ability to capture expression variation of genes for each cell type across all samples. For the former, our method was able to achieve around 0.9 in correlation; For the latter, we were able to attain above 0.6 in correlation across samples for around 80% of genes. Our method, in both cases, outperformed existing alternatives with averagely 16% less Root-Mean-Square-Errors on ctsGEP estimations.

Our method holds promise for computationally deciphering complex mixtures of cell types, each with differing expression profiles in different individuals, using RNA-seq data measured in bulk tissue.

PB3273. A Novel Gene-Based Test for Sequencing Studies Based on a Bayesian Variable Selection of Rare Variants

Authors:

J. Xu¹, N. Wang², L. Briollais³; ¹Lunenfeld-Tanenbaum Res. Inst., Toronto, ON, Canada, ²Univ. of New Brunswick, Fredericton, NB, Canada, ³Mount Sinai Hosp, Toronto, ON, Canada

Abstract Body:

Background: Next Generation Sequencing (NGS) technology provides opportunities to discover rare variants (RVs) associated with complex human diseases. A usual paradigm for detecting RVs in NGS experiments is to perform a gene-based (or region-based) association test followed by single RV tests in the top selected genes. Gene-based tests often select or assign higher weights to coding variants to enhance the power to detect associations but to the cost of limiting the possibility for new RV discoveries. On the other end, the inclusion of all RVs in a gene-based test might reduce its power. As an alternative, we propose a novel strategy that performs a variable selection of the RVs to be considered in the gene-based test as a powerful approach.

Methods: Our novel approach extends our previous region-based test for case-control designs using a Bayes Factor statistic (Xu et al., *Biometrics*, 2020) where the association between a set of RVs in the same region (e.g., a gene) and a disease was assessed. Our novel method is based on generalized linear regression models and its conjugate prior (Chen et al., *Statistica Sinica*, 2003), which can handle outcomes of different types (binary, continuous, count), informative functional annotations and unbalanced designs. A birth-death MCMC algorithm is used to select the most important RVs to be considered in the region-based test.

Results: Through simulations of sequencing data with our R package *sim1000G*, we show that performing a variable selection step of RVs in a gene-based test is a more powerful approach than considering all possible RVs in the gene as proposed originally in SKAT and Burden gene-based tests. Assigning weights to RVs in a gene-based test can enhance its power only when those weights are consistent with the variable selection. Weights can be used as prior in our novel Bayesian approach. Application to UK Biobank whole-exome sequencing (WES) data with lung cancer outcome show that our method leads to new gene and RV discoveries. Conclusion: Our new approach improves existing RV gene-based tests while leveraging new RV discoveries.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3274. A novel haplotype based approach allows for conducting ancestry agnostic genome wide association studies.

Authors:

D. Perry¹, M. Gymrek², K. Frazer³, M. D'Antonio¹; ¹Univ. of California, San Diego, San Diego, CA, ²Univ California San Diego, La Jolla, CA, ³UC San Diego, SAN DIEGO, CA

Abstract Body:

Genome-wide association studies (GWAS) are heavily biased towards analyzing individuals of European descent, and translating findings to diverse or admixed populations has proven challenging. It is thus necessary to make GWAS more informative for individuals from non-European backgrounds and enhance equity in the distribution of benefits from genetics research.

Haplotypes may serve as an ancestry-agnostic tool to study genetic associations and have been proposed as an alternative approach because they reduce redundancy due to LD and require a fewer number of tests when compared to single nucleotide variants (SNVs). Haplotype blocks are traditionally defined using recombination hotspots. However, a major downfall to this approach is that the resolution (~700 bp) of recombination hotspots is low compared to each block size (2-10 kb). Therefore, an empirical method to detect haplotype block boundaries may be more appropriate to exploit haplotypes in genetic association studies.

Here, we present a novel method for constructing haplotype blocks. In a given genome block size, we select the SNVs with MAF \geq 20%, then count the number of observed genotype combinations. If this is greater than a predetermined threshold, the haplotype block is defined by these SNVs. Otherwise, SNVs are added until the observed number of genotype combinations exceeds the determined threshold. Once the haplotype block boundaries are set, haplotypes are defined according to the allele frequency of all the SNVs included in each block.

To demonstrate the utility of this approach, we investigated the APOE locus on chromosome 19, where a haplotype consisting of two SNPs (rs429358 and rs7412) is known to have strong associations with neurological disorders and blood traits. GWAS have also described different associations between LDL in European and African individuals in this region. We conducted a GWAS using SNPs on LDL levels in a 250kb region flanking APOE in both African and European individuals in the UK Biobank. We also conducted a GWAS using haplotypes on LDL levels. We then separately finemapped the results from both methods using SuSiE. We observed the same lead haplotype in both African and European individuals, which comprises the previously described APOE- ϵ 2 (rs429358-T; rs7412-T), known to be associated with atherosclerosis and cholesterol levels. Alternatively, SNP credible sets were discordant between Europeans and Africans and did not include rs429358. Our method of constructing haplotypes is robust to differences in LD structure between different populations, making it relevant for analyzing individuals from admixed and diverse populations.

PB3275. A novel method for annotation-agnostic differential transcript usage analysis

Authors:

K. Eldjarn Hjoerleifsson¹, P. Melsted², L. Pachter¹; ¹Caltech, Pasadena, CA, ²Univ Iceland, Reykjavik, Iceland

Abstract Body:

The quantification of RNA reads is a key step in most analyses of RNA-Seq data. Current quantification methods rely on annotations of the organisms' transcriptomes, which may be incomplete or nonexistent. This may lead to data being discarded and to erroneous quantifications. In downstream applications such as eQTL analysis, such errors can propagate and result in missed associations. We present a novel method for associating phenotypes with RNA expression, that can identify expression associations resulting from a wide variety of underlying transcriptional and post-transcriptional events, without requiring a prior annotation of the transcriptome. By constructing a *de Bruijn graph* of all the reads mapping to a single gene, and pruning away nodes that are likely to be erroneous, we obtain a representation of the expression of the gene in our cohort. Each expressed isoform constitutes one path through the graph. We then run associations on the expression of each individual node and a phenotype. Should an isoform of the gene associate with the phenotype, there will be a set of nodes in the graph that uniquely identify the isoform, the expression of which also associates with expression of the phenotype. This method enables discovery of novel alternative polyadenylation, exon-skipping, duplications, insertions, deletions, and circular RNA, among other transcriptional and post-transcriptional variations, without prior knowledge of these events. We show that we can reliably reproduce known associations, and detect, *de novo*, phenotypically relevant transcriptional structures.

PB3276. A novel method for multiple phenotype association studies based on genotype and phenotype network

Authors:

X. Cao, S. Zhang, Q. Sha; Michigan Technological Univ., Houghton, MI

Abstract Body:

Although genome-wide association studies (GWAS) have emerged as a common and powerful tool to detect the complexity of the genotype-phenotype associations, a common limitation of GWAS is that they focus on only a single phenotype at a time. Joint analysis of multiple correlated phenotypes for GWAS can identify and interpret pleiotropic loci which are essential to understanding pleiotropy in diseases and complex traits. Meanwhile, constructing a network based on associations between phenotypes and genotypes provides a new insight to analyze multiple phenotypes, which can explore whether phenotypes and genotypes might be related to each other at a higher level of cellular and organismal organization. Notably, it might broaden the understanding of genetic architecture that exists between diagnoses, genes, and pleiotropy. In this research, we develop a bipartite signed network by linking phenotypes and genotypes into a Genotype and Phenotype Network (GPN). The GPN can be constructed by both quantitative and qualitative phenotypes and is applicable to binary phenotypes that have extremely unbalanced case-control ratios for large-scale biobank datasets. After projecting genotypes into phenotypes, the genetic correlation of phenotypes can be calculated based on the shared associations among all genotypes. Then we propose a novel community detection method to partition phenotypes into disjoint modules based on the genetic correlation. For each module, we can apply multiple phenotype methods to test the association between phenotypes in a module and a SNP. Simulation results show that most multiple phenotype tests based on network modules are much more powerful than those based on all phenotypes, especially when phenotypes are affected by different directions. Furthermore, we apply the proposed method to a set of diseases from the UK Biobank. All multiple phenotype tests based on network modules can identify more potentially SNPs than those without considering network modules.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3277. A pipeline for predicting pathogenicity of monogenic cardiovascular disease genetic variants.

Authors:

M. Ramaker, J. W. Abdulrahim, W. E. Kraus, S. H. Shah; Duke Univ., Durham, NC

Abstract Body:

Large improvements in sequencing capabilities have allowed for increased rare variant detection in large population-based cohorts, yet interpretation of such rare genetic variation has proven difficult. The majority of identified rare variants are of unknown significance even in patients with suspected monogenic diseases. Thus, there is an unmet need for annotation of variants of unknown significance (VUS) to both properly diagnose and better understand monogenic diseases. Furthermore, monogenic cardiovascular diseases encompass a variety of phenotypes that often lead to major cardiac problems including heart failure. Most patients do not harbor a known pathogenic or likely pathogenic variant associated with disease but harbor several VUSs in known monogenic cardiovascular disease genes. Several publicly available in-silico annotation tools predict the pathogenicity of variants across the genome using various statistical and predictive strategies based on measures of conservation, sequence, and protein information amongst others. Additionally, large genomics projects aimed at understanding multi-omic tissue specificity offer a resource for tissue-specific variant interpretation. Here we report the combined use of such resources via machine learning to predict the pathogenicity of genetic variation in 48 monogenic cardiovascular disease genes in a tissue-specific manner. Random forest was trained using six-fold cross validation on ClinVar pathogenic, likely pathogenic, benign, and likely benign variants (n = 26,402) from 48 monogenic cardiovascular disease genes to build a cardiac-specific predictive model of variant pathogenicity utilizing predicted measures of deleteriousness and splicogenicity, local pathogenic variation, cardiac-specific exon expression, and population allele frequency as model predictors. The top-performing model was validated in a held-out subset of variants for which ClinVar clinical significance had changed from benign, likely benign or VUS status to pathogenic or likely pathogenic (or vice versa) from 2014 to 2022 (n = 445) resulting in a ROC AUC of 0.66. Last, we predicted VUS pathogenicity in the CATHeterization GENetics (CATHGEN) cohort. We identified 6 predicted pathogenic VUSs in 6 individuals with hypertrophic cardiomyopathy (HCM). Of those, a highly conserved missense VUS in the myosin heavy chain 7 gene (MYH7) previously reported in HCM patients was coincidentally returned 2 weeks prior via genetic panel testing and is suspected to be the disease-causing variant.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3278. A polygenic framework nominating causal SNPs, their target genes, and cell-types of action

Authors:

A. Kim, S. Gazal; Univ. of Southern California, Los Angeles, CA

Abstract Body:

Genome-wide association studies (GWAS) have identified thousands of disease-associated loci, but they generally do not identify the underlying causal variants, target genes and cell-types, thus limiting our understanding of disease mechanisms. Recent advances in functionally-informed fine-mapping (FIFM) have improved our ability to nominate causal variants by prioritizing variants in disease-relevant functional annotations. However, the current state-of-the-art FIFM method (PolyFun; Weissbrod et al. 2020 Nat Genet) does not leverage the cell-type-specificity of human diseases, thus not optimally maximizing their power. In addition, identifying the function of fine-mapped variants remains a critical challenge as causal variants are predominantly non-coding SNPs that do not necessarily regulate the closest genes.

Here, we propose a novel polygenic framework integrating new cell-type specific regulatory datasets, recent FIFM methods and SNP-to-Gene (S2G) linking strategies to improve nomination of causal variants and directly characterize their function.

First, we improved PolyFun strategy by considering the context specificity of complex traits. Specifically, we optimally select cell-type specific annotations from a set of >1,000 annotations using stratified LD score regression (S-LDSC). Our context-specific strategy refined the fine-mapping results of the default PolyFun, validating 80% of causal (PIP>0.95) SNP-trait pairs and identifying 13% novel SNP-trait relationships (preliminary analysis of 8 UK Biobank traits). Second, we leveraged in vitro and in silico predictions of variant functionality and showed that our strategy identifies a significantly greater ($P < 0.05$) proportion of functional variants directly modulating gene expression. Finally, we built a probabilistic framework estimating the probability for a cell-type to be causal and leveraging SNP-to-gene maps (Gazal et al. 2022 Nat Genet) to compute SNP-gene-cell-type-disease quadruplet scores, thus easily characterizing the function of fine-mapped variants. To illustrate the benefits of our framework, we highlight several examples of previously undetected causal SNPs as well as their predicted target genes and affected cell-types, providing the molecular basis of variant causality.

Our results indicate the relevance of context-specific FIFM and propose a novel polygenic framework to directly characterize the function of fine-mapped variants. This new method will significantly improve biological interpretation of fine-mapped variants and help the translation of GWAS findings into discoveries that will enhance disease treatment.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3279. A polygenic score method including recessive model for improving odds ratio.

Authors:

R. Ota, S. Morishita; The Univ. of Tokyo, Chiba, Japan

Abstract Body:

For studying polygenic diseases, GWAS has been largely contributing to identifying associated single nucleotide variants (SNVs); however, SNVs for polygenic diseases often have low odds ratio (1.1-1.3) and only explain a small proportion of heritability, which is called "missing heritability." To solve this problem, a number of statistical methods to estimate polygenic scores (PGS) have been proposed. Several PGS has been proposed, including LASSO, lassosum, LDpred, and C+T. All of these methods exploited additive models, which do not consider low-frequency recessive SNVs, and are likely to use a large number of SNVs except for LASSO which is capable of regularizing the number of SNVs in PGS. In an attempt to build a more accurate method that requires a smaller number of essential SNVs, we explore the boosting approach. Adaboost, a classic and widely used boosting method for qualitative phenotype, adopts a linear model for better interpretation of the prediction model and is known to be infrequent to be overfitting. However, Adaboost is not good at capturing low-frequency (recessive) SNVs. To take low-frequency SNVs into account properly, we propose an improved boosting method, **GenoBoost**, that considers the genetic inheritance models (additive, dominant, or recessive). GenoBoost demands no information on LD beforehand but can implicitly exclude the effect of LD, which is the unique nature of boosting algorithm. GenoBoost can be interpreted as an "iterative algorithm for multivariate logistic regression" or an extension of conditional analysis. We also developed a program that can process very large GWAS data such as the entire UK Biobank data, which contains about 300 thousand samples each of which has more than 7 million SNVs, in a reasonable amount of time (12 hours) using a main memory of 32GB. GenoBoost showed the best or comparative odds ratio for some polygenic diseases while using fewer SNVs to achieve the odds ratio. For BC, the odds ratio at high-risk proportion of 5% of GenoBoost was 2.1 and the second-best LASSO was 2.05, and GenoBoost used 300 SNVs while LASSO did 430. We also showed that the GenoBoost's PGS with any genetic model was better than GenoBoost's additive model only PGS, especially at smaller proportions like high-risk proportion of 1%. We also found that some recessive SNVs were reported to be associated with the diseases before. In conclusion, we propose a first PGS algorithm that incorporates any genetic models, as far as we know, and outputs better odds ratios with sparser models than state-of-the-art methods in some diseases, which demonstrates that incorporating the recessive SNVs, some of which were reported, improves the accuracy.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3280. A precise, combinatorial approach for the estimation of *de novo* mutation rate from short-read WGS data.

Authors:

M. Kohailan¹, W. Aamer², N. Syed², S. Padmajeya², S. Hussein², A. Sayed², J. Janardhanan², S. Palaniswamy², N. El hajj¹, A. Akil², K. Fakhro²; ¹Hamad Bin Khalifa Univ., Doha, Qatar, ²Sidra Med., Doha, Qatar

Abstract Body:

De novo mutations (DNMs) are variants found in the genome of a child, yet absent in both parents. While DNMs are a critical driver of diversity in any species, they also play a major role in severe genetic disorders. Thus, it is important to understand the rate, distribution and pattern of DNMs. Considering the rarity of DNMs in the genome, detecting such mutations requires prudent approach that can extract them from NGS data. Previous studies followed a single computational approach to call DNMs. In addition, no such large scale genetic analysis was performed in the Middle-East. Here, we applied a combinatorial approach by using three different tools to generate an integrated list of DNMs per individual. A total of 645 individuals, mainly Middle-Eastern with Arab ancestry, were enrolled in this study; generating 353 trio combinations. For these trios, we identified 24,808 *de novo* single-nucleotide variants (SNVs) and 2,405 insertions-deletions (INDELs), with a median of 70 SNVs and 6 INDELs per individual. We calculated a median *de novo* mutation rate of 1.25×10^{-8} and 1.07×10^{-9} per base per generation for SNVs and INDELs, respectively. We determined the parent-of-origin for around 13% of the *de novo* variants. We found a paternal to maternal DNMs ratio of approximately 3.96:1. We then plotted the number of phased DNMs in each individual against parental age at conception. We observed a significant increase of 1.79 DNMS per year of paternal age and 0.34 DNMS per year of Maternal age. However, this correlation substantially differs between families. We also examined the DNM spectra and mutational signature. We found a clear enrichment of transitions over transversions and that the mutations at CpG sites contribute to a large fraction of DNM events. We then questioned whether DNMs at CpGs are correlated with high methylation levels. To answer this question, we compared the mutation rates at CpGs with respect to the level of methylation, and found that highly methylated CpGs are 2.05 times more likely to have mutations than low-methylation sites. This study illustrates the importance of using combinatorial approaches for DNM calling. It also serves as a reference for DNM discovery in multiplex families from the globally under-represented populations of the Middle-East. Future studies with larger cohorts will be required to shed the light on the genetic architecture of the Arab population, with important implications for screening and intervention strategies.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3281. A Rare Missense Variant of Large Effect is Associated with Cataract in Puerto Ricans

Authors:

J. Shi¹, J. O'Connell¹, B. Hicks¹, W. Wang¹, V. Vacic², A. Auton^{1,2}, S. Shringarpure¹; ¹23andMe, Inc., Sunnyvale, CA, ²23andMe, Inc. Therapeutics Div., South San Francisco, CA

Abstract Body:

Founder populations can enable novel genetic discoveries through enrichment of globally-rare variation due to genetic drift. Here, we identify a novel genetic association for cataract in Puerto Ricans by constructing an imputation panel of Puerto Ricans (PR) and performing GWAS on cataract. We found a rare missense variant association on chromosome 2q31.1 with very high OR, and the variant is also linked with significantly earlier age-at-onset for cataract.

Using the research participant base of 23andMe, Inc., we verified that PR had a founder event and are thus enriched for globally rare variations. We selected a panel of 500 unrelated PR samples for whole genome sequencing (WGS), with a mean depth of 22X generated by Broad. We built an imputation panel with 117 million variants, and imputed the sequence variants into 58,694 additional chip-genotyped and phased Puerto Ricans. We ran GWAS on the imputed PR cohort against the self-reported cataract phenotype with 2,951 cases and 42,069 controls. We identified a missense & splice-region variant on chromosome 2q31.1 with significant association (p -value=1.5e-12, OR=12.904, 95% CI=[6.649, 25.042]) to cataract. In addition, the age-at-onset (AAO) for cataract is significantly lower among risk allele carriers than non-carriers, with 62% of carrier cases developing cataracts before 30 years of age, while only 0.67% of non-carrier cases reported age-of-onset < 30 (binomial p -value = 7.11e-11).

The missense variant is population-specific, with a minor allele frequency (MAF) of 0.089% in PR, but 0% in Europeans, African Americans, East and South Asians, 0.0056% in Latinos (gnomAD v2.1.1). Therefore, its association could only be found through the PR GWAS. In fact, except for the Puerto Ricans, we were not able to include this variant in our GWASs for the Europeans, Latinos, East Asians, South Asians and African Americans due to its 0% MAF in those populations. Our results demonstrate that GWAS in founder populations can identify novel genetic associations for globally-rare variation.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3282. A robust whole-genome Mendelian randomization approach for improved estimation and inference of causal effects

Authors:

H. Zhang^{1,2}, Z. Liu³, X. Lin⁴; ¹Harvard T.H. Chan Sch. of Publ. Hlth., Cambridge, MA, ²Natl. Cancer Inst., Rockville, MD, ³The Univ. of Hong Kong, Hong Kong, China, ⁴Harvard T.H. Chan Sch Pub Hlth, Boston, MA

Abstract Body:

Introduction: Mendelian randomization (MR) is a powerful tool to assess the causal association between modifiable risk factors and disease outcomes using genetic variants as instrumental variables (IVs). The method only requires summary-level statistics from genome-wide association studies (GWAS), hence reducing the logistical cost and facilitating its widespread application.

Method: MR makes several strong and empirically unverifiable assumptions, which can be violated in practice and lead to biased estimates and invalid statistical inferences. For example, the most prevalent MR approach, inverse-variance weighted (IVW) method, can be biased due to the use of weak IVs, pleiotropic effects, or sample overlaps. Other cutting-edge approaches, such as MR-Egger, MR-RAPs and MR-PRESSO, aim to reduce bias in the presence of pleiotropic effects. We develop a whole-genome MR method (WMR) that integrates variants across the genome while accounting for linkage disequilibrium (LD) between variants. We make weaker assumptions about pleiotropic effects by assuming an arbitrary distribution with mean of zero and a constant variance. The method enhances the accuracy of MR estimate, while efficiently reducing the bias in the presence of weak IVs, pleiotropic effects and sample overlaps.

Simulations: Our simulation analyses mimic realistic LD patterns using European haplotype data from Phase 3 of the 1000 Genomes Project. We compare WMR with a number of existing methods, including IVW, MR-Egger, MR-Raps, and MR-PRESSO, based on a range of simulation settings, such as different proportions of causal variations, pleiotropic effect levels, and sample overlap proportions. We find that WMR is robust in the presence of numerous weak IVs, various degrees of pleiotropic effects, and sample overlap proportion. In addition, WMR provides an MR estimate with more precision, i.e., a smaller empirical standard error (SE), compared to existing methods.

Data Analyses: We utilize the proposed WMR methods in conjunction with other existing MR methodologies utilizing the GWAS summary-level statistics from several distinct variables, such as body mass index, lipids-related phenotypes, cardiovascular disease, breast cancer, etc. Consistent with models, the WMR estimations are more precise and have smaller SEs than other methodologies, resulting in more significant MR results.

Conclusion: WMR is a robust and powerful MR method that reduces biases in the presence of a large number of weak instruments and pleiotropic effects and provides accurate and effective causal effect estimates.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3283. A scalable framework for robust linear mixed model association testing

Authors:

G. Kalantzis¹, A. Pazokitoroudi², H. Loya¹, H. Chen³, S. Sankararaman⁴, P. Palamara^{1,5}; ¹Univ. of Oxford, Oxford, United Kingdom, ²UCLA, LA, CA, ³The Univ of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, ⁴UCLA, Los Angeles, CA, ⁵Wellcome Ctr. for Human Genetics, Oxford, United Kingdom

Abstract Body:

Linear mixed models (LMMs) provide state-of-the-art performance in genome-wide association studies (GWAS) but are computationally demanding when the number of analyzed individuals and traits increases. We developed a LMM algorithm, called FMA, which remains scalable while preserving statistical power and robustness to confounding. FMA relies on moment-based multiple variance component estimation and can be used to analyze multiple quantitative traits in parallel. We performed extensive simulations to compare FMA with several scalable methods, including BOLT-LMM, BOLT-LMM-Inf, Regenie, FastGWA, and linear regression (LinReg). We simulated sets of 50 traits with realistic MAF/LD-dependent architectures, 25% trait heritability, 1% or 5% polygenicity, using 387k genotyped variants (MAF>0.001) and 50k UK Biobank (UKB) samples of varying levels of relatedness or population structure. In unrelated samples of homogeneous ancestry, BOLT-LMM achieved the highest increase in association power over LinReg (+3-7.4% χ^2 on top SNPs), while FMA, REGENIE, and BOLT-LMM-Inf performed similarly (+0.8-2.6% χ^2 on top SNPs). When related individuals were included in the analysis, all methods yielded controlled false positive rates (FPR < 5%) with the exception of LinReg (FPR 5.1-5.2%; $p < 1e-4$). In scenarios involving European samples and stratification, where 5% of phenotypic variance was explained by the top 10 principal components (PCs) of ancestry, FMA and BOLT-LMM were calibrated without the need to use PCs as covariates. Regenie, FastGWA, and LinReg were inflated when PCs were not used (5.9-8.2% FPR; $p < 1e-4$), but calibrated when PCs were included. For model fitting (excluding the calculation of test statistics) FMA was faster than BOLT-LMM (x16, or x6.5 for BOLT-LMM-Inf) in analyzing all traits, but slower than REGENIE (x4.4) and FastGWA (x10, or x2.6 including kinship calculation). Finally, we applied FMA (testing with PLINK, using pgen format) and Regenie (using bgen format) to 20 real phenotypes, 446,050 UKB samples, and 38 million imputed variants. FMA+PLINK required 98.8 hours for model fitting and association testing (82.5 and 16.3 hours, respectively), slower by a factor of x1.62 compared to Regenie (4.7 and 56.4 hours). FMA had slightly improved calibration, measured using attenuation ratio statistics computed using LD score regression ($p = 1e-4$), while both approaches resulted in a similar number of associated loci being replicated in association summary statistics from 13 common Biobank Japan traits. Overall, our work presents a new scalable and robust LMM association algorithm and extensive benchmarks of available GWAS methodology.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3284. A scalable pipeline for robust relatedness inference with application to a study of 1,144,542 individuals

Authors:

S. Gaynor¹, J. Staples¹, R. Panea¹, T. Joseph¹, S. Balasubramanian¹, A. Locke¹, A. Ziyatdinov¹, A. Marcketta¹, J. Backman¹, X. Bai¹, W. Salerno¹, J. Kosmicki¹, J. Emberson², R. Collins², J. Torres², P. Kuri Morales³, R. Tapia-Conyer³, J. Alegre³, J. Berumen³, Regeneron Genetics Center, RGC Research Partners, G. Abecasis¹, J. Marchini¹, T. Thornton¹; ¹Regeneron Genetics Ctr., Tarrytown, NY, ²Univ. of Oxford, Oxford, United Kingdom, ³Univ. Natl. Autónoma de México, Mexico City, Mexico

Abstract Body:

To optimize genetic discovery, large-scale studies often include both population-based and family-based studies comprised of closely related individuals. Accounting for relatedness has impact on analyses ranging from principal components analysis (PCA) for population structure inference to genome-wide association and sequencing studies for the mapping of complex traits. For example, inaccurate detection of relationships confounds association analysis and can induce spurious association. However, the identification of familial relationships can fail in the presence of admixture or population structure and poses significant computational costs, particularly for large-scale biobank studies.

We present a cloud-based pipeline for inferring relatedness that can robustly and scalably detect relationships in diverse biobank studies. We implement a comprehensive relatedness pipeline that detects identical-by-descent (IBD) segments using the KING algorithm for relationship estimation and inference, and reconstructs pedigrees using the PRIMUS approach. The pipeline permits complete relationship estimation for additional samples when studies are expanded without study-wide re-estimation required. We use six cohorts, varying in size, population structure, and genotyping and sequencing platform, to demonstrate the performance of the pipeline is robust to the variant set used for IBD segmentation given genome-wide data.

We demonstrate the pipeline to be computationally scalable with on-demand resources in one of the largest genetic collections available. We apply our relatedness pipeline to a large-scale study of 1,144,542 individuals from forty-six cohorts across multiple continents with genome-wide data. The contributing cohorts, including the Mexico City Prospective Study and the UK Biobank, differ in demographic composition and study design, leading to moderate to substantial degrees of relatedness. The analysis was optimized to be fully parallelized and completed in hours. We report over 200,000 first-degree relatives, over 300,000 second-degree relatives within this analysis, including relationships across cohorts and populations. Our results demonstrate the extent to which relatedness can be present in genetic analysis of large-scale studies, and thus the importance of accurately inferring and applying methods for relatedness information.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3285. A scalable statistical framework for genome-wide interaction testing harnessing cross-trait correlations with an application to Alzheimer's Disease

Authors:

S. Bian¹, A. Bass², Y. Liu³, A. Wingo³, T. Wingo³, D. Cutler², M. Epstein²; ¹Dept. of Biostatistics and Bioinformatics, Emory Univ., Atlanta, GA, ²Dept. of Human Genetics, Sch. of Med., Emory Univ., Atlanta, GA, ³Dept.s of Neurology and Human Genetics, Emory Univ., Atlanta, GA

Abstract Body:

Well-powered GWAS have shown that many complex human phenotypes originate from thousands of trait loci. Nevertheless, for many traits, family-based heritability estimates are often considerably larger than the corresponding heritability estimates from GWAS SNP data. For example, the family-based estimates of heritability for Alzheimer's disease (AD) are around 60-80% whereas reported GWAS SNP heritability estimates only range between 6-41%. While even larger GWAS samples may fill this heritability gap, there is interest in exploring whether this missing heritability could also be due to non-additive effects of genetic variation including gene-gene and gene-environment interaction effects. Exploring such non-additive effects is inherently challenging due to many factors including the modest magnitude of interaction effect sizes, the crippling multiple-testing burden, the complications with determining the interacting variable(s), and impractical computational time and cost. However, for a single quantitative phenotype, interaction methods exist that circumvent these issues by assessing whether the variance of the phenotype differs by genotype category. In this work, we propose a scalable method for interaction testing in the spirit of these variance-based approaches but instead leveraging valuable information contained within multiple correlated phenotypes for improved performance. Specifically, we can show that SNPs with interactive effects yield differential correlation patterns among phenotypes per genotype category, which we can formally test. Our proposed test first applies linear regression to assess relationship between SNP genotype and pairwise cross-product term among phenotypes. We then combine the resulting pairwise cross-product regression p-values together in a Cauchy aggregate statistic to form an optimal test. Our method, which we call SCAMPI, is computationally scalable to genome-wide analyses (with similar run times to variance-based interaction methods), can handle large number of phenotypes, and can adjust for confounders. Type I error and power simulations verified that SCAMPI was well calibrated and had ability to detect even sparse interaction effects observed among large group of phenotypes that were modeled. We further applied SCAMPI to a GWAS study of AD pathologies/cognitive trajectory within the ROS/MAP study. Considering variants with $MAF \geq 0.05$, SCAMPI identified interaction effects among these phenotypes within known AD-risk genes (e.g. TP63 and DLGAP2) and novel risk genes (e.g. LINC00382). SCAMPI is also scalable to large biobank data. SCAMPI is implemented as an R package for public use.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3286. A simple distance-based model predicts effector genes at GWAS loci

Authors:

D. Seaton¹, G. Atla¹, H. Tran², C. Robins³, E. Dermitzakis⁴, R. Scott¹, T. Johnson¹; ¹GlaxoSmithKline, Stevenage, United Kingdom, ²GlaxoSmithKline, Collegeville, PA, ³GlaxoSmithKline, Atlanta, GA, ⁴GlaxoSmithKline, Geneva, Switzerland

Abstract Body:

The derivation of causal biological insights from common variant studies in human populations requires mapping disease-associated variants to their effector genes. This has led to considerable investment in *in silico* methods to support variant-to-gene mapping. While the best-performing models integrate multiple sources of information, the distance between variant and gene remains the most strongly predictive feature in state-of-the-art models [1, 2]. This is consistent with observations from QTL studies that the proximity of a variant to a gene is a strong predictor of whether it perturbs the expression and/or function of that gene.

We present a simple model of the distribution of gene-perturbing variants in the genome, which we refer to as the Distance-Based Model (DBM). These variants can be divided into two categories: those that affect gene function via regulatory mechanisms, and those that act through a change in protein sequence. The probability of observing such variants depends on genomic position, and we model this as a function of the distances between variants and genes. This model has 4 free parameters, which we fit by reference to the distribution of pQTL lead variants around transcription start sites. We then use this model to infer effector genes at GWAS loci, given the observed positions of GWAS lead variants.

As expected, this model recapitulates the empirical observation that the nearest gene to the GWAS signal is often the effector gene. More surprisingly, when benchmarked alongside the Open Targets L2G model [1] and Effector Index model [2], the DBM achieves state-of-the-art performance in predicting effector genes. For the Open Targets Genetics GWAS loci (June 2021 release), the Area Under the Precision Recall Curve (AUPRC) of the DBM against the Open Targets gold standard sets was 0.75, 0.54, and 0.31 for the high, medium, and low confidence gold standards, respectively. This is similar to the AUPRCs of 0.76, 0.43, and 0.25 of the Open Targets L2G model. Similarly, the AUPRC of the DBM against the EI gold standard was 0.43, while the EI model had an AUPRC of 0.35. These results refine widely used proximity-based heuristics for interpretation of GWAS data, and suggest directions for future development of models to predict effector genes at GWAS loci.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3287. A statistical framework for integrative genetic association analysis.

Authors:

J. Okamoto¹, F. Luca², R. Pique-Regi³, A. Helms¹, L. Wang¹, J. Morrison¹, X. Wen⁴; ¹Univ. of Michigan, Ann Arbor, MI, ²Wayne State Univ., Detroit, MI, ³Wayne State Univ, Detroit, MI, ⁴Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Integrative genetic association data are routinely used in post-genome-wide association studies (GWAS) to prioritize functional units that may affect a complex trait for experimental validation. Transcriptome-wide association studies (TWAS) are a popular class of mechanism-aware methods that have identified many causal genes by testing associations between predicted expression and a complex trait. Here, we introduce a novel statistical framework that seamlessly performs multiple tasks using TWAS and colocalization data: causal gene implication and gene set enrichment analysis. First, we propose an evidence integration procedure, INtegration of TWAS And ColocalizaTion (INTACT), that preserves uncertainty from TWAS and colocalization by systematically combining both gene-level results into a probabilistic quantification of "causality". INTACT is designed to be a flexible tool that can use output from any TWAS or colocalization approach. Then, we describe a gene set enrichment estimation method (INTACT-GSE) that utilizes results from INTACT. Using simulations, we observe that INTACT implicates causal genes with higher power than colocalization-only approaches. Additionally, INTACT maintains proper false discovery rate control, in contrast to TWAS-only approaches. We find that INTACT-GSE offers more-accurate enrichment quantification than a widely-used two-stage approach. We then explore the extent to which we can identify trait-relevant genes by explicitly linking genes to the transcriptome. We apply our methods to identify core genes and pathways for 4 GWAS traits for which much of the underlying molecular biology is already known (serum urate, IGF-1, male testosterone, and female testosterone levels). We integrate the GWAS data with GTEx data to generate TWAS and colocalization results. INTACT implicates 14, 35, 7, and 7 core genes for each trait, respectively. We compare the set of core genes implicated by INTACT to the set that is in close proximity to a GWAS hit (within 100 kb). For each trait, we find that some core genes that are in proximity to a GWAS hit are also implicated by INTACT (33%, 37%, 21%, and 46% of core genes in proximity to a GWAS hit for serum urate, IGF-1, male testosterone, and female testosterone, respectively). Although INTACT identifies fewer core genes across traits, there are cases in which it implicates core genes that the proximity-based method does not. These results may suggest gene expression does not have a significant role in some molecular mechanisms underlying complex traits and that our method may complement a proximity-based approach. INTACT-GSE identifies enrichment in 9 pathway-tissue pairs of interest.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3288. A statistical framework for local genetic correlation across populations using GWAS summary data.

Authors:

C. Zhang¹, Y. Zhang², H. Zhao³, Q. Lu⁴, Y. Ye², Y. Shi², K. Liang⁵; ¹Yale Univ., new haven, CT, ²Yale Univ., New Haven, CT, ³Yale Univ. Sch. of Publ. Hlth., New Haven, CT, ⁴Univ. of Wisconsin-Madison, Madison, WI, ⁵Peking Univ., Beijing, China

Abstract Body:

A growing number of studies have discovered that the genetic architecture of complex phenotypes varies across populations, with genetic differences resulting primarily from differences in linkage disequilibrium (LD), minor allele frequencies (MAF), cross-population correlations of causal SNP effects, and overall heritabilities. As the number of genome-wide association studies (GWASs) in non-European groups has been increasing, a number of methods have been developed for evaluating the *global* genetic correlation between populations to shed light on genetic heterogeneity and improve polygenic risk prediction across populations. However, there is a lack of statistical methods to assess shared genetic associations in a *local* genomic region rather than the entire genome between populations. To fill in this gap, we introduce HYPERGNOVA, a method for estimating local genetic correlations across populations in order to better understand etiological mechanisms shared by multiple populations. To expand the global genetic association across populations, HYPERGNOVA uses summary-level data from GWASs to account for specific genomic regions by identifying local, heterogeneous etiologic sharing among diverse populations. We show through simulations that HYPERGNOVA gives an unbiased estimate for both global and local genetic correlation across populations and that it performs comparably to existing approaches at the global level. In addition, we will show our results in discovering population-specific and population-shared genomic regions among 24 common disorders and traits between East Asians and Europeans.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3289. A transcriptomic signature of late-life depression.

Authors:

S. Matan-Lithwick¹, D. A. Bennett², Y. Wang³, D. Felsky¹; ¹Krembil Ctr. for Neuroinformatics, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada, ²Rush Alzheimer's Disease Ctr., Rush Univ., Chicago, IL, ³Rush Univ., Chicago, IL

Abstract Body:

Background: Depression is a neuropsychiatric illness that affects more than one million Canadians annually. The impact of depression is especially clear among the elderly, as it impacts daily function and may be a risk factor for dementia. While genes associated with mid-life depression have been identified, the transcriptomic signature of late-life depression has not been described. We hypothesized that neocortical gene expression would be associated with symptoms of late-life depression proximal to death, independent of pathologic AD diagnosis and medication status.

Methods: Bulk tissue RNA sequencing data from frontal cortex of 1,001 elderly brain donors were analyzed (mean age at death: 89.7yrs [range: 67-108]). All donors had genotype, demographic, and clinical assessments within one year prior to autopsy, as well as detailed postmortem neuropathological characterization. Differential expression analysis was performed with robust linear modeling including technical and demographic covariates, cell type proportions, educational attainment, APOE e4 genotype, and medication status for AD- and depression-prescribed drugs. We then included main effects of depressive symptom burden proximal to death (CESD-sum) and pathologic diagnosis of AD (NIA-Reagan criteria).

Results: After false discovery rate correction (FDR $q < 0.05$), only one gene, Prader Willi/Angelman region RNA1 (PWAR1), was associated with depressive symptoms ($t=5.2$, $q=0.005$); greater PWAR1 abundance was linked to higher symptom burden. At $q < 0.1$, 14 genes showed association. Notably, many of these genes (e.g. CTDSPL2, ACR2B-AS1, ADGRE2, MRM1, IRF8, COL19A1) have been previously implicated in unipolar depression or bipolar disorder. Gene set enrichment analysis revealed upregulation of processes related to energy metabolism (top: "oxidative phosphorylation", $p=2.1 \times 10^{-8}$) and downregulation of DNA modifying processes (top: "DNA conformation change", $p=2.0 \times 10^{-7}$), among others. Results were not changed when controlling for smoking and alcohol consumption, and no significant associations were observed for depression medication status (top $q > 0.23$).

Conclusions: Here we describe a cortical transcriptomic signature of late-life depressive symptoms. Among our top signals are genes with known links to mid-life depression, as well as biological processes relevant to energy metabolism, synaptic plasticity, DNA modification, antigen presentation, and response to pH. Our work provides a depression-specific expression signature for elderly frontal cortex and lays the foundation for investigation of specific mechanisms toward precision therapeutics.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3290. A two-stage mixed effects model to analyze longitudinal zero-inflated microbiome count data

Authors:

J. Wang, C. Reyes-Gibby, S. Shete; U.T. MD Anderson Cancer Ctr, Houston, TX

Abstract Body:

Technological development has provided valuable resources to investigate human microbiome. There is of great interest to study the microbiome longitudinal changes associated with risk factors and clinical outcomes. Such analysis was challenged because of the zero-inflated microbiome data and correlation of the longitudinal data repeatedly collected within the same patient. The current approaches for analyzing longitudinal zero-inflated microbiome abundance data focused on testing the covariate-taxon associations, where the time-varying microbiome abundance is the dependent variable; but ignored the taxon-outcome associations, where the non-time-varying clinical outcome is the dependent variable in the model. In this study, we proposed a two-stage mixed effects model for analyzing the association between zero-inflated longitudinal count data and clinical outcome. Specifically, the longitudinal microbial abundance count is first modeled as a function of time based on the zero-inflated negative binomial mixed effects model; and then the summaries of the temporal patterns are assessed for their associations with the clinical outcome by using the regression models (e.g., linear regression). We conducted simulation studies to show that the two-stage mixed effects model can provide accurate estimations for the regression coefficients of the association between the longitudinal trend of microbial abundance and the outcome. The approach was applied to the study of longitudinal patterns in oral microbiome and oral mucositis in the patients with squamous cell carcinoma of the head and neck.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3291*. A virtual transcriptome approach identifies drug repurposing candidates for Alzheimer's disease.

Authors:

M. Grabowska¹, Q. Feng², W-Q. Wei¹; ¹Dept. of BioMed. Informatics, Vanderbilt Univ. Med. Ctr., Nashville, TN, ²Div. of Clinical Pharmacology, Dept. of Med., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract Body:

Background: Treatment options for Alzheimer's disease (AD) remain limited, complicated by high preclinical and clinical failure rates of new AD drugs. Drug repurposing offers several advantages over traditional drug development, including higher success rates, shorter development times, lower costs, and increased assurance of drug safety. We propose a virtual transcriptome approach to identify drug repurposing candidates for AD, with clinical validation of identified drug candidates using de-identified EHRs from Vanderbilt University Medical Center (VUMC). **Methods:** We impute virtual transcriptomic signatures for AD from existing GWAS summary statistics for 762,917 individuals (86,531 cases and 676,386 controls) using S-PrediXcan and S-MultiXcan. S-PrediXcan and S-MultiXcan leverage eQTL data from the Genotype-Tissue Expression (GTEx) project to predict tissue-specific and multi-tissue gene expression from GWAS summary statistics, respectively. We construct three AD virtual transcriptomic signatures using: (1) all available GTEx tissues, (2) GTEx brain tissues, and (3) GTEx tissues with demonstrated relevance to AD (brain, whole blood, spleen, and skin). We identify drug repurposing candidates for AD by querying the imputed AD transcriptomic signatures against drug signatures available in the Connectivity Map (CMap) database to find drugs capable of inducing opposing changes in gene expression. We then validate promising repurposing candidates using clinical data in VUMC's de-identified EHR database to determine whether exposure to a repurposing candidate is associated with a lower prevalence of AD in individuals over 60. We use a 2:1 propensity score matching approach with sex, race, and comorbidities (coronary artery disease and rheumatoid arthritis diagnoses at the time of cohort entry, i.e., at age 60) as covariates in defining a control cohort. **Results:** Aspirin was identified as one of the top ten drugs with a negative connectivity score computed by CMap for the AD transcriptomic signature constructed using all GTEx tissues. In the VUMC EHR, we further validated that AD prevalence is significantly lower in individuals exposed to outpatient aspirin compared to matched controls never exposed to aspirin (OR 0.54, 95% CI 0.47- 0.66, $P = 4.08 \times 10^{-12}$). **Conclusions:** Our findings suggest that aspirin exposure may be associated with lower occurrence of AD in individuals over the age of 60. We plan to expand our clinical validation analyses to investigate other drug repurposing candidates suggested by our virtual transcriptome approach to identify high-priority repurposing candidates for further investigation in clinical trials.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3292*. Accurate and cost-effective imputation of genotypes at whole genome level with Sparse Denoising Autoencoders.

Authors:

S. Loguercio¹, R. Dias², D. M. Rogers³, D. Evans¹, S-F. Chen¹, K-Y. Chen¹, L. Chan¹, A. Torkamani¹; ¹Scripps Res. Translational Inst., La Jolla, CA, ²Univ. of Florida, Gainesville, FL, ³Oak Ridge Natl. Lab., Oak Ridge, TN

Abstract Body:

Genotype imputation is a key component of genetic association studies, where it increases power, facilitates meta-analysis, and aids interpretation of signals.

Current statistical imputation methods require access to high-performance computing environments and large, privacy-sensitive, WGS reference panels. The most common strategy to access state-of-the-art genomic imputation is to submit genotype data to imputation servers, resulting in privacy and scalability concerns. Moreover, the accuracy of current statistical techniques is known to degrade in regions of low and complex linkage disequilibrium.

Artificial neural network-based imputation approaches may overcome these limitations by encoding complex genotype relationships in easily portable inference models. Recently, we demonstrated a general strategy for unphased genotype imputation with sparse denoising autoencoders (DSAE), using the HRC reference panel and limited to human chromosome 22. Our DSAE-based imputation strategy achieved superior accuracy across the allele frequency spectrum and across genomes of diverse ancestry, while delivering at least 4-fold faster inference run time relative to standard imputation tools - and without having to transfer private genotype data to external servers.

Here we extend the pilot study on chr22 to the entire human genome, using the larger and more diverse TOPmed reference panel (97K reference samples) and phased imputation.

As autoencoder training is computationally intensive - shifting the computational burden to model trainers, with performance gains for end-users - we leverage the massive GPU resources of a large supercomputing facility (OLCF Summit HPC) for hyperparameter optimization, training and fine tuning of several thousands of autoencoder models in parallel - one for each genomic segment, with boundaries defined by recombination.

We present preliminary results assessing the performance of our fully trained autoencoders in comparison with modern imputation methods (Minimac4, Beagle5, Impute5) across a range of independent datasets, genotyping array marker sets, minor allele frequency spectra, and diverse ancestry groups.

Moreover, since no minimum training size standards have been determined for deep learning-based imputation in genomics, we also report a comparison of the training accuracy results for imputation with HRC and TOPMED reference panels.

Our work provides an efficient genotype imputation platform at whole genome scale with substantial speed, accuracy and privacy benefits for genome association studies and clinical applications in precision medicine.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3293. Accurate and efficient estimation of local heritability using summary statistics and linkage disequilibrium

Authors:

H. Li¹, R. Mazumder², X. Lin¹; ¹Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, ²Massachusetts Inst. of Technology, Boston, MA

Abstract Body:

Heritability, defined as the proportion of variability in the phenotype that is attributable to genetic factors, is a fundamental and important parameter in statistical genetics. Many existing heritability estimation methods have been developed in the framework of the restricted maximum likelihood (REML) method under linear mixed models using data from genome-wide association studies (GWAS), but the requirement to access individual-level genotypic and phenotypic data greatly limits the applicability of these methods. Several have been proposed in the last few years to circumvent the need to use individual-level data by using GWAS summary-statistics to estimate heritability, such as LDSC and GRE. However, these approaches produce less efficient estimators the precision of which is less than individual-level data based REML heritability estimate. We introduce a novel REML-score equation based estimating procedure that yields highly statistically efficient heritability estimators similar to REML, but only requires GWAS summary-statistics and the in-sample linkage disequilibrium (LD) information. The efficiency of our estimator is guaranteed as the estimating equations coincide with the REML score equations constructed using individual-level data. The relative efficiency (RE) of our estimator compared to REML is as high as 92% while other state-of-the-art summary-statistics-based methods, such as LDSC and GRE, have a RE lower than 25%. Furthermore, we propose a sparse representation of the LD matrix using a sum of a low rank and a banded matrix, which not only reduces the storage cost and thus improves the portability of the LD matrix, but also increases the computational efficiency of our estimating algorithm. We demonstrate the statistical efficiency of our estimator and the advantages of the proposed sparse representation of the LD matrix both theoretically and using extensive simulations. We apply our method to the summary-level data from the UK biobank to estimate the local heritabilities of 22 common traits and diseases. The increased precision of heritability estimates based on our algorithm will also enable other more powerful summary-statistics-based analyses, such as the estimation of genetic correlation and the construction of polygenic risk scores.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3294. Accurate *in silico* confirmation of rare copy number variant calls from exome sequencing data using transfer learning.

Authors:

R. Tan¹, Y. Shen^{1,2,3}; ¹Dept. of Systems Biology, Columbia Univ., New York, NY, ²Dept. of BioMed. Informatics, Columbia Univ., New York, NY, ³JP Sulzberger Columbia Genome Ctr., Columbia Univ., New York, NY

Abstract Body:

Exome sequencing is widely used in genetic studies of human diseases and clinical genetic diagnosis. Accurate detection of copy number variants (CNVs) is important to fully utilize exome sequencing data. However, exome data is noisy. None of the existing methods alone can achieve both high precision and recall rate. A common practice is to perform heuristic filtration followed by manual inspection of read depth of putative CNVs. This approach does not scale in large studies. To address this issue, we developed a transfer learning method, CNV-espresso, for *in silico* confirming rare CNVs from exome sequencing data. CNV-espresso encodes candidate CNVs from exome data as images and uses pre-trained convolutional neural network models to classify copy number states. We trained CNV-espresso using an offspring-parents trio exome sequencing dataset, with inherited CNVs as positives and CNVs with Mendelian errors as negatives. We evaluated the performance using additional samples that have both exome and whole-genome sequencing (WGS) data. Assuming the CNVs detected from WGS data as proxy of ground truth, CNV-espresso significantly improves precision while keeping recall almost intact, especially for CNVs that span small number of exons. CNV-espresso can effectively replace manual inspection of CNVs in large-scale exome sequencing studies.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3295. Accurate variant calling of the camouflaged LPA KIV-2 VNTR in whole exome sequencing data

Authors:

S. Schoenherr, S. Di Maio, P. Zöschner, L. Forer, F. Kronenberg, S. Coassin; Med. Univ. of Innsbruck, Innsbruck, Austria

Abstract Body:

Background: Recent studies showed that some of the strongest variant signals for phenotypes can be found in protein-coding variable number tandem repeats (VNTRs). The *LPA* gene locus is a prominent example: It (a) controls >90% of Lipoprotein(a) [Lp(a)], which is a strong genetic risk factor for cardiovascular disease variance and (b) contains a 5.6-kb-large protein-coding VNTR with 10 to 40 Kringle IV-2 (KIV-2) repeats, resulting in >40 isoforms of the apolipoprotein(a) [apo(a)]. Up to 70% of the *LPA* coding sequence can be within the KIV-2 VNTR. The number of the KIV-2 repeats inversely correlates with the Lp(a) concentrations and mutations hidden in the KIV-2 region have been shown to explain a considerable amount of Lp(a) variance. However, mutation detection is difficult as the KIV-2 VNTR is camouflaged in current reference databases by several other highly homologous kringle domains in *LPA*, which lead to paralogous sequence variants, if not properly addressed during read alignment and variant calling. In previous work, we developed a targeted amplicon-sequencing approach for the KIV-2 region and reported a first map of the high genetic variability in the KIV-2 region, including SNPs with very strong effect on the Lp(a) variance.

Results: In the work at hand, we expanded our approach to accurately call variants in the KIV-2 region in whole exome sequencing (WES) data to maximize the utility of publicly available datasets. We evaluated its performance by comparing variants called from WES data to a gold-standard variant calling set derived from a targeted PCR-based sequencing approach, which selectively amplifies only the KIV-2 region and is thus not subject to paralogous variants originating from other kringle domains (8 samples, thereof 2 samples with no KIV-2B subtype, resembling the KIV-2B population frequency). We show that the selected read extraction strategy from WES is critical for the overall performance (F1 score range between 0.40-0.96) and also dependent on the KIV-2 subtype (i.e. specific haplotypes). The overall performance of our approach (F1-Score of 0.96, sensitivity of 0.91) improved by 1.4 to 2.4-fold compared to previous published strategies.

Conclusions: Our approach enables highly sensitive and specific mutation screening in the large *LPA* KIV-2 VNTR and is customizable to other medically relevant camouflaged genes.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3296. Adjusting for genetic confounders leads to reliable detection of causal genes from transcriptome-wide association studies

Authors:

W. Crouse¹, S. Zhao², K. Luo¹, S. Qian¹, M. Stephens¹, X. He¹; ¹Univ. of Chicago, Chicago, IL, ²Dartmouth Coll., Hanover, NH

Abstract Body:

While GWAS have identified many loci associated with complex traits, causal genes in these loci often remain unknown. A number of methods have been developed to leverage expression QTL data to nominate candidate genes, including Transcriptome-wide association studies (TWAS), colocalization analysis, and Mendelian Randomization (MR) methods that use cis-eQTLs as instrumental variables. All these methods, however, suffer from various issues, particularly false positive findings. TWAS may find associations in non-causal genes when their eQTLs are shared with nearby causal genes or are in linkage disequilibrium (LD) with nearby causal variants. Colocalization methods typically assume a single causal variant for both gene and trait, are sensitive to parameters, and still cannot guarantee causality. For MR methods, the key instrumental variable assumption is often violated due to the pleiotropic effects of genetic instruments. This problem is exacerbated by the small number of genetic instruments and their correlations due to LD.

The fundamental problem of existing methods is that, when assessing the role of one gene on the phenotype, nearby variants and nearby genetic components of expression can be correlated with the eQTL(s) of the test gene while also affecting the phenotype directly, thus acting as “genetic confounders”. This motivates our approach, causal TWAS (cTWAS), which jointly models the effects of all nearby gene expression traits and nearby variants, which controls for potential genetic confounders. To make the model identifiable, we use a Bayesian variable selection strategy that learns parameters from genome-wide data. In simulations using data from UK Biobank (UKBB), existing methods (e.g. Fusion, SMR, coloc, FOCUS) all suffered from high false positive (FP) rates. In contrast, cTWAS produced calibrated FP rates while maintaining power.

We applied cTWAS to UKBB GWAS summary statistics of low density lipoprotein (LDL) cholesterol using eQTL from liver tissue. Genes identified by cTWAS are enriched for cholesterol-related gene sets, and cTWAS demonstrates high precision in distinguishing known genes regulating LDL cholesterol from nearby “bystander” genes. cTWAS also identified novel genes and pathways related to LDL cholesterol for further study. In applying cTWAS more broadly, using all tissues from GTEx, to complex traits such as Crohn’s Disease and Blood Pressure, cTWAS identified hundreds of putative causal genes. In conclusion, cTWAS solves a fundamental challenge of eQTL-GWAS analysis, reducing false positives relative to competing methods. cTWAS is available in an efficient and easy-to-use R package.

PB3297. Admixture mapping for phenome-wide discovery in a diverse health system biobank

Authors:

S. Cullina^{1,2}, R. Shemirani^{1,2}, B. Rowan^{1,2}, N. Abul-Husn^{3,2,4}, S. Asgari^{1,2,4}, E. Kenny^{4,3,2}; ¹Icahn Sch. of Med. at Mt. Sinai, New York, NY, ²Inst. for Genomic Hlth., Icahn Sch. of Med. at Mount Sinai, New York, NY, ³Dept. of Med., Icahn Sch. of Med. at Mount Sinai, New York, NY, ⁴Dept. of Genetics and Genomic Sci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Admixed individuals, who's genomes reflect recent ancestry from two or more continents, comprise over one third of the U.S. population. Despite many common heritable diseases being enriched in admixed populations, most genomic discovery approaches are tailored to more homogenous populations. Admixture mapping is a method that utilizes differences in disease prevalence and allele frequency between ancestral populations of admixed individuals for association testing. We have developed a generalizable pipeline and best practices by which local ancestry (LA) haplotypes can be inferred and utilized for admixture mapping in a diverse biobank in New York City (NYC). Individual-level ancestry proportions were calculated using genotype array data for 53,900 individuals in the BioMe Biobank at Mount Sinai, NYC. Participants were assigned to groups based on self-report race/ethnicity and patterns of recent admixture, enabling definition of population groups and optimizing the selection of global reference panels. Genotype data was phased and RFMIX2 was used to perform two- (African (AFR) and European (EUR) ancestry) or three-way (AFR, EUR, and Native American (NAT) ancestry) LA inference, for defined African/African-American (AA) and Hispanic/Latino(a) (HL) groups, respectively. Admixture mapping is currently being performed using generalized linear models in which LA haplotypes are tested for association with 1,740 phecodes from electronic health records as well as a curated set of over ~200 biomarkers and other quantitative traits. To assess the quality of LA calls, we compare the R2 correlation between the sum of LA haplotypes per individual and their global admixture proportions. We observe strong correlation in both HL (R2: AFR 1, EUR 0.96, NAT 0.96) and AA (R2: AFR 1, EUR 0.99). Variance components using LA haplotypes are being calculated phenome-wide using the HAMSTA method. Population-specific phenome-wide significance thresholds are being estimated using the STEAM method which accounts for population composition and history. We will present results from the association, annotation and finemapping of LA haplotypes, replicating known and showcasing novel associations. Large efforts to increase diversity and representation in genomic research mean that biobanks will become increasingly admixed, motivating the development of generalizable pipelines like this for well-calibrated admixture mapping.

PB3298. Allele frequency differences of causal variants explain the bulk of low portability of cross-ancestry PRS

Authors:

X. Liu¹, M. Saitou², A. Dahl¹, Q. Wang³; ¹Univ. of Chicago, Chicago, IL, ²Norwegian Univ. of Life Sci., Ås, Norway, ³Osaka Univ., Osaka, Japan

Abstract Body:

Genome-wide association studies (GWAS) are overwhelmingly biased toward European ancestries. Nearly all existing studies agree that transferring genetic predictions from European ancestries to others results in a substantial loss of accuracy. This is known as low portability of polygenic risk scores (PRS) and is one of the most important barriers to clinical deployment of PRS. Yet, it remains unclear how much different genetic factors, such as linkage disequilibrium (LD) differences, allele frequency differences or causal effect differences across ancestries contribute to low portability. In this study, we used gene expression levels in lymphoblastoid cell lines as a simplified model of complex traits in order to dissect how much each genetic factor contributes to PRS portability in a setting with minimal nongenetic differences. In stark contrast to the very low *cis*-genetic correlation estimates between European and African ancestries from previous studies, we found that *cis*-genetic effects between European and Yoruban have nearly perfect genetic correlation ($r=95\%$, S.E.=9%). We demonstrated through theory and realistic simulations that the previously reported low genetic correlations were artifacts of statistical bias. We derived a mathematical model to tease apart the genetic factors that may lead to loss of portability. We found that cross-ancestry LD differences and population-specific effects together explain a small proportion (<10%) of loss of portability. In contrast, allele frequency differences of causal variants have a striking impact on portability. For example, we observed a reduction of more than 40% in portability when the causal *cis*-variant is common in European (training population) but rare in Yoruban (prediction population). Importantly, this affects a sizable fraction (15.6%) of genes on the genome. We conclude that genetic effects are highly similar across ancestries, but that many causal variants with allele frequency differences severely decrease PRS portability. Our study thus provides evidence that large GWAS in diverse non-European populations are required for accurate PRS prediction in non-European population and, thus, for equitable clinical use of PRS.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3299. Allelic imbalance of chromatin accessibility in cancer identifies candidate causal risk variants and their mechanisms.

Authors:

D. Grishin¹, A. Gusev²; ¹Dana-Farber Cancer Inst., Cambridge, MA, ²Dana-Farber Cancer Inst., Boston, MA

Abstract Body:

Understanding the functional impact of non-coding variants remains a major challenge in cancer genetics. In the case of non-coding germline risk associations from GWAS, many associations are in high LD and cannot be resolved by statistical fine-mapping. In the case of non-coding somatic drivers from tumor sequencing, existing datasets are underpowered for discovery with frequency-based methods. For both domains, methods that can infer the functional impact of individual variants within regulatory elements are thus urgently needed. Here we studied allelic imbalance of chromatin accessibility in 409 ATAC-Seq samples across 23 cancer types. To this end we previously developed stratAS, a statistical model of allelic imbalance that aggregates signals across individuals while modeling individual-level somatic copy number variation. We discovered 7,262 germline allele-specific accessibility QTLs (as-aQTLs) and found that they are highly enriched for cancer risk heritability across seven common cancer GWAS (e.g. prostate cancer as-aQTLs with a 145 ± 35.7 ($p=6.3 \times 10^{-5}$) fold enrichment for prostate cancer risk) and are caused by genetic variants that alter transcription factor binding and gene expression. To connect as-aQTLs to putative risk mechanisms, we introduced the Regulome-Wide Associations Study (RWAS). RWAS identified accessible peaks genetically associated with cancer risk at >70% of known breast and prostate loci (compared to <45% for a conventional Transcriptome-Wide Association Study) and discovered novel risk loci in all examined cancer types. Motivated by these findings, we developed siamAS, a predictor of allelic imbalance that uses a novel “Siamese” neural network approach that trains two mirrored networks on allele-specific features. We trained siamAS on our allele specificity data incorporating >7,000 features from multiple variant effect predictors. In held out data, siamAS achieved a classification AUC of 0.92, which substantially outperformed any individual predictive feature (e.g. CADD score with AUC of 0.55). We applied siamAS to variants within regulatory elements and demonstrated a significant enrichment in cancer risk heritability for variants classified by our model as functional (e.g. 42.5 ± 20.8 fold breast cancer risk heritability enrichment at top as-aQTLs predicted by siamAS). Additionally, we applied siamAS to non-coding somatic mutations in TCGA and showed statistically significant classification accuracy (AUC > 0.9 for top 10 most imbalance/balanced somatic mutations). In summary, our results establish cancer as-aQTLs, RWAS and siamAS as powerful tools to study the genetic architecture of cancer risk.

PB3300. Alpha-2A adrenergic receptor (*ADRA2A*) modulates susceptibility to Raynaud's disease.

Authors:

A. Tervi, V. Lammi, FinnGen, C. A. Heckman, S. E. Jones, H. M. Ollila; Inst. for Molecular Med. Finland, FIMM, HiLIFE, Univ. of Helsinki, Helsinki, Finland

Abstract Body:

The autonomic nervous system controls physiological functions in the body that are not under direct voluntary control and are not typically consciously directed. The targets of the autonomic nervous system include, for example, body temperature, heart rate, respiration, blood pressure regulation, and vascular tone. In some instances, however, the autonomic nervous system can malfunction causing symptoms and diseases of dysautonomia and affecting many different targets of the autonomic nervous system at once. Raynaud's disease is dysautonomia where exposure to cold or stress increases the vascular tone of distal arteries causing vasoconstriction and hypoxia, particularly in fingers and toes. Using genetic and electronic health record data from the UK Biobank and FinnGen data freeze 9 we identified 6,940 individuals with a diagnosis for Raynaud's disease or Raynaud's phenomenon and 816,332 disease-free controls. Genetic analysis identified the same risk locus at the *ADRA2A* gene region independently in both cohorts. A meta-analysis combining UK Biobank and FinnGen identified rs7090046 as the lead variant associated with Raynaud's disease ($P=1.1e-30$). Functional analysis using RNA expression from GTEx indicated that the genetic variants modulate *ADRA2A* expression in a tissue-specific manner in the distal arteries (rs7090046, $P=1.3e-13$, effect size (NES) = 0.305). Our results indicate that *ADRA2A* modulates vascular tone in Raynaud's disease and provides the first functional evidence for understanding the mechanisms in dysautonomia.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3301. AlphaCluster: Coevolutionary driven residue-residue interaction models enable quantifiable clustering analysis of *de novo* variants to enhance predictions of pathogenicity

Authors:

J. Obiajulu, R. Kuang, G. Zhong, W. K. Chung, Y. Shen; Columbia Univ., New York, NY

Abstract Body:

Missense variants have highly variable effects and effect size, which often makes it challenging to distinguish pathogenic and non-pathogenic variants and subsequently implicate new genes for disease association in studies. Importantly, missense variants can be the sole molecular mechanism for some genetic disorders, and so statistical approaches tailored for the analysis of missense variants are critical. Analysis of the clustering of missense variants is a promising approach which leverages the fact that missense variants in protein domains often have similar effects on function. Here we describe a new clustering analysis approach, AlphaCluster, a statistical method which quantifiably analyzes the spatial clustering of *de novo* variants by mapping missense residues onto the protein tertiary structure. We show that our approach can quantify the evidence supporting pathogenic missense variants and increase the power to detect clustering when compared to available genomic clustering tools. Using AlphaCluster, we identify two genes newly implicated at the genome-wide level in autism spectrum disorder, namely *GABBR2* and *SATB2*, and eleven in neurodevelopmental disorders (NDD). We also apply AlphaCluster to protein complexes and detect an association between the gamma aminobutyric acid receptor complex (GABA-A α ;1 β ;2 γ ;2 receptor) and Kv1.2 potassium channel with NDD.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3302. An accelerated, massively scalable variant calling and filtering workflow for the detection of de novo mutations in whole genome sequencing data.

Authors:

E. Dawson^{1,2}, M. Yeager³, M. Dean², D. Karyadi², J. Israeli¹; ¹Nvidia Corp., Santa Clara, CA, ²NCI, Rockville, MD, ³FNLRC/NCI, Rockville, MD

Abstract Body:

De novo mutations are important contributors to human disease and variation. Such variants are usually detected using trio studies, in which an offspring sample and both parents are analyzed in tandem. The three samples are each aligned, variants are called, and then filtered to identify Mendelian inheritance violations and putative de novo mutations (DNMs). Trio studies involve significant computational resources because of the need to analyze all three samples, and often there is need to do them quickly to identify the variant causing the disease in the child. We developed a pipeline implemented in the Workflow Description Language for accelerated analysis of trio data. NVIDIA Clara Parabricks-accelerated versions of DeepVariant and GATK HaplotypeCaller are run concurrently with Strelka2. glNexus is then used for joint genotyping of the HaplotypeCaller and DeepVariant calls. A series of filtering steps, including taking the multi-caller intersection, is performed to generate putative de novo mutations. The number of putative DNMs output by our pipeline is in line with other studies, and manual review of variants called in Genome in a Bottle trios indicated high precision among variants called by all three callers. The native task parallelism of WDL allows our pipeline to run independent tasks within a single trio in parallel. We extended the scalability of the standard Cromwell WDL runner by automating WDL input creation and Cromwell instantiation based on comma-delimited manifests of samples. This additional layer of sample-level parallelism enables scaling further across SLURM clusters or the cloud with minimal setup. The integration of accelerated tools reduces the runtime per trio compared to community versions of the tools, which in turn reduces the computational burden of de novo mutation calling in trios and improves scalability and ease of use.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3303. An accurate and efficient causal gene network inference method that handles many confounding variables.

Authors:

J. Kvamme, A. Fu; Univ. of Idaho, Moscow, ID

Abstract Body:

Learning complex regulatory relationships among genes has been a challenge in biology. Several methods have been developed to conduct causal inference for molecular phenotypes (e.g., gene expression and DNA methylation), using genetic variants as instrumental variables under the principle of Mendelian randomization. However, these methods are often limited to mediation and ignore other possible regulatory relationships, or do not account for confounding variables well. Here, we introduce a new causal network inference method for trios consisting of a genetic variant (denoted by V) and two associated molecular phenotypes (denoted by X and Y). Our method, Mendelian Randomization Genomic Network (MRGN), improves existing methods by i) inferring diverse regulatory relationships for a trio; ii) allowing for the inclusion of many confounding variables; and iii) eliminating the need for a large set of independence tests to infer each causal edge.

Specifically, MRGN performs conditional and marginal tests to detect five basic models: mediation ($V \rightarrow X \rightarrow Y$), v -structure ($V \rightarrow X \leftarrow Y$), conditional independence ($X \leftarrow V \rightarrow Y$), fully connected ($X \leftarrow V \rightarrow Y$ and $X - Y$), and the null model ($V \rightarrow X$; no relationship between X and Y). The conditional tests regress X (or Y) on Y (or X), V , and the confounding variables. Marginal tests are used to test for significant correlation between V and X (or Y). Additionally, if V has a rare variant, MRGN performs a permutation test like that in the GMAC method (Yang et. al., 2017) for improved calculation of the p -values for the regression coefficients in the conditional tests.

We test the performance of MRGN by simulating trios from the five basic models with confounding variables. We investigate four simulation parameters: strength of the effect, noise in the residuals, minor allele frequency, and the number of confounders. We compare our method with GMAC, a method designed to detect only mediation, and MRPC (Badsha and Fu, 2019), our other causal inference method designed for generic network inference. For each trio, confounders are identified from a candidate pool before causal inference. Across different scenarios, MRGN correctly detects substantially more edges than MRPC while incurring a few additional false positive edges (recall 0.944 vs 0.141; precision 0.832 vs 0.989, respectively). Additionally, while having the added flexibility to infer the entire network, MRGN also performs comparably with GMAC in detecting mediation (recall 0.918 vs 0.967; precision 0.789 vs 0.754, respectively). Lastly, our method is nearly 15 times faster than GMAC and 8 times faster than MRPC (0.35s, 5.18s, and 3.04s per trio, respectively).

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3304. An allelic series rare variant association test for candidate gene discovery

Authors:

Z. McCaw, B. Ungen, F. Casale, T. Karaletsos, D. Koller, T. Soare; Insitro, South San Francisco, CA

Abstract Body:

A central task in genetics and in drug discovery is identifying genes that influence a molecular trait or disease process. In genome-wide association studies, common variants (minor allele frequency [MAF] > 1%) are typically linked to the phenotype of interest using variant-level association tests. Rare variants (MAF ≤ 1%), by contrast, are typically analyzed using gene-centric approaches, particularly the burden and sequence kernel association tests (SKAT). We sought to develop a gene-based rare variant association test that targets allelic series: cases where increasingly deleterious alterations of a gene lead to increasingly large effects on the phenotype. The proposed allelic series test operates on rare coding variants. Using the Ensembl Variant Effect Predictor (VEP), these variants are annotated as synonymous, benign missense, deleterious missense, or protein truncating. Synonymous variants and those lacking annotations are removed. Gene-level allelic series scores are constructed by aggregating indicators or counts of benign missense, deleterious missense, or protein truncating variants across a gene. The indicators or counts are scaled by a weight that increases with predicted pathogenicity, reflecting the hypothesis that more deleterious alterations will have larger effects. Different methods of weighting and aggregation lead to different allelic series tests. These are combined into an omnibus test using the Cauchy aggregation method.

Through extensive simulations, we show that the proposed allelic series test maintains the type I error in the absence of association, and improves power when more deleterious variants in fact have larger effect sizes. We apply the allelic series test to perform rare variant analysis of lipid traits (total cholesterol, low and high density lipoprotein, triglycerides) using whole exome sequencing data on 145,735 subjects from the UK Biobank. We compare the proposed allelic series test with standard rare variant association tests, including burden and SKAT, replicating known associations and identifying novel candidates.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3305. An alternative approach to the estimation of biological age

Authors:

K. Fischer¹, N. Taba¹, M. Mändul¹, A. Kolde¹, R. Mägi²; ¹Univ. of Tartu, Tartu, Estonia, ²Inst. of Genomics, Univ Tartu, Tartu, Estonia

Abstract Body:

Given a set of age-related biomarkers, the biological age of an individual is often defined as the average chronological age of all individuals with a similar biomarker profile. Being “biologically older” than one’s chronological age is seen as an indicator of a worsened health status, leading to higher disease risks and shorter-than-average residual life expectancy. Conventionally, various regression approaches are used to estimate biological age based on a model with chronological age as dependent variable and omics markers as covariates. We discuss the plausible underlying causal association structures and study, whether, and under which assumptions the difference between biological and chronological age estimated by conventional methods could be a meaningful summary of the individual’s risk profile. Using the metabolomics profiles for the Estonian Biobank participants, we show that the conventional biological age estimates can easily be affected by time-dependent confounders, that can lead to biased estimates of actual risk level as well as invalid conclusions on the effects of risk factors. We propose an alternative definition and estimation strategy for the biological age, using the concepts of survival analysis. The new estimate is directly related to the underlying risk level and is therefore easily interpretable. Using simulations as well as the example of the Estonian Biobank, we compare our parametric and semiparametric approaches to the biological age estimation with the conventional method. We also show how our approach can be used in the estimation of “heart age”, as a tool for personalized feedback on cardiovascular disease risks. We conclude that when there are time-dependent confounders associated with the biomarker profile, younger or older “biological age”, when estimated as a regression prediction for age, does not necessarily correspond to lower or higher disease or mortality risks. The proposed alternative approach would lead to estimates that are more straightforward to interpret and can be used while communicating the omics-based personalized risk estimates to individuals.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3306. An evaluation of ancestry specific polygenic risk scores (PRS) for uterine fibroids across populations

Authors:

J. Piekos¹, J. N. Hellwege², O. Dikilitas³, I. J. Kullo³, D. J. Schaid³, T. L. Edwards², D. R. Velez Edwards⁴; ¹Vanderbilt Univ., Nashville, TN, ²Vanderbilt Univ. Med. Ctr., Nashville, TN, ³Mayo Clinic, Rochester, MN, ⁴Vanderbilt Univ Med Ctr., Nashville, TN

Abstract Body:

Uterine leiomyomata (or fibroid, UF) are common (prevalence up to 75% in women), heritable (approximately 35%), and can negatively interfere with a woman's life if symptomatic and lead to surgical interventions such as hysterectomy or myomectomy. We constructed polygenic risk scores (PRS) using PRScsx and genome wide association summary statistics from FinnGen (FG) and Biobank Japan (BBJ). We computed three scores with PRScsx according to genetic ancestry of source data: European and East Asian, respectively, and a meta score. We applied each PRS to women from the Electronic Medical Records and Genomics Network (eMERGE) (N = 25,973) and BioVU (N=9,759) and performed analysis in three strata of women: cross ancestry (CA) including all regardless of race/ancestry, European ancestry (EA), and African ancestry (AA). Using 10-fold cross validation of logistic regression models, (UF ~ PRS + 10 principal components [PC]) we validated all three PRS as significant predictors of UF status in both datasets for EA and CA populations ($P < 0.00185$, multiple testing correction). Odds Ratios (OR) (95% Confidence Interval [CI]) of FG PRS from the meta-analysis were 3.40 (2.41 - 4.80) in EA and 1.98 (1.49 - 2.64) in CA and BBJ PRS was 2.45 (1.93 - 3.11) in EA and 2.33 (1.90 - 2.87) in CA. No PRS significantly predicted UF status in either AA population. Meta-analysis of area under the receiving operator curve (AUROC) found AUROC (95% CI) for FG PRS in EA to be 0.58 (0.55 - 0.62) and 0.61 (0.58 - 0.64) in CA, BBJ PRS 0.59 (0.56 - 0.63) in EA and 0.63 (0.60 - 0.66) in CA, and meta PRS 0.58 (0.55 - 0.62) in EA and 0.62 (0.59 - 0.65) in CA. Cross validation revealed each PRS had more predictive power when applied to CA compared to EA but PRS has larger effect sizes in EA. PRS was then used as the predictor for phenome wide association studies (PheWAS), adjusted for age, BMI, and 10 PC, in each dataset separately and meta-analyzed. FG PRS significantly associated ($P < 2.78 \times 10^{-5}$) with UF phecode (218.1) when applied to BioVU EA and CA and remained significant in CA meta-analysis. BBJ and meta PRS associated with UF phecode in eMERGE EA and CA and all remained significant in meta-analysis. No PRS significantly associated with UF in any AA populations. Additionally, we observed the phecode "excessive or frequent menstruation" to be moderately associated ($P < 2.78 \times 10^{-4}$) with the BBJ PRS in eMERGE CA and both CA and EA in the meta-analysis. Ovarian cysts were moderately associated with the FG PRS when applied to BioVU CA and EA and remains marginally significant in the CA meta-analysis. We observe ancestry specific PRS perform as well as meta-score, however PRS performs better when applied to CA populations as opposed to a single EA stratum.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3307. An Exomiser-based R pipeline for gene burden testing aids novel gene discovery in rare Mendelian diseases.

Authors:

V. Cipriani, L. Vestito, J. Jacobsen, D. Smedley; Queen Mary Univ. of London, William Harvey Res. Inst., London, United Kingdom

Abstract Body:

Recent efforts, such as the 100,000 Genomes Project (100KGP) in the UK, have paved the way for the availability of large sequencing datasets in rare Mendelian diseases. The scale of such datasets now allows for the application of case-control association methods that have been more typically used to identify gene susceptibility in complex disorders, e.g. rare variant gene-based burden testing for novel Mendelian disease gene discovery. Yet, analytical tools for those analyses at scale are not largely available. In a recently published preliminary report of the rare disease data component of the 100KGP (27,591 rare disease families, a total of affected and unaffected individuals of 57,002 and over 197 different rare disorders available at the time of the analysis), we have developed an Exomiser-based analytical framework for gene burden testing. Exomiser is a phenotype-aware (Human Phenotype Ontology, HPO-based) variant prioritization software for sequencing data that has been largely adopted in the scientific community for the search of Mendelian causative variants. This analysis led to the identification of 3 new disease-gene discoveries that have been recently independently confirmed and 19 new associations. We have now extended our Exomiser-based analytical framework into an R pipeline for gene-burden testing and novel gene discovery in rare Mendelian diseases, beyond the application to the 100KGP data. A generic user with access to any large-scale sequencing datasets is now able, first, to apply Exomiser on any available single samples and/or single families for rare variant filtering and annotation and, after defining tailored case and control sets within the dataset, perform a set of gene burden analyses, either genome-wide or restricted to a gene list of interest, including testing for excess in cases of predicted loss-of-function or to be highly pathogenic variants. The R pipeline is complemented with visualization scripts to produce volcano, Manhattan, variant lollipop and HPO-based plots. By making our analytical framework suitable for generic use beyond the original application to the 100KGP data and available as a GitHub repository, we expect to aid substantially novel gene discovery in rare Mendelian diseases.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3308. An experimentally-based functional gene embedding

Authors:

F. Brechtmann¹, T. Bechtler¹, B. Clarke², C. Mertes¹, O. Stegle², J. Gagneur¹; ¹Technical Univ. of Munich, Garching, Germany, ²German Cancer Res. Ctr. (DKFZ), Heidelberg, Germany

Abstract Body:

Gene embeddings, i.e. numerical representations of gene function, are of high relevance for modeling in genomics. Here we propose a generic gene embedding with distinctive features: Our embedding is based on multiple experimental data modalities excluding text-mining sources, to prevent ascertainment bias towards well-studied genes. Specifically, we integrate gene expression across human tissues (GTEx), protein-protein interactions extracted from STRING, and two recently published datasets: a genome-wide deletion screen (DepMap), and a functional gene embedding derived from an autoencoder trained on hundreds of millions of protein sequences (Elnaggar et al.).

Using our embedding, we first predict curated trait-gene associations. For 9 out of 10 traits, our embedding performed on par or better than using an embedding of the STRING network. Additionally, in 4 out of the 10 traits, our joint embedding outperformed any input modality considered individually. Second, we asked whether our 900-dimensional embedding can predict gene-level GWAS signals. To this end, we trained a gradient boosted tree to predict gene-aggregated GWAS signals obtained using MAGMA (de Leeuw et al.). We obtained a median R² of 6.6% across 25 blood biomarkers. This performance was on par with a dedicated study (Weeks et al.) which was using a 57,543-dimensional feature matrix. As a last task, we considered predicting cancer driver genes and improved the mean precision by 62% in predicting COSMIC cancer driver genes over OncoVar. For all these prediction tasks, we used a single embedding demonstrating its generality.

Overall, our embedding captures different aspects of gene functions and can be easily integrated into diverse prediction tasks that can benefit from a general-purpose gene embedding.

PB3309. Analysis of follow up data in large biobank cohorts: a review of methodology

Authors:

A. Kolde¹, M. Mändul¹, M. Käärik¹, P. Joshi², K. Fischer¹; ¹Univ. of Tartu, Tartu, Estonia, ²Univ Edinburgh, Edinburgh, United Kingdom

Abstract Body:

Survival analysis is a field of statistics with a long history and well researched in terms of model-fitting in the context of (randomized) clinical trials. Since large omics-based biobanks utilize different study design than clinical trials, it is necessary to investigate whether a survival model needs to be modified in order to assure validity of the results. Additionally one needs to take into account that the classical Cox PH model is computationally prohibitive and that might be a major shortcoming in GWAS setting.

First, we aim to investigate applicability of Cox PH model for biobank setting by choice of different timescales. We were interested in potential bias of different models as well as ways to improve power when high censoring is present. One of the earlier proposed solutions has been the usage of parental lifespan and offspring genotype instead of e data for participants. So far it has been known that this approach increases power, but potential bias has not yet been investigated. Second, we aim to investigate bounds and limitations of the two step martingale residual (MR) based approach for Cox modeling for high-dimensional omics data as a possible way to reduce computational burden. With the MR approach, the analysis simplifies to fitting only one Cox PH model for technical covariates after which all the association testing in GWAS is reduced to a simple linear regression task, while still providing the hazard ratio (HR) estimates.

For small HRs, we show that the choice of timescale does not have much effect on precision, but for bigger HRs it is important to take left-truncation into account to decrease bias. However, if the aim is to maximize the power for association discovery rather than minimizing biases, using the participant's age as the time scale (ignoring left-truncation) yields the highest power. We also propose to use the two step martingale residuals based approach in GWAS settings, showing acceptable precision and no loss of power in case of small effect sizes. Nonetheless, for predictions and PGRS calculation we recommend recalculating effect sizes using the widely accepted and conventional Cox PH model.

The conclusions are mainly based on simulations, but we illustrate the results also on survival data in the Estonian Biobank cohort.

Abstract Body:

The genetic basis of multiple sclerosis (MS) in adults has been extensively studied and more than 230 susceptibility variants have been identified, to date, through GWAS; less is known about genetic contributions to MS occurring in children (<18 years, 'pediatric-onset' MS) which comprises ~5% of patients. MS prevalence is higher in regions farther from the equator, supporting the hypothesis that vitamin D exposure has a protective effect on MS risk. Mendelian randomization studies have identified causal associations between lower serum vitamin D and increased risk of MS. Vitamin D is important for many biological processes. After being ingested or absorbed, serum vitamin D is first converted to 25-hydroxyvitamin D [25(OH)D], its more stable form, and then to 1,25-dihydroxyvitamin D [1,25(OH)₂D]. Previous studies have established that 25(OH)D signals through the nuclear vitamin D receptor (VDR), a ligand-regulated transcription factor that modulates vitamin D regulated gene expression. Directly testing for associations between VDR binding and disease phenotypes in large-scale human studies poses many challenges. SNPs associated with genetic variation in VDR binding affinity (VDR binding variants or 'VDR-BVs') have been recently identified using ChIP-exo data from calcitriol-stimulated lymphoblastoid cell-lines followed by Allele-seq. We recently studied these VDR-BVs as genetic IVs in adult-onset MS and identified strong evidence for association with several VDR-BVs. The objective of this study was to study adult-onset MS VDR-BV candidates for a role in pediatric-onset MS. We utilized 524 pedMS cases and 1330 controls of European ancestry from the U.S. Network of Pediatric MS Centers and Kaiser Permanente Northern California. Genotyping was performed using Illumina Infinium 660K OmniExpress and OmniExpressExome BeadChip arrays and imputed against reference haplotypes from Phase 3 of the 1000 Genomes Project using IMPUTE4. After quality control measures, SNPs were excluded if minor

ASHG 2022 Annual Meeting Poster Abstracts

allele frequency (MAF) <5%. This resulted in 10 candidate VDR-BVs for analysis. Associations between VDR-BVs and pediatric-onset MS were tested using logistic regression in *PLINK*, and models were adjusted for the first three genetic principal components. One VDR-BV was associated with pediatric-onset MS at $p < 0.05$ (OR: 1.20, 95% CI: 1.03-1.39): rs2531804. This variant is located on chromosome 6 and is upstream of *TEC*. These findings provide further evidence that at least one known VDR-BV associated with adult-onset MS vitamin D is also implicated in pediatric-onset MS.

Dept. of Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract Body:

Although the genetic etiology of Alzheimer's Disease (AD) varies among ancestrally diverse populations, the influence of genetic variation on the transcriptome within these populations and its association to AD has not been extensively investigated. Multi-ancestry AD datasets featuring both genetic information and gene expression measurements are needed to support expression quantitative trait loci (eQTL) studies in populations underrepresented in genetic research. In this work, we have compared eQTL associations in case/control AD sample populations of both Hispanic (HIS) and non-Hispanic white (NHW) ancestries. We analyzed cohorts of HIS from Cuba, Puerto Rico, and Peru and NHW ancestries ($N_{his}=295$, $N_{nhw}=241$) with corresponding array-based genotypes and RNA-seq mRNA expression levels from whole blood, along with clinical AD diagnoses ($N_{his_case}=149$, $N_{his_control}=146$, $N_{nhw_case}=121$, $N_{nhw_control}=120$). Cis-regulatory eQTL associations between genetic variants and gene expression levels were assessed via linear regression across 14,894 genes, adjusting for age, sex, experimental factors, and ancestry-based principal components. This was repeated across all sample set combinations of ancestry-AD pairings (ancestry=[HIS, NHW, both] * AD=[case, control, both]).

The number of genome-wide significant (p -value $< 10e-7$) eQTL signals varied by ancestry, with the HIS cohort showing 567 eQTL associations (independent of AD status), the NHW cohort 812, and both ancestries combined 1,367. When further sub-setting sample sets to AD cases only, 225 and 253 significant eQTL signals were observed for HISP and NHW cohorts respectively, which impacted 194 (HIS) and 195 (NHW) genes. Interestingly, these ancestry-aware, case-only eQTLs were remarkably distinct between the two ancestries, with only 4 (~0.84%) of the eQTLs and only 3 (0.82%) of the impacted genes being shared by both ancestral cohorts. Of particular interest is the appearance of the variant '22:26184047:T:C' within *MYO18B* (a gene linked to both paired helical filament tau measurement and neurofibrillary tangles measurement phenotypes in reported GWAS studies), as differentially significant in the HIS cohort ($P_{his_case}=2.73e-7$, $P_{his_control}=0.86$) but not in the NHW cohort ($P_{nhw_case}=0.90$, $P_{nhw_control}=0.91$).

We have observed differences in eQTL signals relative to AD diagnosis status between HIS and NHW sample populations, which may indicate the presence of novel ancestry-specific effects impacting the genetic etiology of AD through changes in gene expression.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3312. Ancestry-Specific Polygenic Risk Scores for Telomere Length in TOPMed

Authors:

J. Jin¹, M. A. Taub¹, T. W. Miller-Fleming², M. P. Conomos³, A. Reiner³, N. J. Cox², N. Chatterjee¹, R. A. Mathias¹; ¹Johns Hopkins Univ., Baltimore, MD, ²Vanderbilt Univ. Med. Ctr., Nashville, TN, ³Univ. of Washington, Seattle, WA

Abstract Body:

Telomeres shorten in replicating somatic cells, and telomere length (TL) is associated with age-related diseases. While prior genome-wide association studies using laboratory assays of TL identified genetic loci associated with TL in European and Asian populations, recently published work from the NHLBI Trans-Omics for Precision Medicine (TOPMed) program has expanded our knowledge of TL genetics to include ancestrally diverse African and Hispanic/Latino groups. Despite little evidence of effect-size heterogeneity across ancestry groups, this study identified differences in genetic determinants of TL across ancestries based on differing allele frequencies and an initial polygenic risk score (PRS) analysis revealed cross-population differences in PRS distributions comparing European and African ancestry individuals. This work expands this prior PRS analysis to further leverage the ancestral diversity of TOPMed. In this follow-up, we used TOPMed whole genome sequencing (WGS) of whole blood for genotyping and the bioinformatic estimation of TL in a trans-ethnic sample, including 46,613 European (EUR), 24,891 African (AFR), 4,650 Asian (mainly East Asian, EAS) and 13,860 Hispanic/Latino (LAT) individuals. Using summary statistics from TL GWAS performed separately on each group, we developed ancestry-specific PRS using three methods: (1) “Top-SNP PRS”, calculated as the weighted sum of the number of effect alleles for SNPs reaching genome-wide significance ($p \leq 5 \times 10^{-8}$) in the European-only GWAS, weighting by the GWAS summary statistics; and two methods that borrow information across ancestries: (2) weighted LDpred2, a weighted sum of the ancestry-specific PRS obtained by the LDpred2 algorithm using ancestry-specific GWAS summary statistics, and (3) MEBayes, a novel LD-based method which jointly models the correlated ancestry-specific GWAS summary statistics. On a validation set of 14,387 held-out multi-ancestry individuals in TOPMed, we saw an explained variance (R^2) of 0.034, 0.046 and 0.047 on EUR; 0.016, 0.022 and 0.027 on AFR; 0.029, 0.048 and 0.046 on EAS; and 0.021, 0.033 and 0.031 on LAT for the Top-SNP, weighted LDpred2 and MEBayes approaches, respectively. We observe that the two multi-ancestry PRS, weighted LDpred2 and MEBayes, show substantially improved prediction accuracy on the non-European populations (AFR, LAT, and EAS) compared to the Top-SNP PRS. We are applying these multi-ancestry PRS to perform a phenome-wide association study on individuals in the BioVU database (72,597 EUR, 15,615 AFR, 2,392 LAT, 884 EAS) to further test the association between our TL PRS and 1,800 clinical traits, including age-related diseases.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3313. Application of the colorectal cancer polygenic risk score to the VA CSP #380 “Prospective Evaluation of Risk Factors for Large (≥ 1 cm) Colonic Adenomas in Asymptomatic Subjects” longitudinal colonoscopy screening cohort

Authors:

X. Qin^{1,2}, B. Sullivan^{2,1}, T. S. Redding IV¹, D. Weiss³, S. Pyarajan⁴, Y. Shi⁴, A. Madison¹, K. J. Sims¹, C. Williams^{1,2}, J. Dominitz⁵, D. Lieberman^{6,7}, E. R. Hauser^{2,1}; ¹Cooperative Studies Program Epidemiology Ctr.-Durham, Durham VA Med. Ctr., Durham VA Hlth.Care System, Durham, NC, ²Duke Univ. Sch. of Med., Durham, NC, ³Perry Point VA Med. Ctr., Perry Point, MD, ⁴Massachusetts Veterans Epidemiology Res. and Information Ctr. (MAVERIC), VA Boston Hlth.care System, Boston, MA, ⁵VA Natl. Gastroenterology and Hepatology Program, Washington, DC, ⁶Portland VA Med. Ctr., Portland, OR, ⁷Oregon Hlth.& Sci. Univ., Portland, OR

Abstract Body:

Background: VA CSP #380 is a longitudinal study of 3121 participants aged 50-75 enrolled for screening colonoscopy from 1994-1997. Follow-up using the VA electronic health records is ongoing. The goal of our analysis was to apply the well-calibrated colorectal cancer (CRC) polygenic risk score (PRS) of Huyghe et al. (2019) and Thomas et al. (2020) to long-term programmatic screening and surveillance colonoscopy outcomes. Method: Advanced neoplasia (AN) cases are those participants with invasive CRC or advanced adenoma (AA) at any time within 10 years of follow up, with AA defined as an adenoma >10 mm, an adenoma with villous histology or high-grade dysplasia on at least 1 exam. Controls are individuals with no adenomas or no advanced adenomas at all exams. A total of 612 individuals were genotyped with the Illumina Infinium Omni2.5-8 v1.3 Beadchip. Imputation using the TopMed panel was performed using Shapeit4 and Minimac4. After QC, 137 of the 140 CRC-risk SNPs were used in current PRS analysis as implemented in PRSice. We evaluated the association of the PRS with AN using the rstanarm joint model incorporating colonoscopy outcomes over time, accounting for age, sex, ancestry principal components and differential surveillance. The PRS was divided into tertiles and the frequency of participants with CRC ever, AA ever, and control was calculated for each tertile. Results: Outcomes were assessed at 1471 colonoscopies occurring across 10 years. Among the 612 with a CRC PRS, 22 were in the CRC group, 167 with AA, and 423 were controls. The CRC PRS was significantly associated with the occurrence of AN ($p=0.0057$), even after accounting for differential surveillance ($p=0.0056$). The lowest PRS tertile included 26.8% controls, 14.5% AA and 9.1% CRC. The highest PRS tertile included 12.8% controls, 15.1% AA and 31.8% CRC. Conclusion: In an independent longitudinal screening colonoscopy cohort, the CRC PRS was significantly associated with advanced neoplasia. More individuals with CRC were in the highest PRS tertile. These results suggest that the CRC PRS may be useful for risk prediction during long-term colorectal cancer screening by helping better target scarce resources to the highest risk individuals most likely to benefit.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3314. Applying human phenomics to electronic health records provides a framework for understanding skin-aging related phenotypes

Authors:

A. Abbasi¹, M. Liu¹, B. Riley-Gillis¹, J. Waring², H. Jacob¹, S. Manson Brown³, T. Cheng³, R. Mehta³, N. Smaoui¹; ¹AbbVie, North Chicago, IL, ²ABBVIE, NORTH CHICAGO, WI, ³AbbVie, Irvine, CA

Abstract Body:

Standard disease classification and defining human phenotypes are incomplete and imprecise because biological mechanisms underpinning human diseases and phenotypes are not yet captured even with different coding systems and methods. Such methods are arbitrary (e.g., hypertension), based on a location or organ (e.g., tumors), or have been used since physicians originally described certain diseases (e.g., Alzheimer's diseases) over a century ago, which cause confusion and uncertainty in diagnosis, drug discovery and medical care. In this analysis, we used the UK Biobank linked to primary care electronic health records (EHR) data to identify and reclassify skin-aging related phenotypes in 502,505 participants. Using EHR-based phenotyping, we improved our phenotype classification and increased sample size up to 40 times more than using any given combinations of ICD10 from disease data curation. For instance, we identified 9,327 individuals with dry skin (an increase from 219 patients using ICD10 codes only) and demonstrated that dry skin is associated with environmental exposures (air pollution, $P=0.002$) and lifestyle factors (trouble falling sleep, $P=2.7 \times 10^{-11}$ and smoking, $P=5.5 \times 10^{-6}$). Given that clinical information spanning several decades is available through EHR repositories, the use of EHR-based deep phenotyping can provide value beyond our current understanding of disease and phenotype classification and clinical research. Future research from this group will explore the value of deep phenotyping by applying machine learning approaches to big data and further develop genome-wide association analysis.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3315. Assessing the safety of lipid-modifying medications among East Asian adolescents using genetics: Evidence from Hong Kong's "Children of 1997" birth cohort

Authors:

S. Luo¹, Y. Chan¹, H. Lam², C. Tang¹, B. He¹, M. Kwok¹, C. Schooling^{1,3}, G. Leung¹, S. Au Yeung¹; ¹The Univ. of Hong Kong, Hong Kong, Hong Kong, ²The Chinese Univ. of Hong Kong, Hong Kong, Hong Kong, ³City Univ. of New York, New York, NY

Abstract Body:

Background 3-hydroxy-3-methylglutaryl coenzyme A (HMGCR) reductase inhibitors (statins) are the first-line pharmacologic treatments for children and adolescents who have elevated low-density lipoprotein cholesterol (LDL-C). However, the long-term safety of statins and other common lipid-modifying medications (proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors) among adolescents in East Asia is unclear. **Methods** This is a genetic study focusing on two known protein-encoding genes (*HMGCR* and *PCSK9*) of lipid-modifying drug targets using the data from participants at age of ~17.5 years in the Biobank Clinical Follow-up (n=3,353) of Hong Kong's "Children of 1997" population-representative Chinese birth cohort. Genetic variants strongly associated with LDL-C (p -value 5×10^{-8}) and in low linkage disequilibrium ($r^2 < 0.1$) within the corresponding gene were selected. We derived a weighted genetic risk score (GRS) using the effect size estimates from East Asian Genome-wide association studies to mimic the effects of each drug. The efficacy outcomes included cholesterol-related serum nuclear magnetic resonance (NMR) metabolomics, whilst other metrics from NMR metabolomics (e.g., amino acid and ketone bodies) and extensive health phenotypes, (e.g., anthropometric and haematological traits, renal, liver and lung functions) were considered as safety outcomes. The association of each GRS of drug target on the outcomes was assessed using multivariable linear regression, adjusted for age at sample collection, sex and the top 6 principal components of ancestry. **Results** Genetic inhibition of HMGCR was associated with a substantial reduction in cholesterol-related NMR metabolomics, e.g., total cholesterol (-0.72 standard deviation (SD) per GRS, 95% confidence interval (CI) -0.38 to -1.06), clinical LDL-C (-0.78 SD, 95% CI -0.43 to -1.12) and apolipoprotein B (-0.77 SD, 95% CI -0.42 to -1.12). Similar efficacy was seen for genetic inhibition of PCSK9. Genetic inhibitions of lipid-modifying drug targets were not associated with any of the safety outcomes assessed in adolescents from the "Children of 1997" birth cohort after correcting for multiple comparisons (p -value < 0.001). **Conclusion** As a proof of concept, this study assessed the efficacy and safety of drug targets among late adolescents. This study provided genetic evidence that the pharmacological actions of common lipid-modifying medications (e.g., statins and PCSK9 inhibitors) in terms of their primary drug target are generally safe in adolescents. Larger studies are needed for replication.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3316. Assessing the value of non-coding variants in 500,000 whole-genome sequences in the discovery of gene-phenotype associations

Authors:

Y. Lo¹, S. Donthi¹, E. Arner², E. Dermitzakis³, J. Davitte¹, P. Gormley⁴, R. Scott², E. Ingelsson³, A. Cortes², **J. Liu¹**; ¹GSK, Upper Providence, PA, ²GSK, Stevenage, United Kingdom, ³GSK, San Francisco, CA, ⁴GSK, Cambridge, MA

Abstract Body:

Whole-genome sequencing (WGS) studies of large cohorts provide almost complete coverage of the human genome, allowing us to explore gene-phenotype associations in genomic regions that are not well captured by targeted sequencing and array-based genotyping methods. While large-scale exome sequencing studies have demonstrated the power of gene-based rare-variant collapsing methods for drug discovery, extending these approaches to non-coding regions is challenging due to smaller WGS sample sizes, the difficulty of aggregating non-coding variants by annotation class, and mapping these annotations to genes. Using the largest WGS cohort to date of ~500,000 participants of the UK Biobank, we investigate the additional value of non-coding variants for the discovery of gene-phenotype associations. We explore various strategies to aggregate rare non-coding variants by function. These methods incorporate information from multi-omics data such as alternative splicing and chromatin accessibility, enabling the mapping of these non-coding regions to the genes they act on. We perform region-based association tests to evaluate the burden of rare non-coding variants on hundreds of quantitative and binary traits.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3317. Assessment of correlated multi-SNP Mendelian Randomization method using brain eQTLs to discover schizophrenia genes as a case study

Authors:

D. Baird¹, J. Robinson², Y. Huang¹, H. Runz¹, C-Y. Chen¹, T. Gaunt², E. Tsai¹; ¹Biogen, Cambridge, MA, ²Univ. of Bristol, Bristol, United Kingdom

Abstract Body:

Mendelian Randomization (MR) analysis on cis acting gene expression quantitative trait loci (eQTLs) is used to nominate genes involved in regulation of disease traits. As MR is typically based on a single SNP, we performed a correlated multi-SNP MR between brain eQTLs and schizophrenia to evaluate the potential of this method in gene discovery.

eQTLs were selected from the MetaBrain cortex dataset and schizophrenia SNPs from the PGC 2014 GWAS, both were European samples. Within the 1Mb regions of interest (sentinel eQTL $p < 5 \times 10^{-5}$), eQTL and GWAS SNPs effects were harmonized and then LD clumped ($r^2 < 0.36$, $p < 5 \times 10^{-5}$). An Inverse Variance Weighted (IVW) fixed effects model was fitted using the pairwise LD matrix for the region, as well as the Egger intercept test and IVW PCA method (Burgess, 2017) to assess robustness of findings. A single SNP Wald ratio (WR) effects analysis based on the independent eQTLs within the region available after LD clumping ($r^2 < 0.01$, $p < 5 \times 10^{-5}$) was also conducted.

Correlated multi-SNP IVW analysis was performed on 10,146 gene regions and the WR analysis on 24,891 independent eQTLs spanning these regions. IVW and WR Z scores agreed closely for genes which had a single SNP only ($r=0.96$) compared to genes which had multiple SNP instruments ($r=0.71$). 50 genes had a Bonferroni corrected IVW $p < 4.93 \times 10^{-6}$ and 58 eQTLs for 59 genes had a Bonferroni corrected WR $p < 2.01 \times 10^{-6}$. 24 of the genes detect by IVW and 21 of the genes detected by WR analysis failed the Egger intercept test ($p < 0.05$) used to indicate bias due to directional pleiotropy. After filtering for the genes which passed the intercept test, 16 genes were Bonferroni significant in both analyses, directionality agreed between effect estimates and the Z scores were highly correlated ($r=0.90$). 10 extra genes were found in the IVW analysis. 3 genes were not associated in the IVW PCA model (at $p < 0.05$) indicating instrument selection could be biasing these IVW estimates. As an illustrative example, *POM121L2* returned a more significant IVW estimate on the correlated SNPs (IVW $B = 0.080$, $SE=0.016$, $p=7.41 \times 10^{-7}$, $n_{snps}=36$) compared to the WR analysis (top WR: $B=0.056$, $SE=0.019$, $p=3.43 \times 10^{-3}$). 22 genes were Bonferroni significant in the WR analysis but not the IVW, and 9 of these genes were also not identified by the IVW PCA method. For example, *ZNF322* was not associated in the multi-SNP analysis (IVW $B = 0.00043$, $SE=0.011$, $p=0.70$, $n_{snps}=77$) but is detected in the WR analysis (top WR: $B=-0.24$, $SE=0.045$, $p=7.56 \times 10^{-8}$).

We have demonstrated that multi-SNP and single SNP MR agree for most genes, but it is possible for the multi-SNP to both find additional genes and identify erroneous genes, particularly in more LD complex regions.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3318. Association Between Brain Structure and Alcohol Use Behaviors in Adults: A Mendelian Randomization and Multiomics Study

Authors:

L. A. Mavromatis¹, D. B. Rosoff^{1,2}, R. B. Cupertino³, H. Garavan³, S. Mackey³, F. W. Lohoff¹; ¹Section on Clinical Genomics and Experimental Therapeutics, Natl. Inst. on Alcohol Abuse and Alcoholism, NIH, Bethesda, MD, ²NIH-Oxford-Cambridge Scholars Program; Nuffield Dept. of Population Hlth., Univ. of Oxford, Oxford, United Kingdom, ³Dept. of Psychiatry, Univ. of Vermont Coll. of Med., Burlington, VT

Abstract Body:

Background: Past studies have identified associations between brain macrostructure and alcohol use behaviors. However, determining the directionality of these associations is impeded by the limitations of observational studies and practical and ethical barriers to randomized control trials.

Methods: In this study, we used summary statistics from genome-wide association studies of European ancestry cohorts ($N_{\text{total}} = 763,874$) to perform bidirectional Mendelian randomization (MR) to find evidence of causal relationships between brain structure and alcohol use. Our primary analyses evaluated structural magnetic resonance imaging phenotypes (global cortical thickness and surface area ($N = 33,709$) and left/right subcortical volumes ($N = 19,629$)) and three alcohol use behaviors (alcoholic drinks per week ($N = 537,349$), binge drinking frequency ($N = 143,685$), and alcohol use disorder ($N = 29,502$)). We performed multivariable MR (MVMR) to evaluate the robustness of our bidirectional MR findings and transcriptome-wide association studies (TWAS) and cell-type enrichment analyses to investigate the biology underlying identified relationships.

Results: Our primary MR analyses identified negative associations between genetically-predicted global cortical thickness and binge drinking ($\beta = -2.52$, 95% CI [-4.13, -0.91]) and drinks per week ($\beta = -0.88$, CI [-1.37, -0.40]) at a false discovery rate (FDR) of 0.05. These associations remained significant in MVMR models that accounted for neuropsychiatric phenotypes, substance use, trauma, and neurodegeneration. TWAS of global cortical thickness and alcohol use behaviors identified five genes at the 17q21.31 locus oppositely associated with cortical thickness and binge drinking and/or drinks per week (FDR = 0.05). Cell-type enrichment analyses implicated glutamatergic cortical neurons in alcohol use behaviors.

Discussion: These findings show that associations between global cortical thickness and alcohol use may reflect a predispositional influence of cortical structure. 17q21.31 genes and glutamatergic cortical neurons may play a role in this association. While replication studies are needed, these findings should enhance the understanding of relationships between brain structure and alcohol use.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3319*. Association of genetically predicted iron homeostasis biomarkers in type 2 diabetes and glycemic traits: A two-sample Mendelian Randomization study

Authors:

Y. Liang¹, S. Luo¹, T. Wong¹, B. He¹, C. Schooling^{1,2}, S. Au Yeung¹; ¹The Univ. of Hong Kong, Hong Kong, Hong Kong, ²City Univ. of New York, New York, NY

Abstract Body:

Introduction: Previous Mendelian Randomization (MR) studies suggested that iron status is positively associated with type 2 diabetes (T2D). However, these studies included highly pleiotropic instruments related to hereditary haemochromatosis (HH) and did not comprehensively assess causation for different iron homeostasis biomarkers. We conducted a MR study to address these research gaps using the most up-to-date genome-wide association study (GWAS) of iron homeostasis biomarkers.

Methods: We extracted instruments from the largest GWAS ($N \leq 246,139$) of iron homeostasis biomarkers (i.e., ferritin, serum iron, total iron-binding capacity (TIBC), and transferrin saturation (TSAT)) and applied them to the largest suitable summary statistics from GWAS of T2D (DIAMANTE $N = 933,970$ and FinnGen $N = 252,162$), glycemic traits (fasting glucose ($N = 209,605$), two-hour glucose ($N = 64,469$), glycated hemoglobin ($N = 149,006$), and fasting insulin ($N = 158,550$)). Inverse-variance weighted (IVW) was the main analysis method, with sensitivity analyses including MR-Egger and weighted median, as well as exclusion of instruments which are highly pleiotropic instruments from *ABO* and HH-related genes. Hemoglobin (Hgb) was used as a positive control outcome.

Results: Using IVW, all four iron homeostasis markers were not associated with T2D ($OR_{\text{ferritin}}: 0.99$, 95%CI 0.89 to 1.10; $OR_{\text{serum iron}}: 1.05$, 95%CI 0.98 to 1.12; $OR_{\text{TIBC}}: 0.96$, 95%CI 0.91 to 1.01; $OR_{\text{TSAT}}: 1.01$, 95%CI 0.96 to 1.06). Ferritin, serum iron, and TSAT were associated with lower HbA1c and higher Hgb, while TIBC had opposite associations. We did not find strong evidence for an effect of iron homeostasis biomarkers on any other glycemic traits considered. These findings were similar to sensitivity analyses. However, when restricting to instruments in HH or with concordant effects which included HH instruments, higher iron status was associated with a higher risk of T2D.

Discussion: This study suggests iron homeostasis biomarkers unlikely plays a role in etiology of T2D in the general population. However, whether the positive association of HH and T2D reflects the consequence of severe iron overload or pleiotropy requires additional investigations.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3320*. Association testing in admixed and multiethnic data sets nominate genetic modifiers of age at onset of Alzheimer's disease

Authors:

E. Blue, J. Broome, D. Xue; Univ. of Washington, Seattle, WA

Abstract Body:

Alzheimer's disease (AD) is a leading cause of dementia and mortality in the United States, exhibiting phenotypic, genetic, and allelic heterogeneity. Although age-at-onset (AAO) of AD is highly heritable, few genome-wide association studies (GWAS) of AD incorporate a survival analysis framework. Our adapted linear mixed model with orthogonally partitioned structure for survival analysis traits yields results highly concordant with a Cox mixed-effect model for GWAS in 0.5% the time ($|r_{\text{beta}}| = 0.97$, $|r_{\text{log10p}}| = 0.93$). We performed GWAS for AAO of AD in two data sets enriched with multiplex families: the Columbia University Study of Caribbean Hispanics with Familial and Sporadic Late Onset Alzheimer's disease (CU-LOAD) and the multiethnic National Institute on Aging Genetics Initiative for Late-Onset AD study (NIA-LOAD). Phenotype and genotype data underwent quality control, genotype imputation, then association testing, adjusting for sex, *APOE* $\epsilon 2$ and $\epsilon 4$ allele counts, principal components capturing population structure, and genetic relatedness. The CU-LOAD GWAS representing 1305 cases and 1734 controls identified a significant association with AAO of AD at 14q24.3 ($p < 5e-08$), while another 15 loci reached suggestive evidence of association ($p < 1e-06$) ($\lambda = 0.99$). The signal at 14q24.3 is explained by the *PSENI* p.G206A allele implicated in early-onset autosomal-dominant AD. This causal variant has half the allele frequency (MAF = 0.5% vs. 1.1%), twice the effect size estimate ($\beta = 0.95$ vs. 0.44), and is 2.5Mb from the GWAS peak. Two loci nearly reached genome-wide significance in the NIA-LOAD GWAS representing 2307 cases and 2241 controls ($p < 7e-08$; 4q31.3 and 19q13.32; $\lambda = 1.02$). Fifteen loci had suggestive evidence of association ($p < 1e-06$), implicating genes linked to familial forms of dementia (*CHMP2B*, *PDGFRB*), their interactors (*VEGFC*), or AD risk (*RBFOX1*). The AAO-associated alleles can vary in frequency by orders of magnitude across populations, but global and local ancestry proportions among carriers do not consistently over-represent the population with the maximum reference allele frequency. Given inconsistent evidence of replication for AD GWAS loci identified in samples representing different populations and the association of local ancestry at *APOE* with risk of AD, future studies may need to match for global or local ancestry and enrichment for families affected by AD to replicate these results.

PB3321*. Asymmetric non-portability across populations of different ancestry.

Authors:

J. Ballard, L. O'Connor; Broad Inst., Cambridge, MA

Abstract Body:

Polygenic risk scores (PRS) have the potential to improve clinical outcomes by identifying individuals who are genetically predisposed to developing certain diseases (Khera et al. 2018 Nat Genet). However, it has been shown that PRS trained on individuals of European ancestry (EUR) are not portable to individuals of African ancestry (AFR) due to differences in allele frequency (AF) and linkage disequilibrium (LD) patterns (Scutari et al. 2016 PloS Genet, Martin et al. 2019 Nat Genet). Here, we performed simulations to investigate the portability of PRS from African to European individuals as well. We found that non-portability is directionally asymmetric: PRS trained in AFR were more portable to EUR ($r^2_{AFR \rightarrow EUR} = 0.27$ vs. $r^2_{AFR \rightarrow AFR} = 0.34$) than PRS trained in EUR were to AFR ($r^2_{EUR \rightarrow AFR} = 0.15$ vs $r^2_{EUR \rightarrow EUR} = 0.40$).

To find the source of this asymmetry, we performed simulations with population specific LD and population specific AF (but a cross-population genetic correlation $r_{crosspop} = 1$), as well as with identical LD and AF for both populations but $r_{crosspop} < 1$; LD and AF both contributed to asymmetric non-portability. Differences in effect sizes, i.e. cross-population genetic correlation $r_{crosspop} < 1$, contribute to non-portability but not to asymmetric non-portability in these simulations. When we examined asymmetry in pairs of all five populations (EUR, AFR, EAS, SAS, and AMR), we found strong asymmetry due to both AF and LD in population pairs that involved AFR, indicating that training in AFR produces much more accurate predictions in non-AFR populations than training in non-AFR populations and testing in AFR. In non-AFR population pairs, we observed little to no asymmetry. This is likely explained by the fact that AFR individuals have a larger number of common haplotypes and common SNPs, allowing the information captured by training in AFR to sufficiently account for LD and AF in other populations, but not the other way around. We derived a formula for the expected accuracy of an optimal PRS under a Gaussian model; consistent with the simulations, it predicts that asymmetric AF and LD differences cause asymmetric non-portability between EUR and AFR.

PB3322. Auxiliary classifier generative adversarial network for phenotypic conditional genomic data synthesis.

Authors:

E. U. Lim¹, A. Lim^{1,2,3}, C. S. Fann^{1,2}; ¹Inst. of BioMed. Sci., Academia Sinica, Taipei, Taiwan, ²Taiwan Intl. Graduate Program in Molecular Med., Natl. Yang Ming Chiao Tung Univ. and Academia Sinica, Taipei, Taiwan, ³ASUS Intelligent Cloud Services (AICS), Taipei, Taiwan

Abstract Body:

The utilization and translation of genomic data from large biobanks has revolutionized the field of biomedical research, drug development and precision medicine. Despite the advances in genetic epidemiology research, limited sample size of certain rare diseases and minority population remains a critical issue. As an alternative to collecting more samples, generating realistic synthetic human genomic data by mimicking the population structure can uplift the sample size of disease cohorts or minority groups. Besides, the availability of extensive phenotypic data from biobanks provides an unprecedented opportunity for researchers to make use of phenotypic information in the human genomic data augmentation process. In this regard, we propose an Auxiliary Classifier Generative Adversarial Network (ACGAN) tailored for genomic data synthesis that takes into account the dimensionality structure of haploid genotype (haplotype) data and the categorical phenotypic traits labels. The output haplotype data can optionally be transformed into genotype data, unordered representation of the base pair sequences, for post data augmentation analyses. As an initial proof of concept, we applied the ACGAN on phased haplotype data of individuals with or without type 1 diabetes (T1D) from UK Biobank. The input data consists of a class label representing T1D case or healthy control, as well as a set of sequences of haplotype base pairs with select single nucleotide polymorphisms (SNPs), of which includes 2 known SNPs, rs2476601 and rs6679677, in the *PTPN22* gene associated with increased risk of T1D as reported by prior genome-wide association studies (GWAS). T1D was chosen due to the high heritability and high accuracy of existing polygenic risk score (PRS) models, which enable further evaluation of the generated samples' utility. According to the allele frequency spectrums of the real and generated samples, the ACGAN is capable of capturing the overall allele frequency distribution including low frequency alleles, which was addressed previously as a challenge in other studies. Overall, the results show that our proposed ACGAN provides a novel and promising approach for performing phenotypic conditional human genomic data augmentation in population genetics and genetic epidemiology research applications.

PB3323. Being overweight in late life can be a causal factor contributing to longevity: a Mendelian Randomization study.

Authors:

H. Duan, R. Holmes, K. Arbeev, D. Wu, A. Yashin, S. Ukraintseva; Biodemography of Aging Res. Unit, Social Sci. Res. Inst., Duke Univ., Durham, NC

Abstract Body:

Introduction: Recent research suggested that being overweight may be optimal for survival in late life. However, biological mechanisms of this phenomenon are poorly understood. Mendelian Randomization (MR) could be a useful tool for clarifying causal relationships between longevity and weight/BMI in human data. The *APOE* $\epsilon 4$ allele is known for its associations with both lower weight/BMI and reduced survival in older adults, so it could be used as an instrumental variable in respective MR study.

Methods: We conducted MR analysis in the Health and Retirement Study data subsample of individuals aged 75+. We used the number of *APOE* $\epsilon 4$ alleles as an *instrumental variable (IVar)*; binary BMI variable (BMI between 25-30 ('overweight') vs. BMI < 25, at ages 75-85) as *exposure*; and two binary 'longevity' variables (**1.** survived age 85+ vs. died before 85; and **2.** survived age 90+ vs. died between 80 and 85) as *outcomes*. The non-stratified samples included 3338 and 1664 participants, respectively. Analyses were done in sex and race strata as well. The SAS software was used to estimate initial models, and then summary statistics from these models were used in the R-package *MendelianRandomization*. F-value > 10 criteria was applied to ensure the strength of *IVar*. The causal effect was evaluated using Inverse-Variance Weighted (IVW) and maximum likelihood (ML) methods.

Results: The MR study revealed that having BMI in 'overweight' range 25-30 at ages 75-85 has significant causative effect on survival 85+ (causal estimate=1.56, IVW *p-value*=2.92E-06, ML *p-value*=0.007) in non-stratified sample, as well as in females (causal estimate=1.58, IVW *p-value*=4.7E-05, ML *p-value*=0.018, N=1877) and whites (causal estimate=1.20, IVW *p-value*=5.1E-05, ML *p-value*=0.006, N=2797). Similarly, being overweight had significant causative effect on living to age 90 and beyond in non-stratified sample (causal estimate=1.70, IVW *p-value*=1.68E-06, ML *p-value*=0.013), as well as in females (causal estimate=1.58, IVW *p-value*=3.25E-05, ML *p-value*=0.021, N=976) and whites (causal estimate=1.25, IVW *p-value*=5.17E-05, ML *p-value*=0.0098, N=1407).

Conclusion: Results of our MR study strongly suggest that being overweight in late life (ages 75-85) is one of the causal factors contributing to extreme longevity. It might reflect a better ability of the body to resist the aging-related physical decline, and/or be a sign of better resilience of overweight people, which warrants further investigation.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3324. Bi-ancestral phenome-wide association of complement component 4 haplotypes in 550,000 individuals

Authors:

S. Venkatesh¹, M. Kim², M. Gandal², G. Voloudakis¹, P. Roussos¹; ¹Icahn Sch. of Med. at Mount Sinai, New York, NY, ²David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract Body:

The major histocompatibility complex (MHC) locus is critical to the immune response, and contains the strongest genetic association with schizophrenia. Of particular interest is complement component 4 (C4), which is involved in synapse elimination, and thus contributes to the “excessive pruning” hypothesis of schizophrenia. Here we investigate how different C4 haplotypes relate to traits across the electronic health record (EHR), with a particular focus on neuropsychiatric disorders. We impute C4 haplotypes in over 550,000 Million Veteran Program (MVP) individuals across European and African ancestries.

We impute C4 haplotypes in the MVP using the C4 reference panel from Kamitaki et al. 2020 that was built in a cohort of diverse ancestry. We perform C4 haplotype-wide association studies for selected phenotypes, C4 phenome-wide association studies, and C4 medication-wide association studies. We perform mediation and variance partition analyses to explore the relationship among C4 haplotypes, genetic liability and EHR features. Finally, we use PRS-CS to calculate polygenic risk scores (PRS) for a variety of disorders to understand their relationship with C4 haplotypes. We exclude the MHC region from these calculations in order to assess genetic liability outside the MHC locus.

We find 156 FDR-significant associations between C4 haplotype BS and phenotypes in Europeans. This includes neuropsychiatric phenotypes such as schizophrenia (confirming established results from Sekar et al. 2016), mood disorders, as well as 146 non-neuropsychiatric phenotypes such as ulcerative colitis and psoriasis. We also find 82 significant associations between C4 haplotype BS and medications in Europeans, including olanzapine, prednisone, budesonide (prescribed for ulcerative colitis) and fluocinonide (prescribed for psoriasis). We find FDR-significant associations in Africans as well, such as the association between C4 haplotype AL and chronic pharyngitis and nasopharyngitis. We also explore the relationship between PRS and C4 haplotypes using mediation and variance partition analyses, and find that schizophrenia PRS accounts for approximately 50% of C4 haplotype BS’s effect on schizophrenia.

Overall, C4 haplotypes have strong associations across the EHR and a complex relationship with overall genetic liability in neuropsychiatric disorders. In particular, C4 haplotype BS has 238 FDR significant associations in Europeans. To follow up on these results, we plan to explore whether there is evidence of evolutionary trade-offs among C4 haplotypes.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3325. Boosting SNP discoverability: How genetic architecture impacts the power of multi-trait GWAS

Authors:

Y. Suzuki¹, H. Ménager², C. Nerin¹, R. Torchet², P. Lechat², L. Troubat¹, H. Aschard¹, H. Julienne^{1,2}; ¹Inst. Pasteur, Université de Paris, Dept. of Computational Biology, Paris, France, ²Inst. Pasteur, Université Paris Cité, Bioinformatics and Biostatistics Hub, Paris, France

Abstract Body:

Despite the ever-increasing sample size of Genome-Wide Association Study (GWAS) summary statistics, many causal SNPs for human complex traits remain undetected by univariate GWASs. To overcome this lack of statistical power, investigators have developed multi-trait GWAS methods. However, multi-trait methods entail challenges, such as data harmonization, computational cost, and missing values. More critically, there is no established strategy to astutely select sets of traits to maximize the statistical power of multi-trait GWAS. To address these practical obstacles and investigate the impact of genetic architecture on SNP discoverability, we implemented a python package *JASS* (Joint Analysis of Summary Statistics) with specific attention to computational efficiency (e.g. on 62 traits and ~7 million SNPs, JASS runs in <20 minutes). We applied JASS on 1620 sets of two to 62 traits randomly selected out of 108 traits curated summary statistics (<https://jass-beta.pasteur.cloud/>), and derived for each set the association gain (i.e. the number of new associations identified) achieved by multi-trait test over the original univariate tests. We assessed the effect of multiple factors on this gain and identified five key features: the polygenicity (the number of causal SNPs), the mean effect size (average genetic effect that causal SNPs have on the trait), the genetic covariance between traits, the environmental covariance between traits, and the orientation of genetic and environmental signals. Together, these five features had a substantial predictive power ($R^2 \sim 0.4$, P value < 2.2e-16), providing a strong indicator of the multi-trait performance. Mean effect size was the largest contributor (P value = 3.6e-14). Moreover, we observed a large contribution of nonlinear interactions between the five features (R^2 increased from 0.25 to over 0.4 by including non-linear interactions). We also found that the contribution of the environmental covariance was more important than the genetic covariance (permutation importance ~0.12, ~0.05, respectively). Further refined investigation might provide investigators a powerful tool to select trait to include in their multi-trait association tests and effectively uncover associations with low discoverability in univariate GWAS.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3327. Broad- and narrow-sense heritability-contributing regions are shared across age, genetic sex and geographical cohorts.

Authors:

D. Udwin¹, S. Zhang¹, S. P. Smith¹, L. Crawford^{1,2}, S. Ramachandran¹; ¹Brown Univ., Providence, RI, ²Microsoft Res. New England, Cambridge, MA

Abstract Body:

Genome-wide association (GWA) summary statistics exhibit heterogeneity when individuals from the same database are partitioned based on certain covariates. The goals of our work are to explore whether this heterogeneity extends to genome-wide narrow-sense heritability and to identify genomic regions that contribute to the broad-sense heritability of complex traits. To address the first aim, we make use of the existing Heritability Estimator of Summary Statistics (HESS) model; in the second aim, we introduce the Epistatic and Additive Variance Estimation (EAVE) framework, which uses Haseman-Elston (HE) regression to estimate the proportion of phenotypic variation explained by nonlinear genetic effects. We utilize a population of 349,411 unrelated white British individuals from the UK Biobank and partition their data according to genetic sex, age (<62, 62-69, 70-74, >74) and geographic locations of birth. We find:

(1) Genetic sexes have different genome-wide narrow-sense heritabilities for triglyceride levels, but the same top-contributing region: Chromosome 11:116383348-117747110, which includes genes *APOA1*, *APOA4* and *APOA5*. Likewise, age-stratified cohorts do not have the same genome-wide narrow-sense heritability for cholesterol, but do share the same top-contributing region: Chromosome 19:9238393-11284028, containing *APOC1*, *APOC2*, *APOC4*, *APOC2*, *APOE* and *LDLR*. Narrow-sense heritability is conserved across birthplace cohorts with the top-contributing region being mutual: Chromosome 20:32813441-34960446, containing *GDF5*, *FAM83C* and *FER1L4*.

(2) The homogeneity of heritability-contributing regions holds from an epistatic perspective. 86 of the top one hundred regions that contribute to triglyceride levels through epistatic effects are shared between the genetic sexes ($p = 5.971e-114$). The number of top one hundred epistatic heritability-contributing regions to cholesterol that are shared between any two age cohorts ranges from 78 ($p = 3.014e-93$) to 82 ($p = 3.551e-103$). Of the 45 possible comparisons between pairs of birthplace cohorts, 19 share a significant number of mutual top heritability-contribution regions to height (here, significance is indicated by p-value below 0.05 / 45, to account for multiple testing). On average, these pairs of cohorts share 17 of the top one hundred epistatic heritability-contributing regions ($p = 3.713919e-05$).

We conclude that heritability-contributing regions with respect to both additive and genetic variation are shared across cohorts for select traits. We add that given precomputed genomic relatedness matrices, EAVE produces estimates in 99 seconds for $n=100K$ using 36 CPUs.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3328. BTS: Bayesian Tissue Significance scores for functional evaluation of GWAS results

Authors:

M. Ionita, **P. P. Kuksa**, Y. Leung, K. Clark, O. Valladares, L-S. Wang; Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Summary statistics from genome-wide association studies (GWAS) are often used in downstream analyses, such as fine mapping or determination of functional context (i.e., affected tissues, biological mechanisms and target genes). The increasing sizes of both association studies and functional genomic (FG) and annotation data provide an opportunity to perform unbiased analyses, using fast algorithms to search for associations between the putatively causal GWAS variants and thousands of cell type-specific functional annotations. To this end, we propose BTS (Bayesian Tissue Significance score), an efficient computational framework for joint estimation of causal variants and their enrichment in annotation tracks. BTS is a novel algorithm that combines GWAS summary statistics, linkage disequilibrium and functional annotations into a Bayesian model, with significantly reduced complexity for large-scale evaluation. We connect BTS with FILER (Kuksa et al, 2022), a large-scale functional genomics repository, to allow for systematic annotation of GWAS variants across >1,100 cell types and >190 genomic and molecular functions. BTS evaluates genome-wide models for each functional annotation, then prioritizes the ones with the highest association between likely causal variants and the annotation. Due to careful management of data and intermediate results, BTS is up to 100 times more efficient than existing approaches, which allows for fast, unbiased analysis of data across all available tracks.

To systematically evaluate GWAS results and screen for the relevant functional contexts, we used the harmonized FG and annotation data collection from FILER including >60,000 datasets of tissue-specific regulatory elements, transcription factor binding or chromatin states. We applied BTS to three immune-related GWAS: Rheumatoid arthritis (RA), Lupus and Inflammatory Bowel Disease. We found that BTS prioritized tissues, loci and variants that agree with the known or suspected biological mechanisms of these diseases. For instance, in the RA GWAS, 80% of the annotations prioritized by BTS are in immune tissues or organs, mainly T and B cells. Further, BTS prioritized loci near genes such as MICA/MICB, TAP1, TSBP1 and the HLA genes. 159 of these loci overlap enhancers in immune organs or cell types, and 35 overlap DNase hypersensitivity sites. Among the loci overlapping immune enhancers, 54% are immune-specific, while the others are active across multiple tissue categories. Overall, using BTS for unbiased prioritization of GWAS results and their functional contexts can inform follow-up studies and suggest mechanisms and therapeutic targets for future research.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3329. Building ancestry-informed tools for more inclusive genomics and improved clinical interpretation in admixed populations

Authors:

E. Atkinson¹, T. Tan¹, Y. Wang², J. Mauer³, N. Shah¹, G. Tietz¹, K. Tsuo⁴, M. Kamariza⁵, A. Martin², M. Santoro⁶; ¹Baylor Coll. of Med., Houston, TX, ²Massachusetts Gen. Hosp., Boston, MA, ³Univ.e Federal de Sao Paulo, Sao Paulo, Brazil, ⁴Harvard Univ., Cambridge, MA, ⁵Harvard Univ., Boston, MA, ⁶Federal Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract Body:

Genetic studies offer a promising basis for understanding pathophysiology and identifying new molecular targets for medicine. Recent landmark papers have made major strides in our understanding of the genetic architecture of complex disorders, however, these studies are based overwhelmingly on subjects of European ancestry and their results may not fully generalize to other populations. Due to the paucity of methodological and computational approaches that account for their additional genomic complexity, admixed populations, including African American and Latinx individuals, make up more than a third of the US populace, yet face severe disparities in health research and treatment due to being systematically excluded from statistical genomic studies. To reap full and equitable benefits from existing mixed ancestry cohorts and ongoing large-scale data collection efforts, there is an urgent unmet need for the development of tools facilitating the well-calibrated study of complex psychiatric traits in admixed peoples alongside the recruitment of more diverse study participants.

We recently released a novel local-ancestry aware GWAS model, Tractor, which corrects for fine-scale population structure at the genotype level, better localizes GWAS signal, identifies ancestry-specific loci that would have been missed with standard procedures, and produces ancestry-specific effect size estimates and p values. Building off of this work, we present novel computational strategies for ancestry-informed gene discovery, including a statistical method for rare variant association studies in admixed cohorts, the creation of local ancestry informed polygenic risk scores that are more accurate in their prediction for diverse populations, and a strategy leveraging the naturally varying haplotype structure in admixed cohorts to better understand gene-gene interactions at clinically meaningful loci. We benchmark these new computational tools in simulation and using the large and diverse All of Us Project Dataset. This work fills a gap in existing resources and will improve our understanding of complex diseases across understudied populations. The inclusion of diverse participants in genomics efforts directly improves understanding for these individuals who bear a disproportionate health burden, as well as offering the opportunity to expand and accelerate findings relevant for individuals of all ancestries. Our work will lead to a more complete representation of genetic risk across the allele frequency spectrum and across populations, and strives for more equitable genomics research and health outcomes.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3330. Burden testing of imputed rare variants to inform therapeutic hypotheses

Authors:

Z. Fuller, J. O'Connell, A. Kwong, G. C. Partida, K-H. Lin, A. Auton, X. Wang; 23andMe, Sunnyvale, CA

Abstract Body:

A fundamental goal of human genetics is to identify variants in patients that underlie disease. Towards that end, several recent studies have demonstrated the utility of investigating the association between the burden of rare loss-of-function (LoF) mutations in genes and health-related traits to inform potential therapeutic targets. Because such mutations exist at the rare end of the frequency spectrum, these studies have typically relied on whole exome sequence data to call variants with extremely low minor allele counts. While exome sequencing cohorts now approach sample sizes on the order of hundreds of thousands of individuals, burden testing remains underpowered to detect associations for weak or moderate effect sizes and diseases with low prevalence. Moreover, larger sample sizes are still required to observe compound heterozygote or homozygote LoF carriers in the majority of genes and heterozygous carriers in shorter genes or those under stronger selective constraint. Here, we show we can reliably impute rare variants at frequencies of $1e-4$ or lower in over 6 million samples from the 23andMe, Inc. research cohort. Using these imputed rare variants, we replicate associations between rare predicted LoF mutations and disease traits in gene-based burden tests from previous whole-exome studies and discover novel gene-trait associations. We demonstrate how burden tests can help inform directionality and provide additional evidence for or resolve conflicts from eQTL signals. Together, these results highlight the promise of imputed rare variants in large sample sizes to identify novel gene-trait associations and provide estimates of effect direction to inform therapeutic hypotheses.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3331. Calcium signaling in Alzheimer's disease: Insights from *PTK2B* and *miR146a* interaction analyses.

Authors:

A. Yashin, D. Wu, K. Arbeev, O. Bagley, H. Duan, R. Holmes, S. Ukraintseva; Duke Univ., Durham, NC

Abstract Body:

Background and objective. Several recent studies emphasize an important role of *PTK2B* and *miR142a* genes in Alzheimer's disease (AD). *PTK2B* is also known for participation in calcium induced regulation of ion channels, and *miR146a* for its involvement in regulation of neuroinflammation. These and many other properties of *PTK2B* and *miR146a* resulted from experimental studies with laboratory animals and cellular cultures. We hypothesize that interactions of SNPs from the *PTK2B* gene and *miR146a* gene is associated with AD in humans. The objective of this study is to test this hypothesis using human data. **Data and method.** To test this hypothesis, the data from Cardiovascular Health Study (CHS), Framingham Health Study (FHS) and Health and Retirement Study (HRS) were analyzed using logistic regression model with the interaction term. Linkage disequilibrium among SNPs from corresponding genes was used in clumping procedure ($R^2=0.1$) to reduce the number of tests and increase the Bonferroni correction threshold (BF) in analyses of association of SNP-by-SNP interactions with AD. **Results.** Analyses showed that interaction of SNPs rs751019 from the *PTK2B* gene and rs2910163 from the *miR146a* gene is significantly associated with AD ($\beta= 0.42$, $p=1.16E-02$, $BF=5.00E-02$). Further analyses showed that the interactions of rs751019 SNP from the *PTK2B* gene and two SNPs from the *miR146a* gene: rs2910164 and rs2961920 SNPs are also statistically associated with AD in CHS data ($\beta= 0.43$, $p=1.21E-02$, for rs751019 and rs2910164 pair and $\beta= 0.40$, $p=1.76E-02$ for the rs751019 and rs2961920 SNP-pair). Note that rs2961920 and rs2910163 are in LD with rs2910164 SNP and can serve as proxy for this SNP. To replicate these findings, we performed interaction analysis of these genes using HRS data. This analysis did not find rs751019 among pairs of interacting SNPs significantly associated with AD. However, it detected nominally significant association of interaction of SNPs rs1776858 from the *PTK2B* gene and rs2961920 with AD: $\beta= 0.39$, $p=6.90E-03$. It turns out that SNPs rs751019 and rs1776858 are in LD with $D'=0.70$ and $R^2=0.46$. Analysis of FHS data confirmed statistical significance of association of interactions between rs751019 and each of three SNPs from the *miR146a* gene with AD, however, the association effect is opposite to that obtained in CHS data. **Conclusion.** Obtained results elucidate a mechanism that may link disruptions in calcium signaling with AD in humans. The presence of flip-flop effects in the results of interaction analysis of CHS and FHS data may be explained by the presence of unobserved influential factors that differ in populations of study subjects of these studies.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3332. Calibrated and adaptive prediction interval improves polygenic score (PGS) performance in diverse populations

Authors:

Z. Xu¹, K. Hou¹, Y. Ding², B. Pasaniuc³; ¹Univ. of California, Los Angeles, Los Angeles, CA, ²UCLA, Los Angeles, CA, ³Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract Body:

Accuracy of PGS varies across individuals from different continental ancestral populations (Martin et al. 2019 Nat Genet), and individuals from different covariate groups, such as sex, age, and socioeconomic status even within a single ancestry group of individuals with European ancestries (Mostafavi et al. 2020 eLife). Such variable prediction accuracy stems from several factors, including differences in minor allele frequency, linkage disequilibrium tagging of causal effects, gene-environment interaction, and confounding factors captured in genome-wide association studies. These components lead to the limited portability of PGS to predict phenotypes at an individual level and weaken personalized usages of PGS. Here, we develop a new approach, calibrated polygenic score (CalPGS), to provide calibrated and individualized prediction intervals that account for variable prediction accuracy by covariate. CalPGS leverages a held-out calibration data set where both phenotypes and covariates are measured for each individual to generate prediction intervals for test individuals. In simulations and real data results, we find that CalPGS prediction intervals for all test individuals are well-calibrated (i.e. the true phenotype is contained in the interval at a pre-specified probability level) and each individual's credible interval size varies as a function of its covariates. Of note, CalPGS framework can generate prediction intervals for all existing PGS methods that produce point prediction. We use UK Biobank data to investigate the utility of CalPGS. First, we perform a comprehensive survey of covariate factors impacting PGS prediction accuracy across 110 publicly available PGS within individuals of European ancestries and of diverse ancestries in UK Biobank. We find that PGS accuracy stratifies across covariates encapsulating a wide range of socio-demographic factors (including deprivation index, income, education years) and genetic ancestries. For example, the prediction accuracy of education years can differ by up to 125% between individuals in the highest and lowest quintile group of income. Finally, with these identified covariate factors, we apply CalPGS to individuals from UK Biobank to demonstrate CalPGS provides calibrated and adaptive prediction intervals across diverse populations. CalPGS prediction intervals cover true phenotypes adaptively and consistently across traits and covariate groups at the pre-specified level of 95%, improving upon the under-coverage of baseline methods (as low as 80%).

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3333. CARMA: Novel Bayesian model for fine-mapping with high-dimensional functional data

Authors:

Z. Yang¹, C. Wang¹, A. Khan², B. Vardarajan¹, R. Mayeux¹, K. Kiryluk¹, I. Ionita-Laza¹; ¹Columbia Univ., New York, NY, ²Columbia Univ., NEW YORK, NY

Abstract Body:

We propose a novel Bayesian model for fine-mapping in order to identify putative causal variants at GWAS loci. Relative to existing fine-mapping methods, the proposed model has several appealing features, such as assuming a heavy-tail distribution on effect sizes, joint modeling of summary statistics and large number of functional annotations, and accounting for discrepancies between summary statistics and external linkage disequilibrium values in meta-analysis settings. Using simulations, we compare performance with commonly used fine-mapping methods, including fastPAINTOR and SuSiE, and show that the proposed model has smaller credible sets with high power when using in-sample LD, and lower FDR/higher precision and higher coverage for credible sets when using external LD. We further illustrate our approach by applying it to a meta-analysis of Alzheimer's Disease GWAS data where we prioritize putatively causal variants and genes, including NDUFS2, INPP5D, SORL1, BIN1, CD2AP, CASS4, PICALM, MS4A6A and others.

PB3334. Causal inference for the relationship between transcription and DNA methylation in breast cancer.

Authors:

B. Karki, J. Kvamme, A. Fu; Univ. of Idaho, Moscow, ID

Abstract Body:

DNA methylation, an epigenetic mechanism, plays an important role in transcription regulation and in complex diseases. Whereas methylation in gene promoters is known to be generally associated with silencing, the relationship between transcription and methylation in other parts of the gene is much less clear. Additionally, substantially different transcription and methylation profiles have been observed among breast cancer subtypes, but it is unclear whether and how these differences are influenced by different relationships between the two processes.

Here, we study the relationships between transcription and methylation in estrogen receptor positive (ER+) and negative (ER-) patients, using data from The Cancer Genome Atlas (TCGA) consortium. We formulated trios, each consisting of the copy number alteration (CNA) of a gene, expression (Exp) of this gene, and methylation (Me) of a site located near or in the same gene. Since CNA is prevalent in cancer, it is a highly effective instrumental variable for this causal inference. In each subtype, we further derived principal components from genomewide expression and methylation data, and identified those that are significantly associated with each trio as potential confounding variables.

We applied MRGN (see our other abstract on this method), a novel causal network inference method that accounts for many confounding variables under the principle of Mendelian randomization, to each of the 310,412 trios in each subtype. In 563 ER+ patients, we identified 39% of the trios to have more than one edge: specifically, 14% of all the trios are mediation ($CNA \rightarrow Exp \rightarrow Me$ or $CNA \rightarrow Me \rightarrow Exp$), 14.5% conditionally independent ($Me \leftarrow CNA \rightarrow Exp$), 3.1% the v-structure ($CNA \rightarrow Exp \leftarrow Me$ or $CNA \rightarrow Me \leftarrow Exp$), and 5.9% fully connected among the three nodes. In 187 ER- patients, since the sample size is much smaller, we identified many fewer trios (21%) with more than one edge: 9.5% are mediation, 8.8% conditionally independent, 1.4% v-structure, and 1.2% fully connected. Our analysis provides a first comprehensive picture of causal relationships between transcription and methylation in the two subtypes.

PB3335. Cell composition inference and identification of layer-specific transcriptional profiles with POLARIS.

Authors:

J. Chen, T. Luo, M. Jiang, J. Liu, G. P. Gupta, Y. Li; Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract Body:

Spatial transcriptomics (ST) technology, which provides spatially resolved transcriptional profiles, facilitates advanced understanding of key biological processes related to health and disease. Sequencing-based ST technologies (exemplary platforms include Spatial Transcriptomics and Visium) are widely adopted because they can provide whole-transcriptome profiles as well as a hematoxylin and eosin (H&E) stained histology image. However, these technologies are limited by their resolution, examining spatial spots of 2-100 micrometer in diameter where each spot can easily contain tens of cells of different cell types. Lack of knowledge in the number of cells at each spot nor the cell type composition can lead to invalid downstream analysis, which is a critical issue recognized in ST data analysis. In addition, existing methods tend to under-utilize histological images, which conceptually provide important and complementary information including anatomical structure and distribution of cells. To fill in the gaps, we have developed POLARIS, Probabilistic-based cell compOSition inference with LAYer infoRmatIon Strategy, a versatile ST analysis method that can perform cell type deconvolution, identify genes differentially expressed across anatomical or functional layers, as well as enhance ST data resolution. POLARIS integrates single-cell RNA-seq reference and ST data with annotated layer information. By examining a histology image and its coordinated expression profiles, one can reasonably infer layers or sub-regions that correspond to different biological functions (e.g. cancer vs non-cancer regions in a tumor biopsy, different layers in brain cortex, ventricle and artery areas in heart). By explicitly allowing and modeling layer-specific expression patterns, POLARIS can not only identify cell type composition with high accuracy, but also detect layer-wise differentially expressed (LDE) genes while simultaneously correcting for differential cell composition. Key advantages of POLARIS include flexibility and ability to leverage histology images, which enables POLARIS to obtain super-resolution inference based on images in areas without transcriptomic measurements, and to predict cellular composition purely from H&E images. We apply POLARIS to mouse cortex, developing human heart, and Her2+ breast cancer samples. POLARIS robustly demonstrates high deconvolution accuracy compared to state-of-the-art deconvolution methods, accurately predicts cell composition solely from images, and identifies LDE genes that are biologically relevant and meaningful.

PB3336. Characterizing copy number variations and their association with plasma proteins using short and long-read sequencing

Authors:

D. Schmitz¹, Z. Li², N. Rafati³, A. Ameer¹, V. Lo Faro¹, Å. Johansson¹; ¹Dept. of Immunology, Genetics and Pathology, Sci. for Life Lab., Uppsala Univ., Uppsala, Sweden, ²Twelve Bio ApS, Copenhagen, Denmark, ³Dept. of Med. Biochemistry and Microbiol., Natl. Bioinformatics Infrastructure Sweden, Sci. for Life Lab., Uppsala Univ., Uppsala, Sweden

Abstract Body:

Introduction

Structural variations (SVs), including copy number variations (CNVs), affect around 20 million bases in the human genome. CNVs that include regulatory or protein-coding regions could dramatically influence the expression or function of the encoded protein. Traditional methods used for CNV detection are array-based, suffer from poor resolution and lack the ability to accurately detect breakpoints. This study aims to identify CNVs in a Swedish cohort and explore the effect of CNVs on plasma proteins, using whole-genome sequencing (WGS) data for unbiased assessment of CNVs.

Methods

A total of 1,021 individuals were sequenced using Illumina next-generation sequencing (30x coverage), and disease-related 438 plasma proteins were measured. We identified CNVs using CNVnator, and summarized the detected CNVs into a cohort matrix. Associations between polymorphic CNVs, identified in at least three individuals, and protein levels were identified using linear regression analyses. We validated a selection of polymorphic copy number variable regions (CNVRs) in 15 individuals using long-read PacBio SMRT sequencing.

Results

A total of 184,183 non-overlapping polymorphic CNVRs were detected in the cohort. Among 872 individuals with CNV and protein data available, we identified 17 CNVRs to be associated with 17 plasma proteins after Bonferroni correction ($p < 6.19 \times 10^{-10}$). Of these CNVRs, six could be validated using long-read sequencing, including a CNVR within the V-set and transmembrane domain-containing protein 1 (*VSTMI*) gene, which was associated to measurements of Osteoclast-associated immunoglobulin-like receptor (OSCAR). Two other CNVRs appeared to be clusters of many short repetitive elements and one a common complex inversion. The remaining eight CNVRs could not be validated due to lack of evidence or low coverage.

Conclusions

Our findings provide insight into the involvement of CNVs on plasma proteins as well as the application of WGS approaches using both short and long reads for CNV detection.

PB3337. Characterizing features affecting Local Ancestry Inference in Latin American populations

Authors:

J. Mauer¹, A. Maihofer², C. Nievergelt², S. Belangero¹, M. Santoro¹, E. Atkinson³; ¹Univ.e Federal de Sao Paulo, Sao Paulo, Brazil, ²Univ California San Diego, La Jolla, CA, ³Baylor Coll. of Med., Houston, TX

Abstract Body:

Latin American populations have a complex ancestry makeup resulting from historical admixture events from multiple continental areas. In recent years, there has been significant effort in improving methods for admixed populations using Local Ancestry Inference (LAI), including the development of the gene discovery method Tractor. Reference panels are broadly required for genomic pipelines, including these new ancestry-informed strategies, yet are sorely lacking for many diverse populations, particularly those who have some Amerindigenous (AMR) ancestry. Here, we comprehensively test analytic strategies for LAI using existing resources to observe characteristics that impact its performance with particular attention to three-way admixed populations reflective of Latin America. After simulating LD-informed admixed data under a variety of 2 and 3 way admixed Latinx demographic models, we implement and tune LAI pipelines (using RFMix v1) and quantify their accuracy rates. Specifically, we assessed 1) the impact of reference panel composition, 2) demographic features of the cohorts including proportions of major ancestry groups and number of generations since admixture, 3) genetic data technology (genotyping arrays versus sequencing, the impact of imputation), and 4) the analytic thresholds in pipelines such as window size. For reference panel testing, we tested reference panel combinations comprising individuals from the Human Genome Diversity Project and the Thousand Genomes Project in three settings: 1) a very well matched panel but with low sample size; 2) including admixed individuals in the reference versus restricting to homogeneous individuals; or 3) a large reference that is poorly matched. We benchmarked the compute time and quantified the accuracy of each reference panel combination, simulation model and software setting to assess their respective performance. We observe that Amerindigenous ancestry tracts suffer from notably reduced accuracy as compared to European and African tracts. When miscalls occur, LAI error rates are more frequent in the direction of calling European ancestry in Amerindigenous simulated sites than other error modes. We additionally distribute a pipeline for calculation of the LAI true positive rate that can be used for benchmarking options for reference panel composition across other user-specified demographic models. Though our investigations are directly responsive to realistic admixed Latin American cohort compositions, the trends we characterized will also be broadly useful to inform characteristics that influence local ancestry inference across diverse admixed populations.

Informatics, Univ. of Cincinnati Coll. of Med., Cincinnati, OH, ⁹Ctr. for Genetic Med., Northwestern Univ., Chicago, IL, ¹⁰Dept. of BioMed. Informatics, Columbia Univ., New York, NY, ¹¹Feinberg Sch. of Med., Northwestern Univ., Chicago, IL, ¹²Mayo Clinic, Rochester, MN, ¹³Div. of BioMed. Informatics and Genomics, John W. Deming Dept. of Med., Tulane Univ. Sch. of Med., New Orleans, LA, ¹⁴Publ. Hlth.Sci. Div., Fred Hutchinson Cancer Ctr., Seattle, WA, ¹⁵Div. of Med. Genetics, Sch. of Med., Univ. of Washington, Seattle, WA

Abstract Body:

The development of polygenic risk scores (PRSs) is an attempt to understand the polygenic component of risk for complex traits. Pairs of complex traits may share environmental and/or genetic components suggesting similar biological mechanisms. Analyzing the association between PRSs and traits in deeply phenotyped biobanks and cohorts may illuminate shared genetic components. We sought to elucidate what phenotypes may be associated with colorectal cancer (CRC) through a shared polygenic component by assessing the association between a CRC PRS and phecodes in the electronic medical records and genomics (eMERGE) phase 3 study (N= 87,271 adults after quality control; 12,034 African genetic ancestry, 2,221 Asian genetic ancestry, 73,016 European genetic ancestry). The PRS contains ~1M SNPs and was developed (N=120,184) and validated (N=72,791) in individuals of European ancestry (PMID: 32758450). As the eMERGE data contains relatives, we used a linear mixed model approach that adjusts for relatedness among the participants and included the covariates age, sex, and first four principal components of ancestry (<https://github.com/eamosenthal/MMPheWas>). We defined significance using a Bonferroni correction: $p < 0.05 / (\text{Number top level phecodes}) = 9.2e-5$. We replicated the positive association with CRC ($p=1.2e-64$), as expected. We detected a negative association between CRC PRS and eye phenotypes, including poor visual acuity ($p=4.4e-17$; myopia subphenotype $p=9.2e-17$), cataract ($p=5.2e-7$), retinal disorders ($p=5.3e-7$) and corneal disorders ($p=4.6e-6$). The associations with eye phenotypes remained for controls without CRC (N=45,020, $p<2.8e-5$), indicating that the association is not due to confounding with CRC, such as earlier death. We replicated this finding in unrelated UK Biobank European ancestry participants (N= 433,767), using a linear model analysis adjusting for age, sex and the first four principal components of ancestry, finding a negative association between the CRC PRS and myopia ($p=0.006$). The finding of the same PRS predicting both CRC and eye phenotypes supports the need for objective discovery approaches.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3340. Combining family history with a polygenic risk score enables highly effective risk stratification for glaucoma

Authors:

S. Macgregor¹, W. HE², Y. Wu¹, D. A. Mackey³, J. E. Craig⁴, A. W. Hewitt⁵, P. Gharahkhani¹; ¹QIMR Berghofer Med. Res. Inst., Herston, Australia, ²QIMR Berghofer Med. Res. Inst., Brisbane, Australia, ³Lions Eye Inst., Perth, Australia, ⁴Flinders Univ., Adelaide, Australia, ⁵Univ. of Tasmania, Hobart, Australia

Abstract Body:

Glaucoma is a leading cause of irreversible blindness. Timely diagnosis is key as current treatments cannot restore lost vision. However, the disease often goes unnoticed in its early stages (e.g. 50% non-diagnosis rate, even in developed countries) and all too frequently diagnosis comes after retinal ganglion cell damage has occurred. As glaucoma only affects around 3% of people over 50 years of age, most people are not at high disease risk and it is currently not feasible to screen the whole population. We sought to explore population subgroups with elevated risk who may benefit most from increased surveillance.

We explored the utility of two predictors of increased disease risk: family history and polygenic risk scores (PRS). To explore family history we used data from a Canadian cohort study (CARTaGENE, N=29222 with GWAS data) where participants reported if they had a sibling affected by glaucoma. For the PRS we computed a previously published score (2020) and a new score derived from a multitrait analysis of a large glaucoma GWAS together with GWAS data on two glaucoma risk factors (intraocular pressure and retinal nerve damage, assessed via a machine learning based approach).

In CARTaGENE 1% of participants reported having a sibling affected by glaucoma. Having an affected sibling was associated with a 6.2 fold increased risk of glaucoma compared to those without an affected sibling (proportion affected 17% vs 2.5%). Within the family history positive group, the new PRS (2022) improved prediction compared to the 2020 PRS. Each standard deviation increase in the new PRS was associated with an odds ratio of 1.9. Taken together, PRS + family history clearly stratified individuals into risk categories: in people with an affected sibling the proportion affected was 32% (SD 7%) in the top 20% of the PRS, but only 5% (SD 4%) in the bottom 20%. Future studies should expand the relative types considered as well as examine reporting biases in glaucoma.

Many guidelines prioritize individuals for glaucoma surveillance based on family history but including PRS would greatly improve the allocation of finite resources. Low PRS individuals with a family history of glaucoma have risk similar to the general population, whilst those with a high PRS are at extremely high risk.

PB3341. Common and Rare Variants Genetic Association Analysis of Late-Onset Alzheimer's Disease in 500,000 Exomes from UK Biobank

Authors:

Y-C. Hwang, A. Fungtammasan; DNAnexus, Mountain View, CA

Abstract Body:

Late-onset Alzheimer's Disease (AD) has been causing more than 1 in 9 people aged 65 and older with dementia. The lifetime cost of care for a person with Alzheimer's is expensive and there is no effective cure. The disease can be caused by genetic, environmental, or other unknown factors. A well-known genetic variant of a person's risk for AD is the variant on the *APOE* gene. However, the specific gene set that directly causes AD are not found yet.

In this study, we performed a genome-wide association study (GWAS) on AD using UK Biobank (UKB) data to discover variants in genes that are associated with AD. UKB is a large prospective population-based initiative. It has collected extensive phenotypic data of half a million participants, aged 40-69 years, from the UK. The resource also includes various genetic data, including genome-wide genotype array, whole exome sequencing (WES), and whole genome sequencing (WGS) data for each participant.

Genetic variants are called per-individual level as well as at cohort-level of all participants. We used the cohort-level variants of the 500k participants of UKB, and derived a binary trait, as an individual's AD risk by proxy - based on each participant's ICD-10 code, age, and their parental diagnoses and ages. After quality controls of the genotype and phenotype data, we found 46,893 cases (AD) and 287,169 controls (non-AD). We applied REGENIE, a machine learning based method, for fitting the whole-genome regression model and testing for associations in a gene-based manner. Compared with Jansen, et al., we rediscovered variants associated with AD, including variants in *APOE*, and extended to more variants and genes. The entire analysis took less than 6 hours of wall-clock time, which is made possible by both the efficiency of the algorithm, the method, and the scalability of the DNAnexus cloud environment.

We further streamlined this computational-intensive analysis flow as a pipeline, which allows us to scale-up the analysis to higher-dimensions such as WGS cohort, and find associations to dozens of other phenotypes and traits of interest. The entire analysis is performed on the cloud-based UKB Research Analysis Platform and under UKB application number '46926'.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3342. COMPADRE: a robust, cloud-optimized genetic relatedness platform

Authors:

G. Evans¹, L. E. Petty², A. S. Petty², J. T. Baker¹, H-H. Chen², R. J. Bohlender³, C. D. Huff³, J. E. Below²; ¹Vanderbilt Univ., Nashville, TN, ²Vanderbilt Univ Med Ctr., Nashville, TN, ³Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract Body:

Scalable, robust methods that enable accurate relationship estimation in the absence of known pedigree structure are critical for large-scale genetic research such as disease gene mapping and linkage analysis. Despite their growing importance, available tools fail or exhibit biased results in the presence of population structure (e.g., recent admixture), data heterogeneity (e.g., comprising sequence data of varying read depth, libraries, or multiple arrays), and diversity (e.g., datasets spanning multiple distinct populations). We propose a multifaceted approach to improve and combine three existing programs - ERS (Estimation of Recent Shared Ancestry), a program that estimates pairwise relationships from shared genomic segments, PRIMUS (Pedigree Reconstruction and Identification of the Maximum Unrelated Set), a program that utilizes identity-by-descent (IBD) proportions to reconstruct pedigrees, and PADRE (Pedigree-Aware Distant Relatedness Estimation), a program that estimates distant relatedness across pedigrees using shared segments - into a new platform, COMPADRE (COMBined PADRE). COMPADRE's streamlined infrastructure reduces computational footprint (20%) and reconstruction runtime (35%) and improves the proportion of completed reconstructions previously affected by family network assessment errors (25%) relative to PRIMUS. It supports minimal imputation for cross-platform data harmonization and has increased relationship confidence in pedigree reconstruction (>10%) in early iterations by leveraging shared segments' length and distribution to reduce second- and third-degree relationship estimation ambiguity. Moreover, we have built a robust pipeline to generate simulated genetic data en masse reflecting key difference conditions (admixture, diverse populations, heterogeneity, and varied relatedness degree) to both supplement COMPADRE benchmarking relative to existing tools (Bonsai, DRUID, PRIMUS, PADRE) and serve as a community resource. Leveraging a novel multiprocessing framework and on-demand reference to 1000 Genomes Project data, this pipeline enables parallelized, highly specific, and interoperable genotype data generation that is significantly faster (>10x) and more efficient than prior implementations.

We have validated our findings in Vanderbilt University's biobank (BioVU) and are expanding our characterization analyses to UKBioBank and the National Institutes of Health's All of Us dataset. Public availability of these results will ensure appropriate relatedness utilization from key DNA biobank resources, bias reduction, and disease gene discovery power improvements.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3343. Comparing methods to adjust for fine-scale population structure in rare variant analyses.

Authors:

K. Marker^{1,2}, R. Shemirani³, M. Lin¹, E. Kenny³, G. Belbin³, C. Gignoux^{1,2}; ¹Colorado Ctr. for Personalized Med., Univ. of Colorado Anschutz Med. Campus, Aurora, CO, ²Human Med. Genetics and Genomics Program, Univ. of Colorado Anschutz Med. Campus, Aurora, CO, ³Inst. for Genomic Hlth., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

When there is a difference in average trait value or disease prevalence between subpopulations, fine-scale genetic differences in rare variants can induce population structure that cannot always be corrected with traditional approaches. This is increasingly a problem as very large sample sizes are needed to detect rare variant associations. Datasets from multiple studies will often be combined or external controls will be used to increase sample size. Fine-scale ancestry differences between cohorts will induce population structure bias that can confound rare variant association studies if the fine-scale population structure is not properly adjusted for. We compare four methods for capturing and adjusting for fine-scale population differences: including identity-by-descent (IBD) clusters, kinship clusters, PCA using only rare variants, and Uniform Manifold Approximation and Projection (UMAP) projections. To accomplish this, we have developed a simulation framework to generate 9 populations from a continental European demographic model with stepping stone migration using msprime. We first simulate base populations and then use those populations to simulate the derived populations with migration between the populations. The ancestry differences within these populations replicate fine-scale ancestry found within the White British population in the UK Biobank. Using a phenotype simulator, APRICOT, we simulate phenotypes under varying geographic conditions to induce fine-scale population structure. Finally, we run rare variant associations using these simulations to compare adjustment by IBD clusters, kinship clusters, rare variant PCA, and UMAP projections.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3344. Comparing the relationships of genetically proxied PCSK9 inhibition with mood disorders, cognition, and dementia between men and women: a drug-target Mendelian randomization study

Authors:

A. Bell¹, D. B. Rosoff^{1,2}, L. A. Mavromatis¹, J. Jung¹, J. Wagner¹, F. W. Lohoff¹; ¹NIH, Bethesda, MD, ²NIH-Oxford-Cambridge Scholars Program; Nuffield Dept. of Population Hlth., Univ. of Oxford, Oxford, United Kingdom

Abstract Body:

Proprotein convertase subtilisin/kexin 9 (PCSK9) inhibitors (PCSK9i) are important therapeutic options for reducing cardiovascular disease risk; however, questions remain regarding potential differences in the neuropsychiatric impact of long-term PCSK9 inhibition between men and women. While randomized controlled trials (RCTs) investigating these effects may be burdensome and costly, PCSK9 has a well-characterized genomic profile which can be used to assess the genetic basis of its physiological effects. We therefore used single-nucleotide polymorphisms (SNPs) in PCSK9 from predominantly European ancestry-based genome-wide association studies (GWAS) summary-level statistics of low-density lipoprotein cholesterol (LDL-C), sex-specific GWASs of anxiety, depression, cognition, and dementia, and drug-target Mendelian randomization (MR) methods to investigate potential neuropsychiatric consequences of inhibiting PCSK9 in men and women. Broadly, we failed to find genetic evidence that PCSK9 inhibition was related to risk for 13 neuropsychiatric endpoints in either men or women. We observed some isolated, nominally significant effect estimates for certain outcome-sex combinations; however, none passed correction for multiple comparisons. Further, corresponding MR analyses using polygenic instruments for LDL-C, the main biological target of PCSK9i, failed to find an impact of LDL-C on depression risk among women. Other mood-related endpoints were also null, including extreme irritability; self-harm; and panic attacks. Similarly, PCSK9 inhibition was not associated with sleep disturbances, dementia, or cognition. Our results indicate that genetically proxied PCSK9 inhibition displays a neutral neuropsychiatric profile with no major sex-specific differences and underscores the importance of genomic techniques such as MR for investigating potential adverse outcomes without requiring human experimentation. These findings may have important clinical implications for lipid-lowering drug prescribing practices and side effect monitoring.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3345. Comparison of trans-ancestry meta- and mega-analyses of cis-eQTLs in whole blood and LCLs

Authors:

P. Nandakumar¹, E. Bullis¹, T. Cavazos², B. Hicks¹, D. Hinds¹, K. Kukar¹, Y. Liang¹, S. Micheletti¹, M. Moreno¹, J. O'Connell¹, A. Petrakovitz¹, S. Pitts², R. Sauteraud², A. Sugathan², C. Wong¹, the 23andMe Computational Biology Team, the 23andMe Research Team, K. Fletez-Brant², V. Vacic²; ¹23andMe, Inc., Sunnyvale, CA, ²23andMe, Inc. Therapeutics Div., South San Francisco, CA

Abstract Body:

Expression quantitative trait loci (eQTL) studies are useful for variant-to-gene mapping and mechanistic interpretation of signals from genetic association studies. Unfortunately, tissue samples are difficult to obtain and as a result, eQTL studies are almost always underpowered. One way to increase sample sizes is to combine individual eQTL studies; however the choice of framework to use is not obvious. To address this question, we conducted a trans-ancestry fixed-effects meta-analysis and mega-analysis in each of whole blood (n=2,712 across three datasets) and lymphoblastoid cell line (LCL; n=1,164 across three datasets) data, in cohorts of primarily African and European ancestries. For the meta-analyses, we combined cis-eQTL 1Mb window statistics in each study produced using FastQTL for each dataset, with each individual study adjusted for age, sex, genetic principal components (PCs), and 15-35 PEER factors, as recommended by the authors. For the mega-analyses, which, with combination of individual-level data, have the benefits of identifying secondary signals and lower MAF eQTLs, we merged the individual-level genotype and expression datasets, and ran the FastQTL linear model adjusting for age, sex, global genetic PCs, 35 global PEER factors, and a study covariate. Considering the intersecting set of variant-gene pairs for comparison, while both the meta- and mega-analyses demonstrate power improvements compared to the individual datasets, the meta-analyses were better powered than the mega-analyses (LCL eGene counts: 10,744 in meta-analysis, 10,357 in mega-analysis; whole blood eGene counts: 12,619 in meta-analysis, 11,071 in mega-analysis), with similar effect sizes but smaller standard errors. We then investigated if additional PEER factors would improve the results of mega-analysis and computed 50 to 200 PEER factors in increments of 50 for 1000 randomly selected top variant-eGene pairs from the initial mega-analyses, and compared the overall AIC improvement with increasing PEER factors. We observed that 100 PEER factors for LCL data and 200 PEER factors for whole blood appeared optimal among the tested models. The final mega-analyses including the larger numbers of PEER factors produced roughly comparable numbers of eGenes as the meta-analyses (LCL: 11,260; whole blood: 12,627) but at the expense of significantly larger computational cost. Our results suggest that meta-analysis is a cost-efficient way to maximize power in eQTL studies; however, if longer PEER run times are not an issue, mega-analysis allows interrogation of eQTLs with smaller MAFs.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3346. Constructing and benchmarking omnibus polygenic risk scores using GWAS summary statistics

Authors:

Z. Zhao¹, J. Song¹, J. Miao², Z. Sun¹, G. Song¹, Q. Lu¹; ¹Univ. of Wisconsin-Madison, Madison, WI, ²Univ. of Wisconsin-Madison, Madison, WI

Abstract Body:

Recent advancements in genome-wide association studies (GWASs) and polygenic risk score (PRS) methodology exhibit promising improvements in prediction accuracy for many complex traits. However, existing methods for PRS model fine-tuning and performance benchmarking require individual-level genotype and phenotype data independent from training GWAS dataset in order to avoid overfitting. These data can be difficult to obtain in practice due to limited data availability and the equally important need to maximize the training GWAS sample size. Therefore, it has been a long-standing challenge in the field to optimize and benchmark PRS models without individual-level data. To address this challenge, we introduced PUMAS that performs cross-validation to fine-tune PRS models using GWAS summary data. Here, we introduce two important extensions to this framework. First, PUMAS now accounts for linkage disequilibrium (LD) and thus can be applied to almost all PRS models without requiring SNP pruning. Second, we introduce a highly innovative strategy to combine multiple PRS models into an omnibus score using GWAS summary data alone. Through extensive simulations, we show that our summary statistics-based approach (PUMAS) has consistent and robust performance compared to Monte Carlo cross-validation based on individual-level genotype and phenotype data. Applied to 16 complex traits in the UK Biobank, PUMAS can accurately pinpoint the best tuning parameters for LDpred2, PRS-CS, and lassosum, and also closely approximate predictive R^2 acquired from external validation. The omnibus PRS, obtained through aggregating multiple fine-tuned PRS models, outperforms single PRS models without requiring additional data. We demonstrate that our approach achieves highest prediction accuracy for all 16 complex traits in UK Biobank, with an average increase of 7.01% in R^2 compared to the best performing PRS method for each trait. Finally, we apply our method to 85 well-powered GWAS with publicly available summary statistics and provide an atlas of fine-tuned and omnibus PRS. Using PRS-CS as the baseline, our omnibus PRS approach shows an average 22.6% increase in predictive R^2 , showcasing substantial improvements compared to the state of the art. Taken together, PUMAS makes it possible to comprehensively evaluate and optimize PRS prediction accuracy across a plethora of PRS methods for hundreds of GWAS, and will likely have broad and impactful influences over how PRS models are constructed in the future.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3347. Controlled Discovery and Localization of Causal Variants via Bayesian Linear Programming

Authors:

A. Spector¹, L. Janson²; ¹Stanford Univ., Stanford, CA, ²Harvard Univ., Cambridge, MA

Abstract Body:

Identifying genetic variants which cause complex traits is a crucial task in statistical genetics. However, high linkage disequilibrium in genetic loci can make it challenging or impossible to isolate causal variants even when a causal variant clearly exists somewhere within a locus. A popular alternative is to output small regions of the genome, called credible sets, which each contain at least one causal variant with high confidence (Wang et al., 2020). Such analyses aim to (1) discover as many credible sets as possible while (2) minimizing the size of each credible set, all while (3) controlling the false discovery rate (FDR).

With this motivation, we introduce Bayesian Linear Programming (BLiP), a Bayesian method for detecting and localizing causal variants. As an input, BLiP can take nearly any Bayesian fine-mapping model, such as SuSiE, allowing it to incorporate sophisticated models and arbitrary prior information based on (e.g.) functional annotations. Given such a model, BLiP yields a set of credible sets for causal variants which verifiably maximize a resolution-adaptive notion of statistical power, meaning intuitively that BLiP makes the largest number of discoveries at the finest possible resolution while provably controlling the FDR. BLiP is extremely computationally efficient and in simulations, it often dramatically improves the power of the underlying model and can even simultaneously reduce the false discovery rate. Furthermore, applying BLiP can be as easy as running one or two lines of code, as we have released two open-source packages `pyblip` (Python) and `blipr` (R) implementing BLiP.

We applied BLiP to analyze four complex traits (height, cardiovascular disease, LDL cholesterol and HDL cholesterol) on a sample of ~318,000 individuals of British ancestry from the UK Biobank. In particular, we ran BLiP on top of a SuSiE model previously fit by Weissbrod et al. (2020). Despite requiring less than one minute of additional computation per trait, SuSiE + BLiP had 30-50% higher power than SuSiE alone. In particular, SuSiE + BLiP made discoveries at a finer resolution (15-25% finer on average) than SuSiE alone and furthermore made 15-20% more discoveries per trait. Of the new discoveries made by SuSiE + BLiP, we found that 45-65% could be corroborated by a separate study in the NHGRI-EBI GWAS Catalog, giving additional evidence that BLiP meaningfully enhanced SuSiE's power to find real causal variants. Overall, BLiP is a promising method to detect and localize causal variants which can wrap on top of nearly any Bayesian fine-mapping model with minimal computational cost.

PB3348. Copy-number variants as modulators of common disease susceptibility.

Authors:

C. Auwerx, N. Tesio, C. Clark, A. Reymond, Z. Kutalik; Univ. of Lausanne, Lausanne, Switzerland

Abstract Body:

We previously called copy-number variants (CNVs) in 331'522 UK Biobank participants, identifying 131 associations across 47 quantitative traits. Here, we interrogate whether CNVs also affect susceptibility to 60 common manually curated ICD10-based clinical diagnoses. We adapted our pipeline to accommodate the low number of disease cases and CNV carriers by complementing Firth-fallback logistic regression with various additional tests (i.e., Fisher tests, residual regression). To account for different modes of CNV action, genome-wide associations scans (GWAS) were performed according to mirror, U-shape, duplication-only, and deletion-only models, resulting in 309 independent signals across 221 CNV regions (CNVRs) and 54 diseases. Involved CNVRs were depleted from highly constrained genes ($p_{pLI} = 9.2e-5$; $p_{LOEUF} = 2.7e-4$) and all increased disease risk. We identified 71 signals overlapping a single protein-coding gene, recovering well-known associations, e.g., *BRCA1* and *LDLR* deletions increased the risk of ovarian cancer ($OR > 27$; $p = 1.9e-7$) and ischemic heart disease ($OR > 10$; $p = 1.2e-6$), respectively. Conversely, 73 signals mapped to intergenic or non-coding RNA (ncRNAs) regions, suggesting that CNVs also impact disease risk through disruption of regulatory mechanisms and/or modulation of ncRNAs. Some signals were corroborated by single nucleotide polymorphism (SNP)-GWAS signals for the same disorder, such as a 7p21.3 duplication overlapping a recently published Alzheimer's disease locus ($OR > 81$; $p = 1.7e-7$). Other signals were supported by colocalization with CNV signals for disease-relevant biomarkers. For example, our analysis revealed that altered dosage of 17q12 (*HNF1B*), which we previously found to alter renal biomarkers, increased chronic kidney disease risk ($OR > 9$; $p = 8.7e-9$), additionally exposing a role in hepatic fibrosis ($OR > 35$; $p = 1.4e-6$). We then explored the pleiotropic effect of disease-associated CNVRs. While 76% of the CNVRs associated with a single disease, up to 9 associations were found for the 16p11.2 BP4-BP5 CNVR, including know associations with schizophrenia and anemia, as well as novel ones with cardiac, pulmonary, renal, and immune disorders. Twelve CNVRs associated with the total number of diagnoses (burden), including recurrent deletions of 16p11.2 BP4-BP5, 22q11.2, and 16p12.2, the latter being associated with hypertension ($OR > 2.2$; $p = 1.6e-10$), cardiac conduction disorders ($OR > 2.6$; $p = 1.2e-10$), and ischemic heart disease ($OR > 2.2$; $p = 2.7e-6$), suggesting a crucial role in cardiac health. Together, these results shed light on the understudied role of CNVs in common diseases within the general population.

PB3349. Credible set determination for multi-ancestry fine-mapping.

Authors:

J. Shen, A. Wang, F. CHEN, C. Haiman, D. Conti; Univ. of Southern California, Los Angeles, CA

Abstract Body:

Trans-ethnic genetic studies may increase power to detect novel risk variants and improve fine-mapping resolution by leveraging evidence from diverse populations and accounting for the difference in linkage disequilibrium (LD) across ethnic groups. Here, we expand upon our previous approach for single and multi-population fine-mapping through Joint Analysis of Marginal SNP Effects (mJAM) to develop an approach for determining credible set SNPs. The approach utilizes mJAM to use population-specific summary statistics to fit a single conditional model that incorporates corresponding ancestry-specific reference linkage disequilibrium (LD), and fixed-effects meta-analysis of joint effects. The mJAM framework can be used to first select index SNPs using any feature selection approach, such as forward selection, Bayesian selection, or regularized regression techniques. Then, given a set of index SNPs within each region, the posterior credible set probability (PCSP) of a SNP is defined as a combination of two probabilities: one models the marginal association between the candidate SNP and the outcome; the other models the mediation effect of the index SNP on the candidate SNP, borrowing from a mediation framework. These PCSPs are then used to construct credible sets. We first illustrate mJAM through two implementations for selection: mJAM-SuSiE (a Bayesian approach) and mJAM-forward selection. We then compare these approaches to fixed-effect meta-analysis, COJO stepwise selection, and MsCAVIAR. When available, we also compare credible set performance. Through simulation studies based on realistic effect sizes and levels of LD, we demonstrate that mJAM performs better than other existing multi-ethnic methods for identifying index SNPs and corresponding credible sets that include the underlying causal variants. In a real data application, we apply this approach to the most recent summary statistics from a cross-ethnic prostate cancer GWAS.

PB3350. Cross-trait meta-analysis reveals shared genetic architecture between PCOS and chronic inflammation markers

Authors:

G. Brixi^{1,2}, L. Petersen^{1,3,1}, J. Canseco Neri⁴, J. Li¹, J. Hu^{5,6}, X. Han⁷, S. Mahalingaiah^{1,4}, L. Liang¹; ¹Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, ²Harvard Univ., Cambridge, MA, ³Los Alamos Natl. Lab, Los Alamos, NM, ⁴Boston Univ., Boston, MA, ⁵Brigham and Women's Hosp., Boston, MA, ⁶Harvard Med. Sch., Boston, MA, ⁷Harvard T. H. Chan Sch. of Publ. Hlth., Boston, MA

Abstract Body:

Polycystic ovarian syndrome (PCOS) is a common hormonal disorder with a prevalence of approximately 10% worldwide, and is the leading cause of female infertility. PCOS is known to be closely related to inflammatory markers, but the genetic and causal basis of this relationship is not yet understood. We report results of the largest-to-date meta-analysis of PCOS using data from UK Biobank, Partners Biobank, and prior studies of FinnGen, Estonian Biobank and additional cohorts (cases = 10,005, controls = 498,227). We further conduct meta-analyses for inflammation markers combining recent proteome and biobank cohorts (N ranges from 38860 to 505,690) to obtain the largest GWAS for a broad panel of 138 inflammation markers. We find statistically significant (FDR<0.05) genetic correlation between PCOS and CRP ($R_g = 0.35$, $P = 1.0 \times 10^{-5}$), leptin ($R_g = 0.4$, $P = 0.33 \times 10^{-5}$), white blood cell count ($R_g = 0.21$, $P = 8.0 \times 10^{-4}$), lymphocyte count ($R_g = 0.19$, $P = 1.1 \times 10^{-3}$), and SLAMF1 ($R_g = 0.52$, $P = 1.3 \times 10^{-3}$). We further find statistically significant genetic correlation between PCOS and SHBG ($R_g = 0.40$, $P = 1.1 \times 10^{-14}$), and BMI ($R_g = 0.34$, $P = 3 \times 10^{-13}$). Our findings highlight the genetic architecture underlying PCOS which is closely related to obesity and chronic inflammation. The results further our understanding of PCOS pathogenesis and enable our downstream analyses for causal inference between inflammation status and PCOS based on Mendelian randomization.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3351. *De novo* mutation hotspots in homologous protein domains identify function-altering mutations in neurodevelopmental disorders.

Authors:

J. Hampstead¹, L. Wiel¹, H. Venselaar¹, L. Vissers¹, H. Brunner¹, R. Pfundt¹, G. Vriend², J. Veltman³, C. Gilissen¹; ¹Radboud Univ. Med. Ctr., Nijmegen, Netherlands, ²Baco Inst. of Protein Sci., Baco, Philippines, ³Newcastle Univ., Newcastle-upon-Tyne, United Kingdom

Abstract Body:

Variant interpretation remains a major challenge in medical genetics. While *de novo* mutations (DNMs) are an established cause of approximately 50% of severe developmental disorders (DDs), the mechanisms by which these mutations cause disease are less well understood. Most genes are currently associated to DDs through an enrichment of protein-truncating variation; these genes are assumed to cause disease through haploinsufficiency, or the functional loss of an essential allele. However, in specific genes we observe that disease-causing missense DNMs cluster in functionally important positions; these mutations are thought to be function-altering, and cause disease through gain-of-function or dominant negative mechanisms. The contribution of function-altering mutations to developmental disorders is not well characterised, and these mutations are very difficult to identify due to their comparatively small mutational target.

To address this challenge, we developed a Meta-Domain HotSpot (MDHS) method that leverages protein domain homology to aggregate missense mutations across conserved protein consensus positions within domain families. This approach increases our statistical power to detect domain consensus positions likely to harbour function-altering variation contributing to DDs. We applied MDHS to a dataset of 45,221 DNMs from 31,058 patients with developmental disorders and identified three significantly enriched missense DNM hotspots in the ion transport protein domain family (PF00520). The 37 unique missense DNMs that drive enrichment affect 25 genes, 19 of which have been previously associated with DDs through protein-truncating variant enrichment. 3D protein structure modelling supports the function-altering effects of these mutations. DD genes with missense mutations at hotspot positions have a unique, brain-specific expression pattern in tissue, and we used this pattern alongside *in silico* predictors and population constraint information to identify candidate DD-associated genes. We also propose a lenient version of our method, which identifies 32 hotspot positions across 16 different protein domain families. These positions are enriched for likely pathogenic variation in clinical databases and DNMs in other genetic disorders. Overall, we provide compelling evidence that the aggregation of mutations over homologous protein domains is a scalable approach towards understanding the contribution of function-altering mutations to DDs.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3352. Deep Learning-based Phenotype Imputation on Biobank-scale Data Increases Genetic Discoveries

Authors:

U. An¹, A. Dahl², N. Cai³, A. Pazoki¹, M. Alvarez¹, S. Bacanu⁴, A. Schork⁵, K. Kendler⁴, P. Pajukanta¹, J. Flint¹, S. Sankararaman¹; ¹UCLA, Los Angeles, CA, ²Univ. of Chicago, Chicago, IL, ³Helmholtz Zentrum München, Neuherberg, Germany, ⁴Virginia Commonwealth Univ., Richmond, VA, ⁵Copenhagen Univ. Hosp., Copenhagen, Denmark

Abstract Body:

Biobanks that collect diverse phenotypic and genomic data across large numbers of individuals have emerged as a key resource for human genetics research. However, phenotypic measurements vary drastically in availability across individuals so that the ability to accurately impute or “fill-in” missing phenotypes in these datasets is critical to harness their power. To address a need for a reliable and fully-featured imputation method, we developed AutoComplete, a deep-learning based imputation method based on an auto-encoder architecture designed for highly incomplete biobank-scale phenotype data. AutoComplete can impute binary and continuous phenotypes simultaneously while scaling to datasets with half a million individuals and millions of entries. To handle the absence of ground truth in incomplete datasets, we developed a realistic procedure to simulate missing values as reflected in the real data by implementing copy-masking which propagates missingness patterns already present in the data, from which AutoComplete learns imputation.

AutoComplete greatly improved imputation accuracy over existing methods across a broad range of simulations of missing data. In comparison to the next-best method (SoftImpute), the average squared Pearson correlation coefficient r^2 of AutoComplete improved by 18% across a group of 230 phenotypes related to cardiometabolic conditions and a group of 370 phenotypes related to psychiatric disorders (11% and 25% within each individual dataset).

We demonstrate the utility of imputing highly missing phenotypes for the purpose of improving association power for genome-wide association studies (GWAS). As a verification of this procedure, we simulated highly observed phenotypes to be 67% missing and applied AutoComplete to recover them for GWAS. In total, 116 of 118 recovered significantly associated SNPs were also strongly associated with the originally observed phenotypes. We then imputed 8 highly missing phenotypes which were clinically relevant to psychiatric disorders. Imputing these phenotypes using AutoComplete lead to a five to ten fold increase in sample size, and we observed an increase in the total number of significantly detected loci across all phenotypes of interest from 4 to 173, with the mean increase being 21 loci (minimum increased 4 and maximum 37). Among phenotypes with notable increases in loci were Medication for MDD (from 1 to 14 loci) and Cannabis consumption frequency (from 0 to 23 loci). AutoComplete can scale to ~300,000 individuals and ~400 phenotypes from the UKBB with ease converging within ~6 hours. Our results illustrate the value of deep-learning based imputation to genomic discovery.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3353. Deep Representational Clustering for Genetic Endotype Discovery from Clinical Data

Authors:

A. Averitt^{1,2}, J. Mower¹, N. Banerjee¹, M. Cantor¹, Regeneron Genetics Center, GHS-RGC DiscovEHR Collaboration; ¹Regeneron Genetics Ctr., Tarrytown, NY, ²Columbia Univ., New York, NY

Abstract Body:

Endotypes are distinct, genetically motivated pathophysiological mechanisms of disease that play a critical role in precision medicine. We hypothesize that clinical data are reflective of the mechanism of disease and can be exploited to discover previously unknown endotypes. Typical methods of endotype discovery from clinical data (ex, hierarchical clustering or latent class mixture models) are often unable to accommodate different data modalities and are not suitable for use with high dimensional or noisy data. We propose a method of deep representational clustering of clinical data for endotype discovery. Our method employs a multi-headed autoencoder that (i) accommodates multi-modal data; (ii) denoises clinical features; and (iii) learns efficient representations of patients' states. A density-based algorithm then partitions the learned representations into clusters that correspond to endotypes. To evaluate the model, we applied it to electronic health record (EHR) data from Geisinger Health System to discover endotypes of Type 2 Diabetes (T2D) (N=10,751). To evaluate the learned endotypes, we characterized the clinical and genetic differences between clusters.

Our method identified 3 endotypes of T2D, referred to as #1 (N=7,238), #2 (N=2,271), and #3 (N=1,242). When compared to other T2D patients, #1 is characterized by *poorly controlled T2D* (ex, elevated blood glucose and HbA1c); #2 is characterized by *well-controlled T2D* (ex, normal HbA1c and glucose); and #3 is characterized by *cardiovascular comorbidities* (ex, hypertension and hyperlipidemia). Using case-only GWAS to test for endotype-specific genetic signal, we identified a genome-wide significant association between a common intronic variant within the FER gene and #1 (OR=1.44 [1.26, 1.64], $p=4.54e^{-8}$). FER has been previously associated with T2D and is thought to influence insulin action and glucose metabolism via adiponectin. We also found an association between a variant near the ROBO2 gene and #2 (OR=1.94 [1.54, 2.45], $P = 2.48e^{-8}$). This locus has been associated with T2D via pancreatic beta cell dysfunction. These distinct genetic signals across loci have been previously associated with T2D and provide support for the biological relevance of our EHR-derived endotypes. A review of functional relevance of the clusters' genetics is in progress.

This research presents a deep representation clustering method for endotype discovery from clinical data. When applied to real-world data of T2D patients, the model automatically learns phenotypically distinct clusters that demonstrate differing genetic architecture that is suggestive of differing mechanisms of disease.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3354. Deep sequencing of DNA from urine of kidney allograft recipients to estimate donor/recipient-specific DNA fractions

Authors:

A. Belkadi; Weill Cornell medicine in Qatar, Doha, Qatar

Abstract Body:

Kidney transplantation is the treatment of choice for patients with end-stage kidney failure, but transplanted allograft could be affected by viral and bacterial infections and by immune rejection. The standard test for the diagnosis of acute pathologies in kidney transplants is kidney biopsy. However, noninvasive tests would be desirable. Various methods using different techniques have been developed by the transplantation community. But these methods require improvements. We present here a cost-effective method for kidney rejection diagnosis that estimates donor/recipient-specific DNA fraction in recipient urine by sequencing urinary cell DNA. We hypothesized that in the no-pathology stage, the largest tissue types present in recipient urine are donor kidney cells, and in case of rejection, a larger number of recipient immune cells would be observed. Extensive in-silico simulation was used to tune the sequencing parameters: number of variants and depth of coverage. Sequencing of DNA mixture from 2 healthy individuals showed the method is highly predictive (maximum error < 0.04). We then demonstrated the insignificant impact of familial relationship and ethnicity using an in-house and public database. Lastly, we performed deep DNA sequencing of urinary cell pellets from 32 biopsy-matched samples representing two pathology groups: acute rejection (AR, 11 samples) and acute tubular injury (ATI, 12 samples) and 9 samples with no pathology. We found a significant association between the donor/recipient-specific DNA fraction in the two pathology groups compared to no pathology ($P = 0.0064$ for AR and $P = 0.026$ for ATI). We conclude that deep DNA sequencing of urinary cells from kidney allograft recipients offers a noninvasive means of diagnosing acute pathologies in the human kidney allograft.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3355. DeepPerVar: a multimodal deep learning framework for functional interpretation of genetic variants in personal genome

Authors:

Y. Wang^{1,2}, L. Chen³; ¹Biogen, Cambridge, MA, ²Indiana Univ. Sch. of Med., Indianapolis, IN, ³Univ. of Florida, Gainesville, FL

Abstract Body:

Understanding the functional consequence of genetic variants, especially the noncoding ones, is important but particularly challenging. Genome-wide association studies or quantitative trait locus analyses may be subject to limited statistical power and linkage disequilibrium, and thus are less optimal to pinpoint the causal variants. Moreover, most existing machine learning approaches, which exploit the functional annotations to interpret and prioritize putative causal variants, cannot accommodate the heterogeneity of personal genetic variations and traits in a population study, targeting a specific disease. By leveraging paired whole genome sequencing data and epigenetic functional assays in a population study, we propose a multi-modal deep learning framework to predict genome-wide quantitative epigenetic signals by considering both personal genetic variations and traits. The proposed approach can further evaluate the functional consequence of noncoding variants on an individual level by quantifying the allelic difference of predicted epigenetic signals. By applying the approach to the ROSMAP cohort studying Alzheimer's disease (AD), we demonstrate that the proposed approach can accurately predict quantitative genome-wide epigenetic signals and in key genomic regions of AD causal genes, learn canonical motifs reported to regulate gene expression of AD causal genes, improve the partitioning heritability analysis, and prioritize putative causal variants in a GWAS risk locus. Finally, we release the proposed deep learning model as a stand-alone Python toolkit and a web server.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3356*. Deep-PheWAS.R: an innovative R package for phenome wide association of novel phenotypes.

Authors:

R. Packer¹, A. T. Williams¹, W. Hennah^{2,3}, M. Eisenberg¹, K. A. Fawcett¹, W. Pearson¹, A. Guyatt¹, A. Edris^{1,4}, E. Hollox¹, B. S. Rao⁵, R. J. Bratty⁵, L. V. Wain¹, F. Dudbridge¹, M. Tobin¹; ¹Univ. of Leicester, Leicester, United Kingdom, ²Orion Pharma, Espoo, Finland, ³Univ. of Helsinki, Helsinki, Finland, ⁴Ghent Univ., Ghent, Belgium, ⁵Orion Pharma, Nottingham, United Kingdom

Abstract Body:

Background: Phenome-wide association studies (PheWASs) can be used to better understand the pleiotropic effects of genetic variants and to inform drug development. Current PheWAS approaches have several limitations. The phenotypes generated rely on a single data field or coding ontology and do not take advantage of all available data. Further there are no existing tools to develop new phenotypes. Online PheWAS resources, which allow fast retrieval of pre-existing results, only allow single nucleotide polymorphisms (SNPs) as inputs and retrieve results only for genetic models tested, whilst de novo per variant alternatives are computationally inefficient and can result in inflated type I error. **Methods:** Deep-PheWAS.R (DPR) addresses these limitations through enhanced phenotype development and flexible, efficient association testing. To study phenotypes not well captured by current classification trees, DPR creates novel clinically-curated composite phenotypes (combining primary and secondary care data), quantitative phenotypes from primary care data, disease progression phenotypes and drug response phenotypes. Existing classification structures are exploited by using Phecodes and individual data-field phenotypes. Optimised for use with UK-Biobank data, DPR can be adapted to other data sources and all phenotypes can be edited using in-built functions. Association is optimised for SNP inputs by integrating with PLINK2 and supports additive, dominant, recessive, or genotypic models. NonSNP inputs such as complex structural variants and genetic risk scores (GRS) are analysed through regression models in R. To highlight some of these features we applied DPR to rs7193778 (previously associated with urate levels) and a lung function GRS created using 279-variants. **Results:** DPR created 2246 phenotypes. Rs7193778 showed association (false discovery rate <1%) with 46 phenotypes, 13 at genome-wide significance, 12 of which are not reported on GWAS catalog. The strongest association was with blood sodium, a phenotype derived using measurement data from primary care ($P=6.49 \times 10^{-45}$, $BETA=0.07$). Our lung function GRS showed association with 47 traits including association with exacerbation of COPD and age-of-onset of COPD both of which are unavailable in existing PheWAS resources and have no published GWAS results on GWAS catalog. **Conclusion:** We present Deep-PheWAS.R, an R package that addresses several limitations of existing PheWAS approaches. This includes the ability to analyse more informative composite phenotypes, greater flexibility in the type of genetic variation that can be studied and assessing associations with genetic risk scores.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3357*. Defining longitudinal disease trajectories in 146,000 individuals with hypertension from Penn Medicine Electronic Health Records

Authors:

P. Singhal¹, L. Guare¹, A. Lucas², C. Morse³, M. Byrska-Bishop⁴, M. Guerraty³, D. Kim^{5,6}, M. Ritchie^{1,6,7}, A. Verma^{3,2}; ¹Dept. of Genetics, Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, ²Corporal Michael Crescenz VA Med. Ctr., Philadelphia, PA, ³Dept. of Med., Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, ⁴New York Genome Ctr., New York, NY, ⁵Dept. of Biostatistics, Epidemiology, and Informatics, Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, ⁶Inst. of BioMed. Informatics, Univ. of Pennsylvania, Philadelphia, PA, ⁷Ctr. for Precision Med., Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Many chronic diseases are associated with hypertension (HTN), yet we are currently unable to predict which future disease states are likely in an individual diagnosed with HTN. Interrogation of the comorbidity architecture of HTN using temporal individual-level electronic health record (EHR) data is needed to better predict the disease trajectory individuals will follow after a HTN diagnosis. Currently, there is no clear best way to model longitudinality in the EHR given irregular visits over the course of a patient's disease journey. This leads to the challenge of extracting meaningful temporal patterns at the health system and individual levels. We developed a framework to identify disease trajectories in Penn Medicine EHR data for a cohort of 146,654 individuals with HTN. We first generated a disease co-occurrence network using all ICD codes for each individual appearing after HTN onset (3,642 codes). The Ising Model, a probabilistic graphical model, was leveraged to estimate pairwise occurrence between each condition while taking into account all other conditions. This generated an undirected disease comorbidity network with significant pairs of conditions ($\beta > 0$). Directionality was determined by calculating relative risk (RR) in both directions, yielding 73,729 significant pairs of conditions ($RR > 1$). Trajectories were then assembled step-by-step using an iterative RR framework starting from HTN (I10*) outward to ICD neighbors while masking codes earlier in the trajectory at each step. Each individual was binned into a single trajectory starting from HTN out to the 5th neighbor condition. This uniquely eliminated insignificant disease pairs and identified the conditions that could function as "sign-posts" in a disease path. Our results yielded numerous positive-control trajectories with early symptoms that developed into concrete diagnoses and then chronic disease outcomes. For example, individuals on a "hepatic" path have HTN trajectories that go from "abnormal liver function lab" to "inflammatory liver disease", while individuals on a "renal" path go from "albuminuria" to "chronic kidney disease". Some novel connections between autoimmune and gynecological conditions (stratified analyses), as well as neuro-immunological connections, were identified. Our results demonstrate the potential for stronger characterization of the different disease trajectories and outcomes for patients with HTN. Further, the goal of this work is to train a model to predict comorbid conditions and disease trajectories that may present in the future for individuals with HTN, which may lead to the design of improved precision medicine strategies.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3358*. Deprivation index as a predictor in PheWAS recapitulates associations between socioeconomic status and phenotypes captured by ICD9 codes.

Authors:

M. March¹, F. Mentch², H. Qiu³, P. Sleiman⁴, H. Hakonarson²; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Children's Hosp. of Philadelphia, Philadelphia, PA, ³Children's Hosp. of Philadelphia, Philadelphia, PA, ⁴Rhythm Pharmaceuticals, Boston, MA

Abstract Body:

PheWAS analyses are typically used to examine the impact of a single genetic marker (usually single nucleotide polymorphisms) on an entire catalog of phenotypes derived algorithmically from diagnosis codes. However, other properly encoded predictive variables can be used in place of genotypes, and several examples of PheWAS performed with quantitative traits as the inputs have been published. A method for combining socioeconomic variables from the American Community Survey into a deprivation index based on census tracts was applied to the cohort of patients collected by the Center for Applied Genomics (CAG) at The Children's Hospital of Philadelphia. The resulting deprivation index was run through a PheWAS analysis containing the phecode phenotypes based on ICD9 codes as well as additional quantitative traits derived from lab test results. Strong associations were found for conditions expected to positively correlate with the deprivation index, including acute respiratory illness ($p = 3.2E-31$, OR = 4.2 in African ancestry), atopic dermatitis ($p = 7.2E-18$, OR = 3.2 in African ancestry), and obesity ($p = 8.3E-30$, OR = 19.4 in European ancestry, $p = 5.4E-17$, OR = 3.4 in African ancestry). Marked differences exist between cohorts of European and African ancestry: 141 phenotypes are significantly associated after Bonferroni correction in the African ancestry cohort, 33 in the European ancestry cohort; acute respiratory illness is significant in African Americans, while acute sinusitis is significant in both populations; otitis media is significantly associated in European but not African ancestry. Additionally, associations with conditions that would be predicted to be inversely associated with the deprivation index, like allergic reactions to food, were observed with the expected direction of effect ($p = 9.5E-08$, OR = 0.27). The deprivation index recapitulated associations between socioeconomic status and phenotypes previously described in the literature, while providing a wealth of information for potential data mining. Efforts are underway to understand the contributions of the components of the deprivation index to various phenotypes and to consider the confounding variables of geography and distance.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3359. Detecting haplotype association using synthetic genetic variants

Authors:

Y. Guan; Duke University, Durham, NC

Abstract Body:

Consider any k consecutive genotypes to define a synthetic genetic variant as follows: substituting each genotype with a matrix, with M_0 for homozygous reference allele, M_2 for homozygous variant allele, and $M_1 = 1/2(M_0 + M_2)$ for heterozygous; multiplying the k matrices to obtain a product matrix $M = P_1 \dots P_k$ where P_j equals M_0 or M_1 or M_2 depending on genotypes; computing $\log \text{tr}(M)$ (log of trace of M) and we obtain the dosage of the synthetic genetic variant. We may test for association between the synthetic genetic variant and a phenotype of interest. (The choice of M_0 and M_2 is a matter of design and the synthetic variants works for the simplest choice of M_0 and M_2 .)

The synthetic genetic variants have the following features: 1) they incorporate haplotype information without the need of phasing. To see this, for two adjacent heterozygous, the product matrix $M = 1/4(M_0M_0 + M_0M_2 + M_2M_0 + M_2M_2)$ averages over all four possible phase between two heterozygous SNPs. 2) Missing genotypes can be handled cleanly. Imputation outputs probabilities of the missing genotypes being homozygous reference allele p_0 , or homozygous variant allele p_2 , or heterozygous p_1 . We use $(p_0 M_0 + p_1 M_1 + p_2 M_2)$ in place of either M_0 or M_1 or M_2 to compute matrix multiplication. 3) We can tune k to let synthetic genetic variants reflect different scales of genetic variations. 4) Synthetic genetic variants can serve as surrogates for genetic background of an allele, which allows us to study genetic interactions between genotypes and their genetic backgrounds.

We demonstrate via simulation that synthetic genetic variants have better power to detect association than the single SNP test when there exists allelic heterogeneity. Using a legacy genome wide association dataset we demonstrate the usefulness of the synthetic genetic variants by uncovering association between *CDKN2A* and type 2 diabetes in European samples, a confirmed genetic association in East Asian samples that cannot be detected in European samples via single SNP test.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3360*. Detecting shared and sex-specific causal genetic effects on complex traits

Authors:

W. Zhang, H. Najafabadi, Y. Li; McGill Univ., Montreal, QC, Canada

Abstract Body:

Sex differences in health and diseases are prevalent. Understanding sex-specific biological pathways is important to research and health care. However, identifying sex-specific genetic effects is challenging, because a sex-stratified genome-wide association study (GWAS) or a variant-by-sex interaction test may be under-powered.

We propose SharePro to detect shared and sex-specific genetic effects. With sex-stratified GWAS summary statistics and matched linkage disequilibrium (LD) information, SharePro introduces a sparse projection to group genetic variants in high LD into effects and assess their roles in females and males. Posterior probabilities of genetic effects being shared or sex-specific can be accurately derived by efficient variational inference.

We conducted simulations to assess the accuracy and computational efficiency of SharePro. As expected, when all genetic effects were sex-specific, SharePro achieved comparable performance in identifying true causal effects as fine-mapping sex-stratified GWAS summary statistics separately. When all genetic effects were shared, SharePro was comparable to fine-mapping sex-combined GWAS summary statistics. Importantly, when the genetic effects were partially sex-specific, SharePro outperformed existing approaches. For instance, when 50% of the genetic effects were sex-specific, SharePro achieved an area under the precision-recall curve (AUPRC) of 0.73 while eCAVIAR and fastPAINTOR had an AUPRC of 0.49 and 0.58, whose computation time was 112 times and 215 times longer than SharePro, respectively. Next, we applied SharePro to investigate 20 traits and diseases in large cohort studies. We found that hormonal traits had widespread sex-specific genetic effects, with only 25% of causal genetic effects shared between females and males for testosterone level. Neurological diseases and behavioral traits exhibited moderate sex-specific genetic effects. For example, 56% of causal genetic effects on schizophrenia were shared. For biochemistry traits, genetic effects with a large effect size, which may correspond to core biological pathways, were mostly shared, although sex-specific genetic effects with a weak-to-moderate effect size also existed. For example, 78% of causal genetic effects on lipids were shared and enriched in cholesterol metabolism pathways.

In summary, we have developed SharePro for characterizing shared and sex-specific genetic effects. The accuracy and computational efficiency of SharePro supports its wide utility in profiling sex-dimorphic genetic architecture and identifying potential targets for individualized treatment and intervention.

PB3361. Detecting Somatic Mosaicism at Tandem Repeats

Authors:

A. Sehgal¹, M. Gymrek²; ¹Univ. of California, San Diego, La Jolla, San Diego, CA, ²Univ California San Diego, La Jolla, CA

Abstract Body:

Somatic mosaicism, in which a mutation occurs post-zygotically, has been implicated in several developmental disorders, diseases and cancers. Short tandem repeats (STRs) consist of repeated sequences of 1-6bp and comprise more than 1 million loci in the human genome. Somatic mosaicism at STRs is known to play a key role in the pathogenicity of loci implicated in repeat expansion disorders, and is highly prevalent in cancers exhibiting microsatellite instability. While a variety of tools have been developed to genotype germline variation at STRs, no method currently exists for systematically identifying mosaic STRs (mSTRs). Here, we introduce mosaicSTR, a novel method for detecting mSTRs from individual next-generation sequencing datasets. Unlike many existing mosaicism detection methods, mosaicSTR does not require a matched control sample as input. We show that mosaicSTR accurately identifies mSTRs in simulated data and demonstrate its feasibility by identifying candidate mosaic STRs in whole genome sequencing (WGS) data for individuals sequenced by the 1000 Genomes Project. MosaicSTR takes as input a vector of observed repeat copy numbers $R = \{r_1, r_2, \dots, r_n\}$, where r_i is the number of copies of the repeat observed in the i th read. For each STR locus, $\langle A, B \rangle$ denotes the diploid germline genotype, f denotes the fraction of chromosome copies harbouring an additional allele C resulting from a mosaic mutation, and Θ represents additional error parameters. mosaicSTR models the observed repeat copy numbers (R) as a mixture, in which $1-f$ copies come from germline alleles A and B , respectively, and f copies come from the mosaic allele C . It then applies an expectation-maximization approach to iteratively infer maximum likelihood values for C and f . Finally, it applies a likelihood ratio test to test the null hypothesis that $f=0$. We developed a framework to simulate observed repeat copy numbers (R) for given values of A , B , C , f , and STR error parameters Θ and for different sequencing coverage parameters. We found that mosaicSTR can accurately infer mosaic fractions (f) down to 2% at $>50x$ coverage. We additionally applied mosaicSTR to WGS data from individuals sequenced by the 1000 Genomes Project and identified candidate STRs with mosaic alleles.

PB3362. Detecting variable-number tandem repeat (VNTR) variation using Oxford Nanopore sequencing data at population scale.

Authors:

D. Beyter, S. Kristmundsdóttir, M. Hardarson, H. Hauswedell, H. Jónsson, H. Eggertsson, G. Sveinbjornsson, A. Oddsson, G. Holley, O. Stefansson, S. Stacey, S. Gudjonsson, P. Olason, T. Rafnar, G. Masson, U. Thorsteinsdottir, P. Sulem, A. Helgason, D. Gudbjartsson, B. Halldórsson, K. Stefansson; deCODE Genetics, Reykjavik, Iceland

Abstract Body:

Variable number tandem repeats (VNTRs) are associated with a number of diseases and other traits, and are a major source of genetic variation, comprising a large fraction of structural variants. Long-read sequences present an opportunity to greatly improve the discovery and genotyping of VNTRs. While the error rates of long-reads are continually decreasing, current error rates make VNTR allele discovery challenging, especially in low-coverage samples. We analyzed 6,503 individuals long-read sequenced to a coverage of 10-20x. Our large sample size, combined with long-range phasing of the individuals allows us to accurately determine VNTRs, both in motif composition and allele length. We aggregate phased long-reads from a single haplotype shared by multiple individuals to increase read coverage in order to accurately reconstruct VNTR alleles via multiple sequence alignment. This method allowed us to accurately genotype VNTR alleles in 77,586 regions and impute into 173,025 individuals.

PB3363. *Detection of underdiagnosis of complex diseases due to underrecognition of high polygenic risk*

Authors:

C. Marquez-Luna¹, I. Forrest¹, A. Duffy¹, H. T. Vy¹, R. Do²; ¹Icahn Sch. of Med. at Mount Sinai, New York, NY, ²Icahn Sch. of Med., New York, NY

Abstract Body:

Underdiagnosis is defined as a failure to diagnose a disease correctly. Studies have reported evidence of underdiagnosis of complex diseases in healthcare systems. However, it's difficult to accurately quantify the extent of underdiagnosis in a disease. As a result, the range in which complex diseases are underdiagnosed is still unknown. New statistical approaches are needed to quantify the underdiagnosis rate of common diseases.

A polygenic risk score (PRS) of disease potentially has clinical utility for risk stratification. Its distribution can reflect the true prevalence of inherited polygenic risk to disease. We developed a statistical test that leverages the PRS distribution of diagnosed cases and controls and quantifies the underdiagnosis rate of disease in individuals with high PRS. This test evaluates whether there is an excess proportion of undiagnosed individuals with high PRS compared to a reference PRS distribution under a 0% misclassification rate.

First, we conducted extensive simulations to evaluate the statistical properties of the PRS underdiagnosis test and show that the method has sufficient statistical power under a wide range of disease prevalence and sample size parameters. Next, we estimate the underdiagnosis rate for six complex diseases: atrial fibrillation, depression, coronary artery disease, breast cancer, schizophrenia, type 2 diabetes, and breast cancer. We analyzed on avg 311K samples of British ancestry in UK Biobank and built three PRS sets for each disease: healthy (reference), diagnosed, and undiagnosed. For the PRS underdiagnosis test, we calculated disease-specific unadjusted polygenic risk scores and estimated the excess proportion of undiagnosed individuals at PRS cutoffs of 2.5-, 3- and 4-fold increased inherited genetic risk for each disease. We observed marked excess of undiagnosed individuals for four out of six diseases across all three high PRS cutoffs. For the PRS cutoff of 4-fold risk, we found that across the six diseases, we observed an underdiagnosis rate of 26.2%, 22.3%, 10%, 7.3%, 7.1%, and 1.9% for each disease listed, respectively. We show underdiagnosis at 2.5- and 3-fold increased PRS risk at lower rates. We show the robustness of our findings by performing multiple sensitivity analyses. Furthermore, we validated our underdiagnosis inference using electronic health records and observed higher rates of symptoms and medications in undiagnosed individuals with specific diseases.

In conclusion, we present evidence of marked underdiagnosis of genetically at-risk individuals due to underrecognition of high PRS in a large healthcare system.

PB3364. Developing an African American population-based transcriptome prediction model from the GENE-FORCAST cohort

Authors:

G. Goodney¹, A. Gaye¹, G. Gibbons²; ¹Natl. Human Genome Res. Inst., Bethesda, MD, ²Natl. Heart, Lung, and Blood Inst., Bethesda, MD

Abstract Body:

African Americans have historically been and remain an underrepresented population in biomedical research. This disparity has translated to genomic research and disease prediction models. By creating reference and prediction models that are trained on individuals of the same ancestry, we will have stronger prediction performance and have insight into gene expression and genotype interactions that may not translate across populations. Using genotype and gene expression data from 505 patients from the Genomics, Environmental Factors and Social Determinants of Cardiovascular Disease in African-Americans Study (GENE-FORECAST) cohort, we have trained a cross-validated elastic net prediction model to be used with the Predixcan suite of software developed by the Im lab. Since most reference and prediction models are currently based on individuals with European ancestry, our goal is to improve prediction performance with a trained model that has similar ancestry to the population being tested. Incorporating diverse populations in reference and prediction models is necessary in genomic research going forward. Initial results show that ~4,558 genes have robust prediction performance after stringent filtering ($R > 0.1$ and $p\text{-val} < 0.05$). Further mixing of PEER and elastic net parameters will improve the strength of this model.

PB3365. Development and validation of an RNA-seq-based transcriptomic risk score for asthma

Authors:

T. Mersha¹, X. Cao², L. Ding³; ¹Cincinnati Children S Hosp. Med. Ctr., Cincinnati, OH, ²Univ. of Cincinnati, Cincinnati, OH, ³Cincinnati Children s Hosp. Med. Ctr., Cincinnati, OH

Abstract Body:

Most complex diseases are influenced by several loci, each with a small effect on its own, and polygenic approaches that group individual variants collectively influence a phenotypic trait offer a more predictive value than is possible by single variant approaches. The most popular polygenic approach is polygenic risk score (PRS). In this study, we are now adapting PRS approaches to transcriptomics data with the objective of developing and validating an RNA-seq-based transcriptomic risk score (RSRS) for disease risk prediction that can simultaneously accommodate demographic information. We analyzed RNA-seq gene expression data from 441 asthmatic and 254 non-asthmatic samples. Logistic least absolute shrinkage and selection operator (Lasso) regression analysis in the training set identified 73 differentially expressed genes (DEG) to form a weighted RSRS that discriminated asthmatics from healthy subjects with area under the curve (AUC) of 0.80 in the testing set after adjustment for age and gender. The 73-gene RSRS was validated in three independent RNA-seq datasets and achieved AUCs of 0.70, 0.77 and 0.60, respectively. Enrichment pathway analysis found that these genes were significantly ($P < 0.0001$) enriched for DNA replication, recombination, and repair, cell-to-cell signaling and interaction, and eumelanin biosynthesis and developmental disorder. Further in-silico analyses of the 73 genes using connectivity map shows that drugs (mepacrine, dactolisib) and genetic perturbagens (PAK1, GSR, RBM15 and TNFRSF12A) were identified and could potentially be repurposed for treating asthma. These findings show the promise for RNA-seq risk scores to stratify and predict disease risk.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3366. Differential gene expression analysis based on linear mixed model corrects false positive inflation for studying quantitative trait

Authors:

S. Tang¹, A. Buchman², D. Bennett², Y. Wang³, Q. Zheng⁴, J. Yang⁵; ¹Emory Univ., Dept. of Biostatistics and Bioinformatics, Atlanta, GA, ²Rush Alzheimer's Disease Ctr., Rush Univ. Med. Cente, Chicago, IL, ³Rush Univ. Med. Ctr., Chicago, IL, ⁴Univ. of Louisville, Dept. of Bioinformatics and Biostatistics, Louisville, KY, ⁵Emory Univ., Ctr. for Computational and Quantitative Genetics, Dept. of Human Genetics, Atlanta, GA

Abstract Body:

Differential gene expression (DGE) analysis has been widely conducted in biomedical research to identify genes expressed differentially with respect to a trait of interest using RNA sequencing (RNA-Seq) data. Because of expensive RNA-seq cost and difficult accessibility of relevant tissues, most previous studies are limited to dozens of samples and dichotomous traits under general laboratory settings. Most existing DGE methods are developed specifically for handling small sample sizes and dichotomous traits. However, an increasing number of population-based RNA-Seq data have been profiled for cohorts with hundreds of sample sizes and for studying both dichotomous and quantitative traits. Therefore, a DGE method suitable for studying quantitative traits while controls for false positive rate is of pressing need. We propose to use the linear mixed model (LMM) implemented by the Genome-wide Efficient Mixed Model Association (GEMMA) tool to conduct DGE analysis for quantitative traits. We show that the LMM controls false positive rate through our application studies of the RNA-Seq data of dorsolateral prefrontal cortex (DL-PFC) samples (n=632) for studying quantitative Alzheimer's Disease (AD) and Alzheimer's Disease-Related Dementias (ADRD) traits. Q-Q plots showed well control of false positive rates for DGE results by LMM (with genomic control factors ~1) versus the clearly inflated results by standard linear regression model without mixed effects (with genomic control factors >3). LMM identified 39 potentially significant genes with differential expression for AD/ADRD, which had p-values < 0.001 for at least one AD/ADRD trait. Among these 39 potential differentially expressed genes, we identified 2 significant for cognition decline rate, 5 significant for β -amyloid associated genes, 4 significant for tangle density, and 2 significant for global AD pathology burden, which had p-values less than the Bonferroni corrected significance threshold (3.49×10^{-6}). We further conducted DGE analysis in additional RNA-Seq validation data of DL-PFC (n=238), muscle (n=273), and spinal cord (n=236), for both AD/ADRD traits and motor metrics, which validated 13 of these 39 DGEs for AD/ADRD traits and 21 for motor metrics. In conclusion, LMM-based DGE corrects for false positive inflation which is a common issue of the standard linear regression model for studying population-based RNA-Seq data. Our real application results not only showed the effectiveness of the LMM method, but also suggested that motor functions might share gene regulatory mechanisms with AD/ADRD. A pipeline for conducting DGE for quantitative traits by GEMMA will be available on Github.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3367. Differentially Private Release of Genomic Summary Statistics Using Factorization Mechanisms

Authors:

S. Neel¹, L. O'Connor², H. Cho²; ¹Harvard Univ., Boston, MA, ²Broad Inst., Cambridge, MA

Abstract Body:

Summary statistics and allele frequencies reported by genome-wide association studies (GWAS), even large ones, can compromise the privacy of individuals in the dataset (Homer et al., 2008). Over the last decade, differential privacy (Dwork et al., 2006) has become the standard method for preserving privacy in the release of aggregate statistics, by adding a controlled amount of noise to the released data. However, the high-dimensional nature of genomic summary results has thus far prevented a practical application of differential privacy in genomics. Prior work on differentially private GWAS requires an overwhelming level of noise, or focuses on releasing only a small number of top SNPs. In this work, we address the problem of privately releasing full GWAS summary statistics with practical accuracy guarantees, preventing an adversary from inferring the phenotype of a study participant based on their genotype. We investigate two algorithmic approaches to cope with the high dimensionality of the data. First, we consider a matrix factorization-based approach for exploiting the latent structure of the genotype data to minimize the noise required for privacy. While small problem instances can be optimally solved via a semi-definite program, we adopt a more efficient gradient-based optimization for large-scale datasets. Second, we consider a model-based approach based on inferred tree sequences (Kelleher et al., 2019), whereby genealogical patterns in the data inform the construction of more effective differentially private mechanisms. We empirically evaluate the improvement of our approaches upon standard differential privacy mechanisms. Finally, we outline the remaining challenges in developing a fully-differentially private GWAS pipeline.

PB3368*. Differentiate association and causal effects of cardiovascular disease risk factors on Alzheimer's disease and its age-at-onset.

Authors:

J. La¹, X. Fan^{1,2}, X. Gao^{3,4,5}, E. Martin^{6,7}, Y-J. Li^{1,2}; ¹Duke Molecular Physiology Inst., Duke Univ., Durham, NC, ²Dept. of Biostatistics and Bioinformatics, Duke Univ., Durham, NC, ³Dept. of Ophthalmology and Visual Sci., The Ohio State Univ., Columbus, OH, ⁴Dept. of BioMed. Informatics, The Ohio State Univ., Columbus, OH, ⁵Div. of Human Genetics, The Ohio State Univ., Columbus, OH, ⁶John P. Hussman Inst. for Human Genomics, Univ. of Miami, Miller Sch. of Med., Miami, FL, ⁷John T. MacDonald Fdn. Dept. of Human Genetics, Univ. of Miami, Miami, FL

Abstract Body:

Alzheimer's disease (AD) is one of the most common neuro-degenerative diseases with over 6.2 million people diagnosed in the US. Along with age and genetic risk factors (e.g., *APOE*), growing evidence from epidemiological studies linked various cardiovascular disease (CVD) risk factors to AD. However, whether these associations are causal to AD remain unclear. This study aims to delineate association and causal relationships between CVD risk factors and AD via polygenic risk score (PRS) and Mendelian Randomization (MR). For AD outcomes, we utilized the pooled genome-wide imputed genotype data of 9,219 AD cases and 10,345 controls from 20 cohorts of Alzheimer Disease Genetics Consortium. For exposure factors, genome-wide association study (GWAS) summary statistics of various CVD risk factors, including lifestyle factors were collected from the IEU OpenGWAS project. For each exposure factor, we compiled multiple sets of independent SNPs at different p-value thresholds (i.e., $P < 5 \times 10^{-8}$, 10^{-6} , 10^{-5}) and filtered by LD (clumping $r^2 < 0.001$) to construct optimal CVD-PRSs in the AD dataset with the best model fit. Generalized linear mixed models (GLMM) and linear mixed models (LMM) were used to test for CVD-PRS association with AD and age-at-onset (AAO) of AD, respectively, adjusting for sex, 10 principal components, and a random intercept by cohort. Causal effects were evaluated by the two-sample MR approach, where GWAS summary statistics for AD phenotypes were generated from the same GLMM and LMM models above. Markers meeting $p < 5 \times 10^{-8}$ from the exposure GWAS and not associated with AD outcomes ($p > 0.01$) were selected as instrumental variables (IV). We tested the validity and pleiotropy of IV by a heterogeneity test, and evaluated causal effects by the MR inverse variance weighted method, and then followed by sensitivity analysis using weighted median, MR-Egger, and MR-PRESSO. Our PRS analysis identified four shared CVD risk factors (coronary heart disease, hypertension, LDL cholesterol and total lipids in small LDL) associated with increasing AD risk and decreasing AAO of AD (e.g., LDL: OR (95%CI)=1.08 (1.05, 1.11), $P=1.78 \times 10^{-6}$; beta (SE)=-0.36 (0.07), $P=6.25 \times 10^{-7}$), and three additional ones showed nominal significant association with AAO of AD only. Among them, causal effects were presented in type-2 diabetes, hypertension, LDL cholesterol and total lipids in small LDL on AAO of AD, but only hypertension on AD risk. Further analysis of the expanded list of CVD biomarkers is ongoing. The findings of several CVD risk factors with causal effect on AAO of AD are novel and valuable to future development of lifestyle intervention to delay the AAO of AD and reduce AD risk.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3369. Discovery of clinically relevant gene-phenotype associations from 454,712 whole exomes in the UK Biobank

Authors:

P. Fizev¹, J. McRae², A. Metwally², T. Hamp³, Y. Yang¹, Z. Ni⁴, J. Schraiber¹, F. Aguet¹, H. Gao⁵, Y. FIELD², K. Farh⁶; ¹Illumina, Inc, Foster city, CA, ²Illumina, Inc, Foster City, CA, ³Illumina, Inc, Cambridge, United Kingdom, ⁴Dept. of Statistics, UW Madison, Madison, WI, ⁵Illumina, inc., Foster City, CA, ⁶Illumina, Foster city, CA

Abstract Body:

To what extent is a person's genetic susceptibility to common diseases, such as diabetes and cardiovascular disease, explained by a few rare genetic mutations with severe effects compared to a large collection of common variants with modest effect sizes? We employ PrimateAI-3D, a novel machine learning method for variant pathogenicity prediction with best-in-class performance, in order to identify rare deleterious variants that cause penetrant, early-onset disease across 454,712 exomes from the UK Biobank. Compared to other methods, our pipeline finds 20% more gene-phenotype associations with lower false discovery rate. Furthermore, PrimateAI-3D scores of rare missense variants in relevant genes are predictive of quantitative biomarkers and age of onset of dyslipidemia more than other pathogenicity scoring methods. We find that the majority of the population carries one or more rare penetrant variants, and that for healthy members of the general population, personal genome sequencing can reveal actionable genetic findings that strongly influence their resistance or susceptibility to disease.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3370. Discovery of rare variants associated with alcohol problems improved by leveraging machine learning phenotype prediction and empirical functional variant weighting.

Authors:

M. Ahangari¹, A. Gentry¹, R. Kirkpatrick², T-H. Nguyen¹, K. Kendler², S-A. Bacanu², R. Peterson², B. Riley², B. Webb³; ¹Virginia Commonwealth Univ., Richmond, VA, ²Virginia Commonwealth Univ, Richmond, VA, ³RTI Intl., Research Triangle Park, NC

Abstract Body:

Alcohol use disorder (AUD) is moderately heritable with significant social and economic impact. Genome-wide association studies (GWAS) have identified common variants associated with AUD. However, rare variant investigations have yet to achieve well-powered samples sizes. One strategy to increase power is to predict risk in individuals not directly measured using machine learning methods. Power may also be increased if the impact of variation on functional elements can be empirically estimated for the outcome of interest. In this study, we conducted an interval-based exome-wide analysis of Alcohol Use Disorder Identification Test Problems subscale (AUDIT-P) using both predicted risk and empirical functional weights in the UK Biobank (UKB). This research has been conducted using the UKB (application 30782). AUDIT-P was directly measured in 157,162 UKB participants and predicted using MAGIC-LASSO in the remaining 345,374 participants. Limiting the 200k exome release to unrelated individuals of European ancestry resulted in a sample of 147,386 individuals with 51,357 observed and 96,029 unmeasured but predicted AUDIT-P for exome analysis. Sequence Kernel Association Test (SKAT) was used for rare variant (MAF < 0.01) interval analyses using default and empirical functional weights. Empirical functional weights were constructed using annotations found significant by stratified LD Score Regression analysis of predicted AUDIT-P GWAS. Thus, providing prior functional weights specific to AUDIT-P. Based on the correlation between measured and predicted AUDIT-P, the effective sample size was increased by 56%. There was no evidence of inflation when using default vs empirical weights. ADH1C and THRA gene intervals were significant (FDR $q < 0.05$) using default and empirical weights. The most significant association was found using predicted AUDIT-P and empirical weights in the ADH1C gene (SKAT-O $P_{\text{Default}} = 1.06 \times 10^{-9}$ and $P_{\text{Empirical weight}} = 6.25 \times 10^{-11}$). This represents significant improvement over associations using directly measured AUDIT-P and default SKAT weights with the majority of performance increase coming from the increase in effective sample size. These findings highlight the successful leveraging of machine learning to increase effective sample size for underpowered phenotypes, and prior empirical functional weights based on common variant GWAS data to refine and increase the statistical significance in interval-based tests compared to default SKAT weights. Future directions include improving the performance of empirical functional weights in interval-based tests of rare variants.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3371. Disentangling the common genetic architecture and causality of rheumatoid arthritis and systemic lupus erythematosus with COVID-19 outcomes: genome-wide cross trait analysis and bi-directional Mendelian randomization study

Authors:

J. Zhao¹, M. Yao¹, X. Huang¹, Z. Liu²; ¹The Univ. of Hong Kong, Hong Kong, Hong Kong, ²Univ. of Hong Kong, Hong Kong, China

Abstract Body:

COVID-19 may cause a dysregulation of the immune system and has complex relationships with multiple autoimmune diseases, including rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). However, little is known about their common genetic architecture. We analysed summary-level genetic data from the latest COVID-19 host genetics consortium and international consortia to examine the shared genetic etiology and causal relationship between COVID-19 and RA/SLE. The cross-trait meta-analysis identified 46, 47, and 19 shared genetic loci for severe COVID-19, COVID-19 hospitalization, and SARS-CoV-2 infection with RA, and 19, 24, and 11 shared loci with SLE, respectively. The shared genes were enriched in the spleen, lung, whole blood, and small intestine, and are involved in immune function, inflammation and coagulation. Co-localization analysis identified eight shared loci in *TYK2*, *IKZF3*, *COL11A2*, *PSORS1C1*, *MANEAL* and *COG6* genes for COVID-19 with RA, and four in *CRHR1*, *FUT2* and *NXPE3* genes for COVID-19 with SLE. Bi-directional Mendelian randomization analysis suggested RA is associated with higher risk of COVID-19 hospitalization. Our novel findings can help better understand the common biological processes of COVID-19 and autoimmune diseases.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3372. Disentangling the genetic overlap and causal relationship between primary open-angle glaucoma, brain morphology, and major neurodegenerative disorders.

Authors:

P. Gharahkhani¹, S. Diaz-Torres^{1,2}, W. HE¹, J. ONG¹, S. Macgregor¹; ¹QIMR Berghofer Med. Res. Inst., Brisbane, Australia, ²Faculty of Med., Univ. of Queensland, Brisbane, Australia

Abstract Body:

Primary open angle glaucoma (POAG) is an optic neuropathy characterized by progressive degeneration of the optic nerve that leads to irreversible visual impairment. POAG endophenotypes such as intraocular pressure (IOP) and vertical cup-to-disc ratio (VCDR) of the optic disc are the major risk factors for POAG. Multiple epidemiological studies suggest an association between POAG or its endophenotypes and major neurodegenerative disorders (i.e. Alzheimer's disease, amyotrophic lateral sclerosis, frontotemporal dementia, and Parkinson's disease). However, the nature of the overlap between these neurodegenerative disorders, brain morphology and glaucoma remains inconclusive.

In this study, we performed a comprehensive assessment of the genetic and causal relationship between POAG, brain morphology, and the major neurodegenerative disorders specified above. Leveraging genome-wide association data from magnetic resonance imaging of more than 600 brain regions, POAG and its endophenotypes, and the four major neurodegenerative disorders, this study found a causal relationship between POAG or its endophenotypes and brain morphology in 22 regions using a Mendelian randomization (MR) framework. We also identified genetic overlap between POAG or its endophenotypes and neurodegenerative disorders using genomic structural equation modeling. However, we did not find strong evidence of causal association between the major neurodegenerative disorders and POAG or its endophenotypes using MR and genetic colocalization analyses. Similarly, the brain regions that were causally associated with the neurodegenerative disorders did not overlap with those causally associated with POAG or its endophenotypes.

To the best of our knowledge, this is the first study that comprehensively examined the genetic overlap and causal relationship between POAG, brain morphology and neurodegenerative diseases. Our findings indicate distinctive and likely independent neurodegenerative processes for POAG although several regions of the genome contribute to neurodegeneration of both the optic nerve and neurodegenerative disorders.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3373*. Distinct explanations underlie gene-environment interactions in the UK Biobank

Authors:

A. Durvasula¹, A. L. Price²; ¹Harvard Med. Sch., Boston, MA, ²Harvard Sch Pub Hlth, Boston, MA

Abstract Body:

Gene-environment interactions have been widely hypothesized to impact the genetic architecture of complex diseases and traits (Li et al. 2019 Cell). While interactions have been identified at individual loci, little is known about the overall contribution of gene-environment interactions to complex trait architectures. Here, we leverage the large size of the UK Biobank to quantify the genome-wide effects of gene-environment interactions across 49 complex traits and 8 environmental variables. We specifically assess the interaction between polygenic scores (PS) (trained in N=337K British samples; Weissbrod et al. 2022 Nat Genet) and each environmental variable (E) in N=47K non-British European validation samples, in a model that includes PS, E, and PSxE. We identified 36 significant interactions (FDR < 5%) spanning 17 traits and 7 environmental variables, although the interactions explained an average of <0.01% of trait variance (implying a <1% contribution to trait variance after summing across E variables and correcting for the partial accuracy of PS). Below, we highlight 3 examples with distinct underlying explanations. First, we identified a significant interaction between BMI PS and physical activity ($p=5E-5$); we determined that both the variance of the PS and the SNP-heritability vary as a function of physical activity, implying that the interaction is driven by changes in genetic variance. Second, we identified a significant interaction between Type 2 Diabetes PS and time spent napping ($p=5E-12$); we determined that the SNP-heritability varies as a function of time spent napping, but the variance of the PS does not, implying that the interaction is driven by changes in total environmental variance rather than genetic variance. Third, we identified a significant interaction between All Autoimmune Disease PS and alcohol consumption ($p=4E-4$); we determined that the variance of the PS varies as a function of alcohol consumption, but the SNP-heritability does not, implying proportionate effects on both genetic and total environmental variance. We identified additional interactions corresponding to each of these explanations. Overall, our results provide insights into subtle interactions between genetic and environmental variables, as well as the distinct explanations underlying the interactions.

Ctr., Providence, RI, ¹¹Cole Eye Inst., Cleveland Clinic Fndn., Cleveland, OH, ¹²Dept. of Ophthalmology, Cleveland Clinic Lerner Coll. of Med. of Case Western Reserve Univ., Cleveland, OH

Abstract Body:

Primary open-angle glaucoma (POAG) is an age-related eye disease that is the leading cause of irreversible blindness worldwide. Early POAG intervention is essential for mitigating severe outcomes. POAG is highly heritable, yet approximately 90% of the genetic component has yet to be discerned. The largest-to-date cross-ancestry POAG genome-wide association study identified 127 POAG-associated variants. Aggregating these variants via a genetic risk score (GRS) may be useful for risk stratification and informing recommendations for clinical POAG screening. We calculated 127-variant GRS for European-descent (EUR), African-descent (AFR), and Hispanic (HIS) Veterans in the Million Veteran Program. GRSs were unweighted or weighted by published cross-ancestry effect estimates. Models were either unadjusted or adjusted for age, sex, and 10 sample-specific principal components (PCs). To evaluate GRS performance, we constructed receiver operating characteristic curves and estimated the area under the curve (AUC). AUC estimates in EUR and HIS Veterans were higher than in AFR Veterans in unadjusted models; this trend was reversed in adjusted models. Consequently, we explored the estimated proportion of POAG variance explained by: (i) age and sex, (ii) age, sex, and 10 PCs, and (iii) age, sex, 10 PCs, and each GRS (unweighted and cross-ancestry meta-weighted) in our models. We calculated coefficients of determination (R^2) on the observed scale (Nagelkerke's) and the liability scale using a fixed disease prevalence of 2.4% as well as increases in R^2 with the addition of each variable to the model. We found that covariates alone (age, sex, and 10 PCs) explained a higher proportion of POAG variance in AFR Veterans (Nagelkerke's $R^2=0.103$; liability $R^2=0.063$) than in EUR and HIS Veterans (Nagelkerke's $R^2=0.002$ and 0.0343 ; liability $R^2=0.0023$ and 0.030 , respectively). Adding the unweighted GRS resulted in a larger increase in R^2 in EUR and HIS Veterans than in AFR Veterans (Nagelkerke's R^2 increase= 0.045 , 0.051 , and 0.024 ; liability R^2 increase= 0.052 , 0.046 , and 0.016 , respectively). This trend was consistent with the addition of weighted GRS (Nagelkerke's R^2 increase= 0.056 , 0.062 , and 0.03 ; liability R^2 increase= 0.065 , 0.056 , and 0.019 in EUR, HIS, and AFR Veterans, respectively). These observations suggest that, in our adjusted models, covariates alone were more informative for AFR Veterans while a GRS was more informative for EUR and HIS Veterans. Thus, these findings highlight the need for increased inclusion of diverse populations, specifically of African descent, in POAG genetics to inform the development of more equitable GRS-based tools.

PB3375. DNARecords: An extensible sparse format for petabyte scale genomics analysis

Authors:

A. Mañas Mañas¹, A. Dixit², L. Seninge³; ¹Coral Genomics, Almería, Spain, ²Coral Genomics, San Carlos, CA, ³Coral Genomics, San Francisco, CA

Abstract Body:

Recent growth in population scale sequencing initiatives involve both cohort scale and proportion of genome surveyed, with a transition from genotyping arrays to broader genome sequencing approaches. The resulting petabyte scale datasets can be challenging to analyze. Here we introduce DNARecords a novel sparse format for large scale genetic data. The structure enables integration of complex data types such as medical images and chemical structures towards the development of machine learning methods to predict disease risk and drug response. We demonstrate its speed and memory advantages for various genetics analyses including PCA and prioritizing drug targets. These performance advantages will become more pronounced as it becomes feasible to analyze variants of lower population allele frequencies. We provide an open source software plugin, built on top of Hail, to allow researchers to write and read such records as well as a set of examples for how to use them.

PB3376. DosaCNV: A deep multiple instance learning framework for jointly predicting copy number variation pathogenicity and gene dosage sensitivity.

Authors:

Z. Liu, Y. Huang; Pennsylvania State Univ., State College, PA

Abstract Body:

Since copy number variation (CNV) is a major contributor to human genetic diversity, being able to correctly predict CNV phenotypes would drastically improve our ability to understand the genetic basis of evolution and disease development. It has been shown that pathogenicity of large CNVs may be attributable to reduced or gained gene product of dosage sensitive genes. Adopting this idea, existing methods predict CNV pathogenicity mainly from two separate perspectives: (1) estimate gene-level dosage sensitive scores based on clinically curated CNVs, then use simple mathematical functions to aggregate those scores based on overlapped genes of novel CNV to make variant-level pathogenicity prediction, or (2) estimate CNV pathogenicity directly by using variant-level features such as variant length and how many dosage-sensitive genes are overlapped. However, these two perspectives should be modeled as one continuous biological process since CNV pathogenicity is a joint effect of gene dosage sensitivities. Here we present a deep multiple instance learning model, DosaCNV, which jointly models gene-level dosage sensitivity with CNV-level pathogenicity in a biologically coherent manner to improve predictions at both gene and variant level. In addition, DosaCNV uses over 40 gene-level features (genomic, epigenomic, evolutionary, functional) to capture gene dosage sensitivities. Compared to previous methods, DosaCNV shows unmatched performance in (a) predicting pathogenicity of clinically curated copy number deletions, (b) prioritizing pathogenic copy number deletions from case-control data of neurodevelopmental disorders, and (c) predicting ClinGen haploinsufficient genes. Taken together, DosaCNV has the potential to leverage large-scale CNV data to discover disease-specific essential genes and relate those genes to CNV pathogenicity, which makes DosaCNV an accurate and practical computational method for both basic and translational research.

PB3377. DrFARM: Identification and inference for master regulator variants in multi-trait GWAS

Authors:

L. Chan¹, G. Li¹, E. B. Fauman², M. Laakso³, M. Boehnke¹, P. X. K. Song¹; ¹Univ. of Michigan, Ann Arbor, MI, ²Pfizer, Cambridge, MA, ³Univ. of Eastern Finland, Kuopio, Finland

Abstract Body:

To understand the mechanism of pleiotropy in the metabolism pathway, we develop a new statistical methodology to identify master variants that involve multi-channels of genetic regulations to simultaneously influence several different traits. Advances in technologies have significantly accelerated the availability of various multi-omics data types, an unprecedented opportunity arises in the discovery of master regulator variants, such as pleiotropic variants. Existing statistical methods for this type of analysis are based mostly on testing for marginal associations of single variants with one-dimensional traits, which may lose statistical power when traits are correlated. In addition, carrying over false positives from the single-variant analyses to the pleiotropic traits analyses is problematic, leading to the finding of spurious master regulator variants. Our proposed statistical approach, termed **Debiased-Regularized Factor Analysis Regression Model (DrFARM)** aims to overcome these technical shortcomings. Built upon a joint regression model, DrFARM allows both high-dimensional genetic variants and multilevel dependencies so that several types of correlations may be incorporated into the model specification, such as kinship for relatedness and population structure. Being a one-stage analysis strategy, this joint modeling approach gives rise to the capacity of controlling an overall error and carrying out adequate uncertainty quantification for valid inferences. Taking both strengths from the debiasing technique in the high-dimensional inference and the Cauchy combination test with correlated p-values, we establish a valid post-variable selection inference on the discovery of master regulator variants. Through extensive simulations, we show DrFARM enjoys an appropriate control of the false discovery rate and exhibits desirable statistical power. In an application of the **Metabolic Syndrome in Men (METSIM)** cohort data analysis, we identified 386 potential master regulator variants at $p < 7.2 \times 10^{-11}$. Among them, two variants, rs138640017 and rs11131799, are linked to putative causal genes, GLDC and ADA, respectively. Our findings suggest vertical pleiotropy of glycine and multiple glycine adducts at GLDC and anti-correlated horizontal pleiotropy of N-acetylglucosamine and aspartate at ADA, which is consistent with their known biology.

PB3378. Effect of type 2 diabetes and its genetic susceptibility on severity and mortality of COVID-19 in UK Biobank

Authors:

W. Chung^{1,2}, A. Lee², Y. Cho², J. Li¹, T. park³, L. Liang¹; ¹Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, ²Soongsil Univ., Seoul, Korea, Republic of, ³Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract Body:

Although Type 2 diabetes (T2D) and its related-traits have been known as one of the important risk factors for the severity and mortality of COVID-19, the effect of T2D, T2D-related traits and their genetic susceptibility on COVID-19 are largely unknown. We analyzed the population-based cohort data of 459,188 individuals from UK Biobank along with COVID-19 test results and information on individuals' hospitalization and death-related records during the period from March 11, 2020 to December 20, 2021. First, we investigated the association of T2D, T2D-related traits and their genetic susceptibility of T2D with severity of COVID-19 using multivariable logistic regression and cumulative logit model adjusted for potential confounders. To capture overall genetic susceptibility for T2D, we computed polygenic risk scores (PRS) based on summary statistics from UK Biobank, representing an individual's overall genetic risk for T2D trait. In the multivariable logistic models, we found that the odds ratio (OR) of T2D for COVID-19 infection was 1.555 ($P=3.49 \times 10^{-86}$) and OR of PRS for T2D with one-unit (=standard deviation) increase in PRS was 1.064 ($P=3.11 \times 10^{-12}$) when adjusted for the potential confounders including age, gender, genotyping array and four genotype PCs, indicating the roles of T2D-related genetics in the pathogenesis of COVID-19 infection. Next, we performed multivariable Cox proportional hazard models to investigate the effect of T2D patients infected with COVID-19 on the survival times. The estimated survival curves and pairwise log-rank tests showed that the estimated hazard for COVID-19 infected T2D patients were 4.67 times ($P=9.88 \times 10^{-324}$) and 2.58 times ($P=6.20 \times 10^{-231}$) higher than individuals without COVID-19 infection and T2D, respectively and the hazard ratio (HR) of PRS for T2D with one-unit increase in PRS was 1.088 ($P=4.76 \times 10^{-14}$). Furthermore, we found the mortality of COVID-19 infected T2D patients was dramatically increased compared to T2D patients not infected with COVID-19 and the mortality of individuals with high genetic susceptibility for T2D was increased as well.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3379. Efficient multivariable Mendelian randomization for confounder adjustment using public GWAS databases

Authors:

J. Morrison; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Mendelian randomization (MR) is a form of instrumental variable (IV) analysis in which genetic variants are used as instruments to test for and estimate the causal effect of an exposure on an outcome. Recently, MR has become increasingly popular, in part because it can be performed using on summary statistics from genome-wide association studies (GWAS) which are readily and publicly available. However, genetic variants often display horizontal pleiotropy, a violation of standard MR assumptions in which variants affect the outcome through pathways not mediated by the exposure of interest. Horizontal pleiotropy mediated by heritable confounders is particularly problematic because it leads to systematic correlation in variant-exposure and variant-outcome associations that is not reflective of a causal effect. If heritable confounders are known or suspected, multivariable MR (MVMR) can be used to adjust for the confounding bias. As the number of GWAS with available summary statistics increases, this strategy becomes a promising option for obtaining accurate causal estimates. However, existing MVMR methods perform poorly for moderate or large numbers of traits, suffering either from bias that increases dramatically with the number of included traits or untenable computational demands. We propose an alternative MVMR method using a fast variational algorithm to optimize the joint likelihood, called Empirical Shrinkage Mendelian Randomization (ESMR). We show that ESMR has low bias regardless of the number of traits included and has computational time scaling linearly in the number of adjusted traits. In addition to performing well in the multivariable setting, ESMR is unbiased in the univariable case, even when the exposure GWAS is under-powered, a setting where alternative methods have large weak-instrument bias. Additionally, we propose a semi-automated algorithm for identifying heritable confounders in public GWAS databases, which can then be adjusted for using ESMR. This creates a pipeline that allows researchers to inform their MR analyses using existing wealth of GWAS results.

PB3380. Efficient tests of marginal epistasis reveal the impact of interactions on complex traits

Authors:

A. Pazokitoroudi, B. Fu, S. Sankararaman; Univ. of California, Los Angeles, Los Angeles, CA

Abstract Body:

The contribution of epistasis (gene-gene interaction) to human complex trait variation remains poorly understood. Methods that aim to explicitly identify pairs of SNPs associated with a trait suffer from low power due to the large number of hypotheses tested. An alternate approach involves testing whether a single SNP modulates variation in a trait against the background of all (or a subset of) SNPs across the genome. While overcoming the limitation of low power, tests of marginal epistasis are infeasible on Biobank-scale data where hundreds of thousands of individuals are genotyped over millions of SNPs. We present a scalable method to estimate the marginal epistatic effect. Our algorithm is a streaming randomized method-of-moments estimator that has a runtime sub-linear in the size of the genotype matrix while using a constant amount of memory thereby able to test for epistasis of a single SNP with a background of half a million SNPs across ~300K individuals in a few hours. Across extensive simulations, we find that our method accurately estimates additive and epistatic effects across a range of genetic architectures while also controlling false positive rates.

We applied our method to 16914 trait-loci pairs corresponding to 10846 loci associated with 57 traits ($p < 5e-8$) in GWAS to discover 346 trait-loci pairs (254 loci across 34 traits) with significant evidence for marginal epistasis ($p < 5e-8$). We validated 183/346 pairs as remaining significant by testing on imputed genotypes and as being robust to population stratification.

We then partitioned significant marginal epistatic effects with respect to the same vs distinct chromosomal regions to find 16/346 (on the same chromosome) and 76/346 (on the distinct chromosomes) trait-loci pairs with statistically significant epistasis effects. Notable examples of marginal epistasis include loci for mean platelet distribution width and blood monocytes phenotypes are located on *TUBB1* and *FLT3* genes respectively ($p < 1e-50$). Our results provide evidence for epistatic effects underlying complex traits that can now be interrogated in large sample sizes.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3381*. Elucidate trans-ancestry cross trait genetic architecture for tobacco and alcohol use phenotypes using 3 million Individuals.

Authors:

X. Wang, GWAS and Sequencing Consortium of Alcohol and Nicotine Use; Penn State Coll. of Med., Hershey, PA

Abstract Body:

Genome-wide association meta-analysis (GWAMA) is a useful approach to improve the power of detecting associations using summary statistics. Recently, GWAMA starts to include non-European samples to further improve power, pinpoint causal variants, and elucidate genetic architecture. Genetic effects may differ among ancestries, due to genetic and non-genetic influences. Modeling the trans-ancestry genetic effect distribution will improve the power for association analyses, quantify the extent of genetic heterogeneity, and elucidate cross-trait genetic architecture. Borrowing ideas from analysis of variance, we propose a mixed effect meta-regression model MEMO to partition the genetic effects into components that remain constant across ancestries, vary with ancestries, and vary independently of ancestries. We use principal components of allele frequencies from each study as a proxy for ancestry to capture genetic effects variation. The intercept of the model captures shared effect across ancestries. We further use a random effect to capture how genetic effects vary independently from ancestries. By imposing a Dirichlet-Multinomial prior on regression coefficients, MEMO borrows strength across variants, learns the genetic trans-ancestry effect distribution, and fine-maps causal variants. We apply our method to 21 cohorts of tobacco and alcohol use traits, including 23andMe, UK BioBank, Biobank Japan and China Kadoorie Biobank, with 3 million samples (79% European, 9.2% East Asian, 8.8% Admixed American, 3% African American), and discover 722 loci ($p < 5e-9$) across five traits, where 124 loci are novel compared to other methods. Our method fine-maps 23% of loci to less than 6 variants, significantly improving over ancestry-specific results. On average, 78% of loci show a homogenous effect. 14% of the loci are best supported by a model with distinct effects between European and Asian ancestry. In MEMO model, by using components that remain constant across ancestries, defined as partial residual, we observe 0.1 increase ($p = 3e-20$, t-test) in genetic correlation estimates. Moreover, within-trait genetic correlation increased from 0.61 to 0.78 ($p = 5e-15$) with across-traits from 0.36 to 0.45 ($p = 1e-14$). Additionally, genetic correlations rise for studies with different ancestry (0.38 vs 0.53, $p = 2e-28$), while preserve for the same ancestry studies (0.45, $p = 0.75$). Our results indicate partial residual can better capture genetic correlation, especially for studies with different ancestries. Together, our results represent a significant step forward in understanding the genetic architecture of tobacco and alcohol use in trans-ancestry samples.

Hlth.Sci., Keck Sch. of Med., Los Angeles, CA, ¹²Dept. of Quantitative and Computational Biology, Univ. of Southern California, Los Angeles, CA

Abstract Body:

Admixture mapping is a powerful alternative to genome-wide association studies. The heritability explained by local ancestry, h_A^2 , which serves as a proxy measure for the narrow-sense heritability h^2 , also provides crucial insight into the genetic architecture of a disease or trait. However, current approaches to estimate h_A^2 are computationally limiting for large-scale datasets, and are susceptible to biases due to stratification in ancestral populations. Although existing summary statistics-based methods developed for GWAS distinguish biases from heritability, they fail to fully capture the extensive correlations between markers. Here, we present a novel method, Heritability estimation from Admixture Mapping Summary Statistics (HAMSTA), which uses admixture mapping summary statistics to infer variance components due to local ancestry effects and to distinguish biases due to ancestral stratification. HAMSTA takes into account the long-range nature of the local ancestry correlations, which is crucial for accurate inference. Through extensive simulations, we first demonstrate that HAMSTA computes unbiased estimates of h_A^2 in presence of ancestral stratification, in contrast to estimates obtained from GREML and LDSC. Second, across a range of trait architectures, HAMSTA provides unbiased estimates of biases due to ancestral stratification in observed test statistics with greater precision than LDSC, resulting in $\sim 10\times$ more statistical power on average. Lastly, we find that using a significance threshold corrected by HAMSTA estimates achieves a family-wise error rate of $\sim 5\%$, unlike existing approaches for FWER estimation in admixture mapping. Having demonstrated that HAMSTA is unbiased and more powerful compared to individual-level and other summary-data based approaches, we applied HAMSTA to 26 phenotypes of 17,299 African American individuals in Population Architecture using Genomics and Epidemiology (PAGE) study. We observed significant h_A^2 in 15 phenotypes with an average $h_A^2 = 0.016$ (SD = 0.013), which translates to an average $h^2 = 0.49$ (SD = 0.39). Estimates of h_A^2 are consistent with previous work, where the derived h^2 of height and BMI are estimated to be 0.86 (SE = 0.083) and $h^2 = 0.34$ (SE = 0.095) respectively, and white blood cell count shows highest h_A^2 due to selection at causal variants. The estimated inflation factors have an average of 1.00 (SD = 0.02), suggesting little evidence of bias due to ancestral population stratification in current admixture mapping studies. Overall, HAMSTA provides a fast and powerful approach to estimate genome-wide heritability and biases using summary statistics from admixture mapping studies.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3383. Estimating indirect maternal genetic effects on children's autism spectrum disorder risk

Authors:

Y. Wu, Z. Sun, Q. Lu; Univ. of Wisconsin-Madison, Madison, WI

Abstract Body:

The etiology of autism spectrum disorder (ASD) involves substantial genetic and environmental components as well as their complex interplay. One particular type of gene-environment interplay that caught many geneticists' attention is "genetic nurture": parents' genotypes could influence parental behavior and family environment which in turn affects children's phenotypes. Due to the correlation between parents' and children's genotypes, genetic effect estimates in a regular genome-wide association study (GWAS) are mixtures of direct effects (one's genotypes affecting one's phenotypes) and indirect genetic effects (one's genotypes affecting their children's phenotypes). Careful dissection of direct and indirect genetic effects has revealed strong evidence of maternal indirect effects on birth weight and cognition and have fundamentally changed our understanding of the genetic basis of these traits. Here, we employed an unconventional study design to search for evidence of indirect maternal effects on ASD risk, leveraging a large number of trios of ASD probands and healthy parents from SPARK and Simons Simplex Collection cohorts. We performed a GWAS where the mothers and fathers of ASD probands were coded as cases and controls, respectively ($N = 10,496$). Conditional on children being ASD cases, and assuming no indirect paternal genetic effect, this GWAS estimates the indirect maternal genetic effect on children's ASD risk. We found a suggestive association (rs79371708; $P = 2.4E-7$) at the *TAF4* locus which is a known causal gene for ASD. Complementary to the maternal effect GWAS, we then performed a transmission disequilibrium test GWAS using the same ASD trios, which estimates the effects of transmitted variants alone and thus quantifies the contribution of direct genetic effects. Direct and maternal ASD effects had a moderate genetic correlation of 0.45 ($SE = 0.2$), suggesting a substantially different genetic basis. Genetic correlations between direct/maternal ASD effects and other complex traits also showed divergent patterns. We found significant correlations between maternal ASD effects and major depression, cigarette smoking, and a younger age at first birth. Instead, direct genetic effects on ASD showed significant correlations with cognition and educational attainment. These results showed compelling evidence for indirect maternal genetic effect on ASD and provided critical new insights into how self and maternal genotypes jointly influence ASD risk in children.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3384. eVai's "Suggested Diagnosis" feature: a new AI-based method to increase diagnostic yield in Rare Disease Patients

Authors:

G. Nicora¹, F. De Paoli¹, **I. Limongelli**¹, E. Rizzo¹, R. Bellazzi², P. Magni², S. Zucca¹; ¹enGenome srl, Pavia, Italy, ²Dept. of Electrical, Computer and BioMed. Engineering, Univ. of Pavia, Pavia, Italy

Abstract Body:

Introduction

Variant interpretation (VI) is a complex process whose aim is to identify pathogenic events. The ACMG/AMP guidelines define a widely adopted five-tier system to interpret genomic variants. Despite the importance of these guidelines, class-based systems may not be effective in clinical settings, when thousands of variants per-proband need to be examined to detect few causatives. eVai (www.engenome.com) is a SaaS platform that classifies variants according to ACMG/AMP guidelines. To further boost VI, eVai is equipped with a new feature to Suggest the Diagnosis through a machine learning approach that prioritizes proband's variants according to their clinical score.

Materials and Methods

We developed a "Suggested Diagnosis" model, that assigns a clinical score to each variant based on 3 features sets accounting for: 1) variant pathogenicity including the eVai score proportional to the ACMG/AMP levels of evidence; 2) phenotypic similarity based on Human Phenotype Ontology Terms provided by the user; 3) family segregation information. Outputted clinical scores are exploited to rank probands' variants and to suggest putative causatives. The model was trained on a large in-house dataset of bona-fide variants from diagnosed patients and their family members. We applied this model within the Rare Genome Project CAGI 6 (Critical Assessment of Genome Interpretation) challenge, led by experts at the Broad Institute of MIT and Harvard.

We selected 30 challenging samples from the "Deciphering Developmental Disorder" (DDD) study (PMID:25533962) for which 43% of the causative variants were VUS/LB with a PS <5. We compared this clinical score with eVai's PS.

Results

Our model resulted as a best performer among worldwide solutions on CAGI probands, and it enabled the diagnosis of 2 unsolved cases, increasing the diagnostic yield by 12.5%. On 30 DDD probands, the causative variants were ranked in the top 20 positions by their clinical score in 28 cases, while the eVai score ranked the causative in the top 20 positions in 19 cases.

Conclusion

We developed a Suggested Diagnosis methodology combining guidelines, phenotypic and family information. As demonstrated by the international CAGI 6 RGP challenge, our method ranks causatives in top positions, enhancing diagnostic yield in Rare Patients. On sampled DDD cases, the Suggested Diagnosis boosts eVai's capability to pinpoint the correct diagnosis in the very first positions by 33%.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3385. Evaluating differential expression of imputed miRNA expression in the subgenual anterior cingulate cortex.

Authors:

J. Drake^{1,2}, Z. Taylor^{1,2}, A. Denham^{1,2}, N. Gillespie³, S-A. Bacanu³, J. Shin⁴, T. Hyde⁴, V. Vladimirov^{1,2,4}, ¹Texas A&M Univ., College Station, TX, ²Dept. of Psychiatry, Coll. of Med., Univ. of Arizona, Phoenix, AZ, ³Virginia Commonwealth Univ., Richmond, VA, ⁴Lieber Inst. for Brain Devel, Baltimore, MD

Abstract Body:

Background: As the disease-relevant organ in psychiatric disorders is the brain, postmortem brain gene expression (GE) studies have been conducted to elucidate the neuropathological changes associated with mental disorders. MiRNAs, a class of small non-coding RNAs, have been shown to play important role in regulating gene expression. However, a major challenge using postmortem brain tissues is the presence of a myriad of potential confounds. Thus, to mitigate these issues, several GE imputation algorithms (such as PrediXcan) were developed that impute GE using genomic and expression data in unrelated subjects. In this study, we use PrediXcan to impute miRNA expression in brain and incorporate neuronal cell fractions to improve accuracy. **Methods:** We used miRNA expression data from a large postmortem brain sample and identified 947 miRNAs in 280 subjects (142 MD cases and 138 controls), on whom we also have available GWAS data. For increased robustness, we applied a 10-fold cross-validated elastic net model for each miRNA. To increase the accuracy of our models, we included cell brain fractions, which were derived using single cell GE data in CIBERSORT. Models with an average coefficient of determination (R^2) > 0.01 and a Z-score p-value < 0.05 were retained and used to impute the miRNA expression from the genotype information alone. To validate our ability to impute expressions for disease relevant miRNAs, a differential expression (DE) analysis on the imputed miRNAs was done and compared to the measured DE analysis. **Results:** In the model containing genomic and expression data only, 89 miRNAs were retained (average $R^2 \geq 0.16$), of which 9 miRNA were found to be DE and 5 overlapping with the measured DE analysis. The inclusion of cell fractions in the model led to a substantial increase in the number of miRNAs with imputed expressions, i.e., 518 miRNAs were retained (average $R^2 \geq 0.23$) with 41 DE and 8 overlapping with the measured DE analysis. We observed the inclusion of cell fractions to has a significantly more pronounced effect on the accuracy and number of imputed miRNA. We further observed that the impact of cell fractions on the accuracy of miRNA GE is more pronounced for miRNA whose expression is in the top quantile (TMM log2 mean expression of 9.27) compared to the bottom quantile (TMM log2 mean expression of -0.17), i.e., R^2 of 0.26 vs 0.12, respectively; Welch Two Sample t-test p-value = 4.3×10^{-12} . **Conclusion:** Here we've expanded on previous gene imputation efforts by modeling miRNA in the subgenual anterior cingulate cortex. Additionally, the inclusion of cell fractions highlights how tissue heterogeneity and expression levels impact imputation accuracy.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3386. Evaluating human genetic evidence for existing drug targets in the UK Biobank

Authors:

G. McInnes, D. Jakubosky, A. Leverentz, Z. Romer, B. Gonzalez, N. Karra, B. Cajés, S. Bruse, O. Gottesman; Empirico Inc., San Diego, CA

Abstract Body:

Approximately 90% of drugs that enter clinical trials fail due to insufficient efficacy or concerns regarding safety. Previous studies have shown that drug targets with supportive human genetic evidence for the target-indication pair are up to twice as likely to proceed from phase 1 to approval as those without, providing a strong rationale for incorporating human genetics into the drug discovery process at the earliest possible stage. Large-scale biobanks linked with rich phenotypic information enable the evaluation of associations between sequence variants and thousands of clinically and therapeutically-relevant phenotypes. Analyses focused on genetic variation that is predicted to modulate the function or abundance of a given protein can provide insight into the phenotypic effects of targeting that protein pharmacologically. Rare nonsynonymous variants, particularly loss-of-function variants (LoFs), are among the most powerful naturally occurring tools for understanding the phenotypic effects of pharmacological modulation of a target, however, previous studies investigating genetic support for existing drug targets have largely focused on evaluating associations with common variants in the target gene locus. We utilized data from up to 452,401 individuals in the UK Biobank to evaluate associations between rare nonsynonymous variants in approximately 700 drug target genes (representing over 1,500 drugs), their approved indications and known adverse effects. Indications and adverse/side effects for the approved drugs were derived from Open Targets and mapped to relevant phenotypes in the UK Biobank. Rare predicted-deleterious variants in drug target genes and gene burdens (aggregating carriers of those variants) were tested for association with more than 3,800 paired approved indications using whole genome regression analysis. We find that a substantial proportion of genes targeted by approved drugs have supportive genetic evidence for their approved indication or a related phenotype. Additionally, by conducting phenome-wide association analyses across thousands of binary and quantitative phenotypes, we find an enrichment for phenotypes representing known adverse and side-effects. We further delineate results by mechanism of action (i.e., agonist vs. antagonist), therapeutic area, and target gene conservation. Overall, this study highlights the prevalence of genetic evidence for approved drugs, and the utility of rare nonsynonymous variants as powerful tools for drug discovery and development. This research has been conducted using the UK Biobank Resource under Application Number 34229.

PB3387*. Evaluating strategies to infer continental ancestry using single-cell RNA-seq datasets: an application to the Human Cell Atlas

Authors:

J. Yao¹, S. Gazal^{2,3}; ¹Biostatistics, Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, ²Dept. of Population and Publ. Hlth.Sci., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA, ³Ctr. for Genetic Epidemiology, Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA

Abstract Body:

Characterizing the ancestry of samples in genetic and genomic studies is critical to ensure homogeneity of the datasets or to depict ancestry-specific patterns. Single-cell RNA-seq (scRNA-seq) has emerged as a powerful technique to investigate genome regulation at the cell-type level. However, the information on the ancestry of the samples is often not available. Although it should be feasible to infer ancestry using genetic polymorphisms detected on the reads of scRNA-seq datasets, the low number of polymorphisms present in RNA and genes expressed in scRNA-seq make it unclear how accurate such an approach would be.

Here, we developed and evaluated a pipeline to detect genetic polymorphisms (SNPs) present in scRNA-seq datasets and assessed different strategies to infer the continental ancestry of a sample. First, we developed a pipeline using the recommended GATK pipeline on RNA-seq datasets and a quality control procedure optimally selecting SNPs and samples. Second, we applied this pipeline to detect polymorphisms on four large human scRNA-seq datasets of the Human Cell Atlas (HCA; 217 samples from four different tissues). Third, we compared the accuracy of two probabilistic methods inferring the ancestry of an individual. We considered an estimator based on principal component analysis (PCA) and supervised analyses from the admixture software (Alexander et al. 2009). We used 3,481 sequenced individuals from 67 populations of 6 continental groups from the 1000 Genomes and HGDP projects (1000G+HGDP) to define our reference ancestry datasets. To evaluate these methods, we compared ancestry predictions on each population at a time after removing it from the reference ancestry datasets during each analysis.

We detected between 7,126 and 19,762 common SNPs in the 4 HCA datasets (between 3,272 and 7,320 after pruning to reduce linkage disequilibrium). With these sets of pruned SNPs, PCA and Admixture yielded an average prediction error rate of 0.84% and 0.20%, respectively (vs. 0.23% and 0.06% when using all common sequenced variants) within 1000G+HGDP. When applying Admixture (error rates lower than PCA) to the 4 HCA datasets, we consistently observed a high fraction of European ancestry within samples (mean = 88%, median = 96%), indicating the lack of ancestry diversity across datasets. To summarize, our results highlight that continental ancestry could be estimated as accurately when using genetic polymorphisms from scRNA-seq datasets as when using all present polymorphisms. The application to the HCA also demonstrates the lack of ancestry diversity in publicly available scRNA-seq datasets.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3388. Evaluating the accuracy genotype imputation in selected African populations.

Authors:

R. Nanjala; ICIPE, Nairobi, Kenya

Abstract Body:

The Human Leukocyte Antigen (HLA) region plays an important role in autoimmune and infectious diseases. HLA is a highly polymorphic region and thus difficult to impute. We, therefore, sought to evaluate HLA imputation accuracy, especially in an African population due to their high genetic diversity, and this has not been extensively studied. The study sets were selected from the Gambian individuals within the Gambian Genome Variation Project (GGVP) datasets. The Illumina Omni 2.5 array and H3Africa array data were masked from the GGVP datasets using matching markers. The reference datasets were chosen from the 1000 Genomes population (1kg-All), 1000 Genomes African subpopulation (1kg-Afr), 1000 Genomes Gambian subpopulation (1kg-Gwd), Human Hereditary and Health in Africa (H3Africa) population and the HLA multiethnic population via the Michigan imputation server. HLA-A, HLA-B, and HLA-C alleles were imputed using HIBAG, SNP2HLA, CookHLA and Minimac4. The assessment metric was concordance rate. The best performing tool was HIBAG while the best performing reference panel was the H3Africa reference. The H3Africa array and Illumina Omni 2.5 array performance were comparable showing that genotyping arrays have less influence on HLA imputation in African populations. These findings show that using a larger population-specific reference and HIBAG tool improves the accuracy of HLA imputation in African populations.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3389. Evaluating the impact of parallel mutations on the accuracy of statistical phasing

Authors:

A. Beck¹, Y. Si², H. Kang³, S. Zollner⁴; ¹Univ. of Michigan Sch. of Publ. Hlth., Ann Arbor, MI, ²Univ. of Michigan, Ann Arbor, MI, ³Univ Michigan, Ann Arbor, Ann Arbor, MI, ⁴Univ Michigan, Ann Arbor, MI

Abstract Body:

With the advent of large studies such as TOPMed and UKBB, sequencing data for hundreds of thousands of diverse individuals can allow for the interrogation of rare variants and their functional associations with complex traits. However, many analyses require phased sequencing data, and modern statistical phasing algorithms routinely generate thousands of switch errors per genome. These errors limit the accuracy in which genotypes can be imputed and also impact our ability to identify high-interest variants amongst the myriad of rare variants discovered in large sequencing studies. A potential contributor to such phasing errors is recurrent mutation, which have recently been observed to occur more commonly along the genome than previously thought. Such parallel mutations lead to variants identical by state to appear in multiple haplotype backgrounds.

To assess the performance of phasing algorithms and the influence of recurrent mutation, we simulate diploids with known phasing by pairing male X chromosomes from the 1000 Genomes Project deep-sequencing data. We then infer the phase using SHAPEIT4, EAGLE2, and BEAGLE5 and compare the results to the known phase to generate distributions of errors. On average BEAGLE5 introduces total errors at a higher rate (0.0159 errors per heterozygous site) than both EAGLE2 (0.0148) and SHAPEIT4 (0.0142). In contrast, SHAPEIT4 introduces flips, the occurrence of consecutive switches at heterozygous sites, at the highest rate among the methods, with 0.0058 flips per heterozygous sites compared to EAGLE2 and BEAGLE5's rates of 0.0053 and 0.0052, respectively. The location of phasing errors is highly correlated between methods. To evaluate the impact of parallel mutation, we assess the frequency of CpGs at switch errors and flips, as these sites have the highest mutation rate and typically show evidence of parallel mutations. We find that across all three methods, around 15% of switches and flip errors occur at CpGs, while CpGs constitute 14% of all heterozygous sites, a 1.08-fold enrichment. We also assess the enrichment of other highly mutable subtypes among the locations of phasing errors. Our results show a mild enrichment for CpGs at flips and switches, suggesting that parallel mutations are only a minor contributor to errors in statistical phasing at the site of the mutation. To ensure that this result is not specific to CpGs, other genomic contexts shown to be associated with recurrent mutation should be assessed for enrichment among phasing errors. Further analysis is required to understand if modeling of parallel mutation may improve the statistical inference of phase.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3390. Evaluation of GENESIS, SAIGE and REGENIE for genome-wide association study of binary traits in correlated data

Authors:

A. Gurinovich¹, A. Leshchik², M. Li², H. Bae³, Z. Song⁴, T. Perls⁵, P. Sebastiani¹; ¹Tufts Med. Ctr., Boston, MA, ²Boston Univ., Boston, MA, ³Oregon State Univ., Corvallis, OR, ⁴Boston Univ. Sch. of Publ. Hlth., Allston, MA, ⁵Boston Univ. Sch. of Med., Boston, MA

Abstract Body:

Performing a genome-wide association study (GWAS) with a binary phenotype using family data is a challenging task. Using linear mixed effects models is typically unsuitable for binary traits, and numerical approximations of the likelihood function may not work well with rare genetic variants with small counts. Additionally, imbalance in the case-control ratios poses challenges as traditional statistical methods such as the Score test or Wald test perform poorly in this setting. In the last couple of years, several methods have been proposed to better approximate the likelihood function of a mixed effects logistic regression model that uses Saddle Point Approximation (SPA). SPA is implemented in GENESIS, SAIGE and REGENIE software: three increasingly popular tools that were developed to perform GWAS of binary traits in correlated data. We compared Score and SPA tests using real family data to evaluate computational efficiency and the agreement of the results. Additionally, we compared various ways to adjust for family relatedness, such as sparse and full genetic relationship matrices (GRM) as implemented in both GENESIS and SAIGE, and polygenic effect estimates as implemented in REGENIE. We used the New England Centenarian Study imputed genotype data and the binary phenotype of human extreme longevity to compare the agreement of the results and tools' computational performance. The evaluation suggests that all softwares produce similar, although not identical, results, with SPA adjustment performing better than Score tests. Our evaluation also demonstrates the importance of adjusting by full GRM, especially in small datasets with family data.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3391. Evaluation of germline variants in pediatric low grade glioma using non-negative matrix factorization

Authors:

L. Chapman Hannah^{1,2}, J. Kim¹, D. Stewart¹, Z. Boukouvalas²; ¹Natl. Cancer Inst., Rockville, MD, ²American Univ., Washington, DC

Abstract Body:

Approximately 8-10% of children with cancer harbor rare, pathogenic or likely pathogenic (P/LP) germline variants in known tumor-predisposition genes. Common variants have smaller effect sizes and collectively may affect risk. Most children with brain tumors, however, do not harbor known risk variants. To identify additional risk alleles, we used non-negative matrix factorization (NMF), a feature-reduction algorithm commonly used in somatic mutation analysis, to evaluate common and rare germline variants in a set of low grade gliomas (LGG) from the Pediatric Cancer Genome Project (PCGP) and the St. Jude LIFE (SJLIFE) Study. NMF is an unsupervised method that reduces high dimensional feature spaces to a latent feature space. In this pilot study, variants from chromosomes 17 (harboring known tumor-predisposition genes TP53, NF1 and BRCA1) and 18 (control chromosome) were evaluated. Whole genome sequencing (WGS) data from 51 LGG patients and 44 non-cancer controls from PCGP and SJLIFE were downloaded from St. Jude Cloud. Single nucleotide variants (SNVs) from WGS were called using an ensemble-based pipeline (GEMSCAN) and then filtered based on a set of quality metrics. In the following study NMF was used to identify a latent set of features (variants) within chromosomes 17 and 18, and as a result we are able to evaluate underlying groups within the data. We hypothesized that distinct clusters of cases and controls can be identified within chromosome 17. The analysis included 610,536 germline variants from chromosome 17 for NMF analysis, and 637,822 germline variants for chromosome 18. In this study, NMF is used to extract sets of germline variants from a high dimensional feature space from patients and non-cancer controls. As hypothesized, there was a higher frequency of variants in cancer susceptibility genes in cases versus controls within chromosome 17. NMF-based clustering showed the greatest separation between cases and controls in two regions of chromosome 17 : chr17: 29361553-33291117, which contains NF1 (known to increase risk for brain tumors) and chr17:60189-121767 which contains lincRNA RP11-1228E12.2. The results of these studies could help identify putative germline variants that collectively contribute to cancer risk.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3392. Exome sequencing of 628,388 individuals identifies common and rare variant associations with clonal hematopoiesis phenotypes

Authors:

Abstract Body:

Clonal hematopoiesis (CH) refers to the expansion of certain blood cell lineages and has been associated with aging and adverse health outcomes. Here, we use exome sequence data on 628,388 individuals to identify 40,208 carriers of clonal hematopoiesis of indeterminate potential (CHIP). Using genome-wide and exome-wide association analyses, we identify 24 loci (20 novel) where germline genetic variation influences CHIP predisposition, including missense variants in the DNA-repair gene *PARP1* and the lymphocytic antigen coding gene *LY75* that are associated with reduced incidence of CHIP. We also identify novel rare variant associations with CH and telomere length. Analysis of 5,041 health traits from the UK Biobank (UKB) found relationships between CHIP and severe COVID outcomes, cardiovascular disease, hematologic traits, malignancy, smoking, obesity, infection, and all-cause mortality. Longitudinal and Mendelian Randomization analyses revealed that CHIP is associated with solid cancers, including non-melanoma skin cancer and lung cancer, and that *DNMT3A*-CHIP is associated with the subsequent development of myeloid but not lymphoid leukemias. Our findings demonstrate that CHIP represents a complex set of heterogeneous phenotypes with shared and unique germline genetic causes and varied clinical implications.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3393. Exploiting the mediating role of the metabolome to unravel transcript-to-phenotype associations

Authors:

E. Porcu^{1,2,3}, C. Auwerx^{1,2,3,4}, M. Sadler^{2,3}, A. Reymond¹, Z. Kutalik^{2,3,4}, ¹Ctr. for Integrative Genomics, Univ. of Lausanne, Lausanne, Switzerland, ²Swiss Inst. of Bioinformatics, Lausanne, Switzerland, ³Univ. Ctr. for Primary Care and Publ. Hlth., Lausanne, Switzerland, ⁴Dept. of Computational Biology, Univ. of Lausanne, Lausanne, Switzerland

Abstract Body:

Despite the success of genome-wide association studies (GWASs) in identifying genetic variants associated with complex traits, understanding the mechanisms behind these statistical associations remains challenging. Several methods that integrate methylation, gene expression, and protein quantitative trait loci (metQTLs, eQTLs and pQTLs, respectively) with GWAS data have been proposed to determine their causal role in the path from genotype to phenotype. However, the role of metabolic QTLs (mQTLs) is still underexplored. Here, we developed and applied a multi-omics Mendelian randomization (MR) framework to study how metabolites mediate the effect of gene expression on complex traits. In particular, we combined GWAS, eQTL, and mQTL data in an integrative MR analysis consisting of three steps. First, we map the transcriptome to the metabolome by identifying causal associations between transcripts and metabolites. Next, we screen the metabolites for downstream causal effects on 28 complex phenotypes, resulting in the identification of gene expression -> metabolite -> phenotype cascades. In parallel, we prioritize trait-associated genes by testing the association of transcripts with phenotypes. Third, for transcripts identified in at least one of the previous steps we test whether the identified target genes exert their effect on the phenotype through the metabolite using multivariable MR. In total, we identified 206 transcript-metabolite-trait causal triplets. Sixty-seven of these associations were missed by classical transcriptome-wide MR, which only uses gene expression and GWAS data. Among these, we identify biologically relevant pathways, such as between *ANKH* and calcium levels mediated by citrate and *SLC6A12* and serum creatinine through modulation of the levels of the renal osmolyte betaine. We show that the signals missed by transcriptome-wide MR are found thanks to the gain in power allowed by integrating multiple omics-layer. Furthermore, through extensive power analyses we show that with larger molecular QTL studies and in case of mediated effects, our multi-omics MR framework outperforms classical MR approaches designed to detect causal relationships between single molecular traits and complex phenotypes.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3394. Exploring germline genetics of *in situ* and invasive cutaneous melanoma

Authors:

N. Ingold^{1,2}, M. Seviiri¹, J. ONG¹, D. R. Nyholt², R. E. Neale¹, N. Pandeya¹, D. C. Whiteman¹, C. M. Olsen¹, N. G. Martin¹, D. Duffy¹, K. Khosrotehrani³, G. Montgomery⁴, N. hayward¹, S. Macgregor¹, M. H. Law¹; ¹QIMR Berghofer, Brisbane, Australia, ²Queensland Univ. of Technology, Brisbane, Australia, ³The Univ. of Queensland Diamantina Inst., Woolloongabba, Australia, ⁴Univ. of Queensland, St Lucia, Australia

Abstract Body:

While incidence rates of cutaneous melanoma have risen dramatically over recent decades, mortality rates have remained stable. This is partly due to a sharp increase in diagnosis of *in situ* melanoma over the same time period. Risk of cutaneous melanoma has a large germline genetic component relative to other cancers, but it is unclear if there are specific genetic risks for invasive vs. *in situ* melanoma. Detecting differences in germline risk of *in situ* vs invasive melanoma may provide insights that benefit melanoma screening and surveillance programs.

We performed a series of GWAS meta-analysis (including UK Biobank, QSkin Sun and Health Study, Queensland Study of Melanoma (Q-MEGA), and FinnGen) of invasive vs controls, *in situ* vs controls and invasive vs *in situ* to identify genetic loci associated with a diagnosis of invasive melanoma. The effect estimates generated from the invasive vs *in situ* GWAS were then used to generate a polygenic risk score (PRS) to assess associations between genetic risk *in situ* vs invasive status and invasive melanoma.

The GWAS of invasive (n= 7039) vs controls (n= 649048) identified 14 loci previously associated with melanoma, the *in situ* (n= 2961) vs controls GWAS identified 5 loci, of which the *IRF4* and the *GPR98* loci appeared only for *in situ*. The genetic correlation between *in situ* and invasive was indistinguishable from 1 (rg=0.98, 95% CI = 0.67 to 1.3). The *in situ* vs invasive GWAS revealed one genome-wide significant SNP (rs4566922, P= 3.263e-10, near gene *SLC35B3*) on chromosome 6. We will report on PRS results.

There was considerable overlap in genes detected for *in situ* vs invasive, as expected. We found two loci unique to the *in situ* vs. control GWAS that have previously been reported as melanoma GWAS loci, and one potentially novel loci in the case-case GWAS. While it is difficult to characterize a mechanism for *SLC35B3*'s role in differential melanoma diagnoses, identifying differing genetic loci between *in situ* and invasive melanoma could indicate differing underlying genetics influencing individual risk of an invasive or *in situ* melanoma. Building a PRS around the heritable difference in risk between invasive vs *in situ* melanoma has the potential to help reduce overdiagnosis by shifting screening away from lower risk and towards higher risk individuals. More work is needed to identify, and replicate, genetic loci associated with melanoma status.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3395. Exploring the genetic, socio-economic and environmental determinants of drug adherence

Authors:

M. Cordioli¹, A. Corbetta¹, H. Kariis², S. Jukarainen¹, T. Kiiskinen¹, FinnGen Study, Estonian Biobank research team, S. Ripatti^{1,3,4}, L. Milani², A. Ganna^{1,5,3}; ¹Inst. for Molecular Med. Finland, Univ. of Helsinki, Helsinki, Finland, ²Estonian Genome Ctr., Inst. of Genomics, Univ. of Tartu, Tartu, Estonia, ³Broad Inst. of MIT and Harvard, Cambridge, MA, ⁴Dept. of Publ. Hlth., Univ. of Helsinki, Helsinki, Finland, ⁵Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA

Abstract Body:

One of the major factors behind the efficacy of pharmacological treatments is patients adherence to their prescribed regimen. A comprehensive investigation combining both genetic and socioeconomic factors is lacking. By leveraging genetic data from FinnGen (N = 356,077, >68 million drug purchases) and nationwide socio-economic and health data from FinRegistry (N=5.5 million, > 790 million purchases), we provide a systematic investigation of adherence determinants across 5 classes of medications (statins, blood pressure (BP) medications, breast cancer medications, antiplatelets, anticoagulants).

For each of these, we defined two phenotypes: adherence (ratio between total purchased quantity and length of treatment) and persistence (purchasing for at least one year vs discontinuation after one purchase). We then looked at the associations between the two phenotypes and genetic risk factors (using polygenic scores, PGS), as well as demographic and socio-economic factors (e.g. region of residence, years of education).

The most notable association, shared across all medications, was between adherence and a higher genetic predisposition to participate in follow-up health questionnaires in UK biobank (β : [0.1%:0.3%], P: $[2.5 \times 10^{-12}; 7.6 \times 10^{-3}]$ - β as percentage increase in adherence per PGS standard deviation). Other notable genetic risk factors were higher BMI and diabetes, which both positively correlated with higher adherence to statins (β : 0.2%, P: 1.6×10^{-6} ; β : 0.3%, P: 9.5×10^{-9}) and BP medications (β : 0.4%, P: 2.5×10^{-27} ; β : 0.4%, P: 1.4×10^{-20}).

Associations between PGSs and persistence replicate those observed for adherence, and a PGS for adherence to statins built in Estonian Biobank significantly associated (P: 0.001) with the adherence measured in our data. We further run a GWAS of adherence and persistence to each drug, which identified no genetic variation associated with the two phenotypes.

We then explored the effect of socio-economic factors and found positive associations between adherence to statins and to BP medications and being male (β : [0.8%, 1.5%], P < 2×10^{-16}) and living in Southern Finland (β : [1.5%, 0.7%], P: $[1.5 \times 10^{-5}, 0.004]$), while educational level intriguingly showed a discordant effect between statins (β : 0.3%, P < 2×10^{-16}) and BP medications (β : -0.1%, P: 9.9×10^{-14}).

Overall, results suggest that adherence is related to behavioral traits (e.g. participation in health questionnaires and perception of risk factors) rather than having direct biologic determinants. Further investigation of additional socio-economic determinants will allow for a better identification of patients at risk of being poorly adherent.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3396*. Expression and Splice QTLs found in COVID-19 patients and controls show differential colocalization and heterogeneity between infectious and non-infectious states.

Authors:

Y. Farjoun¹, T. Nakanishi², J. Willett², T. Lu², S. Zhou³, B. Richards²; ¹Lady Davis Inst., Montreal, QC, Canada, ²McGill Univ., Montreal, QC, Canada, ³McGill, Montreal, QC, Canada

Abstract Body:

There are several different explanations as to why expression and splice QTLs do not often colocalize with GWAS results. One of these is that the difference in expression or RNA splicing is localized to a cell state which is not often measured in RNA experiments. Here we present eQTL and sQTL results calculated on RNA samples from release 7 of The BQC19 (*La Biobanque Québécoise de la COVID-19*). Data were processed by following the GTEx eQTL and sQTL pipelines. The differences between infectious and non-infectious states (defined by comparing the sample date to the onset of symptom date), were highlighted by calculating QTLs on the different sets of samples and following up by a test of heterogeneity. To avoid the results being confounded by population, the results were stratified into the two main populations in the study: NFE (Non-Finnish European) and AFR (African/African-American). The resulting 4 subsets range between 50 and 200 samples in size. The QTL calculation was followed up by testing for colocalization with the HGI loci. The “classical” COVID-19 loci, are present and colocalize as eQTL (e.g., *ABO*) or sQTLs (e.g., *OAS1*) in both infectious and non-infectious samples, however, several HGI loci colocalize differentially in infectious-state and noninfectious state. For example, *NAPSA* and *TYK2* only colocalize with the HGI GWAS for the non-infectious samples, while *IL10RB* only colocalizes for infectious samples. While the overlapping *IFNAR2* gene is the most reliable causal gene for the chr21 locus, this indicates that *IL10RB* may be involved in pathogenesis. In addition to the colocalization results, we compared the QTLs and found several examples where the effect differs significantly between infectious and non-infectious states. These results indicate that expression data that are taken at the appropriate time can colocalize well with GWAS data and highlights several new loci as relevant for infection response to SARS-CoV-2. Our results lay the foundation for further analysis to explore the causal role of gene expression and splicing in COVID-19 outcomes. All data and pipelines are publicly available.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3397. Extending Genome-Wide Association Studies to admixed cohorts with high degrees of relatedness.

Authors:

T. Tan¹, N. N. Shah¹, G. E. Tietz¹, P. Turley², W. Zhou³, E. G. Atkinson¹; ¹Baylor Coll. of Med., Houston, TX, ²Univ. of Southern California, Los Angeles, CA, ³Massachusetts Gen. Hosp., Boston, MA

Abstract Body:

Admixed populations comprise more than one-third of the US population but are extremely underrepresented in Genome-Wide Association Studies (GWAS). This lack of inclusion of admixed populations in GWAS contributes to disparities of the applicability and benefits of findings from health research. Recently, more admixed cohorts are being included in large biobanks and cohorts, such as All of Us, reducing gap of resources but also introducing new statistical and computational challenges. Our group has previously developed a generalized linear model (GLM) based method, *Tractor*, for GWAS in admixed samples, which allows for obtaining accurate ancestry-specific effect sizes and boosting discovery power in the presence of effect size heterogeneity across ancestries. However, most GLM-based software makes a strong, but often inappropriate, assumption of sample independence, whereas in actual large-scale collections, samples are generally related at either ancestral or familial level. New, scalable approaches are therefore necessary that can appropriately account for sample relatedness in all levels for admixed populations.

In this project, we propose a new generalized linear mixed model (GLMM) method for association studies in large biobanks or cohorts with admixed populations, while accounting for confounding factors, such as sample relatedness and population substructure. Similar to *Tractor*, our method conducts genetic association tests by leveraging the power of observing granular ancestral patterns with local ancestry inference to produce more accurate effect sizes, localize association signal, and boost power in the presence of effect size heterogeneity across ancestries.

We constructed ancestry-specific genetic relationship matrices and formulated an ancestry-aware mixed-effect model with multiple variance components, with each one capturing ancestry-level variability. We evaluated the performance of our method through extensive simulation studies and real data analysis and showed its various merits compared to the GLM-based GWAS method, such as effective type 1 error control. Our work will particularly increase the inclusiveness of underrepresented admixed cohorts in GWAS efforts and help reduce health disparity in the long term.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3398. Extremely sparse models of linkage disequilibrium in diverse GWAS

Authors:

A. Wohns¹, P. S. Nowbandegani¹, J. L. Ballard¹, B. M. Neale^{1,2}, A. Bloemendal¹, L. J. O'Connor¹; ¹Broad Inst. of MIT and Harvard, Cambridge, MA, ²Massachusetts Gen. Hosp., Boston, MA

Abstract Body:

Statistical methods to analyze genetic association data must account for linkage disequilibrium (LD). LD correlation matrices are large (sometimes terabytes) and methods that rely on them are slow (sometimes taking days). The challenge is exacerbated by ancestral diversity, as LD patterns vary with ancestry. Here, we show that LD can be modeled using extremely sparse matrices, hundreds of times smaller than a correlation matrix, enabling efficient algorithms. Our approach leverages genome-wide genealogies: statistical relationships among linked alleles correspond to genealogical relationships among ancestral haplotypes, and we extract these relationships to produce an LD graphical model (LDGM). We derive LDGMs from genome-wide genealogies, validate their accuracy across continental populations, and demonstrate an LDGM-based method for heritability partitioning.

Genome-wide genealogies can be inferred at scale across ancestrally diverse datasets (Wohns et al., 2022 Science), producing efficient representations of genotype data (Kelleher et al., 2019 Nat Genet). Based on the genealogy we identify conditional dependencies between variants, which are the edges of the LDGM. We prove that the LDGM has desired properties (correctness and minimality). We also infer the LDGM precision matrix, which is a sparse regularized inverse of the population-specific LD correlation matrix. We generated LDGMs across 11M common SNPs (MAF<0.01) in 1000 Genomes (N=2504) and inferred LDGM precision matrices for five continental populations (AFR, AMR, EAS, EUR, SAS). These matrices were extremely sparse, with 20 nonzero entries per row and column. They accurately reproduced the LD correlation matrix, with a mean squared error of 0.0012 for four out of five populations (0.0022 in the admixed AMR population). They were equally accurate on average in UK Biobank European samples (MSE=0.0012).

We developed a heritability partitioning method that operates on LDGMs and GWAS summary statistics. This method combines an accurate maximum-likelihood estimation approach (similar to GCTA) with a flexible model that can handle any number of overlapping annotations (similar to S-LDSC), and it can be applied to GWAS in non-European populations. This method produces more accurate enrichment estimates than S-LDSC in simulations.

In other statistical applications as well, slow operations involving correlation matrices can be replaced with fast ones involving our sparse precision matrices, producing order-of-magnitude improvements in runtime. We will publish our LDGMs with open-source software tools enabling their integration into new and existing methods.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3399. Fine-mapping one chromosome at a time: Software and an initial application to UK Biobank

Authors:

K. Yuan¹, M. Lam², C-Y. Chen³, Y. Chen⁴, M. Yu⁵, T. Ge¹, H. Huang⁶; ¹Massachusetts Gen. Hosp., Boston, MA, ²The Broad Inst., Cambridge, MA, ³Biogen, Cambridge, MA, ⁴broad Inst., Cambridge, MA, ⁵Broad Inst., Cambridge, MA, ⁶MGH, Boston, MA

Abstract Body:

Fine-mapping seeks to find the genetic variants underlying the complex traits or diseases. Current statistical fine-mapping methods jointly model the effects of multiple significant variants. The computation cost dramatically increases as more variants are involved, making it almost impossible to apply to whole chromosome data. Researchers solved this by pre-selecting associated loci and simplifying the problem to fine-mapping a hundreds-of-variants locus. However, the loci definition methods are mainly LD-based and problematic when considering multiple populations. Due to the population-specific LD, the loci definitions might be inconsistent across populations. Even after simplification, most fine-mapping software still cannot handle long-range LD regions, such as the Major Histocompatibility Complex (MHC).

SuSiEx is a cross-population fine-mapping method developed by our group. We extended the single-population fine-mapping method, SuSiE, by considering the causal variants shared across populations. Here, we refactored the code to reduce the memory by designing a lite matrix data structure. We boosted the software speed by enabling multi-thread computing and buffered I/O. The software's speed is ~10x faster, and memory consumption is reduced by more than 90%, making it possible to fine-map a full chromosome.

We applied our software to the alanine aminotransferase of Pan-UKBB European chromosome 22 association results. The memory consumption is ~74GB, and the running time is ~2.36 hours with 40 CPUs (clock speed 2.10GHz). A proper server could be easily found on the Google Cloud Platform (GCP), and the computing cost is less than \$10. The whole chromosome fine-mapping found two credible sets less than the loci-based fine-mapping. The further conditional analysis confirmed that one of the missing credible sets was weakly ($r=0.0419$) tagged to a credible set of a different locus. After conditional on a closer credible set, the p-value of another missing credible set's leading variant increased to $2.5e-8$, much closer to the genome-wide significance threshold.

Our software is the first to fine-map a full chromosome at a time with computational resources currently available from commercial cloud providers. With our software, researchers will no longer be bothered by defining loci before fine-mapping analysis. The loci definition inconsistencies will not be a problem in the cross-population fine-mapping. Besides the convenience, applying our software to whole chromosome data could reduce the false-positive discoveries caused by relatively weak but long-range LD.

PB3401*. Functional Annotations-Informed Whole Genome Sequence Analysis Identifies Novel Rare Variants for AD in the Alzheimer's Disease Sequencing Project

Authors:

S. Lee¹, B. Shi¹, G. Peloso², Y. Wang², N. Heard-Costa³, H. Lin⁴, A. Pitsillides², C. Sarnowski⁵, E. Boerwinkle^{5,6}, P. De Jager⁷, J. Dupuis², S. Seshadri⁸, E. Wijsman⁹, A. DeStefano², M. Fornage^{1,5}; ¹Univ. of Texas Hlth.Sci. Ctr. at Houston McGovern Med. Sch., Houston, TX, ²Boston Univ. Sch. of Publ. Hlth., Boston, MA, ³Boston Univ Sch Med., Boston, MA, ⁴UMass Med. Sch., Worcester, MA, ⁵Univ. of Texas Hlth.Sci. Ctr. at Houston, Sch. of Publ. Hlth., Houston, TX, ⁶Baylor Coll. of Med., Houston, TX, ⁷Columbia Univ Med Ctr, New York, NY, ⁸Glenn Biggs Inst. for Alzheimer's and Neurodegenerative Diseases Univ. of Texas Hlth.Sci. Ctr. at San Antonio, San Antonio, TX, ⁹Univ Washington Sch Med, Seattle, WA

Abstract Body:

Background: Incorporation of functional annotations improves power to identify rare variants (RVs) associated with disease with whole-genome sequencing (WGS) data. We applied an omnibus test in the variant-Set Test for Association using Annotation infoRmation (STAAR-O) framework, incorporating Alzheimer's Disease (AD) specific annotations based on partitioning heritability to identify RVs associated with AD in the multi-ancestry sample of the Alzheimer's Disease Sequencing Project (ADSP). **Method:** We performed association analyses in a sample of 4,074 individuals (1,668 AD cases; 2,406 controls) with WGS as part of the ADSP Discovery/Extension Phase. For each numerical functional annotation from the WGS Annotator, we partitioned all single nucleotide variants (SNVs) into q discrete categories of the continuous functional score ($q=10$). We estimated AD heritability from SNVs in those categories using GCTA. For each functional annotation, we then derived a global weight estimated from the linear regression slope as the average per-SNV AD heritability on the q categories. Among weighted functional scores, we selected the top 12 based on the rank of global weights to leverage the most informative functional annotations for incorporation into the STAAR-O test. We performed an agnostic region-based association analysis using sliding windows, defined as 2kb in length with a skip length of 1kb. Association tests were performed on RVs with minor allele frequency (MAF) $<1\%$, adjusting for sex, sequencing center, platform, study, 4 principal components, and a genetic relatedness matrix. Replication of significant associations was carried out in an independent sample of 10,083 individuals (5,717 AD cases, 4,366 controls) as part of the ADSP Follow-Up Study, using the same analytical models. **Result:** Out of 2.65 million 2-kb overlapping windows with a total minor allele count >10 , two non-consecutive windows on chromosome 17 were associated with AD ($P<5\times 10^{-8}$). Both window associations were replicated ($P=0.003$ and 0.016). The top variant of one significant window was rs534148850 (MAF= 0.0005, $P=5.6\times 10^{-9}$) located downstream of *PLEKHMIP1*, a pseudogene, and *MIR4315-2*, a microRNA with predicted targets enriched in apoptosis pathways. The top variant of the second window was rs532055552 (MAF=0.005, $P=6.2\times 10^{-9}$) located downstream of *CEP112*, a coiled domain-containing protein involved in the regulation of gamma-aminobutyric acid A receptor surface expression. **Conclusion:** By incorporating AD-relevant functional annotations to a powerful RV association framework, we discovered and replicated two novel genetic regions harboring RVs associated with AD.

PB3402. Genealogy-wide association improves detection of rare and low-frequency variants in under-sequenced populations.

Authors:

A. Gunnarsson¹, B. Zhang², P. Palamara²; ¹Wellcome Ctr. for Human Genetics, Univ. of Oxford, Oxford, United Kingdom, ²Dept. of Statistics, Univ. of Oxford, Oxford, United Kingdom

Abstract Body:

The ancestral recombination graph (ARG) compactly represents the genealogical history of a set of individuals at every site along the genome, providing information on both observed and unobserved genomic variation that can facilitate association and other complex trait analyses. We developed an algorithm to efficiently infer large-scale ARGs from SNP array and sequencing data, improving coalescence time inference by extending the sequentially Markovian coalescent model (McVean et al., 2005) to account for allele ages and ARG topology.

We compared our approach to existing ARG reconstruction methods in extensive simulation of SNP array data and observed increased accuracy, including a 36% improvement in Kendall-Colijn distance compared to ARG-Needle (Zhang et al., bioRxiv). We used simulated phenotypes to evaluate linear mixed model association testing of putative unobserved variants in ARGs inferred from array data. While not requiring a sequenced panel, this genealogy-wide association (GeWAS) strategy matched the statistical power of standard GWAS analysis using imputation from thousands of sequenced samples, remaining robust to population structure and SNP ascertainment bias.

We inferred the ARG for UK Biobank individuals from five non-European ancestries, including African (N=6,747), American (N=993), Central/South Asian (N=9,009), East Asian (N=2,763) and Middle Eastern (N=1,616), only using array data. We performed GeWAS testing using the inferred ARGs and compared to a standard GWAS on genotype data imputed using the HRC+UK10K reference panel (N=65k predominantly European haplotypes) in height and six blood-related traits. We used permutation testing to establish genealogy-wide significance thresholds ranging between 1.5×10^{-9} and 6.8×10^{-10} . After stringent LD-based filtering to extract approximately independent associations we found 192 imputed markers and 128 GeWAS markers, 19 of which remained significant after conditioning on any imputed marker. To validate each GeWAS marker, we extracted the most highly correlated variant found in a subset of 9,276 whole-exome sequenced samples, finding 88 unique exome variants. GeWAS markers strongly tagged (average $r=0.74$) these underlying sequencing variants, 8 of which were better tagged than by any imputed variant, and included ARG-specific low-frequency (MAF < 1%) associations with loci harboring common variant signals in European samples.

These results support the use of genealogy-based approaches to complement genotype imputation in the analysis of unobserved genetic variation, particularly for groups that are underrepresented in large-scale sequencing panels.

PB3403. Gene-by-gene and gene-by-sex interactions identified in the UK Biobank using Explainable Boosting Machines.

Authors:

Y. Nagafuchi¹, H. Hidayatullah², D. Mas Montserrat³, A. G. Ioannidis⁴; ¹Stanford Univ. Inst. for Computational and Mathematical Engineering, Stanford, CA, ²Stanford Univ. Dept. of Statistics, Stanford, CA, ³Stanford Univ. Dept. of BioMed. Data Sci., Stanford, CA, ⁴Stanford Univ. Dept. of BioMed. Data Sci., Inst. for Computational and Mathematical Engineering, Stanford, CA

Abstract Body:

We apply Explainable Boosting Machines (EBMs), which are tree-based, cyclic gradient boosting Generalized Additive Models, to the phenotype prediction problem by using single nucleotide polymorphisms identified via genome-wide association studies in the UK Biobank White British individuals.

This approach allows us to maintain interpretability while identifying interacting pairs of features important to explaining the phenotype in question. To detect pairwise interactions, the model first fits the main effects and then efficiently searches all pairwise feature interactions to fit the remaining residuals. Investigating the epistatic interactions identified by this EBM approach, we found both novel and previously-investigated interactions. In addition, we identified strong non-linear interactions between sex and a number of genomewide significant SNPs. Finally, the non-linear functions modeled by our EBMs allowed us to delineate dominant from recessive acting SNP associations and to model the different effect sizes in homozygous and heterozygous individuals.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3404. Gene-sodium intake interactions reveal new blood pressure loci in a multi-ancestry genome wide association study in UK Biobank and CHARGE

Authors:

M. Kho¹, J. Smith^{2,3}, L. Bielak², P. van der Harst⁴, K. Schwander⁵, T. Kelly⁶, C-T. Liu⁷, A. Correa⁸, C. Miller⁹, P. peyser², S. Kardia²; ¹Graduate Sch. of Data Sci., Seoul Natl. Univ., Seoul, Korea, Republic of, ²Univ. of Michigan SPH, Ann Arbor, MI, ³Inst. for Social Res., Univ. of Michigan, Ann Arbor, MI, ⁴Univ. Med. Ctr. Utrecht, Utrecht, Netherlands, ⁵Washington Univ. Sch. of Med., St Louis, MO, ⁶Tulane Univ. SPH and Tropical Med., New Orleans, LA, ⁷Boston Univ. SPH, Boston, MA, ⁸Univ. of Mississippi Med. Ctr., Jackson, MS, ⁹Univ. of Virginia Sch. of Med., Charlottesville, VA

Abstract Body:

High sodium intake is an important risk factor for hypertension. Genome-wide association studies (GWAS) have identified thousands of genetic loci associated with blood pressure (BP) traits, but it remains not fully understood whether sodium intake modifies genetic effects. We conducted genome-wide gene by sodium intake (high intake defined by ≥ 220 mmol/day) interaction analyses on BP traits (systolic BP, diastolic BP, mean arterial pressure, and pulse pressure) using the 2 degrees of freedom (df) joint test followed by 1 df test of interaction effects. The study groups included UK Biobank (UKBB) European ancestry participants with daily sodium intake measured from spot urine samples (N=437,725) and participants from the Gene-Lifestyle Interactions Working Group within the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) consortium across three ancestry groups (European, African, and Asian ancestries) with daily sodium intake measured from 24-hour or half-day urine samples (N=9,669). We identified 19 and nine previously unreported BP loci in UKBB and CHARGE, respectively, based on the 2df joint test. Through a sensitivity analysis using participants without diuretic use, we found ten additional previously unreported BP loci in UKBB. The most significant locus was rs2299871 in *PPARD*, which has been implicated in several cardiometabolic diseases and plays a role in the stimulation of epithelial sodium channel (ENaC)-mediated renal salt absorption impacting blood volume and pressure. We also identified one and seven significant interactions with sodium intake in UKBB and CHARGE, respectively, using the 1df interaction test. Among them, only one of the interaction loci (*TENM2* in CHARGE European participants) had not been previously reported. Our bioinformatics analyses and functional annotations highlighted several biological pathways and genes implicated in BP regulation through ENaC, atherosclerotic progression, dietary lifestyle behaviors, and education. The druggability analysis suggested that several of our newly identified BP genes are druggable targets or targets of approved drugs and/or compounds under investigation including nutrient supplementation. In conclusion, we identified 39 previously unreported loci that were significantly associated with BP measures through GWAS accounting for interaction with sodium intake, which requires further replication. This study highlights the role of sodium intake interactions in the genetic contribution to BP traits as well as potential to identify druggable targets, suggesting novel insights into sodium intake-related BP regulation and potential interventions.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3405. Genetic association models are robust to common population kinship estimation biases.

Authors:

Z. Hou, A. Ochoa; Duke Univ., Durham, NC

Abstract Body:

Common genetic association studies for structured populations, including Principal Component Analysis (PCA) and Linear Mixed-effects Models (LMM), model the correlation structure between individuals using population kinship matrices, also known as Genetic Relatedness Matrices or “GRMs”. However, the most common kinship estimators can have severe biases that were only recently characterized. Here we characterize the effect of these kinship biases on genetic association. We employ a large simulated admixed family and genotypes from the 1000 Genomes Project, both with simulated traits, to evaluate a variety of kinship matrices (every bias type has two locus weight types, and their theoretical limits for the simulation). Remarkably, we find nearly equal association statistics and performance for kinship matrices of different bias types (when all other features are matched). These empirical observations lead us to hypothesize that these association tests are invariant to these kinship biases, which using linear algebra we prove holds exactly for LMM and approximately for PCA. Our constructive proof shows that the intercept and relatedness (PCs in PCA, random effect in LMM) coefficients compensate for the kinship bias, so the result extends to generalized linear models as long as those coefficients are present and are nuisance parameters. Overall, we find that existing association studies are robust to kinship estimation bias, and our theoretical results may help improve association methods by taking advantage of this unexpected robustness, as well as help determine the effects of kinship bias in other settings.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3406. Genetic determinants of a metabolic model for age

Authors:

S. Xiao¹, M. Argentieri¹, A. Nevado-Holgado¹, K. Nho², M. Arnold³, G. Kastenmüller³, R. Kaddurah-Daouk⁴, N. Amin¹, C. M. Van Duijn¹, Alzheimer Disease Metabolomics Consortium, Accelerating Medicines Partnership Program for Alzheimer's Disease (AMP-AD); ¹Univ. of Oxford, Oxford, United Kingdom, ²Indiana Univ Sch. of Med., Indianapolis, IN, ³Helmholtz Zentrum München, Neuherberg, Germany, ⁴Univ. of Duke, Durham, NC

Abstract Body:

Age is a major driver of common age-related diseases. However, the molecular pathways underlying the effects of age on morbidity and mortality are far from understood. We aimed to construct a blood-based metabolic model for chronologic age and determine its genetic determinants. The study is embedded in UK Biobank and includes 118,021 randomly selected participants who are characterized for 249 metabolites using proton nuclear magnetic resonance (¹H-NMR). We used a gradient boosting ensemble decision tree machine learning method (Light GBM) to construct a sex adjusted model for metabolic age allowing non-linear relationships. Recursive feature elimination was used to reduce the number of metabolites and Shapley values were used to evaluate the impact of metabolites. We conducted a genome-wide association analysis (GWAS) to find genetic determinants of metabolic age. Our final metabolomic age model included 57 metabolites ($R^2 = 0.32$ in test dataset). Albumin, omega 6/omega 3 ratio, citrate, leucine, free cholesterol levels in extra small VLDL, tyrosine and triglyceride levels in large LDL are most important features. To evaluate bias due to existing chronic disease, we repeated the analysis in participants without cancer, cardiologic, lung, liver, metabolic, CNS or locomotor disease at baseline. The correlation between the model based on all participants and those healthy at baseline was 0.980 ($SE=7.24*10^{-4}$). In multivariate Cox models, higher metabolic age at baseline significantly increased the risk of mortality ($p=2.20*10^{-16}$) and incidence of liver ($p=7.87*10^{-7}$), pancreatic ($p=2.11*10^{-2}$) and esophageal ($p=3.65*10^{-2}$) cancer, chronic kidney disease ($p=2.20*10^{-16}$), diabetes ($p=2.20*10^{-16}$), hypertension ($p=4.44*10^{-16}$), chronic liver disease ($p=1.16*10^{-12}$), cardiovascular disease ($p=2.68*10^{-11}$), COPD ($p=5.78*10^{-6}$), vascular ($p=1.09*10^{-3}$) and all cause dementia ($p=9.70*10^{-3}$), osteoarthritis ($p=1.39*10^{-3}$) and obesity ($p=6.61*10^{-3}$). The metabolic age is further associated with blood telomere length ($p=1.06*10^{-8}$) and C-reactive protein ($p=2.20*10^{-16}$) at baseline. Our GWAS identified 27 loci ($p<5*10^{-8}$) associated to the metabolic age score. Regions significant in the GWAS are associated with 47 out of 57 metabolites used to estimate metabolic age but 3 novel regions are uniquely associated to metabolic age: *REV3L* (involved in DNA repair), *C12orf43* (WNT signaling), and *FBXO39* (ubiquitination) but not to any of the metabolites used to construct the score. In conclusion, we have constructed a metabolomics model for age that associates with markers of aging, age related disease and mortality and elucidated its genetic architecture.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3407. Genetic Determinants of Circulating Glycine and Cardiovascular Disease: Causal Relationship or Red Herring?

Authors:

S. Biswas¹, J. R. Hilser¹, N. Woodward², P. Huang², J. Gukasyan², Z. Fouladian², S. Charugundla³, A. J. Lusis³, Z. Wang⁴, W. Tang⁴, S. L. Hazen⁴, J. Hartiala⁵, H. Allayee²; ¹Univ. of Southern California, Los Angeles, CA, ²USC Keck Sch. of Med., Los Angeles, CA, ³UCLA Dept of Med., Los Angeles, CA, ⁴Cleveland Clinic, Cleveland, OH, ⁵Univ of Southern California, Los Angeles, CA

Abstract Body:

Introduction: Circulating glycine levels have been linked to decreased cardiovascular risk in multiple studies. However, given the role of glycine in a wide range of metabolic pathways, evidence for a causal association between glycine and coronary artery disease (CAD) has not been conclusive. We sought to untangle the genetic underpinnings of glycine and its relationship with CAD using Mendelian Randomization (MR) and glycine supplementation in a mouse model of atherosclerosis. **Methods and Results:** We conducted a multi-ethnic weighted Z-score meta-analysis of genome-wide association study (GWAS) results in up to 222,413 subjects of European, Asian, and Hispanic origin from 9 cohorts, including the UK Biobank, Biobank Japan, and the Hispanic Community Health Study. Using Functional Mapping and Annotation of Genome-Wide Association Studies (FUMA), we identified 59 independent loci for glycine, 33 of which were novel. A phenome-wide association scan indicated that most of these variants were associated with other metabolites or CAD risk factors such as BMI, blood pressure, or diabetes (T2D). However, 8 glycine-associated SNPs, including 4 components of the glycine cleavage system (*AMT*, *DLD*, *GLDC*, and *GCSH*), did not yield evidence of pleiotropy. Inverse-variance weighted two-sample MR was performed with the 8 non-pleiotropic SNPs but there was no evidence for a causal association between genetically determined glycine levels and CAD (OR=0.93, 95% CI: 0.66-1.30, p-value=0.66). However, there was modest evidence for causal associations between glycine levels and with systolic blood pressure (Beta= -1.41, SE=0.68, p-value=0.04) and T2D (OR=0.69, 95% CI: 0.53-0.93, p-value=0.03). As a complementary approach, we carried out a dietary glycine study with hyperlipidemic Apoe^{-/-} mice. Feeding of a 2% glycine-supplemented diet led to significant elevations of fasting and non-fasting glycine levels compared to the control 0.3% glycine diet. However, atherosclerotic lesion area was not significantly different between glycine-fed and control groups. **Conclusions:** Our results comprise the largest meta-analysis of glycine to date and yield a more complete picture of the genetic architecture of glycine metabolism. While MR analyses suggested that glycine could be causally related to blood pressure and diabetes, there was no evidence for the same causal relationship with risk of CAD or atherosclerosis in humans or mice.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3408. Genetic evidence of assortative mating in the Japanese population.

Authors:

K. Yamamoto^{1,2}, K. Sonehara¹, S. Namba¹, T. Konuma³, H. Masuko⁴, S. Miyawaki⁵, The Biobank Japan Project, Y. Kamatani⁶, N. Hizawa⁴, K. Ozono¹, L. Yengo⁷, Y. Okada^{1,2,8,5}; ¹Osaka Univ. Graduate Sch. of Med., Suita, Japan, ²Immunology Frontier Res. Ctr. (WPI-IFReC), Osaka Univ., Suita, Japan, ³Japan Tobacco Inc., Takatuki, Japan, ⁴Faculty of Med., Univ. of Tsukuba, Tsukuba, Japan, ⁵Graduate Sch. of Med., the Univ. of Tokyo, Tokyo, Japan, ⁶Graduate Sch. of Frontier Sci., The Univ. of Tokyo, Tokyo, Japan, ⁷The Univ. of Queensland, Brisbane, Australia, ⁸RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan

Abstract Body:

Positive assortative mating (AM) is a commonly observed mating pattern, where individuals with similar phenotypes are prone to get married more often than by chance. Detecting the genetic impact of AM on a polygenic trait has been challenging due to a lack of large-scale spousal data and confounding of population stratification, especially in non-European populations. The recently developed method by Yango et al focused on quantifying the correlation between physically distant trait-associated alleles (i.e., gametic phase disequilibrium [GPD]) using polygenic scores (PGS) derived from partitioned chromosomes (e.g., odd and even numbered chromosomes) without spousal data. Using GPD estimate (θ), they confirmed the genetic evidence of AM on adult height and educational attainment in Europeans. Here, we report the PGS-based analysis of AM in the Japanese population using Biobank Japan Project data and other Japanese independent cohorts ($n = 172,270$). Adopting the leave-one-group-out method, we estimated the GPD estimates across 81 complex traits by calculating the correlation between PGS_{odd} and PGS_{even} with the robust adjustment for population stratification. Our study identified that cardiometabolic diseases (type 2 diabetes [T2D] and coronary artery diseases [CAD]), and behavioral and dietary habits were significantly affected by parental AM ($\theta_{T2D} = 0.018$, standard error [SE] = 0.0025, $P = 5.2 \times 10^{-14}$, $\theta_{CAD} = 0.015$, standard error [SE] = 0.0025, $P = 2.2 \times 10^{-9}$), and this result was population specific. We also identified the shared but heterogeneous impacts of AM on an adult height between the Japanese populations and Europeans from cross-population analysis using the UK Biobank resources ($n = 337,139$, $\theta_{\text{Height in EAS}} = 0.0073$ vs $\theta_{\text{Height in EUR}} = 0.030$). Finally, the consideration of the geographical factor could provide more robust results for the Japanese population. Our study demonstrated genetic evidence of AM in the Japanese population.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3409. Genetic variants associated with serum IGF-1 levels in the Long Life Family Study

Authors:

R. Minster¹, R. A. Sherlala¹, R. K. Cvejkus¹, H. Campbell², A. L. Kuipers¹, M. K. Wojczynski³, B. Thyagarajan⁴, S. V. Ukraintseva⁵, M. F. Feitosa³, J. Mengel-From⁶, J. M. Zmuda¹; ¹Univ. of Pittsburgh, Pittsburgh, PA, ²Washington Univ. Sch. of Med., St. Louis, MO, ³Washington Univ. in St Louis, St Louis, MO, ⁴Univ. of Minnesota, Minneapolis, MN, ⁵Duke Univ., Durham, NC, ⁶Univ. of Southern Denmark, Odense, Denmark

Abstract Body:

Insulin-like growth factor 1 (IGF-1) is the product of a single gene (IGF1) located on the long arm of chromosome 12 and a main ligand in the IGF pathway. The IGF pathway may provide insight into the underlying physiology involving lifespan and healthy aging. Because the IGF pathway is associated with longevity both in human and animal models, performing genome-wide analysis on longevous families may provide additional insights about the biology behind healthy aging. Using data of more than 4,000 participants (aged 24-110 years) from 539 longevous two-generation families, we estimated the heritability of serum IGF-1 to be 0.41 ± 0.04 ($p < 0.0001$), and the proportion of variance attributed to the covariates to be 0.19. Linkage analysis revealed a novel locus associated with IGF-1 levels on 11p14 (peak LOD = 3.48). We also identified a genome-wide significant sequence variant in a discovery association analysis (rs72696993 on 14q21, $p = 4.16 \times 10^{-8}$). Replication analysis of the 212 sequence variants from the discovery analysis with $p < 1 \times 10^{-6}$ in 2,833 participants of the Framingham Heart Study did not replicate rs72696993. However, we confirmed four sequence variants at suggested significance in the discovery located within a previously known IGF-1 locus on 7p12.3. These sequence variants—rs700750, rs700752, rs700753, and rs856582 (all $p \leq 0.00023$) are located in introns 2 and 3 of lincRNA *AC011294.1* and are approximately 800 kb upstream of *IGFBP3*. This locus has been associated with other aging-related traits, such as thyroid-stimulating hormone levels, obesity, and kidney function. Additional genetic studies are required to elucidate the role that IGF-1 plays in age-related morbidity and mortality.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3410. Genetically predicted counts of white blood cells are associated with lower risk of obesity: a Mendelian randomization study

Authors:

Y. Sun, K. Ye; Univ. of Georgia, Athens, GA

Abstract Body:

The prevalence of obesity has increased remarkably worldwide and has been linked to the worsening epidemics of other metabolic diseases. Although white blood cells (WBC) have been shown to be associated with obesity, the causality remains elusive. This study aimed to investigate the causal association between WBC and obesity using bidirectional Mendelian randomization (MR) analyses. Genetic instruments of 20 WBC traits were selected from three genome-wide association studies (sample sizes ranging from 169,219 to 562,243 European individuals). We also leveraged genetic association data on 26 body mass index (BMI)-related traits, including obesity ($n = 50,364$ to $98,697$), overweight ($n = 158,855$), type 2 diabetes ($n = 655,666$), fat mass ($n = 330,762$ to $454,846$), fat-free mass ($n = 331,030$ to $454,850$), BMI ($n = 681,275$), and other related traits ($n = 10,255$ to $232,101$). In the forward MR analysis, one standard deviation (SD) genetic increase in WBC was associated with lower risks of class I obesity (odds ratio (OR): 0.85; 95% confidence interval (CI): 0.78, 0.93; $P = 5.04 \times 10^{-4}$), class II obesity (OR: 0.71; 95% CI: 0.63, 0.81; $P = 2.36 \times 10^{-7}$), class III obesity (OR: 0.63; 95% CI: 0.51, 0.78; $P = 3.44 \times 10^{-5}$), overweight (OR: 0.91; 95% CI: 0.85, 0.97; $P = 3.34 \times 10^{-3}$), and other BMI-related traits. The reverse MR analysis provided strong evidence in support of BMI-related traits causally decreasing the levels of WBC traits. Our bidirectional MR analyses suggested that genetically predicted high WBC was associated with lower risks of BMI-related traits, and BMI-related traits were also negatively associated with the level of WBC. Future studies are warranted to clarify the shared genetic etiology between WBC and obesity and to identify pathways that may underlie both traits.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3411. Genetically-guided phenotype imputation of partial or missing traits in biobank data increases power for genetic discovery

Authors:

C. Eijbouts¹, G. McVean², L. Jostins¹; ¹Univ. of Oxford, Oxford, United Kingdom, ²Genomics plc, Oxford, United Kingdom

Abstract Body:

Biobanks typically provide genetic data on large numbers of individuals, yet diagnoses and other phenotypes of interest are often only available for a subset of participants, or are inconsistent across diagnostic modalities (e.g. between self-reported data and electronic healthcare records), limiting the power and generality of genome-wide association studies (GWAS) in these datasets. We have developed a method to impute traits for which well-powered GWAS cannot be conducted because they are only available in a small subset of samples or because they are completely absent. We use previously-established genetic associations alongside the broad range of phenotypic data available in biobanks to impute and increase GWAS power for such traits. Concretely, we show how genetic associations learned from a small reference sample (e.g. a subset of a biobank, or an external dataset) can inform how relevant phenotypic features available in a larger sample (e.g. comorbidities, medication use) may be used to construct an imputed phenotype which yields increased GWAS power. After demonstrating this concept in simulations, we provide proof-of-concept by using genetic associations for systolic blood pressure learned from 15,433 UK Biobank participants, of which only one was genome-wide significant, to impute the trait in a broader sample of 179,962 participants, recovering 130 independent genome-wide significant loci, of which 55 are supported by previous literature. We then impute transferrin saturation as an example of a trait that is absent in UK Biobank, and find 11 novel associations that have not previously been observed at genome-wide significance, but which are supported by evidence of association at nominal significance in the smaller reference sample. These loci implicate genes that have previously been associated with erythroid traits (*HBSIL*), alcohol consumption (*ALDH1A1*), and risk of liver cirrhosis (*MARCI*). We propose that phenotype imputation guided by genetic associations will enable well-powered analyses of phenotypes that are partially or completely missing from biobanks, increasing the yield of future GWAS and enabling phenotype harmonisation between biobanks.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3412. Genome wide association study of asthma in 1587 French Canadian subjects.

Authors:

A. Eslami^{1,2}, Z. Li², N. Gaudreault², S. Thériault^{1,2}, Y. Bossé^{1,2}; ¹Laval Univ., Quebec, QC, Canada, ²Inst. universitaire de cardiologie et de pneumologie de Québec - Université Laval, Quebec, QC, Canada

Abstract Body:

Context: Asthma is a common respiratory disease with both genetic and environmental risk factors. Heritability estimates for asthma range from 0.55 to 0.90. Numerous genome-wide association studies (GWASs) have been completed and have identified several single nucleotide polymorphisms (SNPs) associated with asthma. **Aims:** Our research aims to perform a GWAS in the Quebec City Case-Control Asthma Cohort (QCCAC) which consists of 1,587 French-Canadian subjects (1,056 asthmatics and 531 healthy controls). We also create a genome-wide Polygenic Risk Score (PRS) to estimate an individual's genetic predisposition for asthma in our cohort. **Methodology:** The genetic association analysis was performed using SAIGE (Scalable and Accurate Implementation of GEneralized mixed model) adjusting for age, sex, and the first 20 ancestry-based principal components. We used summary statistics reported by the Trans-National Asthma Genetic Consortium meta-analysis (23,948 cases and 118,538 controls, 1,991,789 SNPs) to calculate the PRS in our cohort by applying the LDpred2 method, a Bayesian shrinkage approach. The prediction accuracy of models was evaluated by the adjusted area under the receiver operating characteristics curve (AUC). **Results:** Seven distinct genetic loci were identified (a suggestive association threshold of P value $< 1 \times 10^{-6}$) in the GWAS analysis, including asthma-associated SNPs located in *KCNQ5* and *MYL10*. The model with only sex, age, and the first 20 principal components showed an AUC of 0.588 [95% CI: (0.533-0.643)]. After adding PRS to the model the AUC increased to 0.610 [95% CI: (0.556-0.665)]. **Conclusion:** These results suggest that individuals' genetic background may improve asthma risk prediction.

PB3413. Genomes, exomes, and imputation: Comparing technologies for variant association and discovery in large-scale genetic studies

Authors:

T. Joseph¹, S. Gaynor¹, J. Backman², J. Emberson³, R. Collins³, J. Torres⁴, P. Kuri-Morales⁵, R. Tapia-Conyer⁵, J. Alegre⁵, J. Berumen⁶, Regeneron Genetics Center, J. Marchini¹, T. Thornton¹, G. Abecasis⁷; ¹Regeneron Genetics Ctr., Tarrytown, NY, ²Regeneron, Tarrytown, NY, ³Univ. of Oxford, Oxford, United Kingdom, ⁴The Univ. of Oxford, Oxford, Oxon, United Kingdom, United Kingdom, ⁵Natl. Autonomous Univ. of Mexico, Mexico City, Mexico, ⁶Univ. Natl. Autónoma de México, México, Mexico, ⁷Regeneron Pharmaceuticals, Tarrytown, NY

Abstract Body:

Multiple strategies are used to capture genetic variation towards the discovery of genetic factors influencing traits, including imputation from common variants, whole exome sequencing (WES), and whole genome sequencing (WGS). These approaches differ significantly in the technology used, genomic regions targeted, accuracy in detecting rare variants, and per sample cost. We perform the largest systematic comparison of the relative benefits of each approach to date, with a focus on ability to capture variants and detect association signals in coding regions. Our analysis compares each approach in two cohorts: 141,422 individuals of European ancestry in the UK Biobank (UKB), and 9,950 individuals from the Mexico City Prospective Study (MCPS). We apply standardized imputation and filtering approaches, survey genetic variants captured by each technology as characterized by consequence, frequency, and exclusivity to approach, and perform association analyses using both single-variant and gene-based tests. We survey genetic variants discovered by WGS and WES in coding regions. We find differences in variant detection to be highly sensitive to target definition and caller. When applying uniform variant calling and filtering, we find that WGS identifies 2.3% more coding variation using variants annotated with the canonical transcript --- smaller than previous comparisons. Of all coding variants captured by both technologies, 93.2% are observed in both WGS and WES, with 4.5% and 2.3% of variants observed only in WGS or WES, respectively. When variants are annotated by the most deleterious consequence, WGS identifies 4.6% more coding variation, including over 5% specific to WGS. We impute genome-wide variants in 141,422 samples of European ancestry in the UKB using the TOPMed reference panel, and compare association signals to those identified using WGS and WES datasets constructed from the same samples. We identify over 5% more GWAS peaks using the WGS dataset compared to the imputed array and WES datasets. However, when we restrict to independent association signals, defined as GWAS peaks that are greater than 1MB apart, we find only a 2.6% increase for the WGS dataset. Taken altogether, our results suggest there is a large overlap between insights gained from WGS, WES, and imputed array datasets.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3414. Genome-wide analysis of dental caries variability identifies genotype-by-environment interactions

Authors:

T. Zou¹, B. Foxman², D. McNeil³, S. M. Weinberg^{1,4}, M. L. Marazita^{1,4}, J. R. Shaffer^{1,4}; ¹Dept. of Human Genetics, Sch. of Publ. Hlth., Univ. of Pittsburgh, Pittsburgh, PA, ²Dept. of Epidemiology, Univ. of Michigan Med. Sch., Ann Arbor, MI, ³Dept. of Community Dentistry and Behavioral Sci., Sch. of Dentistry, Univ. of Florida, Gainesville, FL, ⁴Ctr. for Craniofacial and Dental Genetics, Dept. of Oral and Craniofacial Sci., Sch. of Dental Med., Univ. of Pittsburgh, Pittsburgh, PA

Abstract Body:

Background: Genotype-by-environment interactions (GEI) are hypothesized to play a role in the etiology of dental caries (i.e., tooth decay), although their effects are difficult to detect. Genetic variants associated with trait variance are prime candidates for GEI, because trait heteroskedasticity across genotype groups can serve as an indicator of a potential underlying interaction effect. The aim of this study was to investigate GEI effects on dental caries by focusing on a set of variants prioritized using genome-wide variance quantitative trait locus (vQTL) analysis.

Methods: We used Levene's test to perform separate genome-wide vQTL scans of ~5 million variants for a quantitative dental caries experience phenotype (i.e., decayed and filled tooth surfaces) in three cohorts (IFS [n=396], COHRA1 [n=328], and COHRA2 [n=773]) and combined results via meta-analysis. All participants were unrelated children of European ancestry at approximately age 5. We prioritized vQTLs with $P < 1E-6$ for GEI testing. Linear regressions were used to test GEI effects on dental caries with prioritized variants and self-reported environmental factors (e.g., demographic, socioeconomic, behavioral and dietary factors) in the three cohorts separately.

Results: A total of 39 independent vQTLs with $P < 1E-6$ were identified across the three cohorts and the meta-analysis. Some of these vQTLs were located in or near genes with plausible biological roles in dental caries (e.g., *IGFBP7*, *SLC5A8*, and *SHH* involved in tooth development and enamel mineralization). In the GEI analysis, we found that children with certain genotypes of prioritized variants exhibited higher caries experience if they had lower parental educational attainment, had lower household/parental income, brushed their teeth less frequently, consumed sugar-sweetened beverages more frequently, were not breastfed, and were female.

Conclusions: We report the first genome-wide vQTL analysis of dental caries and nominate several novel genes and GEI involved in dental caries for further investigations. Our findings expand the current understanding of the genetic architecture of dental caries.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3415. Genome-wide association studies of brain imaging endophenotypes derived from unsupervised learning identifies genes relevant to brain structure

Authors:

Z. Xie¹, K. Patel¹, H. Yuan², S. Islam¹, W. Zhang¹, M. Fornage³, S. Ji², D. Zhi⁴; ¹Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, ²Texas A&M, College Station, TX, ³Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, ⁴U Texas Hlth.Sci. Ctr. at Houston, Houston, TX

Abstract Body:

Understanding the genetic architecture of brain structure is difficult, partly due to lack of descriptors of brain morphology. Existing methods using expert-defined image-derived phenotypes (IDPs) can be incomplete and biased. Here we present an approach of deriving brain imaging phenotypes using unsupervised deep learning. A 3-D convolutional autoencoder consisting of an encoder and decoder is trained on 6,130 UK Biobank participants' T1 and T2 FLAIR brain MRI by foreground mean square error reconstruction loss. Encoder reduces the whole brain MRI that was linearly registered to the MNI152 (Montreal Neurological Institute) space (182x218x182) into 128 dimensional latent space (ENDOs) for both T1 and T2. ENDOs capture all relevant structural variations necessary for the decoder to reconstruct the whole brain MRI. These ENDOs were studied extensively using a wide number of exploratory and statistical approaches and showed strong association with standard image derived phenotypes such as cortical and subcortical structure volumes. We also used decoder perturbation and statistical tests to map the ENDOs back to the brain regions and found meaningful interpretations. Genome-wide association studies of these ENDOs in the held-out UK Biobank white British participants with brain imaging (n=22,962 discovery and n=12,848/11,717 replication cohort for T1/T2) identified 1,132 significant ($P < 5 \times 10^{-8} / 256$) SNP-ENDO pairs, out of which 658 are replicated ($P < 0.05 / 1132$). These replicated associations involve 154 SNPs organized into 43 independent loci. Almost all genes identified such as *ALDH1A2*, *EFNA1*, *2&3*, *AQP9*, *C16orf95*, *CPED1*, *MOV10*, *WNT2B*, *CAPZA1*, *NUAK1*, *RHOC*, *FAM3C*, *DAAMI*, *ST7L*, *UQCC1* were previously associated with brain structure, development and defects, and neuropsychiatric disorders. Interestingly, 40 of these loci were previously associated with imaging-derived phenotype brain morphology GWAS (including GWAS-Catalog and Oxford Brain Imaging Genetics Server where GWAS results of 3,144 imaging-derived phenotypes are hosted), 3 are new loci (rs1149935, rs11021216 and rs1791316) that are not reported in the previous IDP-based GWAS. These results established our unsupervised learning methodology as an effective approach for deriving interpretable endophenotypes for brain imaging data.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3416*. Genome-wide association studies of metabolic traits in Samoans

Authors:

J. Wehr¹, J. C. Carlson¹, E. M. Russell¹, M. Krishnan², S. Liu¹, H. Cheng³, T. Naseri⁴, M. S. Reupena⁵, S. Vialia⁶, J. Tuitele⁷, E. Kershaw¹, R. Deka³, N. L. Hawley⁸, S. T. McGarvey⁹, D. E. Weeks¹, R. L. Minster¹; ¹Univ. of Pittsburgh, Pittsburgh, PA, ²Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ³Univ. of Cincinnati, Cincinnati, OH, ⁴Ministry of Hlth., Apia, Samoa, ⁵Lutia i Puava 'ae Mapu i Fagalele, Apia, Samoa, ⁶Natl. Univ. of Samoa, Apia, Samoa, ⁷Dept. of Publ. Hlth.LBJ Tropical Med. Ctr., Faga'alu, American Samoa, ⁸Yale Univ., New Haven, CT, ⁹Brown Univ., Providence, RI

Abstract Body:

Background: Type 2 diabetes (T2D) is a major public health concern for the nation of Samoa in the South Pacific. There have been no genome-wide studies of T2D or associated phenotypes in individuals of Polynesian ancestry, whose population history might result in allele frequencies allowing for the observation of associations undetectable in other populations. Here, we performed genome-wide association studies (GWAS) of six metabolic traits: T2D, fasting glucose, fasting insulin, and HOMA-IR, as well as T2D among individuals with obesity and T2D among individuals without obesity.

Methods: Genotypes were measured from two sources. First 659,492 variants were genotyped on an Affymetrix 6.0 array in 2,890 Samoan individuals recruited in 2010. We then imputed an additional 9 million variants using a Samoan-specific haplotype reference panel derived from 1,285 Samoan individuals whole-genome sequenced by the TOPMed Program. We performed association testing using linear or logistic mixed models adjusting for fixed effects of age, sex, and principal components of ancestry derived through PC-AiR and for random effects of kinship derived from PC-Relate.

Results: There were seven unique loci associated with metabolic phenotypes at $p < 5 \times 10^{-8}$, and an additional seventeen unique loci were associated at $p < 1 \times 10^{-6}$. The most significant signal is in intron 2 of *PARD3B*: an association between rs76755625 and T2D among individuals without obesity ($p = 9.42 \times 10^{-11}$). This locus has been associated with T2D in an earlier multiancestry GWAS and has been associated body mass index in several GWASs. Notable among the other associating loci, variants in *PPARGCIA* were associated with T2D (peak $p = 4.22 \times 10^{-9}$). This locus has not been associated with T2D in genome-wide association studies to date. It encodes PPAR γ coactivator 1 α , which is a transcriptional coactivator for energy metabolism genes and regulates liver gluconeogenesis. *Ppargcla*-knockout mice exhibit disrupted adipose morphology and abnormal glucose homeostasis.

Conclusion: We observed several known and novel genetic loci associated with metabolic phenotypes in Samoans, suggesting that while some of the genetic architecture of metabolic phenotypes is shared across ancestries, there may be unique associations among Polynesians. We are currently investigating potential associations between these loci and metabolic phenotypes in an independent cohort of Samoan adults. Additional studies will be necessary to validate these associations and the determine the biological underpinnings of these associations, which may point to previously unknown biological mechanisms or social determinants of metabolic health.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3417. Genome-wide association study of obstructive sleep apnea in the Million Veteran Program uncovers heterogeneity by sex and genetic ancestry

Authors:

T. Sofer¹, N. Kurniansyah², M. Murray³, Y-L. Ho³, J. Huffman⁴, K. Cho⁵, P. Wilson⁶, D. Gottlieb⁷; ¹Harvard Med. Sch., Boston, MA, ²Brigham and Women's Hosp., Boston, MA, ³VA Boston Hlth.care System, Boston, MA, ⁴VA Boston Hlth.care System, Jamaica Plain, MA, ⁵VA Boston Hlth.care System, Boston, MA, ⁶Atlanta VA Hlth.care System, Decatur, GA, ⁷Harvard Med. Sch./Brigham and Women's Hosp., Boston, MA

Abstract Body:

Introduction: Obstructive sleep apnea (OSA) is a common condition characterized by repeated collapse of the upper airway during sleep, resulting in decreased ventilation, brief arousals, and intermittent hypoxemia. There are known differences in OSA prevalence between men and women and among race/ethnic groups. Previous studies of OSA genetics have been limited by small sample size and low prevalence of diagnosed OSA, leading to misclassification of OSA cases. **Methods:** We performed a GWAS of OSA in over 550,000 unrelated individuals from the VA Million Veteran Program. Analysis was stratified by sex and race/ethnicity-based groups, followed by meta-analysis. OSA was defined based on electronic health records via an unsupervised clustering algorithm utilizing counts of ICD codes and natural language processing-derived concepts, which estimates a probability of disease and a threshold for binary classification. Decision rules for OSA classification were validated by manual chart review of 100 individuals with at least one OSA ICD code. Association analyses were adjusted for age and 10 first principal components of genetic data computed over all MVP individuals, without and with adjustment for linear and squared terms of BMI. We estimated the heritability of OSA using LD Score regression, with LD scores computed from the analytic dataset. We tested identified OSA associations in GWAS of OSA in the FinnGen and the Mass General Brigham (MGB) biobanks. **Results:** There were 4 HARE groups in the analysis, ordered by sample size: White, Black, Hispanic, and Asian. The sample was 90% male. The prevalence of OSA in men ranged from 25.6% (Hispanic) to 21.3% (White). Among women, it ranged from 16.6% (Black) to 11.9% (Asian). The estimated heritability of OSA was higher by 5-10% in BMI-adjusted compared to BMI-unadjusted analysis, and was substantially higher in race/ethnic group-specific analysis (9-21%) compared to multi-ethnic analysis (~7%). We identified 18 independent common SNPs associated with OSA in multi-ethnic BMI-unadjusted analysis, of which 3 remained associated with OSA in BMI-adjusted analysis. Three additional loci were associated with OSA in BMI-adjusted analysis only. Twelve of the OSA SNPs in BMI-unadjusted analysis and four of the SNPs from BMI-adjusted analysis showed evidence of replication in FinnGen and MGB Biobank (one-sided p-value guided by the direction of association in MVP <0.05). Loci associated with OSA in BMI-adjusted analysis were previously reported as associated with waist-to-hip ratio (adjusted for BMI) and height, supporting the importance of anthropometric measures in OSA beyond obesity.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3418. Genome-wide association study of the human metabolome in diverse ancestries identifies an association of the *OPLAH* locus with 5-oxoproline (pyroglutamic acid) in individuals with African ancestry.

Authors:

M. Krishnan¹, A. Howard¹, H. M. Highland¹, D. Lloyd-Jones², B. Rushing¹, S. Sumner¹, K. E. North¹, P. Gordon-Larsen¹, C. L. Avery¹, M. Graff¹; ¹Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ²Northwestern Univ., Chicago, IL

Abstract Body:

Metabolite genome-wide association studies (GWAS) have identified hundreds of variants, several of which also associate with cardiometabolic diseases. However, the majority of metabolite GWAS's have been published in older adult European ancestral population, limiting inference to a fraction of the world's population. Here we report the results of a GWAS of 7,522 metabolite levels in 714 individuals of African and 1,469 individuals of European ancestry from the Coronary Artery Risk Development in Young Adults (CARDIA) study (total n=2,183; mean age = 43.56, 56.1% female). Metabolomic profiling was performed in CARDIA (n=2,183) using an Ultra performance liquid chromatography-mass spectrometer (UPLC-MS) Orbitrap method. Ancestry-specific GWAS and ancestry-combined (via inverse-variance meta-analysis) GWAS of 8,534,915 (African-ancestry) and 5,886,255 (European-ancestry) TOPMed imputed genetic variants (minor allele frequency (MAF) >0.05) were conducted in CARDIA for 7,522 metabolic peaks adjusting for age, sex and the first five ancestral principal components (PC). Significant loci were identified based on a Bonferroni adjusted *P*-value of 6.6×10^{-13} . Metaboanalyst 5.0 was used to predict functional pathway activity of significant metabolomic peaks based on mass to charge ratios (m/z) using the *mummichog* algorithm. A total of 76, 315 and 486 metabolomic peaks contained at least one significant locus in the African, European, and combined ancestry populations, respectively. In stratified analyses, 15 of the 76 metabolomic identified peaks were unique to African ancestry participants. Eight of these metabolomic peaks contained the 5-Oxoprolinase, ATP-Hydrolysing (*OPLAH*) locus, a gene that catalyzes the cleavage of 5-oxo-L-proline to form L-glutamate. *OPLAH* lead variant rs3935209 (p.Ser284Arg) was common in African-ancestry populations (minor allele frequency [MAF] = 45%), but less frequent among other ancestral groups in the Genome Aggregation Database (MAF < 10%). Mummichog pathway analysis suggested that the identified metabolomic peaks participate in amino-acid-related pathways, specifically D-glutamine and D-glutamate metabolism. Two of these metabolomic peaks were annotated as 5-oxoproline (pyroglutamic acid) supporting the association of *OPLAH* with key cardiometabolic pathways. This study highlights the use of multiethnic and integrative omics approaches to broaden understanding of the genetic architecture underlying metabolites. Further work is needed to refine understanding of mapped loci and characterize identified loci in relation to cardiometabolic diseases.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3419. Genome-wide classification of epigenetic signal reveals regions of enriched heritability in complex immune traits

Authors:

M. Stricker¹, W. Zhang², W-Y. Cheng³, S. Gazal^{4,5}, C. Dendrou², S. Nahkuri⁶, P. Palamara^{1,2}; ¹Statistics Dept., Univ. of Oxford, Oxford, United Kingdom, ²Wellcome Ctr. for Human Genetics, Univ. of Oxford, Oxford, United Kingdom, ³Roche Pharma Res. & Early Dev. Informatics, New York, NY, ⁴Dept. of Population and Publ. Hlth.Sci., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA, ⁵Ctr. for Genetic Epidemiology, Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA, ⁶Roche Pharma Res. & Early Dev. Informatics, Zurich, Switzerland

Abstract Body:

Epigenetics plays a key role in regulating the expression of immune system (IS) relevant genes that dictate the therapeutic options for many diseases, but the link between high-dimensional epigenetic data and IS traits has not been fully explored.

We developed a supervised classification algorithm, called EpiNN, that leverages genome-wide epigenetic data to detect IS-relevant regions. We used a low-dimensional encoding of data produced by the ChromHMM model (Ernst & Kellis 2012) together with a handcrafted list of 888 IS loci to train a convolutional neural network, which obtained a testing AUPRC of 0.93 (SE 0.03). We used the trained model to scan the human genome for new IS regions and built a genome-wide annotation of predicted IS relevance, detecting 2765 loci with high (>0.5) EpiNN score. Of these, 1571 did not have an associated Gene Ontology term, while the remaining 1964 were enriched for IS-related function ($p = 7e-21$). To further validate these loci we performed PCR and Western Blot analyses for a constitutively expressed gene, obtaining evidence for the presence of a novel IS-specific transcription start site.

Next, we used LD score regression (S-LDSC, Finucane et al. 2015) coupled with association summary statistics for 176 traits (average $N = 262k$) to evaluate EpiNN's efficacy in detecting genomic regions enriched for heritability in IS traits. EpiNN's genome-wide IS annotation resulted in a significant enrichment and heritability effect size ($|\tau^*| p < 0.05/176$) for 20/26 IS traits (including e.g. Crohn's disease), remaining significant after conditioning on 97 other functional and evolutionary annotations. We performed a meta-analysis of 63 independent traits to confirm the specificity of the detected enrichments for IS phenotypes. IS-related traits were 4.45x (SE 0.09) more enriched for heritability ($p = 9e-92$) than non-IS traits. EpiNN effect size remained significant after further conditioning on annotations for IS-specific histone marks, ChromHMM, and transcription-based data used during training. Finally, we used S-LDXR (Shi et al. 2021) to test for depletion of squared trans-ancestry genetic correlation in European and East Asian association summary statistics for 15 IS traits (average $N_{EA} = 83k$, $N_{EU} = 235k$). The EpiNN annotation was the second most significantly depleted among 63 tested annotations, indicating ancestry-specific effects that may be driven by gene-environment interactions at IS loci impacted by recent adaptation.

These results underscore the promise of leveraging supervised learning algorithms and large epigenetic datasets to detect genomic regions implicated in specific classes of heritable traits and diseases.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3420. Genome-wide imputed differential expression enrichment (GIDEE) analysis identifies trait-relevant tissues

Authors:

D. Nyholt, A. Ghaffar, The International Headache Genetics Consortium; Queensland Univ. of Technology, Brisbane, Australia

Abstract Body:

The identification of pathogenically-relevant tissues for complex traits can be a difficult task. We have developed a novel pipeline named genome-wide imputed differential expression enrichment (GIDEE), to prioritise trait-relevant tissues by combining genome-wide association study (GWAS) summary statistic data with tissue-specific expression quantitative trait loci (eQTL) data from 49 GTEx v8 tissues. This method can be viewed as an extension of transcriptome-wide association studies (TWAS).

The GIDEE pipeline was applied to 29 GWAS datasets comprising nine ‘training’ datasets and 20 ‘discovery’ datasets. The causal tissues or cell types were uncertain or unknown for the discovery dataset traits, whereas the involvement of specific tissues in the pathogenicity of the training dataset traits had been established and reported in the literature. Therefore, the performance of four enrichment tests and their combinations was benchmarked utilising the GWAS training datasets by comparing the ranks for the known pathogenic tissue.

The best performing enrichment test produced an average rank of 1.55 out of 49 for the known pathogenic tissue across the nine GWAS training datasets. We subsequently applied the best performing GIDEE enrichment test to the 20 GWAS discovery datasets to prioritise their likely pathogenic tissues. GIDEE prioritisation may also help identify suitable proxy tissue/cell models (e.g., using enriched tissues/cells that are more easily accessible). The application of our GIDEE approach to GWAS datasets will facilitate follow-up *in silico* and *in vitro* research to determine the functional consequence of their risk loci.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3421*. Genome-wide study on 72,298 Korean individuals in Korean biobank data for 76 traits identifies hundreds of novel loci.

Authors:

K. Nam, J. Kim, S. Lee; Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract Body:

Population-based biobanks facilitate large-scale genome-wide association studies (GWAS) across numerous phenotypes. These extensive resources helped elucidate genetic components of complex traits and identify individuals with a high risk of disease. However, GWAS on diverse ancestry groups are lacking, resulting in deficits in genetic discoveries and polygenic scores. We report a GWAS of 76 phenotypes on 72,298 Korean individuals from the Korean Genome and Epidemiology Study (KoGES), a large biobank conducted by the National Biobank of Korea. Our analysis discovered 2,237 associated loci, including 117 novel associations, many of which were replicated in Biobank Japan (BBJ) at a nominal p-value. Many of the novel loci had very low minor allele frequency among European, demonstrating power increment by utilizing samples from diverse ancestry groups. To fully use the information in the KoGES data, we applied several up-to-date methods for genetic association tests such as survival GWAS and models to incorporate family disease history, discovering additional associations that are not identified in simple case-control GWAS. We also investigated pleiotropy and found that two neighboring genes in chromosome 12, *ERP29* and *NAA25* were the most pleiotropic genes with 28 associated phenotypes. To find East Asian-specific genetic associations, we conducted meta-analyses for 32 phenotypes using KoGES and BBJ GWAS results. We identified 379 novel associations and demonstrated the improved predictive performance of polygenic risk scores (PRS) by using the meta-analysis results. We believe that our results will contribute to elucidating the genetic architecture of complex traits by providing East Asian GWAS on many phenotypes. All the analysis results are publicly available at <https://koges.leelabsg.org>.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3423. GrafPop: A tool to quickly infer subject ancestry from multiple large genotype data sets.

Authors:

Y. Jin, M. Feolo, L. Phan, B. L. Kattman, J. R. Brister; Natl. Ctr. for Biotechnology Information, Natl. Library of Med., NIH, Bethesda, MD

Abstract Body:

GRAF-pop is a unique model-free algorithm to infer subject ancestry from genotypes (Y. Jin et al., 2019). Instead of using dimension reduction methods such as principal component analysis (PCA), it compares sample genotypes across a preselected set of SNPs to the allele frequencies of several reference populations with known ancestry backgrounds, then transforms the statistical scores and eventually project them onto a 2D plane to cluster the subjects. The algorithm was first implemented in the GRAF-pop feature of the GRAF (Genetic Relationship And Fingerprinting) software package, using the 10,000 fingerprint SNPs for ancestry inference. The GRAF-pop software tool can infer subject ancestry very quickly. The results obtained from genotype data collected using different methods and covering different SNPs are comparable and can be plotted in the same graph. GRAF-pop initial version, using only 10,000 SNPs unrelated to ancestry, can clearly cluster subjects into continental level populations (European, African, etc.). In addition, it can distinguish South Asians from East Asians and separate the geographic complex “Hispanics” population into two clusters. GRAF-pop is currently used in NCBI dbGaP curation pipeline and the Allele Frequency Aggregator (ALFA) project to provide population allele frequency from millions of dbGaP subjects (<https://www.ncbi.nlm.nih.gov/snp/docs/gsr/alfa/>).

In this presentation I will present an improved implementation of the GRAF-pop algorithm in a new tool GrafPop that uses 10x more markers (100K) to provide more precise clustering. GrafPop can cluster subjects with much finer granularities, for example, Central, Southern and Northern Europeans can now be separated into different clusters. GrafPop tolerates some errors and missing values in the data and hence preprocessing (e.g., filtering, imputing, deduplicating) is unnecessary. The tool quickly estimates the ancestry components for every subject in the data sets and returns results in tables and displays them in scatter plots for convenience of visual inspection.

Addition improvements include 1) support for common genotype input formats including PLINK binary data sets and large, zipped VCF files generated by whole genome sequencing; 2) SNPs are not required to be labeled with dbSNP rs IDs.

GrafPop is released as a stand-alone software, which is independent of the GRAF software package, and is freely downloadable from the following webpage: <https://www.ncbi.nlm.nih.gov/projects/gap/cgi-bin/Software.cgi>.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3424*. GWAS meta-analysis of DXA-derived bone mineral density identifies 42 novel loci and uncovers biological pathways not previously identified in larger studies of ultrasound-derived bone mineral density.

Authors:

M. Frysz^{1,2}, T. Lu³, H. Lu⁴, B. H. Mullin⁵, F. Rivadeneira⁶, J. Tobias^{1,2}, B. B. Richards³, C. Ohlsson⁷, D. Kiel⁸, C. Medina-Gomez⁴, J. P. Kemp^{9,2}, on behalf of the GEFOS/GENOMOS/CHARGE; ¹Univ. of Bristol, Bristol, United Kingdom, ²MRC IEU at the Univ. of Bristol, Bristol, United Kingdom, ³McGill Univ., Montreal, QC, Canada, ⁴Erasmus MC, Rotterdam, Netherlands, ⁵The Univ. of Western Australia, Perth, Australia, ⁶Erasmus MC Rotterdam, Rotterdam, Netherlands, ⁷Gothenburg Univ., Gothenburg, Sweden, ⁸Hebrew SeniorLife, Boston, MA, ⁹Inst. for Molecular BioSci., The Univ. of Queensland, St Lucia, Australia

Abstract Body:

Background: Osteoporosis (OP) is a skeletal disorder characterized by low bone mineral density (BMD), and an increased risk of fracture (FX). BMD measured by dual-energy X-ray absorptiometry (DXA) at the femoral neck (FN) and lumbar spine (LS), is used to diagnose OP. GWAS has identified >500 BMD-associated loci. However, >90% were detected in a GWAS of BMD estimated by ultrasound (eBMD), which correlates moderately with DXA BMD ($r=0.3 - 0.6$), but is not used to diagnose OP. Aim: To conduct the largest GWAS meta-analysis of FN- and LS-BMD and identify novel biological pathways that regulate DXA BMD and were not detected in larger studies of ultrasound eBMD. **Methods:** GWAS of FN and LS-BMD (adjusted for age & sex) was conducted in ~17 cohorts, and meta-analyzed using a fixed-effects method (NTotal~148,000). Conditional and joint analysis was used to identify novel DXA BMD-associated SNPs that were statistically independent of published eBMD-associated SNPs. SNP-based heritability was estimated by LD-score regression. Candidate genes involved in BMD regulation were identified using downstream analyses including (but not limited to) expression QTL analysis of bone resorbing cells, and serum protein QTL analysis. **Results:** Independent SNPs in 165 and 190 loci were associated ($P<5\times 10^{-8}$) with FN- and LS-BMD respectively. They explained 12% and 14% of FN- and LS-BMD variance and accounted for ~50% of the total estimated SNP heritability of FN- ($h^2_{SNP}=23\%$) and LS-BMD (27%). Novel BMD associated SNPs mapping to the calcium-sensing receptor gene (*CASR*) and 41 other loci were detected >1mb from published eBMD associated lead SNPs. SNPs at several novel loci, including *TTL7* and *BCAR1* were robustly associated with FN- and LS-BMD ($P<5\times 10^{-8}$), but not with eBMD ($P>0.02$). Lead SNPs at the remaining 145 FN- and 168 LS-BMD loci mapped to within 1mb of published eBMD SNPs. Unexpectedly, several were robustly associated with increased DXA BMD, and decreased eBMD (e.g., *DLEU1* & *BCAS3*). In contrast, SNPs in ~40 loci were independent of published eBMD SNPs, despite being in close proximity (e.g., *DAAMI* & *JAG2*). Protein QTL analysis implicated TNFRSF11A, an established drug target for OP, among several other proteins that were predicted to regulate BMD but have not previously been linked to skeletal function (e.g., *CFHR1*). **Conclusions:** GWAS of DXA BMD in a sample that was 3-fold smaller than ultrasound eBMD, identified 42 novel loci and implicated biological pathways that may contribute to the regulation of bone density. These findings highlight the importance of analyzing BMD measures used clinically for diagnosing OP and warrant further investigation as they may uncover new drug targets for OP.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3425. GWAS of breast cancer family history reveals evidence for indirect genetic effects on maternal cancer risk.

Authors:

Z. Sun, Y. Wu, Q. Lu; Univ. of Wisconsin-Madison, Madison, WI

Abstract Body:

Breast cancer is the most common cancer among women worldwide and is the most frequent cause of cancer-related mortality in women. To date, genome-wide association studies (GWAS) have found over 200 significant loci associated with the risk of breast cancer. Additionally, data on breast cancer family history in large biobanks, which has been shown to be an effective proxy of disease risk in GWAS, provide new opportunities to further accelerate GWAS findings. However, existing analytic approaches for GWAS of disease family history lack consideration of indirect genetic effects in families: one's genotype can have an effect on other family members' phenotypes. For example, there has been extensive evidence of maternal genetic effects (also known as "genetic nurture") on child's birth weight and cognition. Here, we expand and employ the DONUTS approach developed by our group and leverage well-powered GWAS on breast cancer and breast cancer family history, to investigate an understudied type of indirect genetic effect: how children's genotypes influence their mother's breast cancer risk. We first performed a GWAS of maternal breast cancer history using samples of European descent in UK Biobank (N = 383,034) while adjusting for age and sex. We found 13 genome-wide significant loci with an expected and substantial overlap with known GWAS loci identified in case-control GWAS. However, one locus on chromosome 22 (rs56312415) showed highly suggestive association with breast cancer family history ($p = 9.1 \times 10^{-8}$) but not in case-control analysis ($p = 5.1 \times 10^{-1}$). This variant is in the *TXNRD2* gene, which encodes a protein belonging to the pyridine nucleotide-disulfide oxidoreductase family and is known to play a role in cellular redox environment and breast cancer pathogenesis. We then applied an extension of DONUTS approach to partition direct and indirect genetic effects through jointly analyzing breast cancer family history GWAS and case-control breast cancer GWAS (meta-analysis of Breast Cancer Association Consortium GWAS and UK Biobank; N = 467,890). The *TXNRD2* locus showed a highly significant indirect effect (on maternal cancer risk; $p = 3.3 \times 10^{-8}$) while the direct effect (on self cancer risk) was not statistically significant ($p = 8.3 \times 10^{-5}$). We further performed genetic correlation analysis and identified differential genetic correlations of self/maternal breast cancer risk with depression and educational attainment. These results provide compelling evidence for indirect genetic effects on maternal breast cancer risk and suggest extra caution for integrating family history data into standard GWAS design.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3426. GWAS of pericarditis derived from a natural language processing model on self-reported free text data identifies a genome-wide significant association on chromosome *2q14.1*.

Authors:

C. German, 23andMe Research Team, N. Eriksson, S. S. Shringarpure; 23andMe, Inc., Sunnyvale, CA

Abstract Body:

Pericarditis is a rare condition involving inflammation of the pericardium. It has been reported as a rare outcome following COVID-19 infections and COVID-19 vaccinations. A main barrier to studying the genetics of rare conditions like pericarditis is gathering enough cases to have adequate power. Empowered by the large advances in deep learning, natural language processing (NLP) is an emerging field of artificial intelligence concerned with processing and understanding natural language (speech and text data). Named entity recognition models, a class of NLP models, aim to identify named entities (such as names, locations, etc.) in text data. scispaCy is an open-source python package developed by the Allen Institute for Artificial Intelligence that has various types of pre-trained named entity recognition models fine-tuned to biomedical, clinical, and scientific text. Here we illustrate the utility of this class of NLP models for genetic discovery when used in conjunction with large-scale self reported free text data and genetic data collected through the 23andMe, Inc. direct-to-consumer platform. We gathered self-reported free text data from a cohort of over 1 million genotyped research-consented individuals, where participants were asked to write out health conditions they had that had not been covered by a survey mainly focused on common diseases (prevalence >1%). We then applied a pre-trained NLP model from the scispaCy library on the free text data to identify cases of pericarditis. We used these individuals as cases to run a GWAS and found a genome-wide significant association in the 2q14.1 region (p-value = 2.0e-14) with an odds ratio of 0.733 (95% CI: [0.675, 0.795]). Our results demonstrate that using NLP models on self-reported free text survey data is a viable method for identifying genetic associations in pericarditis. This approach may be useful for other rare conditions when there is free text data available, where case counts are often the limiting factor in discovery.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3427. GWAS of serum ALT and AST using whole genome sequencing data for 119,009 UK Biobank participants yields novel associations with rare variants.

Authors:

A. Holleman, R. A. Hoffing, A. M. Deaton, L. Krohn, P. LoGerfo, P. Nioi, M. E. Plekan, C. Willis, L. D. Ward; Alnylam Pharmaceuticals, Cambridge, MA

Abstract Body:

Liver disease is a leading cause of mortality globally and has increased in incidence over the past two decades. Understanding the genetic contributions to liver disease holds great promise for guiding the development of more effective and safer therapeutics. Research groups including ours previously leveraged biobank-scale genome-wide imputation and whole exome sequencing (WES) datasets to identify numerous associations of genetic variants with both serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST), enzymes that are biomarkers of liver injury and that in combination are predictors of liver disease. In the current study, we furthered our examination of genetic contributors to ALT and AST by analyzing whole genome sequencing (WGS) data from 119,009 UK Biobank participants with European ancestry (a subset of the samples included in our previous analyses using imputed data). We used REGENIE to perform a genome-wide association study of approximately 71 million single nucleotide variants (SNVs) and indels with a minor allele count of at least 10. After applying a strict Bonferroni correction for the number variants tested, we identified 42 candidate loci associated with ALT and 58 candidate loci associated with AST. We found no novel loci that were associated with both ALT and AST (defining novel as not being reported in GWAS Catalog). However, we did uncover novel loci associated with one or the other enzyme. Of the 42 ALT-associated loci, one was novel: a rare intergenic SNV situated between *CYP11B2* and *LY6E* on chromosome 8 (Beta = -1.49; P = 4.33e-14), with the latter gene broadly expressed including in the liver. Of the 58 AST-associated loci, 3 were novel, all located on chromosome 10: a rare 3-base deletion within an intron of *RSU1* (Beta = -0.59; P = 7.83e-12); a locus spanning 170kb and including two rare SNVs, one within an intron of *CYP2C19* (Beta = 1.54; P = 5.09e-11) and the other approximately 1,100 bases upstream of *CYP2C9* (Beta = 1.54; P = 5.11e-11), both of these genes being primarily expressed in the liver; and a rare intergenic SNV located between *CCNJ* and *ZNF518A* (Beta = 1.49; P = 2.02e-10). The association of these variants specifically with ALT or AST, and not with both enzymes, suggests that they may not be informative for liver disease drug target identification. Yet insofar as these loci contribute to normal variation in ALT or AST levels, it may be useful to account for them when examining potential toxic effects of a drug on the liver. Future research plans include analyzing associations of ALT and AST with copy number variants called based on the WGS data for our sample set.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3428. Hand grip strength and its underlying genetics is associated with widespread protein changes revealed by population-based plasma proteomics.

Authors:

Y. Huang, D. Bodnar, B. Sun, C. Whelan, Biogen Biobank Team, K. Meilleur, J. Shi, H. Runz, E. Tsai; Biogen, Cambridge, MA

Abstract Body:

Hand grip strength (HGS) is a proxy measure of general muscle strength and a predictive measure of multiple adverse health outcomes including disability and mortality. Previous studies have shed light on protein changes in human muscle associated with aging and exercise, but most were limited by small sample sizes due to the rarity of muscle tissue samples. Plasma proteins such as creatine kinase have also been used as biomarkers for certain muscular atrophy and injuries, but systematic changes in blood protein concentrations have not been evaluated for general muscle strength. The UK Biobank Pharma Proteomics Project (UKBB-PPP) measured circulating concentrations of 1,463 plasma proteins in 54,306 UK Biobank participants, for whom HGS was also measured at recruitment using hydraulic hand dynamometer. We conducted a proteome-wide association analysis of HGS adjusted for age, sex, height, body weight, and BMI among 48,699 participants that passed data quality control. Out of 1,463 protein species measured in plasma, 75 positive and 928 negative associations were significant after Bonferroni correction ($p < 3.4e-5$). Strongest positive associations were observed for CA14, ENPP5 and EGFR, while top negative associations included LEP, GDF15 and CLMP. Gene-set enrichment analysis (GSEA) using Enrichr identified myoblast proliferation, TGF-beta activation, and myoblast migration as the top enriched pathways for positively associated proteins, while inflammatory pathways including cytokine production and monocyte/lymphocyte chemotaxis were most enriched for negatively associated proteins. To explore proteomic associations with HGS driven by underlying genetic susceptibility, we conducted a GWAS of maximum HGS among 327,290 UKBB participants of European ancestry that were not included in UKBB-PPP and derived a polygenic score using PRS-CS from 1.17 million variants. HGS-PRS was then calculated for 36,367 European UKBB-PPP participants to assess its proteomic associations. 51 plasma proteins showed significant associations with HGS-PRS, of which 23 were positively associated, and 43 were previously associated with HGS. Consistently, GSEA identified muscle-relevant pathways such as myoblast proliferation and calcium transport for HGS-PRS positively associated proteins and inflammatory pathways for HGS-PRS negatively associated proteins. Our analysis reveals systematic associations of HGS with the plasma proteome and the potential impacts of genetic susceptibility to general muscle strength on muscular and inflammatory pathways.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3429. Haplotype-based fine-mapping of variant associations for complex traits

Authors:

A. Massarat, M. Gymrek; Univ. of California San Diego, La Jolla, CA

Abstract Body:

Over the past decade, genome-wide association studies (GWAS) have identified thousands of genomic loci associated with a range of traits in humans. However, identifying the underlying causal variant(s) driving an association signal is challenging. A typical GWAS signal may harbor hundreds of variants in strong linkage disequilibrium (LD) with each other, most of which are not causal for the trait. Further, even when the causal variant is directly genotyped, it may not have the best p-value in the locus. A variety of methods have been developed to perform statistical fine-mapping, with the goal of inferring the candidate causal variants at a particular GWAS signal. However, existing methods face several important limitations: they typically focus on independent contributions of individual bi-allelic variants such as single nucleotide polymorphisms (SNPs) and assume the true causal variant exists within the set of candidate variants being considered at a locus. Yet increasing evidence suggests that many of the strongest GWAS signals are driven by complex variants such as repeats or structural variants that are not typically directly genotyped, are often multi-allelic, and may be in only modest LD with surrounding SNPs. Existing fine-mapping solutions will not produce reliable results for these cases. Here, we present happler, a new fine-mapping method that models the effects of SNP haplotypes (sets of alleles at one or more SNPs inherited on a single chromosome) rather than of individual SNPs. SNP haplotypes are better able to capture effects of variants that were not directly included in a GWAS dataset, such as repeats, structural variants, and rare variants. To identify trait-associated haplotypes, happler constructs binary trees of regression models composed of correlated variants as nodes, where a path from the root to a leaf identifies a haplotype that can be used as input to an existing fine-mapping method to obtain a probability of causality. We demonstrate the utility of our tool using phenotypes simulated based on causal variants not directly genotyped, and show that we can identify haplotypes harboring the true causal variant. We are currently applying our method to real GWAS data for blood and serum biomarker traits profiled by the UK Biobank. Overall, we envision that a haplotype-based approach will improve the ability to fine-map loci driven by complex variants not typically considered in GWAS. Further, we predict that improved identification of causal variants will ultimately better our understanding of the biological mechanisms driving complex traits and improve our ability to predict disease risk for individual patients based on their genotypes.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3430. Hierarchical scanning strategy reveals signal regions in 260 genes implicated in regulation of gene expression on chromosome 19q

Authors:

X. Zhang, W. Bush; Case Western Reserve Univ, Cleveland, OH

Abstract Body:

Hi-C experiments and FISH imaging have provided evidence of chromatin's dynamic 3D folding and looping structures, including hierarchical Topologically Associating Domains (TADs), within the nucleus. TAD boundaries are traditionally called directly from Hi-C data. Regions between TAD boundaries are believed to be isolated environments that constrain enhancer-promoter interactions. However, it's hard to associate the unstable TAD with gene regulation. Besides, we still lack an understanding of the function of the hierarchical TADs and the sub-loops. This study assumed that the sub-loops have a similar enrichment pattern of chromatin interaction as TADs. We further restrict the analysis to focus on the regulation effect of rare genetic variants located within transcription factor binding sites (TFBSs). Instead of calling hierarchical TADs directly from Hi-C data, we implemented scan tests on RNA-seq and WGS data to identify clusters of TFBSs associated with gene expression levels, ignoring the physical distance between the TFBS and gene along the genome. We can then use the identified clusters as a proxy to describe the hierarchical chromatin structures. We first concatenated overlapping TFBSs into single initial scanning units. Then we utilized a flexibly shaped spatial scan framework (PSCAN, Tang et al., 2020) to define scan windows while accommodating the positions of the concatenated TFBSs. For each gene expression trait, p-values from set-based rare-variant variance-effect tests were combined to evaluate the global association; non-overlapping signal regions were also detected. With such a scanning and testing strategy, we can identify tissue- and gene-specific TFBS clusters along the genome and infer the hierarchical insulated loop structures like hierarchical TADs based on these clusters. We applied this scanning strategy to chr19q using GTEx (v7) Whole Blood data (N=369). We defined 4,653 clusters of concatenated TFBSs within the scanning region and applied the afore-described scan test to 302 gene expression traits on chr19q. We identified signal regions for 260 genes, suggesting that the TFBSs residing in the signal regions have a joint effect on gene expression regulation. Further investigation into these signal regions will inform both the cis- and trans-regulation effects of transcription factor binding events. We can infer potential hierarchical structures of chromatin using this approach.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3431. HLA Analysis Tool Kit v2.0

Authors:

W. Choi¹, B. Han²; ¹Seoul Natl. Univ. Graduate Sch., 103 Daehakro, Jongro-gu, Korea, Republic of, ²Seoul Natl. Univ. Coll. of Med., Seoul, Korea, Republic of

Abstract Body:

Fine-mapping association signals arising in Human Leukocyte Antigen(HLA) region can offer important information in investigating immune-related diseases. We previously introduced HLA Analysis Tool-Kit(HATK; Bioinformatics 2021) to facilitate the fine-mapping analysis for researchers, providing (1) preprocessing of DNA and amino acid sequences from the IPD-IMGT/HLA database, (2) preparation of virtual marker data for association test with given HLA type data, and (3) visualization of association signals. Here we present HATK v2.0, which improved in several aspects. First, HATK v2.0 now can handle more non-classical HLA genes such as *HLA-MICA*, *-MICB*, *-V*, or *-E*, while the HATK only worked restricted to the 8 major HLA genes, i.e. *HLA-A*, *-B*, *-C*, *-DPA1*, *-DPB1*, *-DQA1*, *-DQB1*, and *-DRB1*. Second, HATK v2.0 provides automated phasing to its output marker panel, which can make it easier for researchers to conduct downstream haplotype analysis. Although the HATK provided the omnibus test that can perform both the association test of an amino acid locus and conditional haplotype analysis of phased amino acid data, the HATK didn't provide a phasing module. Therefore, researchers were required to phase their data by themselves. Third, researchers can now use HATK v2.0 to generate a custom reference panel that can be used in HLA imputation by CookHLA. Currently, the MakeReference module included in the SNP2HLA software is being widely used for this function given the typed HLA and SNP data. However, this module only works on the outdated version of the IMGT database and is fixed to the outdated hg18 genomic coordinate. HATK v2.0 provides the same functionality but with high flexibility where users can choose a specific IMGT database version and their preferred genomic coordinate. HATK v2.0 is freely available at <https://github.com/WansonChoi/HATK>.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3432. Hybrid autoencoder for robust ancestry inference in the presence of data artifacts and relatedness.

Authors:

M. Yuan¹, H. Hoskens¹, S. Goovaerts¹, N. Herrick², M. Shriver³, S. Walsh², P. Claes^{1,4}; ¹KU Leuven, Leuven, Belgium, ²Indiana Univ. - Purdue Univ. Indianapolis, Indianapolis, IN, ³Penn State Univ, University Park, PA, ⁴Murdoch Children's Res. Inst., Melbourne, Australia

Abstract Body:

Analysis of genetic ancestry remains an important topic in human genetics and bioinformatics. Conventional methods are typically affected by laboratory artifacts and related individuals in the dataset. Thus, complex quality control procedures are often required to ensure accurate inference of genetic ancestry. In this work, we propose a novel hybrid approach, referred to as SAE-IBS, which consists of a Singular Autoencoder (SAE) generalized by an Identity-by-State (IBS) similarity matrix, for robust ancestry inference in the presence of missing data, genotyping errors, and relatedness. SAE-IBS yields an orthogonal latent space, like matrix decomposition-based methods, and can extract more comprehensive latent features by exploiting the non-linear nature of neural network-based methods. We demonstrate that the proposed approach achieves comparable performance with principal component analysis (PCA), the most widely used method for genetic clustering and ancestry inference through classification of global population by continent. Moreover, the ancestry space obtained by SAE-IBS exhibits interesting patterns: it has a PCA-like variance-covariance structure, yet different population groups can be separated with fewer dimensions compared to PCA. This layout remained consistent under different hyperparameter settings and was independent of the dimensionality used to train the model, leading to a strong and desired stability of the population structure inference and an enhanced dimensionality selection after training. Furthermore, with the flexibility in training neural networks, we show that a robust ancestry space in the presence of relatedness can be obtained by simply changing the loss function from L2 norm to L1 norm, whereas the least-square matrix decomposition encountered in PCA leads to sensitivity to relatedness. Finally, we integrate the principle of denoising training into our model and propose an extension by imposing robust projections through the incorporation of an additional loss, i.e., Denoising SAE-IBS-L. The proposed extension reaches higher accuracy than existing methods for projecting poor quality target samples (genotyping errors and missing data) onto a reference ancestry space.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3433. HybridGWAIS-Web: A fast and secure epistasis detection web service

Authors:

L. Wienbrandt, C. Priess, D. Ellinghaus; Inst. of Clinical Molecular Biology, Kiel Univ., Kiel, Germany

Abstract Body:

Genome-wide association interaction studies (GWAIS) have become increasingly important as it is believed that genetic interactions play a significant role in genetic variation causing complex diseases. For assessing gene-gene (GxG) interactions, logistic regression as implemented in the PLINK tool is a powerful and commonly used framework. However, fitting regression models for each pair of markers in a genome-wide data set is an extremely compute intensive task.

We recently demonstrated that we are able to speedup PLINK's epistasis test by a factor of more than 1,600 on a hybrid computing architecture that combines a Field-Programmable Gate Array (FPGA) with a Graphics Processing Unit (GPU). Analysis of our exemplary case-control data set with 16,000 samples typed at 1.2 million markers takes 3:45 hours on our system, while computation with PLINK takes more than 260 days, even when run with 32 threads on a 16-core system with hyper threading.

We now introduce the HybridGWAIS-Web web service which makes our tool, along with the computing power of the hybrid combination of FPGAs and GPUs, freely available. The web service allows researchers to perform GWAIS without access to high-performance computing resources to analyze their genome-wide data sets quickly and conveniently.

Besides the multiplicative logistic regression test (as implemented in PLINK) HybridGWAIS-Web provides other statistical tests as well, such as mutual information, interaction gain, or the BOOST epistasis screening method. Third-order interaction tests between three genetic markers are also available, and linkage disequilibrium (r^2 -correlation) values between each pair of markers can optionally be calculated on-the-fly.

HybridGWAIS-Web combines easy access to our hybrid computing system, many convenient algorithmic features (such as chromosome region selection, result filtering of best results, etc.), user data protection (usage is compliant with the European General Data Protection Regulation (GDPR)), and security (through exclusively encrypted connections, password-protected data access and optional 2-factor authentication).

For now, users can upload data sets for which the predicted runtime analysis would take no longer than one day. In that time, users can run a logistic regression test on a case-control data set with e.g. up to 100,000 samples typed at 1.25 million markers. On a usual CPU-based server-grade compute node these tests would take more than 4 years using PLINK's original epistasis test.

The HybridGWAIS-Web service is freely available at <https://hybridcomputing.ikmb.uni-kiel.de>.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3434*. Identification of age-related genetic and molecular determinants and their link to disease.

Authors:

T-D. Michalettou¹, M-G. Hong², J. Fernandez³, S. Sharma⁴, C. A. Brorsson⁵, R. W. Koivula^{3,6}, J. Adamski⁴, S. Brunak⁷, E. T. Dermitzakis⁸, P. W. Franks⁶, M. McCarthy⁹, E. Pearson¹⁰, J. Schwenk¹¹, M. Walker¹, DIRECT consortium, A. Brown¹⁰, A. Vinuela¹; ¹Newcastle Univ., Newcastle upon Tyne, United Kingdom, ²Natl. Bioinformatics Infrastructure Sweden, Stockholm, Sweden, ³Univ. of Oxford, Oxford, United Kingdom, ⁴HelmholtzZentrum München, Neuherberg, Germany, ⁵Technical Univ. of Denmark, Lyngby, Denmark, ⁶Lund Univ., Lund, Sweden, ⁷Copenhagen Univ., Copenhagen, Denmark, ⁸GSK, Geneva, Switzerland, ⁹Genentech, South San Francisco, CA, ¹⁰Univ. of Dundee, Dundee, United Kingdom, ¹¹KTH Royal Inst. of Technology, Stockholm, Sweden

Abstract Body:

Ageing is a complex process, involving changes in multiple molecular, cellular, tissue and organ systems, which has a great impact on disease risk for many different conditions. To identify the age-related changes in molecular phenotypes that may lead to increased disease risk with age, we evaluated the influence of age, type 2 diabetes (T2D) status, sex and BMI on whole blood and plasma transcriptomic, proteomic and metabolomic data from the DIRECT consortium (N=3,029 participants). We found 10,687 genes (66%) and 287 proteins (77%) were differentially expressed with age (FDR<0.05). We found 148 cases where both the gene and the corresponding protein were associated with age, of which 50% showed an opposite directions of effect. For example, gene *REG4* showed a decrease in expression with age (Pval=2.40e-46, β =-0.058) while the protein abundance increased as participants aged (Pval=2.62e-15, β =0.006). While this result is counter-intuitive, it is in agreement with results of other analyses we have seen, where genetic factors frequently have opposite effects on gene and protein levels. We observe the highest proportion of age associations when analysing metabolite levels. Of the targeted and un-targeted metabolites evaluated (n=349), 78% were associated with age (FDR<0.05), including L-Carnitine (Pval=5.91e-17, β =0.020) and DHEA-S (Pval=4.27e-86, β =-0.056). We additionally evaluated the independent effects of sex, BMI and T2D status on these molecular phenotypes. We found 10191 genes associated with sex, the majority of which overlapped with genes associated with age. T2D status was associated with the largest number of proteins (308 associations) and sex and BMI were associated with similar numbers of metabolites (335 and 305 associations respectively). We found 8 proteins associated only with T2D after controlling for BMI, age and sex, including TSHB, GP6 and SLAMF7. We also find examples of sex-specific effects of age. For example levels of the SOST protein increase with age in men, but decrease in women. Most measured molecular phenotypes are significantly associated with age, however the effect of age frequently differed across related phenotypes. By identifying age-related changes in molecular phenotypes we are one step closer to uncovering the link between ageing and disease, either because these phenotypes are the mediating actors, or because these phenotypes interact with the genetics of the relevant disease.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3435. Identification of key biomarkers associated with obesity using multi-omics data integration

Authors:

A. Liu¹, L. Jiang¹, K-J. Su¹, X. Zhang¹, Y. Gong¹, c. qiu¹, J. Greenbaum¹, Z. Luo¹, Q. Tian¹, Z. Ding², H. Shen¹, H-W. Deng¹; ¹Tulane Univ. Sch. of Med., New Orleans, LA, ²Tulane Univ. Dept. of Computer Sci., New Orleans, LA

Abstract Body:

Obesity has emerged as a major global public health problem in the 21st century, spreading rapidly across both developed and developing countries and disproportionately affecting the most vulnerable and socially disadvantaged populations. Omics-based technologies have been put forward to provide a better understanding of obesity etiology. While each omics technology is capable of depicting a portion of the biological information, integrating multiple types of omics data can provide a more comprehensive picture of the underlying biological processes. Specifically, for obesity, existing research has shown that incorporating data from multiple omics technologies can improve the performance of patient clinical categorization in comparison with only using one single type of omics data. Therefore, to effectively take advantage of the interactions and complementary information in multi-omics data, the application of integrative analysis methods is very necessary. Here, we will apply a multi-omics integrative method using multi-view graph attention networks for binary and multi-class biomedical classification by combining multi-omics data—such as single nucleotide polymorphisms (SNPs), copy number variations, mRNA gene expression, miRNA, DNA methylation and metabolomics. This method jointly explores omics-specific learning with graph attention networks and cross-omics correlation learning with view correlation discovery network (VCDN) for effective multi-omics data classification. We will apply the proposed method on obesity classification tasks in a multiethnic sample (61% Caucasian and 39% African American) from Trans-omics Integration of Multi-omics Studies for Male Osteoporosis Study (n = 919). The top 30 SNPs, copy number variations, mRNA, miRNA, DNA methylation and metabolomics features will be identified by layer-wise relevance propagation as the key important biomarkers associated with obesity. The identification of obesity biomarkers and the understanding of their biological roles would be transformed into consistent benefits for the effective prevention, intervention, and treatment for both obesity and obesity-related diseases.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3436. Identification of rare genetic coding variants associated with Alzheimer's disease.

Authors:

Z. Khurshid^{1,2}, J. Farrell², T. Tong^{1,2}, C. Zhu², E. Martin³, M. Pericak-Vance³, A. Naj⁴, A. Kuzma⁴, L. Cantwell⁴, O. Valladares⁴, L-S. Wang⁴, G. Schellenberg⁴, J. Haines⁵, K. Lunetta⁶, Y. Leung⁴, X. Zhang^{1,2,6}, L. Farrer^{1,2,6}, Alzheimer's Disease Sequencing Project (ADSP); ¹Bioinformatics Program, Boston Univ., Boston, MA, ²Dept. of Med. (BioMed. Genetics), Boston Univ. Sch. of Med., Boston, MA, ³Hussman Inst. of Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL, ⁴Penn Neurodegeneration Genomics Ctr., Dept. of Pathology and Lab. Med., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA, ⁵Dept. of Population and Quantitative Hlth.Sci. Case Western Reserve Univ., Cleveland, OH, ⁶Dept. of Biostatistics, Boston Univ. Sch. of Publ. Hlth., Boston, MA

Abstract Body:

Background: Alzheimer's disease (AD) is the most common cause of dementia resulting in memory loss and an impaired cognitive function. Previous whole exome sequencing (WES) studies of samples including as many as 11,000 subjects have identified genome-wide significant associations with rare variants in several novel genes, but also highlighted the need for investigations in even larger samples. We combined WES and WGS data assembled by the Alzheimer Disease Sequencing Project (ADSP) to increase power for detection of associations with rare variants in gene coding regions.

Methods: We developed an efficient computational pipeline to perform both pre-merging and post-merging genotype, variant and sample-level quality control (QC) on WGS data containing 16,905 individuals (in short, 17K WGS) and WES data for 20,504 individuals. The resultant sample included participants from European (EA, 11,279 AD cases and 8,924 controls), African American (AA, 2,757 AD cases and 4,336 controls), and Dominican (DR 1,438 AD cases and 3,256 controls) ancestries. In the total sample set (joint analysis and ethnicity stratified datasets), we tested for association of AD with 250,465 bi-allelic variants that passed our QC pipeline with minor allele count ≥ 20 , call rate $\geq 80\%$, HWE p -value $\geq 1 \times 10^{-8}$ using a logistic model implemented in GENESIS including covariates for age, sex, exome capture kit, read length, and principal components (PCs) of ancestry. The same model was also implemented without adjusting for age to account for the unique nature of the 20K WES where the selected controls were older than AD cases.

Results: Using a study-wide significant (SWS) threshold of $p = 0.05/250,465 = 2 \times 10^{-7}$ in the joint analysis, we found associations with variants from 7 independent loci. As expected, the top-ranked association was observed with a SNP in APOE (rs429358, $p = 1.12 \times 10^{-209}$) which was also SWS in EAs ($p = 4.77 \times 10^{-74}$), AAs ($p = 2.31 \times 10^{-47}$), and DRs ($p = 1.70 \times 10^{-14}$). Ethnic stratified analysis also showed SWS associations with rs367563342 in ICK ($p = 7.74 \times 10^{-11}$) in EAs and rs200944727 in CPSF1 ($p = 4.02 \times 10^{-8}$) in DRs.

Discussion: We demonstrated how merging WGS and WES datasets can help us increase genetic power and find novel rare coding variants that provide insight into AD pathogenesis. Multiple known and novel AD loci were identified but the known R47H rare variant in TREM2 that reached SWS in prior studies was not found. This could be due to sample set differences, as samples in previous study were enriched for AD cases with familial disease as this wasn't the case for the current WGS and WES samples.

PB3437. Identifying circulating proteins as biomarkers for age at menarche and age at natural menopause: insights from a Mendelian randomization study

Authors:

N. Yazdanpanah¹, M. Yazdanpanah¹, D. Manousaki²; ¹CHU Sainte-Justine, Montréal, QC, Canada, ²Sainte Justine Hosp. Univ. of Montreal, Montreal, QC, Canada

Abstract Body:

Objective: Age at menarche (AAM) and at natural menopause (ANM) in humans are highly heritable traits. In an effort to characterize novel biomarkers associated with the female reproductive lifespan, we aimed to identify circulating proteins, whose genetically predicted levels are associated with age at menarche or natural menopause, by performing a two-sample Mendelian Randomization (MR) study. *Research Design and Methods:* Utilizing *cis* genetic determinants (protein quantitative trait loci or pQTL) of up to 1379 circulating proteins from five large genome-wide association studies (GWAS), we performed a two-sample MR study, to screen for causal associations of these proteins with AAM and ANM in women from the REPROGEN GWAS (n=370,000 for AAM and n=200,000 for ANM). Further, pleiotropy-robust MR methods were used in sensitivity analyses using both *cis* and *trans*-pQTL. As follow-up analyses for the MR-prioritized proteins, we performed colocalization, pathway and enrichment analyses using expression profiles. *Results:* We identified 18 circulating proteins associated with AAM and 14 proteins associated with ANM. Our pathway enrichment analysis suggests involvement of the AAM-related proteins in peptide hormone biosynthesis in pituitary. Among these proteins, HPGDS (*cis*-pQTL: rs1965049) showed colocalization with AAM. Moreover, our pathway enrichment analysis for the 14 proteins associated with ANM demonstrates functional effects of these molecules on the immune system, while we found enriched expression of their *cis*-pQTLs in the immune system and adipose tissue. CPNE1 (*cis*-pQTL: rs12481228) ADAMTS13 (*cis*-pQTL:rs71503194) and LY9 (*cis*-pQTL:rs12128261) proteins strongly colocalized with ANM. *Conclusions:* Our findings highlight a potential role of the genes encoding the prioritized circulating proteins in the physiology of the reproductive lifespan in women, while these proteins can serve as biomarkers predicting age variations in menarche and natural menopause. Further study of the shared and specific proteomic profiles associated with ages at menarche or natural menopause may help identifying pathophysiological pathways and new targets for treatment of extreme variations in timing of puberty or menopause.

PB3438. Identifying common genetic susceptibility underlying comorbid phenotypes using Binomial Regression.

Authors:

S. Ghosh, P. Panja; Indian Statistical Inst., Kolkata, India

Abstract Body:

The models suggested in Multiphen (O'Reilly et al., 2012) and BAMP (Majumdar et al, 2015) provide an alternative to study population-based genetic association with multivariate phenotypes by exploring the dependence of genotype on phenotype instead of the naturally arising dependence of phenotype on genotype. However, these tests for association are based on the null hypothesis of no association with any of the constituent traits of the multivariate phenotype vector. Thus, such tests do not provide evidence of pleiotropy. With respect to a pair of comorbid phenotypes (both binary, a combination of binary and quantitative or both quantitative), we aim to modify the proposed BAMP (Binomial regression-based Association of Multivariate Phenotypes) approach to test the null hypothesis of no association with at least one of the phenotypes versus the alternative hypothesis of association with both the phenotypes. Since the likelihood ratio test requires a constrained maximization (over the two coordinate axes) under the null hypothesis, it is analytically difficult to obtain the asymptotic distribution of the log-likelihood test statistic under the null hypothesis and hence, we use permutation procedures to determine the thresholds for rejection. We carry out extensive simulations under different genetic models and correlation structures of the bivariate phenotype to evaluate the type 1 error rates and power as well as compare the performance of the proposed test procedure to separate univariate tests with standard multiple testing corrections. We find that while combining univariate tests results in inflated probabilities of type 1 error, the proposed test maintains the appropriate size. We also show that an extension of the method to more than two comorbid phenotypes is theoretically straight forward with minimal increase in the computational burden.

PB3439. Identifying composite biomarkers in multi-omics datasets of osteoporosis for drug discovery

Authors:

M. Alam¹, H. Shen², H-W. Deng²; ¹Tulane Univ., New Orleans, LA, ²Tulane Univ, New Orleans, LA

Abstract Body:

Background: Many statistical machine approaches could identify novel features of the etiology of complex diseases by analyzing multi-omics data. However, they are sensitive to some deviations in distribution when the observed samples are potentially contaminated with adversarial corrupted outliers (e.g., a fictional data distribution). Likewise, statistical advances lag behind supporting comprehensive data-driven analyses of complex multi-omics data integration. **Methods:** We propose a novel non-linear M-estimator-based approach, “robust kernel machine regression (RobKMR),” to improve the robustness of statistical regression and the diversity of fictional data to examine the higher-order composite effect of multi-omics datasets. We address a robust kernel-centered Gram matrix to estimate the model parameters accurately. We also propose a robust score test to assess the marginal and joint Hadamard product of features from multi-omics data. We apply our proposed approach to a multi-omics dataset of osteoporosis (OP) from Caucasian females **Results:** Experiments demonstrate that the proposed approach effectively identifies the inter-related risk factors of OP. With solid evidence (at p-values ≤ 0.00001), biological validations, network-based analysis, causal inference, and drug repurposing, the selected three triplets ((DKK1, SMTN, DRGX), (MTND5, FASTKD2, CSMD3), (MTND5, COG3, CSMD3)) are significant biomarkers and directly relate to OP. Overall, the top three selected genes (DKK1, MTND5, FASTKD2) and one gene (SIDT1 at p-values ≤ 0.001) significantly bond with four drugs- Tacrolimus, Ibandronate, Alendronate, and Bazedoxifene out of 30 candidates for drug repurposing in OP. **Conclusion:** We developed a novel robust approach to identify inter-related risk factors in multi-omics data. Benchmarking experiments based on simulation and real datasets analysis demonstrated that our proposed approach provides a competitive performance compared with the existing ones to derive a statistic for testing the inter-related risk factors. Our proposed method can identify significant biomarkers (DKK1, MTND5, FASTKD2, and SIDT1) for OP studies. **Acknowledgments** This work is benefited by the support of U19AG05537301 and R01AR069055.

PB3440. Identifying functionally-related SNPs and genes from phenome-wide genetic effect correlations using GWAS summary statistics

Authors:

L. Chen, J. Tubbs, P. Sham; The Univ. of Hong Kong, Pokfulam, Hong Kong, China

Abstract Body:

We observe a ubiquitous distribution of non-trivial correlations of summary statistics (e.g. Z-scores, log P-values) across numerous genome-wide association studies (GWAS) on distal SNPs and genes, revealing the importance of investigating phenome-wide genetic-effect correlation. Analogous to genetic correlation, it is an aspect of genetic architecture that quantifies the similarity of causal effect sizes between two SNPs across the phenome, but has been relatively unexplored. Inflation of GWAS-wide correlations of summary statistics can arise due to true genetic-effect correlations or through bias by other confounders, such as linkage disequilibrium (LD) and GWAS non-independence. However, no current methods can be used to distinguish between augmentation from a true genetic-effect correlation signal and confounders. We have developed a statistical framework (LRCP) to quantify the contribution of each by examining the relationship between Z-score cross products and LD cross components. **LRCP**, using both likelihood and regression-based methods on cross components of summary statistics, is the first attempt to infer functional relationships of arbitrary SNP pairs from their genetic-effect correlation estimate. Applying LRCP to large collections of GWAS data on quantities of traits, we find some evidence for widespread genetic-effect correlations in the genome, providing a new approach to identify functionally-related SNPs, gene clusters and novel pathways.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3441. Identifying non-common variant sources of clinical comorbidities through integration of electronic health data and genetics for schizophrenia.

Authors:

T. Vessels¹, N. Strayer², K. Choi³, T. J. Morley², L. Han², H. Lee³, J. Smoller^{4,5}, Y. Xu², D. Ruderfer²; ¹Vanderbilt Univ., Nashville, TN, ²Vanderbilt Univ. Med. Ctr., Nashville, TN, ³Massachusetts Gen. Hosp./ Harvard, Boston, MA, ⁴Massachusetts Gen Hosp, Boston, MA, ⁵Broad Inst., Cambridge, MA

Abstract Body:

Background: Patients with schizophrenia (SCZ) have a reduced life expectancy of 10-20 years that is often a byproduct of comorbidity, which accounts for 70% of premature mortalities. We hypothesize that comparing comorbidities from electronic health record (EHR) data to genetic associations will provide insights into which comorbidities are effects of the SCZ genetic etiology vs consequences of treatment, behavior, or other environmental factors. **Methods:** We defined clinical comorbidities from a logistic regression of pairwise comparisons of diagnostic billing codes (PheCodes), adjusting for demographic and other covariates from two health care systems (Vanderbilt University Medical Center, VUMC; Mass General Brigham, MGB). Comorbidities were calculated on 250,000 randomly selected patients from each site individually and then averaged together. SCZ polygenic risk scores (PRS) in 64,190 genotyped patients of European ancestries were generated. A TOST test of equivalence was used to further evaluate the clinically significant SCZ comorbidities on whether they showed a well-powered absence of association with the SCZ PRS. **Results:** Clinical comorbidities were highly consistent across both institutions overall ($r=0.79$) and for SCZ specifically ($r=0.85$). We show significant replication of comorbidities previously identified in the literature including psychiatric conditions, epilepsy, diabetes, and hyperlipidemia (25/39 with $p<0.05$). There is correlation between the clinical and genetic associations both within ($r = 0.53$, $p = 6.2 \times 10^{-118}$) and across institution ($r = 0.49$, $p = 8.4 \times 10^{-81}$). After multiple test correction, there were 59 significant comorbid associations with SCZ. Of these, 11 had significant equivalence of SCZ PRS at both sites, indicating an absence of contribution to phenotypic comorbidity from common variant SCZ genetics. We further limited to those with non-significant SCZ PRS association, resulting in 5 phenotypes: alteration of consciousness, neurological disorders, epilepsy recurrent seizures convulsions, adverse drug events and drug allergies, and convulsions. **Discussion:** These 5 comorbid phenotypes may represent examples caused by other risk factors including rare variation, disease or treatment consequences or medical practice. Adverse drug events and drug allergies could be due to pharmacogenomics or interactions of multiple medications. Investigation into potential causal relationships among the remaining four using more detailed EHR data (e.g. EEGs, medications) and time is ongoing. This work presents an opportunity to identify and interpret non-genetic relationships among disease phenotypes.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3442. Identifying the conserved versus divergent structural sequences of the human pangenome

Authors:

H. Lee, S. Greer, D. Pavlichin, H. Ji; Stanford Univ., Stanford, CA

Abstract Body:

The Human Pangenome haploid assemblies provide an opportunity to determine which sequences are among the most conserved versus divergent in the human population. To conduct this study, we developed and applied a k-mer indexing strategy that enables one to make rapid comparisons among multiple different haploid genomes as well as parental haploid variation. This method was used to characterize 94 haploid assemblies and two reference genomes GRCh38 and CHM13. Highly conserved k-mer sequences had the following properties: (1) occurring only once per a given haploid genome and (2) having the same unique representation across all haploid assemblies. To identify segments indicating structural divergence and variation, we calculated the distance between tandem pairs of these highly conserved sequences. Then, we determined which pairwise segments varied in their distances across the entire pangenome data set. Based on the pairwise distance among 21 million highly conserved sequences, we identified 2,312 loci segments in which the pairwise distance diverged from both the human genome reference and other haploid assemblies among the pangenome set. These divergent pairs were indicators of loci with a structural variation. One-third of these divergent loci were private, occurring in only a single haploid assembly. Interestingly, multiple hotspots were identified across the human genome. In summary, we developed a rapid and scalable framework to characterize highly conserved versus divergent features across large sets of haploid assemblies. We identified a set of highly conserved sequences across the entire pangenome set. In addition, we discovered variable divergent loci that occur in a single or sets of haploid genomes. This k-mer-based analysis can be efficiently scaled to cover more haploid assemblies as they are generated. The outputs include simple-to-understand metrics that are useful in making comparisons from individual patient genomes to the Pangenome reference set.

Blair¹, SALSA-SGC Consortium; ¹Macquarie Univ., Sydney, Australia, ²Kings Coll. London, London, United Kingdom, ³Univ. of Auckland, Auckland, New Zealand, ⁴Univ. of Sydney, Camperdown, Australia, ⁵Univ. of Queensland, Brisbane, Australia, ⁶Harry Perkins Inst. of Med. Res., Nedlands, Australia, ⁷Fiona Stanley Hosp., Perth, Australia, ⁸Flinders Med. Ctr., Adelaide, Australia, ⁹Calvary Hlth.Care Bethlehem, Parkdale, Australia, ¹⁰Concord Repatriation Gen. Hosp., Sydney, Australia

Abstract Body:

Do we really know our extended family? We may know our 3rd degree relatives (first cousins, great grandparents) or 4th degree relatives (e.g. first cousins once removed). But who knows their 5th, 6th, or even 9th degree relatives? We can leverage genomic data and our powerful new identity-by-descent algorithms [1] to uncover these relationships (cryptic relatedness) in large disease cohorts and use these genetic relationships for disease gene discovery.

Next-generation sequencing methods have fast-tracked gene discovery in many genetic diseases, but consequently have depleted the research space of genetically informative families (i.e. more than one affected individual with a DNA sample). This has constrained genetic studies in amyotrophic lateral sclerosis (ALS), where genetic factors remain to be identified in ~90% of patients, and reduced disease penetrance is common. Only 10% of ALS patients have a family history of disease, yet heritability estimates suggest all forms of ALS (familial and ‘sporadic’) have a significant genetic component. To facilitate gene discovery in ALS, we propose ‘creating’ new informative families by detecting cryptic relatedness using identity-by-descent (IBD) methodologies on SNP microarray data from an integrated cohort of 1,939 sporadic and familial ALS and FTD (frontotemporal dementia) patients from Australia and New Zealand. XIBD software [1] performed ~2 million pairwise IBD comparisons on the ALS and FTD patients. For each pair of samples, degree of relationship was estimated using total lengths of inferred IBD segments.

For individuals with a known pathogenic repeat expansion in *C9orf72*, we uncovered cryptic relatedness among 60% of sporadic and familial ALS and FTD patients from Australia and New Zealand. Among sporadic and familial ALS and FTD individuals without a known causal mutation, we identified 55 novel pairs, 1 triad, and a sextet of individuals ranging from 2nd (avuncular) to 6th degree relatives (2nd cousins once removed, the accuracy limit of our methodology). In one novel pair, retrospective genealogy analysis successfully linked the two pedigrees from different neurology clinics in Sydney, Australia. IBD analysis in this pair implicated 6 genetic linkage regions comprising 2.4% of the genome and encompassing 714 genes, defining critical regions for gene discovery.

In the absence of large historical pedigrees, genetic data can be successfully used to accurately uncover cryptic relatedness and confirm founder effects. We have employed identity-by-descent methodologies to genetically ‘create’ 57 new ALS/FTD families for gene discovery efforts.

PB3444. Imaging derived phenotypes of the knee reveal novel genetic and clinical risk factors associated with knee osteoarthritis severity.

Authors:

B. Flynn¹, E. M. Javan¹, E. Kun¹, Z. Trutner², P. Jayakumar², V. Narasimhan¹; ¹The Univ. of Texas at Austin, Austin, TX, ²Dell Med. Sch., Austin, TX

Abstract Body:

Several large-scale studies of the genetic basis of musculoskeletal (MSK) disease including knee osteoarthritis (OA) have been carried out, though almost all rely on pre-existing disease assessment based on patient electronic health records (EHRs). These EHRs for knee OA are often unable to capture information about disease severity, only report individuals who sought care, and provide no additional information about clinically relevant biomarkers of disease progression. Though radiography is a mainstay in the clinical assessment of knee OA, it is challenging to perform manual annotation of disease severity at Biobank scale. To address this limitation, we trained a deep learning model to automatically grade knee OA severity based on the widely used Kellgren-Lawrence (KL) classification system, using training data from 200 dual energy X-ray absorptiometry (DXA) derived X-rays annotated by a team of orthopedic surgeons (AUROC = 0.98). We applied this model to 35,347 DXA images of the UK Biobank, and showed that 1,093 (33%) of the most severe cases (KL>2) not coded in the ICD-10 had self-reported knee pain. To obtain additional endophenotypes associated with knee OA, we performed deep learning based segmentation (98.9% accuracy) to measure the minimum joint space width (mJSW) between the femur and tibia and the tibiofemoral angle (TFA). After controlling for height, sex, age and body fat percentage, KL, mJSW and TFA remain significantly associated with leg pain while walking ($p=1.43e-84$, $p=7.65e-25$, $p=3.48e-9$), with fractures and falls ($p=9.12e-4$ and $p=0.0381$) in the past few years also associated with mJSW. We performed genome wide association studies (GWAS) for mJSW (N=29,257), TFA (N=24,456), and binary KL severity (N=28,435). We report 14 genome wide significant loci associated with mJSW (heritability 40.2%) and 2 loci associated with TFA (heritability 14.9%) not previously described for knee OA by the largest OA GWAS conducted to date, and 1 locus in common. Polygenic risk scores estimated from mJSW were also significantly predictive of OA status. We found no significant genetic associations with KL (heritability 3.5%), though mJSW and KL had a genetic correlation of -0.83 ($p=6.3e-5$). Our results suggest that for complex diseases where radiography is a primary diagnosis tool, image derived phenotyping is a cost-effective and scalable solution for quantifying disease severity, and that systematic measurement of quantitative endophenotypes can enable major increases in statistical power for genetic analyses. Our results also suggest that a major proportion of the risk of knee OA can be localized to common genetic determinants of knee anatomy.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3445*. Impact of heterogeneity-by-ancestry on GWAS in admixed populations.

Authors:

R. Mester, K. Hou, A. Bhattacharya, Y. Ding, K. Burch, B. Pasaniuc; Univ. of California, Los Angeles, Los Angeles, CA

Abstract Body:

Admixed individuals present both a challenge and an opportunity in disease mapping studies due to the unique genetic architecture of admixed populations. As methods for attributing variants to particular ancestry backgrounds become more reliable, disease mapping methods must balance the potential for capturing the additional signal with the anticipated loss of power due to correction for genetic structure within analyses. These tradeoffs become even more complex when causal SNP effect sizes differ by local ancestry. We investigate several statistical and biological factors which may result in this type of causal effect size heterogeneity, including differences of minor allele frequency and linkage disequilibrium across local ancestries.

We assess disease mapping methods in admixed populations to determine which methods are best suited for traits with heterogeneity in allelic effect sizes and frequencies of causal variants. We simulate admixed genotypes and phenotypes with different underlying causal architectures using information from the 1000 Genomes Project. We assess several scores in admixed populations ranging from 1 degree of freedom tests such as ATT, ADM, SNP1, and MIX that model the local ancestry signal to 2 degree of freedom tests such as SUM and TRACTOR that allow for heterogeneity in allelic effects across ancestries. We investigate metrics of both power and effective sample size, such that conclusions can be extended regardless of the number of individuals included in any given study.

We show that 1 degree of freedom tests such as MIX (Pasaniuc et al, 2011) are more powerful when allelic effects are similar across ancestries (Hou et al, 2021), and specifically that MIX has a larger effective sample size when the ratio of causal effects by local ancestry is ≥ 0.75 . However, 2 degree of freedom tests such as TRACTOR (Atkinson et al 2021) perform optimally when causal effects are in opposite directions or a large enough level of heterogeneity in same-direction causal effects is present. Using data from admixed individuals in the UK Biobank, we also investigate the extent to which differential linkage disequilibrium across local ancestries is expected to induce this amount of heterogeneity by local ancestry in causal effect sizes. From both scientific and social perspectives, it is important that admixed populations are incorporated more effectively in genetic studies. By providing direct examples of how these methods work and the benefits that can be derived from them, we enable studies to maximize their power and effective sample size in admixed populations.

PB3446. Implementing Mendelian Randomization to Assess Foetal Risk from Intrauterine Prescriptive Drugs for the Treatment of Diabetes, Hypertension and Thyroidism in Pregnancy

Authors:

C-J. Barry¹, N. M. D. Davies¹, V. Walker¹, A. Havdahl², G. Davey Smith¹, C. Burden¹; ¹Univ. of Bristol, Bristol, United Kingdom, ²Univ. of Oslo, Oslo, Norway

Abstract Body:

Background: Pregnant women are excluded from clinical trials for ethical and practical reasons; thus, little is known about the causal impact of intrauterine medication exposure on developing foetuses, creating high uncertainty within pharmacological research. Yet many chronic conditions necessitate maternal medication use during pregnancy, such as diabetes, hypertension, and thyroid disorders. Left untreated, these conditions have been found to be associated with adverse neonatal outcomes such as preterm birth, intrauterine growth restriction and foetal loss. The objective of this study is to discern whether genetic proxies for maternal drug exposures to medication for the conditions of interest can indicate causal adverse neonatal drug reactions to intrauterine exposure, through the application of Mendelian Randomization (MR).

Methods: We conducted a one-sample within-family MR analysis of maternal genetic drug targets on neonatal outcomes using parent-offspring trio data from The Norwegian Mother, Father and Child Cohort Study (MoBa). We identified genome-wide significant genetic proxies for drug targets related to treatments for the conditions of interest using DrugBank. We investigated the association of these maternal genetic variants with neonatal outcomes such as gestational age, birth weight, mode of delivery and APGAR score. We used within family models including parental genotype to assess potential intrauterine drug exposure effects, whilst controlling for environmental confounding.

Results: The cohort of interest to this study contains complete genetic data on up to 29,964 parent-offspring trios. For the relevant treatments, as indicated by the British National Formulary, we have identified and extracted a total of 1,064 maternal SNPs as potential instruments for maternal-neonatal intrauterine drug exposure. Preliminary summary statistics indicate analysis should be sufficiently powered, using the available linked phenotypic data. Adverse neonatal outcomes of interest to this study include those such as gestational age, birthweight, mode of delivery and Apgar score.

Conclusions: Genetic epidemiological data can provide evidence about the risks to neonates and benefits to mothers of intrauterine medication exposure. A combination of pharmacoepidemiological and genetic data is perhaps the best way to evaluate the potential risks currently associated with maternal medications, when clinical trials are less feasible. Thus, evidence from this study may be used with existing literature, clinical trials, and alternative study types to guide physicians and mothers during pregnancy.

PB3447. Improved breast cancer risk stratification by integration of a cross-ancestry polygenic model with clinical risk factors.

Authors:

P. Tshiaba¹, J. Sun¹, T. Tunstall¹, D. Ratman¹, B. Levy¹, P. Shah¹, J. Weitzel², M. Rabinowitz¹, A. Kumar¹, K. Im¹; ¹MyOme, Inc, Menlo Park, CA, ²Natera, Inc, Austin, TX

Abstract Body:

Breastcancer (BC) is the most common cancer diagnosed among women in the U.S exceptfor skin cancers. However, germline pathogenic mutations in high penetrancesusceptibility genes are rare and are associated with only 5-10% of BCs.Polygenic risk scores (PRS) have been shown to provide genetic informationabout BC risk beyond family history (FHx), but most have been developed forwomen of European ancestry. We developed a cross-ancestry PRS (caPRS) andcombined it with the Tyrer-Cuzick (T-C) clinical model to generate anintegrated risk score (caIRS). Thestudy included a training cohort and two independent validation cohorts consistingof women of diverse ancestries. We used a variety of algorithms to build PRSmodels including PolyPred, LD-Pred2, PRS-CS and PRS-CSx. We defined a caPRS asa linear combination of the best performing PRS model for each ancestry,weighted by fractional ancestry and PRS effect size. Individual ancestryinference and PRS centering were performed using principal components withindividuals in the 5 superpopulations of the 1000 Genomes Project used as thereference. Correlations between the caPRS and clinical variables included inthe T-C model were tested and accounted for during model training. The caIRSwas trained and calibrated in a cohort of 125,317 women. The caIRS wasvalidated in a cohort of 24,878 women from the Women’s Health Initiative (WHI)and a second cohort of 119,187 women from the UK Biobank (UKB). The validationfocused on remaining lifetime risk (RLR); with a RLR of $\geq 20\%$ classified as highrisk. Improvement in risk stratification was assessed using odds ratio (OR) perstandard deviation (SD) of PRS and area under the receiver-operator curve(AUC). caPRSquantile was highly correlated with odds of BC in all population groups tested.The caIRS had a stronger association with BC than the T-C score alone in bothvalidation cohorts, with an overall OR per SD of 1.78 (95% CI 1.69-1.88, $p=2.6 \times 10^{-105}$) compared with 1.35 (95% CI 1.27-1.42, $p=1.4 \times 10^{-23}$) in the WHI and 1.76 (95% CI 1.72-1.80, $p < 10^{-324}$) compared with 1.28 (95% CI 1.25-1.32, $p=5.8 \times 10^{-75}$) in the UKB. The caIRS improved risk prediction in allpopulations tested including self-reported Caucasian, Hispanic, African/AfricanAmerican and Asian women. The largest gain in performance was observed inHispanic women with a 10% increase in AUC. We demonstrated thataddition of a cross-ancestry polygenic risk score to the well-used clinicalrisk predictor Tyrer-Cuzick results in significant improvement in prediction ofbreast cancer with higher gains in multi-ethnic populations like Hispanic womenwhere T-C is less well calibrated.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3448. Improved genotyping of rare variants from AppliedBiosystems™ Axiom™ microarrays, using Support Vector Machine (SVM) prediction models.

Authors:

T. Webster, O. Mizrahi-Man, A. Mittal, J. Schmidt; Thermo Fisher Scientific, Santa Clara, CA

Abstract Body:

Databases such as ClinVar, contain rare genetic variants of importance, and researchers would like to design and use microarrays that detect the occurrence of such rare variants. However, genotyping rare variants is more challenging than genotyping common variants, and false heterozygous (Het) genotypes for rare variants called on microarray platforms can cause problems in the analysis of data by researchers. In 2021 we designed an improved algorithm specifically aimed at genotyping rare variants and developed a number of predictors. The new algorithm (RHA) significantly improved the positive predictive value (PPV) virtually without losing any correct predictions. Here we report on further highly significant improvements by using the RHA predictors and other predictors in an SVM prediction model. Significantly, by changing the probability cutoff values above which the genotype is called Heterozygous in the prediction model, one can tune the genotyping calls towards maximum sensitivity or maximum PPV.

The SVM prediction models were trained on genotypes from the UK Biobank under UK Biobank Resource Application Number 55681. The UK Biobank is a large-scale biomedical database and research resource, containing in-depth genetic and health information from half a million UK participants, all genotyped on Thermo Fisher Scientific's Applied Biosystems™ Axiom™ microarrays. Whole exome sequencing data for an approximately 200,000 subset of participants was also made available at the time of this study and were used as the truth data.

Microarray Het genotypes were collected from ultra-rare variants, those with computed minor allele frequency less than 0.001%, and were divided into training and test set data. In the test set data the RHA algorithm achieved 73.0% PPV while retaining 99.3% of the true Hets produced by the original AxiomGT1 genotyping algorithm. Using the SVM probability as a filter, the tradeoff between %PPV vs %True Hets retained can be tuned within a range of increasing PPV values. One probability cut-off achieves PPV values in the test set data that reach 95% with 93.8% of the true Hets retained, while an alternative cutoff achieves essentially no loss of true Hets (99% retained), while increasing the original PPV to 86.6%. This evaluation of SVM prediction models has been successfully extended to rare genotypes from additional Axiom™ microarrays.

PB3449. Improved Prediction Performance of Polygenic Risk Score with Gene Expression Data

Authors:

H. Xu; Augusta Univ., Augusta, GA

Abstract Body:

Polygenic risk score combines the genetic contribution from multiple genetic variants across the genome and has the potential clinical utilities in predicting disease risk for common human diseases. Current polygenic risk scores are based on the results from genome-wide association studies, where the information are from common genetic variants. With the availability of gene expression data, many gene expressions have been shown to be associated with the disease status. In this study, we build a polygenic risk score based on both common and gene expression data. We incorporate the effects of differentially expressed genes with $FDR < 0.05$ by including them into prediction model with the corresponding effect size estimates. Results from our simulation study show that our polygenic risk score has improved predictability measured by the C-statistic. Our polygenic risk score also has lower prediction error from cross-validation than the risk score without rare genetic variants. We applied our polygenic risk score method to the breast cancer data from the Cancer Genome Atlas to predict the risk of developing breast cancer.

PB3450. Improved risk prediction using functionally calibrated polygenic risk scores in admixed populations.

Authors:

X. Wang¹, S. Gonzales², C. Doyle¹; ¹Univ. of North Texas, Denton, TX, ²Univ. OF NORTH TEXAS, Denton, TX

Abstract Body:

Polygenic Risk Scores (PRS) are summaries of genetic information, typically using summation of effect size weighted allele counts for disease associated genetic variants. PRS can predict the risk of a disease for an individual, guide the selection of treatments, and benefit the development of medicines. Genome-wide association study (GWAS) summary data enables PRS estimation. However, the majority (>78%) of GWAS rely on individuals of European descent. Prediction accuracy with PRS remain moderate for most diseases, especially in admixed populations. This is largely due to challenges in 1) accurately estimating the effect sizes of genetic variants 2) identifying whether these variants are functionally relevant and 3) accounting for ancestry-specific linkage disequilibrium. In this study, we propose a Bayesian method that more accurately estimates the ancestry specific effect sizes of alleles for functionally relevant genetic variants by incorporating ancestry information, multiple GWAS and functional annotations into a prior distribution. PRS employing this method improves prediction accuracy for disease status. Simulation studies demonstrate that the proposed method outperforms alternative methods regarding the area under receiver operating characteristic curve for binary traits and the correlation coefficient between the predicted and observed trait values for quantitative traits. Application to admixed population data from the UK Biobank, and the 41 traits in the electronic Medical Records and Genomics (eMERGE) Network reveals that the proposed method outperforms comparable methods in risk prediction for most of the diseases/traits.

PB3451. Improvements in performance of polygenic risk scores for Alzheimer's disease in the Midwestern Amish using founder population-specific weights

Authors:

M. D. Osterman¹, Y. E. Song¹, L. D. Adams², R. A. Laux¹, L. J. Caywood², M. B. Prough², J. E. Clouse², S. D. Herington², S. H. Slifer², A. Lynn¹, M. Fuzzell¹, S. L. Fuzzell¹, S. D. Miller¹, K. Miskimen¹, L. R. Main¹, D. A. Dorfsman², A. F. Zaman², P. Ogrocki³, A. J. Lerner³, J. M. Vance², M. L. Cuccaro², W. K. Scott², M. A. Pericak-Vance², J. L. Haines¹; ¹Case Western Reserve Univ., Cleveland, OH, ²Univ. of Miami, Miami, FL, ³Univ. Hosp. Cleveland Med. Ctr., Cleveland, OH

Abstract Body:

Alzheimer's disease (AD) is the most common type of dementia and is estimated to affect nearly six million Americans. Risk for AD is multifactorial, including both genetic and environmental risk factors. AD genomic research has generally focused on identification of risk variants. Using this information, polygenic risk scores (PRSs) can be calculated to quantify individual degree of disease risk due to genetic factors. The Amish are a founder population descended from German and Swiss Anabaptist immigrants. They experienced a genetic bottleneck after arrival in the United States, making it likely that their genetic architecture of AD risk is different from the broader European ancestry population. Here, we compare the performance of PRSs derived from genome-wide association studies (GWASs) of Amish individuals to those derived from a large European ancestry GWAS.

Our study population consisted of 1,981 Amish adults recruited from communities in Indiana (IN) and Ohio (OH). Participants were screened for cognitive impairment with further evaluation for AD or non-AD dementia. Genotype data were imputed using the Haplotype Reference Consortium Panel. The Amish individuals were split into two groups based on the primary site of recruitment (IN or OH) to minimize relatedness and allow for a training and validation set. For each group, genome-wide association analysis using a mixed model approach was conducted, accounting for inferred relatedness by use of a genetic relationship matrix. Age, sex, and relationship-adjusted principal component 1 (PC1) and PC2 were considered as covariates. PRSs were then calculated using weights from the other Amish group (i.e. IN Amish weights for OH Amish PRS), with and without a 500kb region surrounding either primary *APOE* variant. Area under receiver operating characteristic curve (AUC) was calculated for predictive models with and without covariate adjustments. The AUCs were then compared to predictive models using PRSs derived from the Jansen et al. (2019) summary statistics.

We found that the AUCs from the non-*APOE* PRS models improved from 0.55 to 0.63 in the OH group by using the IN Amish-specific weights instead of the European ancestry weights. They similarly improved from 0.54 to 0.63 in the IN group. The findings were consistent after inclusion of *APOE* genotype with an improvement in overall model AUC of 0.64 to 0.67 in the OH group and 0.56 to 0.65 in the IN group by using the Amish-specific weights.

The results show improvement in AD prediction through use of Amish-derived PRS weights. This work highlights the value of using founder population-specific weights when performing PRS analysis for founder and other populations.

PB3452. Improving Cross-Population Polygenic Risk Scores with a Tree-Guided Deep Learning Method

Authors:

E. Layne, Y. Li, M. Blanchette; McGill Univ., Montreal, QC, Canada

Abstract Body:

A common issue when training polygenic risk score (PRS) predictors is that training data will often have many individuals of a particular ancestry group (typically European), and relatively few from other backgrounds. Despite ongoing research efforts, there remains a gap in the ability of most PRS methods to generalize across ethnic backgrounds in this context of unbalanced training data.

Here, we present the results from adapting DendroNet, a machine learning that accounts for evolution in the function mapping genotypes to phenotypes, for this purpose. We modify the methodology for a multi-population PRS setting. Our method first constructs a binary tree, representing the relatedness of all population groups in the training set. The model includes a global set of per-SNP effect sizes, along with a set of SNP-specific effect size changes corresponding to each edge in the population tree. Effect sizes used for each population are a sum of the global effect sizes and their changes along the edges leading to it. L1 regularization is used to enforce sparsity amongst the effect sizes. This method combines the advantages of being able to leverage the large sample sizes of European datasets with the ability to learn effect sizes specific to other groups for whom only smaller datasets may be available.

We report results on the task of predicting expression levels of 15,000 genes, using a combined dataset of European and African individuals from the 1000 Genomes Project. We find that in approximately 1% of genes, the use of our framework's population-specific predictions result in a significantly improved predictive power, compared to a population agnostic lasso regression, while losses in predictive power are never observed. Ongoing work is investigating the power of this approach on various UK-BioBank polygenic traits.

Furthermore, we present two different implementations of our algorithm: a memory-efficient coordinate ascent implementation, capable of operating on very large-scale datasets in memory constrained environments, and a gradient-descent implementation, capable of leveraging GPU acceleration for high training speeds.

PB3453. Improving fine-mapping by modeling infinitesimal effects.

Authors:

R. Cui^{1,2}, R. Elzur^{1,2}, M. Kanai¹, J. Ulirsch¹, O. Weissbrod³, M. Daly⁴, B. Neale², Z. Fan⁵, H. Finucane²; ¹Broad Inst. of MIT and Harvard, Cambridge, MA, ²Massachusetts Gen. Hosp., Boston, MA, ³Eleven Therapeutics, Tel Aviv, Israel, ⁴Harvard Med. Sch., Cambridge, MA, ⁵Yale Univ., New Haven, CT

Abstract Body:

Fine-mapping aims to identify genetic variants that causally impact a given phenotype. State-of-the-art Bayesian fine-mapping algorithms (for example: SuSiE and FINEMAP) are widely applied in practice, but it remains challenging to assess their calibration (i.e., whether or not the posterior probability of causality reflects the true proportion of causal variants) in real data, where model mis-specification almost certainly exists and true causal variants are unknown. We first propose a real-data benchmarking strategy, Replication Failure Rate (RFR), that assesses consistency of fine-mapping between different sample sizes of the same cohort. Based on evidence from both RFR and functional enrichment, we believe that SuSiE and FINEMAP are likely miscalibrated in real data. Next, we contend that non-sparse genetic architecture, of several possible model misspecifications we tested in large-scale simulations, is likely the main contributor to this suspected miscalibration. We develop new fine-mapping methods, SuSiE-inf and FINEMAP-inf, that extend the computational ideas of SuSiE and FINEMAP to model infinitesimal effects in addition to a small number of sparse causal effects of interest. Our methods exhibit better calibration in simulations and improved RFR and functional enrichment in real data, with minimal loss of power and competitive computational cost. Furthermore, using the sparse fine-mapped variants generated by our methods to perform cross-population genetic risk prediction in the UK Biobank, we observed a substantial increase in predictive accuracy over SuSiE and FINEMAP. Our work improves our ability to pinpoint causal variants for complex traits, a fundamental goal of human genetics.

PB3454. Improving the accuracy and interpretation of polygenic risk score through modeling the pathways of disease and multiple risk factors

Authors:

Y. Yang, N. Lorincz-Comi, G. Li, X. Zhu; Case Western Reserve Univ., Cleveland, OH

Abstract Body:

Introduction The prediction of complex disease, one of the key components of precision medicine, is of great research and clinical interest. The polygenic risk score (PRS), a composite genetic risk indicator, has become a standard tool for quantifying genetic risk of complex disease. However, traditional PRS typically only explain a limited amount of disease heritability and improves risk prediction for only limited subsets of individuals. Although many improvements to the PRS have been developed, the gap between PRS-explained variance and disease heritability is still substantial. We thus propose a new pathway-guided PRS to improve prediction power and the potential for clinical utility. **Methods** It is well known that complex diseases are associated with multiple risk factors. Many genetic associations with complex disease may be through indirect associations with risk factors. Thus, we can construct a PRS based on direct and indirect genetic effects, which can improve the accuracy and interpretability of a PRS. In the implementation of our new PRS, we first constructed risk factor and disease-specific PRSs, then combined these PRSs into a final disease PRS by using penalized nonconvex regression. The estimated coefficients from risk factor and disease-specific PRSs can be considered the causal effects in multivariable Mendelian Randomization. **Results** We performed a simulation study in which UK Biobank genotype data was used to generate 20 risk factors with heritability $h^2=0.5$ each and the outcome disease was generated by the first 2, 5, or 10 risk factors and direct contributions of selected genetic variants. The results show that as the outcome disease is associated with more risk factors, traditional PRS performs worse while the pathway-guided PRS becomes better. Using 10 risk factors, the pathway-guided PRS explained 64% more of the variance in a continuous trait compared to the traditional PRS. For a binary trait, the pathway-guided PRS boosted the traditional PRS by ~17% in terms of Area Under the ROC Curve. The pathway-guided PRS also reliably selected true risk factors for the outcome disease. **Conclusion** We propose a pathway-guided PRS that is epidemiologically interpretable and can improve disease prediction accuracy. The significant improvement in prediction accuracy over a traditional PRS can be attributed to the leveraging of information on multiple risk factors for the disease of interest. The pathway-guided PRS also has a clear interpretation of risk factors affecting an outcome. We will apply the new pathway-guided PRS method to the prediction of cardiovascular disease outcomes in UK Biobank data and compare our method to existing alternatives.

PB3455. Impseer: Machine learning prediction of imputation quality

Authors:

M. Saad¹, K. Kunji²; ¹Qatar Computing Res. Inst., HBKU Research Complex, QCRI, Qatar, ²Qatar Res. Computing Ctr. (HBKU), Doha, Qatar

Abstract Body:

Background: Imputation is an important step in modern Genome-Wide Association Studies (GWASs) to cost-effectively increase genomic coverage and allow meta-analysis. Even with the decreasing costs of whole genome sequencing, the need for imputation will remain. Determining imputation quality is crucial for downstream association analysis. Here, we propose a machine learning framework to improve imputation quality estimation and therefore increase association statistical power.

Methods: We selected and generated many pre- and post-imputation features that can impact imputation quality, such as allele frequencies, reference and GWAS panel sample size, coverage, and linkage disequilibrium. A C++ program, Impseer, was written to generate these features. XGBoost was used to estimate the Pearson correlation (R^2) between the imputed dosages and the ground truth. Imputation was performed on the 1000 genomes data using Minimac and Impute, and their imputation quality measures, RSQR and INFO, were among the generated features.

Results: XGBoost models using all features predicted R^2 better than Minimac3's RSQR or Impute's INFO alone, with 11.5% and 21% improvement for rare (MAF: 0-0.01) variants and 6.4% and 3.7% improvement for common (MAF: 0.01-0.5) variants when compared to RSQR and INFO respectively. Gains occurred across all chromosomes and MAF intervals tested.

Conclusions: XGBoost predictions should be used instead of RSQR/INFO to determine imputation quality and therefore improve inclusion/exclusion filtering of SNPs for association analysis.

PB3456. Imputation of heritable gene expression reveals transcriptomic associations with neuroimaging phenotypes.

Authors:

N. Hoang¹, N. Sardaripour¹, Y. Chen¹, J. Park¹, M. Benton², J. Capra³, M. Rubinov¹; ¹Vanderbilt Univ., Nashville, TN, ²Baylor Univ., Waco, TX, ³Univ. of California San Francisco, San Francisco, CA

Abstract Body:

Motivation: Transcriptome-level association studies on neuroimaging phenotypes have revealed strong mappings between brain-wide gene expression profiles and measures of healthy brain states, such as intraregional homogeneity of neural activity. However, recent work is limited by the availability of complementary neuroimaging and transcriptomic data for large human populations. Instead, group-average data, such as the Allen Human Brain Atlas (AHBA) of six postmortem brains, are analyzed. While this approach is informative, it does not capture the high degree of individual variability present in human brain organization. This has led to a gap in associating neuroimaging phenotypes and gene expression with respect to individual variability in large populations.

Methods: In this work, we bridge this gap by imputing the heritable expression of several hundred genes in 10 brain regions for 890 individuals from the Human Connectome Project (HCP; 28.68 ± 3.73 mean age, 485 females). We applied PrediXcan to impute the genetically regulated component of gene expression using *cis*-regulatory genetic variants. This allowed us to study the otherwise inaccessible expression profiles for brain regions in living individuals. We found a strong association between the interregional correlations of the imputed gene expression patterns and assayed expression from the AHBA ($r = 0.69$, $p < 0.01$), demonstrating the convergence between measured and imputed expression.

Results: Our transcriptome-wide association studies on neuroimaging phenotypes in the HCP cohort identified 40 genes whose expression across the brain regions of interest correlated with intraregional homogeneity of neural activity. Further, we leveraged the PrediXVU catalog of gene-to-medical-phenome mappings derived from the Vanderbilt University biobank to identify 16 neurological and psychiatric phenotypes associated with these genes ($p \leq 0.01$, FDR).

Conclusions: Collectively, our approach bridges an existing gap in human neuroimaging studies by leveraging gene expression modeling to impute heritable expression in brain regions with existing neuroimaging data for many individuals. This modeling approach, and its rigorous statistical validation, opens a new direction for studying transcriptomic correlates of neural phenotypes. Ultimately, we propose that this approach can help reveal genetic mechanisms underpinning variation in human brain organization, and in this way support future discovery of genes linked to healthy and diseased brain states.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3457. In silico GWAS: the rapid and accurate (pre)computation of genetic disease associations using only population-level data.

Authors:

C. Foley^{1,2}, H. Runz³, B. Sun^{2,3}; ¹Data Sci. and Engineering, Res. and Development, Optima Partners, Edinburgh, United Kingdom, ²Univ. of Cambridge, Cambridge, United Kingdom, ³Biogen Inc., Cambridge, MA

Abstract Body:

Large-scale cohorts and biobanks with genetic measurements have significantly enhanced discovery of genetic links to disease and multi-omic phenotypes. For many diseases however, the extent of their genetic links are either incomplete or unknown. Broadly, resolution of risk variants and risk loci associated with disease can be improved by increasing the number of cohort and biobank samples, under a similar design, thereby increasing power to detect novel associations. There are two important limitations with this approach: (a) additional samples can be very costly to acquire; and (b) a method to pre-compute the expected number of additional risk variants and loci likely to be detected as a function of increased sample-size, for each disease, is currently unavailable. In combination, unsupervised enrolment of additional participants into cohorts and biobanks can be financially costly with few guarantees of enhancing biological insight.

Here we present In silico GWAS (isGWAS), a new algorithm, tool and online portal. Using only cohort and population-level information, isGWAS accurately approximates genetic variant and disease association summary data that is routinely computed in traditional genome-wide association study (GWAS) regression analyses, i.e., beta, standard error and p-values. isGWAS is lightweight and highly computationally efficient relative to traditional GWAS, as it avoids storing and processing individual-level data on each of potentially hundreds of thousands of individuals. For a given disease, users can specify a sample size for a cohort or biobank and isGWAS returns predictions of genetic links to disease. isGWAS therefore overcomes the outstanding challenge of estimating the expected number of additional disease associations identified as a function of sample-size. isGWAS can predict risk variants and loci from large-scale GWAS in currently understudied ancestries and cohorts as well as estimating likely gains in GWAS association signals from cross-cohort and cross-biobank analyses.

We demonstrate the accuracy and impact of isGWAS using Schizophrenia, Parkinson's, ALS and genetic data from several large-scale cohorts and biobanks to: (i) validate the tool by matching predicted results to known disease associated loci; (ii) predict future genetic disease discoveries from biobanks of increasing size; and (iii) combine population biobanks across ancestry to increase GWAS discoveries.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3458. Incorporating functional annotation with bilevel continuous shrinkage for polygenic risk prediction

Authors:

Y. Zhuang¹, N. Y. Kim², L. G. Fritsche¹, B. Mukherjee¹, S. Lee²; ¹Univ. of Michigan, Ann Arbor, MI, ²Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract Body:

Genetic variants in different functional categories have different shares of contribution to the heritability of complex traits, and recent studies have shown that the incorporation of functional annotation can improve the predictive performance of polygenic risk scores (PRSs). In addition, for certain phenotypes where only a small proportion of variants can be considered causal, PRS methods that employ a Bayesian framework with continuous shrinkage can account for such sparsity. It is possible that the annotation group level effect is sparse. However, the number of PRS methods that incorporate both annotation information and apply continuous shrinkage on effect sizes is limited. Here, we propose a PRS method which utilizes the functional annotation with a bilevel continuous shrinkage prior for each variant and each annotation group. This prior accommodates the varying genetic architectures both on the variant-specific level and on the functional annotation level. Computationally efficient Gibbs sampling is used for the posterior update. The proposed method uses GWAS summary statistics instead of individual-level data, and accounts for local linkage disequilibrium (LD) patterns through an external LD reference panel. We conducted simulation studies and investigated the predictive performance in settings with different genetic architectures. Results indicated that when there was a relatively large variability of group-wise heritability contribution, the gain in prediction performance from the proposed method was on average 8.0% higher AUC compared to PRS-CS. The proposed method also yielded higher predictive performance compared to PRS-CS in settings with different overlapping patterns of annotation groups and obtained on average 8.4% higher AUC. We applied the proposed method to both binary traits (e.g., type 2 diabetes) and quantitative traits (e.g., BMI) in three real world data sources (the UK Biobank, the Michigan Genomics Initiative (MGI), and the Korean Genome and Epidemiology Study (KoGES)), and two sources of annotations: ANNOVAR, and pathway information from the Kyoto Encyclopedia of Genes and Genomes (KEGG). While the degree of improvement is not consistent across different traits and sample population, we demonstrated that the proposed method generally improved PRS predictive performance.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3459. Incorporating functional annotations of rare variants in interpretable neural networks identify novel Alzheimer's disease risk loci

Authors:

A. Das^{1,2}, C. Lakhani², T. Raj³, D. Knowles^{1,2}; ¹Columbia Univ., New York, NY, ²New York Genome Ctr., New York, NY, ³Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Rare variants play a significant role in Alzheimer's disease (AD), but identifying their pathological effects remains challenging. However, the increase in whole-genome sequencing data availability now allows us to better investigate functions of non-coding as well as coding rare variants. Studies have used rare variants in burden and overdispersion tests, but limited research exists on building predictive models from rare variants. Previous strategies to identify novel relationships and increase predictive ability of complex diseases include applying machine learning methods and grouping variant-level information on the gene-level. In this analysis, we trained an interpretable neural network to predict AD status from functional annotations of rare variants. We input variant-level annotations into per-gene multilayer perceptrons to create latent gene scores and fed these scores, along with APOE-e4 status, age, sex, and ancestry traits, into a logistic network. Variants were separated by coding and non-coding groups, and annotations were divided by pre-transcriptional and post-transcriptional effects.

To train and test our model, we used data from the Alzheimer's Disease Sequencing Project (ADSP) consisting of whole-genome sequencing data for 5,122 AD cases and 6,599 controls over the age of 65. The majority of individuals were of European (57.2%), African (22.6%), or Hispanic (18.9%) ancestries. Functional annotations were selected from the Whole Genome Sequencing Annotator (WGSAnnot) database, which contains over 800 annotations per variant. Our model predicts AD with 62.5% accuracy and an AUROC of 0.641, which is comparable to accuracies from other AD studies, and outperforms a baseline logistic regression on age, sex, APOE-e4 status, and ancestry (AUROC = 0.630). This indicates that the inclusion of rare variants alongside functional annotations via a carefully designed model structure improved performance. Further, given the interpretable structure of the model, we are able to see which features contributed most significantly to disease prediction. As expected, the well-established AD risk allele, APOE-e4, had a notably larger coefficient than all other features. Additionally, we observed BAG3 as one of the top candidates, which has been associated with Tau degradation, a common AD pathology. Collectively, we present a new approach to predict AD status and identify candidate genes for future studies.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3460. Incorporating related individuals in genome-wide association studies to reduce biases from familial effects and population stratification in Mendelian randomization.

Authors:

W. Jiang, H. Zhao; Yale Univ. Sch. of Publ. Hlth., New Haven, CT

Abstract Body:

Mendelian randomization (MR) is a statistical approach to exploring the potential causal relationships between exposures and outcomes from genome-wide association studies (GWAS). Traditional MR methods assume all collected individuals are independent, therefore only unrelated individuals in GWAS are included in the MR analyses. Nevertheless, these analyses can be biased due to uncontrolled confounding factors between genetic variants and outcomes, such as dynastic effects, assortative mating, and population stratification. Recently, some novel MR methods have been proposed to reduce the biases by considering individuals with specific relationships such as siblings or parent-offspring trios. Since recruiting related individuals usually consumes more resources than recruiting unrelated individuals, the sample sizes in family-based GWAS and corresponding MR analyses are often limited, leading to the lack of statistical power to identify causal relationships.

In this study, to alleviate the biases from familial effects and population stratification and to address the power issue in family-based MR analyses, we proposed a novel MR method that can jointly analyze the data collected from both unrelated and pedigree-based individuals. The proposed method is robust to horizontal pleiotropy by allowing $\leq 50\%$ of selected genetic instrumental variables violating the exclusion restriction assumption. Simulation and real data applications on the UK Biobank data demonstrated that the proposed method has comparable performance with family-based MR methods in terms of alleviating biases. Besides, the method achieved higher power than family-based MR methods due to the increased sample size. Sensitivity analyses were conducted to demonstrate the robustness of the proposed method to horizontal pleiotropy. After considering the potential biases from familial effects and population stratification, we confirmed the previous finding that a high body mass index (BMI) increases the risk of hypertension. In contrast, the causal effect of BMI on educational attainment was significantly reduced after bias adjustment.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3461. Inference for set-based effects in genome-wide association studies with multiple interval-censored outcomes

Authors:

J. Choi¹, R. Sun²; ¹Rice Univ., Houston, TX, ²Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract Body:

Massive genetic compendiums, such as the UK Biobank, have become an invaluable resource for identifying genetic variants that are associated with complex diseases. Due to the difficulties of massive data collection, a common practice of these biobanks is to collect interval-censored data via questionnaires and linkage of routine health check ups. Interval-censored data occurs when the time until an event of interest is known to occur during two time periods, but the exact time is unknown. However, there is a current lack of methodology to perform genetic association testing with interval-censored outcomes. Therefore, researchers are often forced to transform the data, such as into binary outcomes, which can lose information that may help in understanding the etiology of complex diseases. In this work, we develop a set-based inference method for jointly testing the association between multiple interval-censored outcomes and a group of genetic mutations, such as those in a gene or pathway. Combining multiple outcomes in genetic association tests can increase statistical power while identifying key biomarkers that are associated with multiple traits. Simulations show that combining multiple interval-censored outcomes can detect causal variants with increased power over using a test that only considers single outcomes. We further validate the value of jointly testing multiple correlated interval-censored outcomes by testing for the genetic effects of bone fractures and falls data from the UK Biobank. Fracture risk and fall susceptibility, which have been shown to be heritable traits, are important to investigate because of their prevalence in healthcare and the high costs associated with these outcomes. Our test was able to identify genes that have been previously associated with both outcomes. Other novel significant genes were identified as well, showing the potential of jointly testing multiple correlated outcomes to detect genes that are significant but are too weak to detect using a single outcome test.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3462. Insights into the comorbidity between type 2 diabetes and osteoarthritis: a genetics view.

Authors:

A. Arruda; Helmholtz Association Munich, Munich, Germany

Abstract Body:

Osteoarthritis (OA) and type 2 diabetes (T2D) are two of the most prevalent chronic health disorders worldwide. Observational studies report a positive epidemiological association between the diseases beyond their common risk factors, such as obesity and increasing age. Taking into consideration that the world's obesity rates, and average age are rising, this comorbidity pair can be considered an increasing global health challenge. Here, we aim to disentangle the genetic correlation between OA and T2D. Using summary statistics of large-scale GWAS from T2D (n=898,130) and OA phenotypes (n=490,345), we investigate the genetic intersection between the traits by performing statistical colocalization analysis of established association signals. For colocalizing regions, we derive a set of high confidence likely effector genes based on biological lines of evidence, including colocalization with molecular QTL from disease relevant tissues. Additionally, for each of these genes, we perform Mendelian randomization analyses between expression QTL and each disease. Seventeen genome regions show robust evidence of colocalization between T2D and at least one OA phenotype. Sixteen genes were defined as high confidence effector genes, including *TCF7L2* and the obesity related *FTO* and *IRX3* genes. *TCF7L2* is among the leading signals for T2D risk but had not been identified as associated with OA at genome-wide significance levels to date. We find statistical evidence that *TCF7L2* expression is causal for T2D and protective against knee OA. The identified shared effector genes support the epidemiologically known link between BMI and the investigated comorbidity. Moreover, we find that high confidence effector genes for hip OA and T2D are enriched for biological pathways associated with skeletal formation. In summary, we present an approach to disentangle the shared genetic aetiology of T2D and OA based on openly available GWAS summary statistics. By incorporating functional genomics data, we then derive a list of sixteen high confidence effector genes for the comorbidity.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3463. Integrating external controls by regression calibration for genome-wide association study

Authors:

L. Zhu; Michigan Technological Univ., Houghton, MI

Abstract Body:

The genome-wide association study (GWAS) has successfully revealed many diseases associated variants. For a case-control study, the adequate power of association test can be achieved with a large sample size, although genotyping large control samples is expensive. A cost-effective strategy is proposed by integrating external control samples with publicly available genotyped data. However, the naïve integration of external controls may inflate the type I error rates if ignoring the systematic differences (batch effect) between studies, such as the differences in sequencing platforms, genotype calling procedures, population stratification, and so forth. To account for batch effect, we propose to integrate External Controls into Association Test by Regression Calibration (iECAT-RC) in case-control association studies. Simulation studies showed that iECAT-RC not only can control type I error rates but also can boost statistical power in all models. We also applied iECAT-RC to the UK Biobank for the hypertension disease by considering genotype calling as the batch effect. The real data result shows that iECAT-RC can detect additional hypertension associated locus.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3464. Integrating rare and common variant association data to improve therapeutic target discovery.

Authors:

P. LoGerfo¹, L. D. Ward², A. M. Deaton¹, M. E. Plekan¹, C. Willis¹, R. A. Hoffing³, A. M. Holleman¹, L. Krohn¹, P. Nioi²; ¹Alnylam Pharmaceuticals, Cambridge, MA, ²Alnylam, Cambridge, MA, ³Alnylam Pharmaceuticals, Allston, MA

Abstract Body:

GWAS of common variants is a powerful method to detect loci associated with biomarkers and disease. However, most of the trait-associated common haplotypes consist of noncoding variants that span multiple genes, hampering causal gene identification. Although colocalization with eQTL and pQTL data have been useful in some cases to identify causal genes and directions of effect at GWAS loci, these data remain limited.

Rare-variant association studies (RVAS) that aggregate rare coding variants from exome sequencing data complement GWAS and have the advantage of providing a putative causal gene and direction of effect to guide the development of therapeutics. Distance from a sentinel GWAS variant to the closest gene body has been demonstrated as the most predictive feature for choosing a causal gene (Mountjoy et al., Nat. Genet. 2021), as the closest gene is over 50-fold enriched for harboring an independent rare variant association for the same phenotype (Backman et al., Nature 2021). Thus, we used UK Biobank array genotyping data and exome sequencing data to perform RVAS with a GWAS prior, testing only the genes closest to the GWAS sentinel SNPs to lower the multiple testing burden.

One notable result was a GWAS and RVAS association between variants in *MYLIP* and levels of LDL cholesterol. The sentinel SNP for association with LDL at this locus, *rs6920309*, is an intronic SNP 4930 bp from the 5' end of *MYLIP*. Rare (MAF < 1%) predicted loss of function (pLOF) and damaging missense (CADD score > 25) variants in *MYLIP* associate with a 0.16 SD decrease in LDL cholesterol (N = 643 carriers, p = 4.1 x 10⁻⁵). This association surpassed a p-value threshold Bonferroni-corrected for the number of genes tested for association with LDL (N = 202). *MYLIP* regulates LDL cholesterol uptake through direct ubiquitination of the LDL receptor.

These results suggest that inhibition of *MYLIP* gene expression may reduce serum LDL cholesterol levels by enhancing LDL uptake. Targeted silencing of *MYLIP* mRNA may have therapeutic application in reducing the risks of cardiovascular disease posed by elevated LDL cholesterol, though additional research is needed.

PB3465. Integration of gene expression data in Bayesian association analysis of rare variants

Authors:

G. Zhong, Y. Choi, Y. Shen; Columbia Univ., New York, NY

Abstract Body:

The statistical power to identify risk genes by rare *de novo* variants is generally low due to rarity of genotype data. Previous studies have shown that disease risk genes usually have high expression in relevant cell types, although for many diseases the identity of these cell types are largely unknown. Recent efforts in single cell atlas in human and model organisms produced large amount of gene expression data. Here we present two new methods, xTADA and VBASS, that integrate expression data to improve power of rare variants association analysis. Optimized for bulk RNA-seq and single-cell transcriptomics data respectively, xTADA and VBASS model the association of disease risk as a function of expression profiles of relevant tissue or cell types in Bayesian frameworks. VBASS uses both analytical likelihood function and neural network approximations in joint probability calculation, and it learns the importance of cell types jointly from expression and genetics data. On simulated data, both methods show proper error rate control and better power than extTADA, the state-of-the-art Bayesian method. We applied the methods to published datasets and identified more candidate risk genes than extTADA with supports from literature or data from independent cohorts.

PB3466. Integration of International Mouse Phenotype Consortium (IMPC) and UK Biobank data to identify genes associated with blood molecular phenotypes

Authors:

H. Haseli Mashhadi¹, V. Munoz-Fuentes², K. Babalola¹, IMPC Consortium, R. Wilson³, T. Groza⁴, H. Parkinson⁵; ¹European Bioinformatics Inst. (EBI), Hinxton, United Kingdom, ²EMBL EBI, CAMBRIDGE, United Kingdom, ³European Bioinformatics Inst. (EMBL-EBI), Cambridge, United Kingdom, ⁴EMBL - European Bioinformatics Inst., Hinxton, United Kingdom, ⁵EMBL-EBI, Hinxton, United Kingdom

Abstract Body:

The International Mouse Phenotyping Consortium (IMPC, www.mousephenotype.org) is a global research infrastructure which aims to ascertain function to every protein-coding gene, using the mouse as a model. The IMPC focuses on studying genes that are poorly characterised or the function of which is unknown, to ultimately inform human health and disease. In this study, we focused on blood associated phenotypes from the IMPC and the human data from the UK Biobank (www.ukbiobank.ac.uk) to investigate the genes that are associated with haematology and clinical blood chemistry traits. Comparing the two resources, we found 36 (20 haematological and 16 biochemical) traits that had been collected for both species. We investigate sexual dimorphism using data collected from 20K+ wildtype mice and 500K+ humans using a novel method to score the multicentre statistical results. Despite the strong agreement between the data collected by the network of globally distributed centres in the IMPC, our analyses show the agreement between humans and mice in the overall pattern of (males higher) Eosinophil and Monocyte cell counts. We also integrated murine and human gene-phenotype associations using gene orthology, comprising 7,488 mouse-human orthologues that have been studied by the IMPC. Finally, taking advantage of the broad phenotyping pipeline applied by the IMPC, we look at pleiotropic effects of genes associated with blood phenotypes, to uncover relevant physiological pathways. For this study, we acknowledge the UK Biobank for granting access to 500K+ participants in the UK as well as the support by the NIH common fund mechanism: 10U54HG00637 and EMBL-EBI Core Funds.

PB3467. Integrative approaches to unravel sex- and age-associated gene signatures and networks.

Authors:

K. Johnson, A. Krishnan; Michigan State Univ., East Lansing, MI

Abstract Body:

Many complex traits and diseases vary in their incidence and presentation in people of different ages and sexes. Yet, historically, age and sex have been largely ignored in basic/preclinical studies and in translating findings to clinical research and medical interventions. As a result, we lack fundamental understanding of how the genetic basis of physiology and disease is influenced by sex and age. Our goal is to develop a computational, data-driven framework that can aid scientists in systematically bridging these gaps in understanding age- and sex-specific mechanisms. Key to creating these comprehensive frameworks is the massive collection of public omics data. However, there are significant challenges to using these data as-is, foremost being that most samples are not annotated with age and sex. Therefore, we first manually curated ~30,000 microarray and RNA-seq samples associated with age and sex labels. Using this curated gold standard, we trained one-vs-all logistic regression models with elastic net regularization to classify transcriptome samples into age groups separately for females and males. Overall, the classifiers are able to discriminate between age-groups in a biologically meaningful way in each sex across technologies, with slightly lower performance in the middle age groups and in the few age groups where we have a low number of positive examples. In addition, the coefficients of the trained models capture 'gene signatures' that are characteristic to each age group. Enrichment analysis of these gene signatures helped us identify both novel and previously known functions, phenotypes, and diseases associated with the age-group in each sex. We are currently extending these models to predict sex and age-group labels for all publicly available human transcriptomes. Next, we will use these predicted labels to group samples into sex/age-groups, build coexpression networks based on samples within individual datasets, and integrate these networks to build sex- and age-specific gene functional interaction networks. Our gene signatures and networks will be valuable tools for hypothesis generation and studying biological processes as influenced by age and sex.

PB3468. Interrogating causality of epidemiological risk factors on adolescent idiopathic scoliosis: a two-sample Mendelian randomization study.

Authors:

D. Manousaki¹, F. Ghanbari², N. Otomo³, Y. Koike³, A. Khanshour⁴, S. Ikegawa³, C. Wise⁵, C. TERAOKA⁶; ¹Sainte Justine Hosp. Univ. of Montreal, Montreal, QC, Canada, ²Res. Ctr. of the CHU Sainte-Justine Univ. Hosp., Montreal, QC, Canada, ³RIKEN, Yokohama, Japan, ⁴Scottish Rite Hosp. for Children, Dallas, TX, ⁵Scottish Rite for Children, Dallas, TX, ⁶RIKEN IMS, Tokyo, Japan

Abstract Body:

Background: Adolescent idiopathic scoliosis (AIS) is the most common form of pediatric musculoskeletal disorder. Observational studies have pointed to several risk factors for AIS, but almost no evidence exists to support their causal association with AIS. Here, we applied Mendelian randomization (MR), a method known to limit bias from confounding and reverse causation, to investigate causal associations between epidemiological risk factors and AIS risk in Europeans and Asians. **Methods:** For our two-sample MR studies, we used single nucleotide polymorphisms (SNPs) associated with Body Mass Index (BMI), Waist-Hip ratio, Lean mass, childhood obesity, Bone Mineral Density (BMD), 25-hydroxyvitamin D (25OHD), age at menarche, and pubertal growth in large European genome-wide association studies (GWAS), and with BMD and age of menarche in Biobank Japan. We extracted estimates of the above SNPs on AIS risk from the European or Asian subsets of the largest multi-ancestry AIS GWAS (N= 7,956 cases & 88,459 controls). **Results:** The results of our inverse-variance weighted (IVW) MR estimates suggest no causal association between the above risk factors and risk of AIS. Pleiotropy-sensitive MR methods yielded similar results. However, restricting our analysis to European females with AIS, we observed a causal association between estimated BMD and the risk of AIS (IVW MR OR=0.1, 95% CI 0.01-0.7, P=0.02), but this association was no longer significant after adjusting for BMI, body fat mass, and 25OHD, and remained significant after adjusting for age at menarche in a multivariable MR. Moreover, BMD and age at menarche were not associated with risk of AIS in our Asian MR analysis. **Conclusions:** We demonstrated a protective causal effect of BMD on AIS risk in females of European ancestry, but this effect was modified by BMI, body fat mass, and 25OHD levels. Future MR studies using larger AIS GWAS are needed to investigate small effects of the above exposures on AIS.

PB3469. Inverted genomic regions between reference genome builds in humans impact imputation accuracy and decrease the power of association testing

Authors:

C. Chiang¹, L. Xia¹, J. L. Cahoon¹, D. Conti¹, C. A. Haiman¹, L. Kachuri², X. Sheng¹; ¹Univ. of Southern California, Los Angeles, CA, ²Stanford Univ., Stanford, CA

Abstract Body:

Over the last two decades, the human reference genome has undergone multiple updates as we complete a linear representation of our genome. Two versions of human references are currently used in the biomedical literature, GRCh37/hg19 and GRCh38. Conversions between these versions are critical for quality control, imputation, and association analysis. In the present study we show that single nucleotide variants (SNVs) in regions inverted between different builds of the reference genome are often mishandled bioinformatically. Depending on the array type, SNVs are found in approximately 2-5 Mb of the genome that are inverted between reference builds. Coordinate conversions of these variants are mishandled by both the TOPMed imputation server as well as routine in-house quality control pipeline, leading to underrecognized downstream analytical consequences. Specifically, we observe that undetected allelic conversion errors for palindromic variants in these inverted regions would destabilize the local haplotype structure, leading to loss of imputation accuracy and power in association analyses. Though only a small proportion of the genome is affected, these regions include important disease susceptibility loci, resulting in biased variant-specific signals due to poor imputation. For example, the *P*-value of a known locus (rs10763546) associated with prostate cancer on 10q11.22 would drop from 2.86×10^{-7} to 0.0011 in a case-control analysis of 20,286 Africans and African Americans (10,643 cases and 9,643 controls). These errors have implication for GWAS discovery and development and application of polygenic risk scores, which often rely on *p*-values for selection of index variants. We devise a straightforward heuristic based on applying the popular tool *liftOver* to basepairs preceding and succeeding the SNV of interest to easily detect these variants in the inverted regions between genome builds. We show that correcting for these alleles will locally improve imputation accuracy. Our software, *triple-liftOver*, can be found at <https://github.com/GraceSheng/triple-liftOver>.

PB3470. Investigating miRNA role in the neuropathology of Major Depression in a large postmortem brain sample.

Authors:

Z. Taylor¹, J. Drake¹, A. Denham¹, S-A. Bacanau², J. Heon Shin³, J. Kleinman³, T. Hyde³, V. Vladimirov¹; ¹Dept. of Psychiatry and Behavioral Sci., Coll. of Med., Texas A&M Univ., College Station, TX, ²Virginia Inst. for Psychiatric and Behavioral Genetics, VCU, Richmond, VA, ³Lieber Inst. for Brain Dev., Johns Hopkins Univ., Baltimore, MD

Abstract Body:

Major Depression (MD) is a debilitating disorder characterized by low mood and anhedonia that affects roughly one out of every six adults worldwide. Several large GWAS studies have already identified genome-wide significant variants associated with MD. However, little can be said about the functional impact of these variants from the GWAS alone. A complementary approach to understanding the underlying neuropathology of MD involves identifying transcriptome changes associated with major depression in postmortem brain tissues.

MicroRNA (miRNA), a class of small non-coding RNA with important gene regulatory functions and high expression in the brain, has been studied in relation to neuropsychiatric phenotypes. In this study, we used miRNA-Seq to compare the expression of 947 miRNAs between 150 MD patients and 150 matched controls in the subgenual anterior cingulate cortex (sACC). We applied statistical and bioinformatic analyses, e.g., single miRNA differential expression analysis (DEA), weighted gene co-expression analysis (WGCNA), expression quantitative trait loci (eQTL), and miRNA/mRNA correlation-based analyses to detect a set of miRNAs with a converging role in the etiology of MDD. We identified 50 miRNAs whose expression was associated with MD (at FDR of 5%). These included miRNAs that were both previously associated with MD and unique to this study as well as miRNAs associated with neurodevelopment or other psychiatric illness. The network analyses detected two significant miRNA modules associated with MD at the Bonferroni corrected $p \leq 0.05$, the module eigengenes (ME) of which were also negatively correlated with mRNA modules significantly associated with MD. Our eQTL analysis identified 86 significant cis- and 8 trans-eQTLs modulating the expression of these miRNAs. We further showed the eQTLs for these miRNAs are enriched for signals in GWAS of MD. Lastly, we note A to I RNA editing for a number of our top miRNAs highlighting additional biological mechanisms by which miRNA contribute to neuropathology of MD.

In conclusion ours is the largest to date postmortem brain miRNA expression study of major depression, and our ongoing analyses provides solid evidence of the importance of miRNA as a contributing factor to the development of MD.

PB3471. Investigating the effect of body size between menarche and first birth on breast cancer risk in later life: A lifecourse Mendelian randomization study

Authors:

G. Power¹, A. Hughes¹, T. Richardson¹, J. Heron¹, L. Bhatta², B. Brumpton², B. Asvold², J. Tyrrell³, T. Frayling³, A. Havdahl⁴, G. Davey Smith¹; ¹MRC Integrative Epidemiology Unit, Univ. of Bristol, Bristol, United Kingdom, ²Norwegian Univ. of Sci. and Technology, Trondheim, Norway, ³Univ. of Exeter, Exeter, Devon, United Kingdom, ⁴Univ. of Oslo, Oslo, Norway

Abstract Body:

Nulliparity is associated with increased reproductive malignancies and early first full-term pregnancy has been found to reduce risk of breast cancer. There is also evidence that increased weight in childhood is protective against breast cancer. Our research is focused on body size at different time points across the lifecourse and its effect on breast cancer risk, to understand the time frame in which undifferentiated nulligravid breast is most susceptible to carcinogenic insults. However, separating the effects of risk factors at different stages of the lifecourse is challenging due to confounding in conventional epidemiological settings. This is a key motivation behind using a Mendelian randomization (MR) approach.

Conventionally, MR studies use a single measurement to estimate the effects of an exposure on an outcome. Effects obtained are therefore often interpreted as the lifetime effect of the genetically predicted exposure. Our research exploits the notion that genetic associations may arise from the direct effects of the same inherited variants at different stages throughout life. This research seeks to assess the association between genetic variants and measures of body size taken between menarche and first birth at different intervals across the lifecourse. Using previously validated instruments for childhood and adult body size (n=453169) as well as instruments under development using data from several large prospective cohort studies (including Avon Longitudinal Study of Parents and Children (ALSPAC) Cohort (n=13964), HUNT Study (n=7683) and Norwegian Mother and Child Cohort Study (MoBa) cohort (n=36238), we will run univariable and multivariable MR to simultaneously estimate the effects of age-specific genetic proxies for body size on breast cancer. Thus far, we have identified independent associations with body size between menarche and <20 years and childhood body size (mean age: 10 years) as well as body size between menarche and <20 years and adulthood body size (mean age: 56.5 years) using ALSPAC and MoBa cohort data, with genetic correlation coefficients of $r_G=0.68$ and $r_G=0.46$, respectively. We have also successfully used genetic variation to separate the effects of early and later life body size in earlier research, which found novel evidence that higher childhood body size reduces fractures and higher adult body size is a risk factor for fractures. In addition, higher body size in childhood does not have a direct effect on cardiovascular disease in later life, rather, the effect of genetically predicted childhood body size on the cardiovascular disease outcomes analysed are a result of larger body size persisting into adulthood.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3472. Investigating the impact of the rare pathogenic variants linked to Intellectual Disability genes on the cognitive ability in adults: exome analysis of the UK Biobank cohort

Authors:

A. Kumar¹, T. Cuppens², K. Vachon³, M. Leclercq⁴, A. Droit^{5,6}, I. Dunham^{5,7}, F. Bolduc⁸; ¹EMBL-EBI, Cambridge, United Kingdom, ²Ctr. de recherche du CHU de Québec - Université Laval, Québec, QC, Canada, ³Dept. of Pediatric Neurology, Edmonton, AB, Canada, ⁴Université Laval, Québec, QC, Canada, ⁵Ctr. de recherche du CHU de Québec-Université Laval, Québec, QC, Canada, ⁷European Molecular Biology Lab., European Bioinformatics Inst., Cambridge, United Kingdom, ⁸Univ Alberta, Edmonton, AB, Canada

Abstract Body:

Aim/Background: Cognitive impairment, mental retardation, or specific intellectual disability (ID) affected individuals comprise an estimated 3-5% of world population. Extensive research has been done in identification of genetic variants including single nucleotide variants (SNVs) and copy number variants (CNVs) and elucidating their link to ID. Most of this research has been performed on children or young populations pertaining to addressing the developmental delay and early onset of IDs. However, reduced penetrance of these variants has also resulted in unaffected obligate adult carriers in the population. Hence, in the current work we extensively focus on investigating the UK Biobank (UKBB) cohort for the impact of rare (MAF $\leq 1\%$) protein coding pathogenic variants (SNVs) pertaining to genes already known to be associated with ID. **Methods:** 50,000 UKBB samples previously jointly-genotyped (GATK pipeline) were processed for variant annotation and downstream filtering. The variants were annotated for frequency (gnomAD), ensembl-vep annotations, pathogenicity (CADD, Clinvar etc). Subsequently, variants were filtered (MAF $\leq 1\%$) for protein coding, impact on the transcript (high & moderate), variant consequences, pathogenicity and variant quality metrics. Finally, the filtered variants pertaining to non-ID individuals in UKBB were regressed (using a generalized linear model) upon a set of 7 cognitive tests available in the UKBB portal where each individual was assigned a cognitive score based on their respective performances on these tests. **Results:** In the first stage of our analysis we randomly sampled 5000 non-ID UKBB individuals. After applying stringent filtering criteria we retained 39 pathogenic variants across 757 individual carriers. Upon linear regression with one of the cognitive tests (Pairs-Matching Test), variants pertaining to CRB1 (P<0.00125) and PNKP (P <0.03) were found to be statistically significant. This supports our assertion regarding the impact of pathogenic variants ID genes in unaffected carriers. We plan to extend this analysis for full 50K and 500K UKBB individuals and incorporate other cognitive tests for further investigation.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3473. Investigating the potential impact of PCSK9-inhibitors on mood disorders using eQTL-based Mendelian randomization

Authors:

A. Aman¹, E. A. W. Slob², J. Ward¹, B. Cullen¹, N. Graham¹, D. Lyall¹, N. Sattar¹, R. J. Strawbridge¹; ¹Univ. of Glasgow, Glasgow, United Kingdom, ²Univ. of Cambridge, Cambridge, United Kingdom

Abstract Body:

Background: Prescription of PCSK9-inhibitors has increased in recent years but not much is known about off-target effects. *PCSK9*-expression is evident in non-hepatic tissues, notably the brain, and genetic variation in the *PCSK9* locus has been recently shown to be associated with mood disorder-related traits. We investigated whether a genetic reduction in expression of *PCSK9* mRNA might have a causal adverse effect on mood disorder-related traits.

Methods: We used genetic variants in the *PCSK9* locus associated with reduced *PCSK9* expression (eQTLs) in the European population from GTEx v8 as the exposure, proxying PCSK9-inhibitors. The largest European ancestry genome-wide association studies of PCSK9 protein, and LDL cholesterol levels (positive controls), and three mood disorder-related traits (major depressive disorder, mood instability, and neuroticism) were used as outcomes. We conducted summary-based Mendelian randomization analyses to estimate the causal effect of reduced *PCSK9* expression on mood disorder-related traits. The analysis was replicated using data from eQTLGen, Brain-eMETA, and the CAGE consortium.

Results: We find that genetically reduced *PCSK9* gene-expression levels were significantly associated with reduced PCSK9 protein levels but not with increased risk of mood disorder-related traits. Further investigation of nearby genes demonstrated that reduced *USP24*-expression level was significantly associated with increased risk of mood instability (p-value range = 5.2×10^{-5} - 0.03) and neuroticism score (p-value range = 2.9×10^{-5} - 0.02), but not with PCSK9 protein levels.

Conclusion: Our results suggest that genetic variation in this region acts on mood disorders through a PCSK9-independent pathway, and therefore PCSK9-inhibitors are unlikely to have an adverse impact on mood disorder-related traits.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3474. Investigating the relationship between immune disease genetic risk and Alzheimer's Disease incidence.

Authors:

K. Clark, L-S. Wang; Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Alzheimer's Disease (AD) is a neurodegenerative disease characterized by devastating memory loss and cognitive deterioration that affects more than 5 million adults over the age of 65. Physiological changes including amyloid plaque deposition and tau tangles begin 15 to 20 years before symptom onset, making AD difficult to treat beyond symptom management. Recent AD genome-wide association studies (GWAS) have identified more than 20 genetic loci associated with AD, many of which have been shown to play a role in the activation of the innate immune system. However, the biology underlying the association is still unexplained. To address this, we conducted a Polygenic Risk Score (PRS) analysis to identify immune risk factors and comorbidities relevant to AD. Using publicly available GWAS summary statistics, we calculated risk scores for 5 immune traits that have been previously shown to be associated with incidence of AD: Crohn's Disease, Lupus, Rheumatoid Arthritis, Psoriasis, and Multiple Sclerosis. We then applied logistic regression to the scores to identify correlations with AD case/control status in European samples from the National Alzheimer's Coordinating Center (NACC). In the future we plan to repeat this analysis in samples of African and East Asian ancestry. This work will allow us to use the known biological mechanisms behind the chosen immune diseases to better understand AD pathogenesis. This could potentially lead to drug repurposing and the advancement of specialized treatment for people of all ethnic groups.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3475. Investigation of Genetic Variants and Causal Biomarkers Associated with Brain Aging

Authors:

J. Lee, K. Jangho, S. Lee; Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract Body:

Delta age is a biomarker of brain aging that captures differences between the chronological age and the predicted biological brain age. As large-scale datasets such as UK Biobank that contain the neuroimaging data and other biomarkers are becoming readily available, various methods to measure the brain-specific age have been developed. While existing research on delta age has been focused on prediction methods and finding an association with other phenotypes, we identified which groups of biomarkers causally affect the degree of brain aging. Moreover, an appropriate feature attribution method for medical images was used to identify brain regions that drive high delta age. First, we trained a 3D convolutional neural network model for age prediction with the T1-weighted structural brain MRI of 25,656 healthy white British samples in the UK Biobank. The test mean absolute error in the healthy individuals was 2.64 years. A visual saliency map of brain regions from integrated gradients showed that lower volumes in the fornix and the lower part of the thalamus are critical predictors of high delta age. Second, we performed a genome-wide association analysis (GWAS) for 38 million array-genotyped and imputed genetic variants for delta age. The results identified six genome-wide significant loci, including variants in *KLF3*, *AS1* and *STX6*. Additionally, we carried out the same GWAS procedure with the average voxel value of the two regions (lower volume in the fornix and the lower part of the thalamus) to evaluate whether the delta age prediction was truly driven by those regions. We observed nearly identical associated variants and large negative genetic correlations between delta-age and lower volume in the fornix (genetic $\text{corr} = -0.32$) and lower part of the thalamus (genetic $\text{corr} = -0.50$), respectively. Lastly, we examined the causal impacts of 249 metabolomic biomarkers and 61 blood-related phenotypes on brain aging using MR-Egger Mendelian randomization. Eosinophil count ($p\text{-value} = 5.16\text{E-}6$) was the most significant, followed by eosinophil percentage, neutrophil count, and total protein. All of these immune-related biomarkers causally increased the delta age. Our analysis revealed regions in the brain that are susceptible to the aging process and provided evidence of the causal and genetic connections between immune responses and brain aging.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3476. Investigations of the potential causal effects of the immune response to varicella-zoster virus on multiple health conditions: a Mendelian randomization phenome-wide association study

Authors:

X. Yu, H. Guo, A. Lophatananon, K. Mekli, K. Muir; The Univ. of Manchester, Manchester, United Kingdom

Abstract Body:

Background The immune response to infections is partly driven by the individual's genes, especially for genes in the major histocompatibility complex (MHC) region. The identification of herpes zoster virus (VZV) immune response-related genes helped understand the occurrence of disease in those persons infected with the virus. Apart from the infection, the reactivations of VZV can be a potential causal factor for multiple health conditions [1]. **Methods** To explore whether VZV specific immunity has a causal role on multiple health conditions, a Mendelian randomization phenome-wide association study (MR-PheWAS) of anti-VZV IgG levels with 1,730 health conditions was conducted using the UK Biobank cohort. To increase statistical power, we relaxed the p-value threshold of associations from a genome-wide association study. For each trait, we performed five MR approaches on two sets of instrumental variables (IVs), either including single nucleotide polymorphisms (SNPs) in the major histocompatibility complex (MHC) region or not. **Results** We identified 49 SNPs associated with anti-VZV IgG levels as IVs, five of which were located in MHC region. We found 75 traits passed conventional p value thresholds in at least three methods, 60 if we remove IVs in MHC region. Only 28 traits overlapped between the two IV strategies. The overlapping results indicated potential causal effects of higher anti-VZV IgG levels on increased risk of 14 diseases and lower risk of 9 diseases. The anti-VZV IgG levels were causally associated with 5 biomarker-related traits. **Conclusions** The anti-VZV IgG levels were causally associated with multiple health conditions, which provides new insight into these diseases. Attention should be paid to the MHC SNPs when selecting IVs for MR analysis.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3477. Is the portability of polygenic scores a matter of genetic ancestry alone?

Authors:

J. Wang¹, M. Zietz², J. Mares³, V. Narasimhan¹, M. Przeworski³, A. Harpak¹; ¹The Univ. of Texas at Austin, Austin, TX, ²Columbia Univ. Irving Med. Ctr., New York, NY, ³Columbia Univ., New York, NY

Abstract Body:

A major obstacle hindering the broad adoption of polygenic scores (PGS) is their lack of “portability” to people that differ—in genetic ancestry, environmental exposures or other characteristics—from the GWAS samples in which the PGSs were estimated. Currently, it is unclear to what extent the poor portability of PGS is caused by sample differences in genetic ancestry. While previous studies have shown decreased prediction accuracy in other ancestries, these groupings confound changes in allele frequencies and linkage disequilibrium patterns with many other factors, including distinct distributions of environmental effects. We investigate relative prediction accuracy as a function of continuous genetic divergence from the GWAS sample to a target genome, using the fixation index, F_{ST} . Across diseases and physiological traits in the UK Biobank, we find that prediction accuracy does not depend on genetic divergence from the GWAS sample when $F_{ST} < 0.01$, beyond which, prediction accuracy decays linearly with F_{ST} . For each trait, we examine whether covariates such as zip code or reported race explain prediction accuracy above and beyond genetic divergence from the GWAS sample. Finally, we examine how portability depends on genetic divergence from the GWAS sample in the specific genomic loci that contribute to the PGS. Discrepancies between this measure, versus genome-wide genetic divergence, as predictors of portability suggest that the confounding of genome-wide genetic ancestry with other factors partially explains the decrease in portability with genetic distance from the GWAS sample. Together, our analyses help disentangle the factors that impede the portability of PGS to groups underrepresented in a GWAS sample, and guide future decisions on the applicability of PGS to a given target sample.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3478. Isoform level transcriptome wide association study of prostate cancer risk reveals large number of transcript specific associations

Authors:

P. Barman, S. K. McDonnell, Z. Fogarty, D. J. Schaid, S. N. Thibodeau, N. B. Larson; Mayo Clinic, Rochester, MN

Abstract Body:

Prostate cancer (PRCA) is a highly heritable and polygenic disease trait, and large GWAS of PRCA risk have identified hundreds of independent genome-wide significant SNPs. Recent transcriptome-wide association studies (TWAS) leveraging tissue-specific expression quantitative trait loci (eQTL) datasets have linked multiple candidate genes to genetic risk of PRCA. However, these analyses have focused on total expression, and many genes have multiple isoforms with unique protein products. This information is largely lost when modeling total expression, and isoform-dependent associations with risk may go undetected. In this study, we used a large normal prostate tissue eQTL dataset to conduct an isoform-level TWAS (isoTWAS) of PRCA risk based on results from the PRACTICAL PRCA case-control GWAS meta-analysis. Our eQTL dataset consisted of 471 normal prostate tissue samples with available RNA-Seq and imputed Illumina Infinium 2.5M genotype data. Isoform-level expression values were generated using StringTie; after low abundance isoform filtering, expression was observed for 125,403 transcripts from 13,271 genes. We modeled relative isoform abundance using a log-ratio transformation relative to the highest expressed transcripts, and the FUSION TWAS software was used to train expression prediction models for genes with >1 expressed transcript. Further filtering based on minimum cis-heritability ($P < 0.01$) using a 50kb buffer led to successful training of isoform-level models for 11,550 transcripts corresponding to 4850 genes, including 2533 new genes that did meet similar criteria using the same data based on total expression. IsoTWAS was then performed using the PRACTICAL PRCA risk summary statistics, and significant associations were conservatively declared at the gene-level based on a Bonferroni-adjusted result for the top transcript model per gene, with gene-level significance then declared at an $FDR < 0.05$. We identified a total of 427 significant isoTWAS associations with PRCA risk, with the top 3 genes corresponding to *NKX3-1* ($P = 1.7E-40$), *PPP1R14A* ($P = 4.2E-27$), and *SIDT1* ($P = 1.0E-23$). When compared to the previously published PRACTICAL multi-tissue TWAS, 1303/4850 genes (26%) were novel with respect to available analysis results (104 significant at $FDR < 0.05$). For overlapping genes, while many significant isoTWAS genes were also significant in the PRACTICAL multi-tissue TWAS, often the isoTWAS yielded a stronger signal and/or sole evidence of a prostate-specific result. These findings suggest additional focus should be afforded to resolving PRCA genetic risk and the prostate transcriptome at a transcript level.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3479. Joint analysis of GWAS and multi-omics QTL summary statistics reveals a large fraction of GWAS signals shared with molecular phenotypes

Authors:

Y. Wu¹, T. Qi², J. Zeng¹, J. Yang²; ¹The Univ. of Queensland, Brisbane, Australia, ²Westlake Univ., Hangzhou, China

Abstract Body:

Molecular quantitative trait loci (xQTLs) are often harnessed to prioritize genes or functional elements underpinning variant-trait associations identified from genome-wide association studies (GWAS). Here we introduce a method, OPERA, that can jointly analyse summary statistics of GWAS and multiple omics layers of xQTLs to identify molecular phenotypes associated with complex traits because of shared causal variants. Applying OPERA to summary-level GWAS data for 20 complex traits ($n=20,833-766,345$) and xQTL data from five omics layers ($n=100-31,684$) finds ~42% of the GWAS signals shared with at least one xQTL, about half of which are not shared with expression QTLs. The signals shared with multiple molecular phenotypes, such as the *MSMB* locus for prostate cancer, are particularly informative to infer plausible regulatory cascades mediating the GWAS effects. Future studies with more molecular phenotypes, measured considering spatiotemporal effects in larger samples, are required to obtain a more saturated map linking molecular intermediates to GWAS signals.

PB3480*. Latent factor analysis reveals genetic components across GWAS traits

Authors:

A. Omdahl¹, S. Chhetri¹, Y. He², A. Battle²; ¹Johns Hopkins Sch. of Med., Baltimore, MD, ²Johns Hopkins Univ., Baltimore, MD

Abstract Body:

Today's GWAS measure the genetic landscape of thousands of phenotypes. Recent computational methods integrate findings across these studies to clarify relationships between traits and the pleiotropic activity of variants they share. These methods have uncovered novel genetic associations in rare diseases, identified distinct genetic disease etiologies, and prioritized genes regulating cellular development relevant to specific phenotypes. However, these approaches are limited by the number of traits they can jointly analyze, have been applied in few trait contexts, and can be difficult to robustly interpret. Furthermore, the effect of shared participants between studies may confound interpretation of these results and has not been closely examined.

To address these limitations, we present genomewide association sparse matrix factorization (gwasMF), a sparse factor analysis method for finding latent genetic components across GWAS summary statistics. gwasMF groups phenotypes into sparse clusters and identifies SNPs associated with these groups. The method employs weighted alternating-least-squares L1 regression and is initialized to detect broad pleiotropic effects. gwasMF may be applied across multiple cohorts and in specific or diverse sets of phenotypes. We also provide a framework to interpret gwasMF latent factors by projecting them onto a broader set of variants and testing for annotation and tissue-specific enrichment.

When applied to a diverse set of phenotypes, gwasMF identifies tissue-specific latent components and components enriched for pleiotropic SNPs. These sparse factors better group traits in a tissue-specific manner than non-sparse methods. gwasMF applied to Type 2 Diabetes-related phenotypes identifies factors corresponding to previously described pathways of obesity-mediated insulin resistance and beta-cell function. We also examine female infertility using gwasMF, which has no reported GWAS associations, leveraging summary statistics for related phenotypes with known associations where sharing of related genetic influences is likely. Finally, we evaluate the effects of cohort overlap between GWAS studies in the setting of factor analysis using both real and simulated data and consider matrix whitening as a possible solution. These findings merit follow-up to develop best practices for GWAS factor analysis and application of gwasMF to other understudied phenotypes. Future methods development integrating cohort overlap, LD structure, and variant annotations will further enrich the biological interpretability of our method.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3481. Leveraging cohorts from diverse ancestries to uncover generalizable genotype driven fetal- and adult-specific brain transcriptomic mechanisms in psychiatric disorders.

Authors:

A. Jajoo¹, C. Chatzinakos¹, C. Wen², PsychoENCODE Consortium, T. Bigdeli³, M. Gandal², N. Daskalakis¹; ¹McLean Hosp., Harvard Med. Sch., Belmont, MA, ²UCLA, Los Angeles, CA, ³SUNY Downstate Hlth.Sci. Univ., Brooklyn, NY

Abstract Body:

Brain transcriptomic imputation utilizes genotype-expression reference panels to build predictive models genetically regulated gene expression (GReX). GReX models can be applied to GWAS to conduct transcriptome-wide association studies (TWAS) to prioritize gene-trait associations (GTAs) with functional importance. However, reference panels and GWAS studies have been biased toward European Ancestry (EA) samples, posing limitations for the identification of generalizable GTAs. To overcome this challenge, we propose meta-analyzing TWAS results across the ancestries by applying ancestry-specific models to the respective ancestry GWAS. To this effect, we trained ancestry-specific GReX models, of Admixed African Ancestry (AA) and EA, separately for healthy adult DLPFC tissue ($N_{AA}=165$, $N_{EA}=453$ subjects) and fetal brain tissue ($N_{AA}=164$, $N_{EA}=292$). Fetal models predict fewer genes and have lower R^2 model performance for overlapping genes compared to same ancestry adult models ($R^2=0.17$ for EA_adult vs $R^2=.11$ for EA_fetal, $P<e-16$). Within each tissue type, R^2 were comparable between ancestries, but AA models predicted 45% fewer genes compared to same tissue EA models likely due to less power. EA models compared to AA models performed worse in AA test set, while AA models performed comparably in EA test set. We applied these models on GWAS of bipolar disorder (BD), major depressive disorder (MDD), post-traumatic stress disorder (PTSD), and schizophrenia (SCZ), using at least one GWAS for each ancestry within each disorder. The average correlation of GTA z-scores was $Rho=0.49$ between adult and fetal analyses. Fetal tissue yielded a higher percentage of GTAs for SCZ which was expected because of neurodevelopmental origins, but surprisingly this was true for PTSD which has a later age of onset and lower heritability. The common GTAs from fetal and adult analyses tended to cluster in particular genomic regions (e.g, 17q21.31 in PTSD). Furthermore, the general observation is that bi-ancestry TWAS meta-analysis using just EA GReX models yields the least percentage of Bonferroni significant GTAs, while using ancestry-specific GReX models for respective ancestry GWAS yields the highest percentage (e.g., 2x increase in SCZ, 30x increase in PTSD). Our work shows that fetal and adult brain tissue based GTAs reveal shared and distinct genetic underpinnings of psychiatric disorders that operate in multiple stages, and that bi-ancestral TWAS is more beneficial when ancestry-specific GReX models can be applied on respective ancestry-specific GWAS.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3483. Leveraging functional genomic annotations and genome coverage to improve polygenic prediction of complex traits within and between ancestries

Authors:

J. Zeng, Z. Zheng, P. Visscher; The Univ. of Queensland, Brisbane, Australia

Abstract Body:

Polygenic prediction of complex traits, including diseases, plays an important role in research and medical applications of the fast-growing genomic data in humans, but clinical applications in most diseases are currently impeded by the limited prediction correlation between the genetic predictor and outcome. Functional genomic annotations provide orthogonal information about the locations and effects of causal variants underlying complex traits, which can be used to improve polygenic prediction. In this study, we developed a Bayesian method (SBayesRC-eigen) to integrate GWAS summary statistics with functional annotations for polygenic prediction. We derived a low-rank model based on eigen-decompositions on quasi-independent LD blocks so that our method is resource-efficient and scalable to analysis of whole-genome imputed or sequence variants. We analysed 28 traits (including 8 diseases) in UK Biobank using 7 million imputed common SNPs and 96 per-SNP annotations. Compared to SBayesR using 1 million HapMap3 SNPs without annotations, SBayesRC-eigen improved prediction accuracy by 14% in European ancestry and by up to 33% in trans-ancestry prediction, outperforming state-of-the-art methods that incorporate annotations such as LDpred-funct and PolyPred-S. We identified factors affecting accuracy of prediction exploiting annotations, and found that the integration of GWAS with annotation data is most beneficial for traits with low heritability or small sample sizes, provides additional information to allele frequency and linkage disequilibrium categories, and is best used in a unified analysis where all parameters are estimated in one model. In addition, we observed a significant interaction between SNP density and annotation data, evidenced by a 2-fold higher annotation-derived improvement in prediction accuracy from 7 million SNPs. Furthermore, the per-SNP predictability enrichment in the hold-out sample was in proportion to the per-SNP heritability enrichment in the GWAS sample, suggesting that functional genetic architecture is informative to predicting which variants are important for polygenic prediction. Based on these findings, we predict that analysing whole-genome sequence variants with high-quality trait-relevant functional annotations will maximize the accuracy of polygenic prediction within and between ancestries.

PB3484. Leveraging Molecular-Diagnosis Workflow to Identify Modifier Genes in Diseases

Authors:

K. Schmitz-Abe, A. Tam, Q. Li, J. Lin, P. Agrawal; Children's Hosp. Boston, Boston, MA

Abstract Body:

Analysis of genetic data has helped advance the study of many rare diseases in part by providing molecular diagnoses to guide investigation. Meanwhile, many other rare conditions are either non-monogenic, have unidentified modifiers, or are poorly understood at the molecular level and need alternative approaches. We approach this problem by leveraging a collection of genetic and clinical data at Boston Children's Hospital (BCH) and adapting our previously described molecular-diagnosis Variant Explorer pipeline (VExP) for gene-based analysis. This dataset contains 7414 samples from 3093 families, 1240 of which are trios. We capitalize on the richness of this dataset to reduce noise by selecting mutations that meet a full-penetrance dominant/*denovo* model or full-penetrance recessive/compound-heterozygous model. Additionally, we use the results from various mutation-effect and spliceogenicity prediction software, constraint scores and MAFs from gnomAD, and quality scores for the aligned reads in the neural network of our molecular-diagnosis pipeline to score candidate variants. Furthermore, our pipeline facilitates downstream analysis by flagging candidates in genes with matches to key terms found in HGMD, OMIM, MGI, HPO, and Monarch as well as pathways found in GO or KEGG and identified as enriched through our newly developed Monte Carlo approach and providing links to relevant entries in these phenotype and pathway databases. Taking variants that were thus filtered, scored, and flagged by our workflow, we collapsed them by gene in four ways: loss-of-function, missense, synonymous and loss-of-function + missense. Then, we perform a Fisher exact test for each candidate gene between families affected by a particular condition ("cases") and families without the condition of interest ("controls"). In addition to exploring published methods for gene-based analysis, we are applying our *ad hoc* approach to identify potential modifier genes that differentiate fast-progressing cystic fibrosis from slow-progressing cystic fibrosis in patients homozygous for the *CFTR* F508del mutation. Our approach has identified potentially significant associations for known causal gene *CFTR* and potential modifier genes, including *SLC26A9*, *ACE*, *SCNN1D*, and *IL8*.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3485. Leveraging multiple reference panels by stacked regression TWAS identifies 6 novel independent risk genes for Parkinson's disease

Authors:

R. Parrish¹, A. Buchman², Y. Wang², P. De Jager³, D. Bennett², M. Epstein¹, J. Yang¹; ¹Emory Univ., Atlanta, GA, ²Rush Univ. Med. Ctr., Chicago, IL, ³Columbia Univ Med Ctr, New York, NY

Abstract Body:

Existing transcriptome-wide association study (TWAS) methods often assume a single reference panel of transcriptomic and genetic data from a relevant tissue to train imputation models of gene expression to estimate eQTL weights to be integrated with GWAS data. However, multiple reference panels of a given tissue often exist; for example, the Religious Orders Study (ROS), Rush Memory and Aging Project (MAP), and Genotype-Tissue Expression project (GTEx) all profile transcriptomic data from prefrontal cortex tissue. Additionally, there often exist publicly available expression imputation models which utilize a variety of reference cohorts and regression methods. We hypothesize that leveraging expression imputation models of the same target gene that are fitted from multiple reference panels and by multiple regression methods can improve TWAS performance, compared to the standard use of a single reference panel and single regression method.

We developed the Stacked Regression based TWAS (SR-TWAS) tool that uses the ensemble Machine Learning technique of Stacked Regression to form optimal linear combinations of expression imputation models (i.e., base models) of the same target gene and tissue type. By combining these base models, SR-TWAS can leverage multiple reference panels with increased effective training sample sizes as well as multiple regression methods which assume different underlying genomic architecture.

This study conducted a TWAS of Parkinson's disease (PD) using the most recent GWAS summary dataset (n~482k). We applied SR-TWAS to base models trained on multiple reference panels from prefrontal cortex tissue by TIGAR and PrediXcan. SR-TWAS identified 50 significant TWAS risk genes of PD, including 35 novel TWAS risk genes. Of these, 14 are known GWAS risk genes, and 33 are within 1MB of a known GWAS risk gene. From these results we curated 11 independent significant TWAS risk genes by selecting the most significant genes among genes that have shared test regions. We identified 6 novel independent TWAS risk genes. Two of these novel risk genes are known GWAS risk genes (CNTN1, LINC02210) and 3 are within 1MB of known GWAS risk genes (CCNT2, CCDC158, PTP4A2P2).

Our results show the advantage of using multiple reference panels and regression methods for SR-TWAS. Our SR-TWAS tool is expected to increase expression imputation accuracy and TWAS power for mapping risk genes of complex diseases and will be publicly available on Github.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3486. Leveraging multiple traits to detect shared non-additive genetic variation in genome-wide association studies

Authors:

A. Bass, S. Bian, A. Wingo, T. Wingo, D. Cutler, M. Epstein; Emory Univ., Atlanta, GA

Abstract Body:

Detecting and characterizing non-additive genetic variation in genome-wide association studies provides valuable insights into the genetic architecture of a trait. Identifying this variation---such as gene-by-gene or gene-by-environment interactions---can be challenging due to low statistical power and difficulty in specifying unknown (or latent) genetic and environmental variables. While there are strategies to detect non-additive variation for a single trait, there is limited research on incorporating multiple traits even though this can substantially increase power. In particular, a shared interaction effect influences not only the variance of a trait but also the covariance between different pairs of traits, and these differential covariance patterns can be harnessed to improve power. We propose a new framework that leverages this information across multiple related traits to detect covariance quantitative trait loci (covQTL), i.e. any latent non-additive genetic variation that impacts the covariance among traits. Our approach implements a flexible Kernel-based testing procedure that compares the similarity of one or many genotypes to appropriately transformed traits without having to specify the latent variables. The method, called Primary and Latent Covariance Analysis (PLCA), accounts for population structure and other known covariates while being computationally efficient for genome-wide analysis. We validate PLCA on simulated data and demonstrate it on the UK Biobank data using five obesity-related traits measured across 330,328 individuals with over 5 million single nucleotide polymorphisms. We find strong evidence of covQTLs which implies genome-wide polygenicity of non-additive effects. Thus PLCA can be applied to multiple related traits to discover shared non-additive genetic variation and help reveal underlying biological mechanisms in genome-wide studies. PLCA is implemented in the publicly available R package `plca`.

PB3487. Leveraging polygenic risk scores of biomarkers to identify obesity endotypes.

Authors:

M. Bagheri¹, B. De Meulder², M. Shi³, J. Annis¹, J. Peterson¹, E. Brittain¹, J. Ferguson¹, J. Mosley¹; ¹Vanderbilt Univ. Med. Ctr., Nashville, TN, ²Association European Inst. for Systems Biology and Med., Vourles, France, ³VUMC, Nashville, TN

Abstract Body:

Background: Obesity (body mass index [BMI]≥30) is strongly associated with cardiometabolic diseases. However, the risk is not always associated with the severity of obesity, suggesting there are subgroups of obese individuals who do not develop adverse outcomes. We hypothesized that clustering approaches that use multi-omics data can identify biologically-informed subgroups with differing patterns of disease associations and differing underlying risk mechanisms. **Methods:** Genetic data from Framingham/Malmö and KORA/TWINS was used to develop single nucleotide polymorphism-based predictors of expressed proteins and metabolites. The genetically predicted levels of biomarkers were used to impute biomarker levels in 4,625 obese genotyped BioVU participants. We constructed multi-omic clusters of obese individuals, defined as obesity endotypes, using Similarity Network Fusion in conjunction with Consensus clustering. The association between each endotype and 14 cardiometabolic diseases was assessed using multivariable logistic regression models adjusting for sex, age, BMI, lipid profiles, glucose and medications. Pathway and enrichment analyses were performed using Reactome and MetaboAnalyst. **Results:** We identified 5 obesity endotypes that were associated with different diseases: endotype1: chronic kidney disease (OR:1.22, 95% CI:1.03-1.45, p=0.02); endotype2: no association; endotype3: chronic pulmonary embolism (OR:4.58, 95% CI:1.36-13.98, p=0.009); endotype4: atrial fibrillation (OR:0.73, 95% CI:0.57-0.92, p=0.009); and endotype5: hypertension (OR:0.65, 95% CI:0.46-0.95, p=0.02) and peripheral arterial disease (OR:1.28, 95% CI:1.01-1.61, p=0.04). Each endotype was related to distinct pathways; notably endotype2 was related to Interleukin-6 signaling. **Conclusion:** This innovative network modeling provides supporting evidence for obesity endotypes, and novel mechanisms for progression of only some endotypes to cardiometabolic diseases. This may inform future prognostic tools constructed from risk prediction models in precision medicine.

PB3488. Leveraging the use of meta-analysis summary statistics to improve gene expression prediction models.

Authors:

M. Mews¹, A. Naj², J. Below³, B. Kunkle⁴, W. Bush⁵; ¹Case Western Reserve Univ., Cleveland, OH, ²Univ. of Pennsylvania, Philadelphia, PA, ³Vanderbilt Univ. Med. Ctr., Nashville, TN, ⁴Univ. of Miami, Miami, FL, ⁵Case Western Reserve Univ, Cleveland, OH

Abstract Body:

Genetically regulated gene expression as assessed via Transcriptome-wide association studies (TWAS) can be used to elucidate the mechanistic basis of Alzheimer's Disease (AD). However, a limitation of current TWAS approaches is the requirement for individual-level datasets with both genotypes and gene expression values to produce effective prediction models. We sought to improve the predictive performance of existing gene-based models by leveraging easily accessible summary statistics taken from large-scale expression quantitative trait loci (eQTL) meta-analyses.

We used Brain-Cortex *cis*-eQTL data from European-descent individuals (Average N=2,547) and re-ran an eQTL meta-analysis using effect estimates (N=15 cohorts; no GTEx) and their standard errors. To perform gene-based elastic-net regressions using the produced summary statistics, we used the *lassosum* R package (Mak *et al.* 2017) with 1000 Genomes data as a genomic reference and GTEx v8 genotype, normalized Brain-Cortex gene expression and covariate data (N=205) as a testing panel for model validation and dynamic selection of the optimal mixing/penalty parameters. The maximum R² produced by this pipeline was compared to elastic-net models within the PredictDB resource which were generated using only Brain-Cortex GTEx_v8 data where the mixing parameter was set at 0.5. The SNP-weights generated by our models were subsequently applied to AD meta-analysis summary statistics from Kunkle *et al.* 2019 via S-PrediXcan to assess whether predicted gene expression is associated with AD risk.

Our pipeline produced gene-based models that had an R² predictive performance that improved an average of 11.7% (SD: 6.9%) over PredictDB models in 96.2% of genes tested (N=4,540) when restricting our pipeline to identical SNPs found in the PredictDB model. Without this SNP restriction, our models had an improved predictive performance averaging 8.3% (SD: 7.6%) based on R² over PredictDB models in 86.7% of genes tested (N=4,598). The optimal mixing parameter dramatically differed from PredictDB with a median of 0.08 when SNPs were not restricted highlighting the utility of including variants with small effects. Using models with the restricted SNP set, we identified 12 genome-wide significant gene expression models (Effect sizes: -9.0, 1.9) associated with AD relative to only four using PredictDB models (Effect sizes: -0.9, 0.8).

We demonstrate improvement upon existing TWAS reference panels and increase gene-expression predictive performance by leveraging the power of summary statistics. Our findings show AD association studies based on TWAS approaches may be improved by meta-analysis reference panels.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3489. Leveraging tissue-wide functional regulatory information improves portability of trans-ancestral polygenic risk score applications

Authors:

B. Crone, A. Boyle; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Polygenic risk scores (PRS) are an effective tool in stratifying disease risk for individuals of European ancestries. The predictive accuracy of these risk models continues to grow as genome-wide association study (GWAS) sample sizes increase. However, large GWAS cohorts are largely European-centric, restricting power in trait-variant association discovery within understudied non-European populations. Trans-ancestral PRS models take advantage of associations in large European cohorts, but predictive accuracy is hindered by differences in genetic linkage between populations. Recent studies have shown that leveraging functional genomic information in prioritizing non-coding variants in PRS calculation can improve prediction accuracy of both within- and trans-ancestral applications. These functional methods limit prioritized mutations to explicitly modeled cell-type-specific transcription factor binding sites, fail to incorporate perturbations across whole tissues or organs and may not perform well with unknown or missing transcription factor data. Here we present a SNP prioritization model for trans-ancestral PRS applications that encompasses functional regulatory evidence from the RegulomeDB, a genome-wide probabilistic model of tissue-specific regulatory activity with SNP-level resolution. We construct both single-tissue and multiple-tissue models to prioritize functionally-enriched genomic mutations for trans-ancestral PRS applications. We show that by highlighting functional regulatory mutations across whole tissues and organs we improve the predictive accuracy of trans-ancestral PRS models in complex disease by identifying shared regulatory mechanisms across ancestries.

PB3490*. Linking the joint genetic structure of neuroanatomical phenotypes with psychiatric disorders.

Authors:

A. Auvergne, N. Traut, L. Troubat, H. Julienne, R. Toro, H. Aschard; Inst. Pasteur, Paris, France

Abstract Body:

There are increasing evidence that brain magnetic resonance imaging (MRI) phenotypes are linked to mental disorders and that they harbor substantial genetic correlations. However, identifying the architecture linking genetics, MRI traits and mental disorder has proven challenging, and new approaches are needed for deciphering these complex relationships. Here, we show how a genetically-driven approach can reveal latent components underlying MRI phenotypes that are strongly associated with mental disorder.

We first conducted univariate and multivariate genome-wide association studies (GWAS) for nine MRI-derived brain volume phenotypes in 20K UK Biobank participants, using JASS, a robust and computationally efficient multitrait analysis pipeline we recently developed. We clustered these variants based on their multitrait association with MRI phenotypes using an optimized k-medoids approach along an innovative data-driven algorithm for selecting the number of clusters. We then assess the ability of those clusters to distinguish disease-associated and non-disease-associated variants as compared to the original MRI phenotypes. In practice, we derived genetic risk score (GRS) for both the original MRI phenotypes and each inferred cluster, and tested the association between these GRS and six mental disorders: bipolarity, attention-deficit/hyperactivity disorder (ADHD), autisms, schizophrenia, obsessive-compulsive disorder (OCD) and major depressive disorder (MDD).

We observed very limited association between the GRS of MRI phenotypes and disease, with only two of them showing nominal association with some GRS (SCZ, min $P=0.01$, and ADHD, min $P=4 \times 10^{-4}$). Conversely, we identify nominal association with multiple GRS of clusters for all diseases, some of them remaining significant after Bonferroni correction (SCZ, min $P=3 \times 10^{-6}$, and BIP, min $P=4 \times 10^{-5}$). By construction, those associated clusters correspond to linear combination of the volumetric phenotypes studied, and we argue that they can be interpreted as latent endophenotypes. Altogether, this approach can offer a powerful tool to identify genetically-driven neuroanatomical latent structure associated with mental disorders.

PB3491. Local ancestry at the MHC region is associated with disease heterogeneity in a multi-ethnic lupus cohort.

Authors:

O. Solomon¹, C. Lanata², C. Adams³, J. Nititham², K. E. Taylor⁴, S. Chung⁴, M. Dall'Era⁴, J. Yazdany⁴, B. Pons-Estel⁵, T. Tusié-Luna⁶, B. P. Tsao⁷, E. F. Morand⁸, M. E. Alarcón-Riquelme⁹, L. F. Barcellos³, L. A. Criswell²; ¹Univ. of California, Berkeley, Berkeley, CA, ²NHGRI, Bethesda, MD, ³Univ. of California Berkeley, Berkeley, CA, ⁴Univ. of California San Francisco, San Francisco, CA, ⁵Regional Ctr. for Autoimmune and Rheumatic Diseases (CREAR) of Rosario, Rosario, Argentina, ⁶Inst. Natl. de Ciencias Médicas y Nutrición Salvador Zubiran and Inst. de Investigaciones Biomédicas de la Univ. Natl. Autónoma de Mexico, Mexico City, Mexico, ⁷Dept. of Med., Med. Univ. of South Carolina, Charleston, SC, ⁸Sch. of Clinical Sci., Monash Univ. Faculty of Med., Nursing & Hlth.Sci., Melbourne, Australia, ⁹Pfizer—Univ. of Granada—Andalusian Government Ctr. for Genomics and Oncological Res. (GENYO), Granada, Spain

Abstract Body:

Systemic lupus erythematosus (SLE) is an autoimmune disease that results in debilitating clinical manifestations that vary in severity by race and ethnicity with a disproportionate burden for admixed populations. Differences in global and local genetic ancestry can shed light on the mechanisms that contribute to these disparities, including increased lupus nephritis prevalence, younger age of onset, and autoantibody status in non-White populations. A total of 1,139 SLE patients of European, African American, and Hispanic race and ethnicities were genotyped using the Affymetrix LAT1 World array. Global ancestry proportions were estimated using ADMIXTURE and local ancestry was estimated using RFMIXv2.0. Genetic map coordinates were used to generate windows of consecutive local ancestry across the genomes. We tested for associations between SLE manifestations including lupus nephritis, age of onset, and anti-double stranded DNA (anti-dsDNA) autoantibodies with both global ancestry proportions and local ancestry windows. Analyses were conducted genome-wide, at candidate SNPs, and within the MHC region (chr6:28477797-33448354). In African American patients, increased European local ancestry was associated with anti-dsDNA autoantibodies in the 18 of 50 (36%, FDR- $p < 0.05$) MHC windows indicating increased European ancestry in patients with anti-dsDNA autoantibodies in those MHC windows. In Hispanic patients, 10% of MHC windows had statistically significant (FDR- $p < 0.05$) increased Indigenous American ancestry was associated with anti-dsDNA autoantibodies. Significant windows spanned MHC Class I and II genes. These findings provide evidence that local ancestry, specifically within the MHC region, contributes to SLE manifestations in admixed populations.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3492. Loci for Cognitive Preservation in the Midwestern Amish

Hussman Inst. for Human Genomics, Miami, FL, ⁴Univ. of Miami, Miami, FL, ⁵Univ. of Miami, Bristol, TN, ⁶Univ Miami, Miami, FL, ⁷Univ. of Miami, Miami, OH, ⁸Univ. of Miami Miller Sch. of Med. Hussman Inst. for Human Genomics, Elkhart, IN, ⁹Univ. of Miami Miller Sch. of Med., Miami, FL, ¹⁰Case Western Reserve Univ, Cleveland, OH

Abstract Body:

Alzheimer's disease (AD) is a significant cause of morbidity and mortality in the U.S. and continues to grow in prevalence as the population ages. There have been numerous risk loci associated with AD; however, the alternative of identifying loci that decrease AD risk or delay onset may lead to novel therapeutic targets. The Midwestern Amish are an ideal population for studying the genetic underpinnings of cognitive preservation, as they have a lower rate of dementia than the general population, a relatively homogeneous environment, and lower genetic diversity resulting from a founder effect. We define cognitive preservation as the combination of both cognitive resilience and cognitive resistance. We examined 946 individuals (age 75+) at high risk of developing AD; 626 were cognitively unimpaired (CU). We performed both a genome-wide association study (GWAS) and linkage analyses across the autosomes (SNPs = 256,978) and the X chromosome (SNPs = 9,853). GWAS analyses were corrected for sex, age, and relatedness. After adjusting for multiple testing using the simpleM method, suggestive loci ($p \leq 6.4 \times 10^{-4}$) were identified on chromosomes 1, 3, 5, 6, 11, and 13-16. Linkage was performed by generating an all-connecting pedigree leading to a 14-generation 8,222-person pedigree containing all our CU individuals. To be computationally tractable, this pedigree was divided into sub-pedigrees for the linkage analyses. In non-parametric analyses, 27 suggestive ($LOD \geq 1.86$) SNPs were identified on six chromosomes in the two-point and multipoint analyses; no loci reached genome-wide significance. In the parametric analyses, under the dominant model, 72 SNPs reached significance ($LOD \geq 3.3$) across 19 chromosomes in either two-point or multipoint analyses, while 44 loci were significant in both analyses on seven chromosomes. One known AD risk locus, RHOH, was significant under the two-point dominant model (suggestive in multipoint). Under the recessive model, 37 SNPs were significant across 12 chromosomes for either two-point or multipoint analyses, while 30 loci were identified as significant by both analyses on chromosomes 2, 7, and 9, including the known AD gene CNTNAP2 on chromosome 7. Of interest, one locus on chromosome 1 (~165-167Mb, GRCh38) was detected by both the GWAS and recessive parametric linkage analysis. This locus is upstream of POGK, which has shown to have enriched expression in the brain, but the protein function remains elusive. The ability to use both association and linkage in this unique kindred may help illuminate new pathways involved with cognitive preservation, as we have found both known AD risk loci, as well as a plethora of new loci to investigate.

PB3493. Longitudinal, multi-modal EHR prediction of incident CKD and ESRD for risk stratification and genetic studies

Authors:

N. Banerjee¹, X. Ding², A. Averitt³, J. Mower¹, M. Haas¹, M. Cantor¹, GHS-RGC DiscovEHR Collaboration, Regeneron Genetics Center; ¹Regeneron Genetics Ctr., Tarrytown, NY, ²Univ. of Washington, Seattle, WA, ³Regeneron Genetics Ctr., New York, NY

Abstract Body:

Rich longitudinal phenotype data from electronic health records (EHR) provides great opportunities for genetic research, especially for chronic conditions such as chronic kidney disease (CKD). Traditional phenotyping algorithms can generate high-quality case and control labels for specific diseases, but they often require expert knowledge, do not consider long range dependencies and ignore that diseases reside on a continuum.

Deep sequence models and attention mechanisms that consider subtleties of EHR (e.g., the irregularity of inter-visit intervals, and the temporal order of events) have recently seen success in predicting incident disease risk. Using temporal, multi-modal EHR data of 1.9 million patients from Geisinger Health Systems (GHS), we applied BEHRT, a transformer-based deep learning risk model to predict future disease diagnosis. In this work, we have two main objectives: (1) derive quantitative clinical risk scores (CRS) for a given disease given a unified representation of EHR diagnosis, lab and medication data, and (2) perform genetic association studies on the CRSs in 175K GHS patients to facilitate target identification and genetic studies. We illustrate the benefits of the model using CKD and end stage renal disease (ESRD) which often suffers from under-diagnosis. We assessed the model's performance and results show that the model makes incident disease risk predictions with relatively high AUROC/AUPRC in CKD (0.93/0.68) and ESRD (0.97/0.58). Individuals with risk factors for CKD (e.g., diabetes, hypertension and heart failure) are enriched in the higher deciles of CKD and ESRD CRSs. CKD CRS is most correlated with CRSs of cardiometabolic diseases (comorbidities) when compared to ~100 disease CRSs. Preliminary GWAS analysis of the CKD and ESRD CRS showed significant rare variant hits in many previously characterized genes associated with kidney disease (e.g., *PKD1*, *PKD2*). Interestingly, CRS GWAS results showed ~2-fold increase in significant variant hits compared to related binary phenotypes, some of which were in genes with pleiotropic effects (*SH2B3*, *FTO*). These significant CRS hits were directionally consistent with the binary phenotype GWAS. Low genetic correlation (-0.3) between eGFR and CKD CRS suggests that CRS might be finding medical factors contributing to CKD independent of eGFR. Using ESRD CRS we identified a locus ($p < 5E-08$) in *PARP8* involved in type 2 diabetes and a locus in *HCN1* involved in kidney disease. Our findings highlight the utility of temporal, multi-modal EHR data and deep learning approaches to reappraise factors contributing to disease risk, improve phenotype development and facilitate genetic studies.

PB3494*. Low-coverage sequencing imputation with 150,119 UK Biobank reference samples

Authors:

S. Rubinacci^{1,2}, R. Hofmeister^{1,2}, B. Sousa da Mota^{1,2}, O. Delaneau^{1,2}; ¹Univ. of Lausanne, Lausanne, Switzerland, ²Swiss Inst. of Bioinformatics, Lausanne, Switzerland

Abstract Body:

Low-coverage whole genome sequencing (lc-WGS) followed by genotype imputation is a cost-effective technology that can enhance genome-wide analysis and access to personalized medicine. Recent studies show that a shift from SNP arrays to lc-WGS is beneficial, although **with prohibitive computational costs for large reference panels**. Therefore, sequencing projects like the recent UK Biobank (UKB) WGS, bring improved reference panels, but also new computational challenges. We present GLIMPSE2, **a new lc-WGS imputation method**, designed to handle millions of reference samples with an accuracy inaccessible to other methods at sustainable costs. **Using 150,119 UKB samples as a reference panel**, we obtain a reduction of running time of 100-1000 times compared to existing methods, **achieving imputation of a genome for less than 0.10\$**.

Lc-WGS greatly benefits from the UKB reference panel, mainly for very low depth (<0.5x) and at rare variants (<0.1% MAF). For 0.25x and 0.5x, our method imputes variants at 0.01% MAF with $r^2=0.8$ and $r^2=0.89$ respectively. As a comparison, imputation using the UKB Axiom array reaches an accuracy of $r^2=0.71$. By looking at non-homozygous reference calls, we show that **imputation increases “in-silico” the coverage of lc-WGS samples by an order of 10x**, resulting in a striking reduction of sequencing costs.

We evaluated the performance of the UKB reference panel against 1000 Genomes by imputing 276 genomes from the Simons Genome Diversity Project. As expected, the UKB reference panel **substantially improves the imputation of European individuals**, especially those with Northern European ancestry. As a proof of concept, we imputed four ancient Viking samples and show that UKB reference panel brings a significant boost of accuracy (for 0.1x, 1000G $r^2=0.83$; UKB $r^2=0.92$), **implying that Viking ancestry is recovered remarkably well from the UKB**.

Furthermore, in order to **quantify the impact of these results for disease association**, we performed GWAS using 10,000 UKB individuals across 100 quantitative traits, comparing lc-WGS and SNP array to high coverage data. **We found that the UKB Axiom array is quantitatively similar to 0.25x data** (beta $r^2=0.9$, p val $r^2=0.87$), **and inferior to 1x data** (beta $r^2=0.97$, p val $r^2=0.95$). Looking at precision and recall of the hits, **0.5x captures high coverage GWAS signals better than the UKB Axiom array**, suggesting it is better suited for fine mapping. These results are also confirmed in a **polygenic risk score** analysis.

Overall, we demonstrate the remarkable performance of lc-WGS imputation from the UKB reference panel with a competitive financial cost, that could lead to a boost of sample size and signal of future genomic studies.

PB3495. Low-coverage sequencing induces uncertainty in polygenic scoring

Authors:

E. Petter¹, Y. Ding¹, K. Hou¹, A. Gusev², N. Zaitlen¹, B. Pasaniuc¹; ¹UCLA, Los Angeles, CA, ²Dana-Farber Cancer Inst., Boston, MA

Abstract Body:

Polygenic scores (PGS) have emerged as the standard approach to predict phenotypes from genotype data in a wide array of applications in personalized medicine. PGS have the potential to identify patients at high risk of disease for personalized monitoring and treatment. The standard approach for PGS computation estimates risk as a linear combination of alleles that a given individual carries weighted by their effect size. Most PGS applications assume the genotype data to be error-free, ignoring possible uncertainties introduced by sequencing or imputation. Genotyping error has the potential to bias the PGS accuracy and implementation. This carries implications for clinical use of PGS, particularly for applications in which individuals in the target population are sequenced at different sequencing-depth (as coverage impacts error rate) as well as for applications in which individuals in the target data are genotyped using different genotyping arrays.

In this work, we investigate the impact of genotyping error on PGS performance, and present a procedure for estimating PGS uncertainty due to genotyping error in low-coverage whole-genome sequencing (lcWGS) data. Our approach probabilistically samples genotypes based on their allele count posterior probabilities, and approximated the distribution of possible PGS for every given individual. The variance of the individual PGS distribution quantifies the uncertainty level of the PGS estimate.

We leverage paired germline SNP array data and lcWGS (median coverage 0.1x) of 802 patients from the Dana-Farber PROFILE cohort to investigate the impact of coverage on PGS uncertainty and accuracy.

We found that even in this cohort, which employed the same sequencing technology and similar sequencing depths for all individuals, there is a strong correlation between the individual coverage level with the PGS uncertainty ($P < 2.2e-16$) and the accuracy of the PGS estimate compared to an array-based PGS of the same individuals ($P < 1.2e-7$). We propose a probabilistic procedure for risk stratification that incorporates the individual level of uncertainty in the PGS estimation, and show that in simulations it improves classification precision by up to 6% compared to classification that does not account for PGS uncertainty.

Our results illustrate the importance of considering PGS uncertainty due to genotyping error, especially in cohorts with varying sequencing depths. We show PGS uncertainty can be quantified and used to improve risk stratification in a manner that could impact patient care.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3496. LT-Free: A novel method for leveraging family history in genetic association studies of arbitrarily complex diseases.

Authors:

J. Matthews, M. Thompson, N. Zaitlen; Univ. of California, Los Angeles, Los Angeles, CA

Abstract Body:

Rich phenotypes collected in biobanks have provided opportunities to improve genetic association study power via alternative analysis methods (1). For example, the LT-FH method leveraged family history data to estimate genetic liability for a given trait, thereby improving study power (2). However, this method imposes assumptions about underlying trait genetic architectures and requires external estimates of heritability and generational prevalence. Here we introduce LT-Free as a freer and interpretable model that does not require external information and does not assume any underlying model of genetic architecture. Briefly, LT-Free allows an arbitrary latent phenotype value for each combination of case-control status, sex, and family history data observed in the data. LT-Free then alters these phenotypes to optimize association test statistic values at SNPs known to be associated with the target phenotype. In data simulated under the LT-FH model, we find that LT-Free needs around 50 known GWAS SNPs to train on before it achieves comparable association statistics at held-out SNPs compared to LT-FH. Further, once the simulated genetic architecture deviates from the LT-FH model, fewer SNPs are needed. For example, under a strong sex effect, as few as 5 SNPs are needed before LT-Free obtains higher association statistics than LT-FH. We then apply LT-Free to 9 diseases in the UKBB and similarly meet or exceed the performance of LT-FH in 8 of the 9 diseases with significant improvement in 6 diseases: heart disease ($p = 6.2e-5$), COPD ($p = 1.2e-6$), bowel cancer ($p = 7.0e-5$), depression ($p = 2.5e-4$), hypertension ($p = 9.4e-4$), and lung cancer ($p = 2.2e-4$). In the one disease in which LT-Free did not perform as well as LT-FH, type II diabetes, the difference in association statistics between methods was not significant. In heart disease, we observe evidence of different latent phenotypes estimated across sexes and parental origin. We then run our method on 5 psychiatric phenotypes from the Denmark iPSYCH project. For all target phenotypes, we use our latent phenotypes as outcomes in GWAS to find more associations. Finally, we introduce a method of using LT-Free to obtain disease specific prevalence and heritability estimates without the need of an outside study, such as a twin study. Family history data is a powerful way to improve genetic association studies. By modeling this data with more general models, we can both improve study power and gain insights into genetics architectures. PB3497. LTPI: A generalized liability threshold model combining dichotomous and continuous phenotypes in EHR increases the association power

Authors:

C. Lee, A. Khan, W. Chen, K. Kiryluk, I. Ionita-Laza; Columbia Univ., New York, NY

Abstract Body:

Electronic health record (EHR) data can provide valuable information for case-control association studies. However, it is unclear how best to combine case-control status with individual health records. Recently, an association test based on posterior mean genetic liability conditional on the disease status and family history has been proposed (LTFH) (Hujoel et al., 2020). Despite its importance, the lack of family history data often limits its application. We propose a model that can additionally leverage rich phenotypic data (including dichotomous and continuous traits) provided by the EHR data. We have developed an association framework (LTPI) based on posterior mean genetic liability and maximum likelihood estimator under a liability threshold model conditional on the case-control status of the disease or phenotype of the interest and diverse EHR phenotypic features. Through simulations we show increased statistical power of LTPI relative to LTFH, and further show applications to several diseases in the UKB data.

We validated the performance of LTPI by simulating 100,000 genotypes and 100,000 phenotypes for parent-offspring trios and conducting association analyses using LTPI, LTFH, and the conventional GWAS methods (case-control). We confirmed that all three methods control FPR under the null. We assumed random effects of 500 causal SNPs for five dichotomous and continuous traits and generated liability and disease case-control status of the parent-offspring trios. We fixed heritability (0.5), prevalence (0.05), and genetic correlations (0.1) of the traits. The cross-validation analysis of 10 simulations showed that the statistical power of LTPI, 37.66% (1.49%; standard error), was more significant than LTFH, 33.08% (2.2%), by 13.84% and GWAS, 25.86% (1.64%), by 45.63%. We also combined LTPI and LTFH using the Cauchy combination method. The power of the combined method was 47.72% (2.21%), which is 44.27% greater than LTFH and 84.53% greater than the GWAS.

PB3498. Machine learning approach for identifying diabetes nephropathy and non-diabetic chronic kidney disease cases and controls using urinary high-throughput transcriptomic data.

Authors:

M. Traglia¹, W. Ruan², R. Y. Liu³, R. Thomas¹, A. Wu²; ¹Gladstone Inst.s, San Francisco, CA, ²Univ. of California San Francisco, San Francisco, CA, ³Impetus Bioscientific Inc, Millbrae, CA

Abstract Body:

Diabetic nephropathy (DN) is a common kidney complication, which affects 20-25% of the diabetic population and the leading cause of renal failure. Timely diagnosis and treatment are critical but biased by confounding factors including non-diabetes related chronic kidney disease (CKD). Invasive kidney biopsy, though considered as the golden standard, is not favored due to the 2% mortality rate, leaving DN under and misdiagnosed. Here, we modeled a non-invasive machine learning classifiers that distinguish DN, CKD and control subjects leveraging high-throughput transcriptomic data obtained from urine samples of 1,941 subjects.

We implemented a supervised learning pipeline using random Forests (randomForestSRC R package) that uses ethnicity, age, sex, BMI, retinopathy, albumin-to-creatinine ratio, eGFR, in addition to expression levels of genes assayed with bulk RNA-seq in the urine sediments of the subjects. We applied feature selection using Recursive Feature Extraction (msvmRFE [Duan et al., 2005]) on the clinical variables and the top 200 differentially expressed genes from three contrasts (DN-controls, CKD-controls and DN-CKD). We trained three pairwise classifiers on 70% of the datasets (480 DN, 427 CKD and 451 controls) using the top 100 ranked features.

The three classifiers performed with strong predictive value and sensitivity in the remaining 30% of the dataset (DN vs NEG: sens=1, spec=0.98, AUC ROC=0.99; CKD vs NEG: sens=0.96, spec=0.94, AUC ROC=0.95; DN vs CKD: sens=0.93, spec=0.89, AUC ROC=0.91).

The ongoing collection of 200 additional subjects will allow the development of a unique classification model which may improve early detection and treatment to prevent end-stage kidney diseases.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3499. Machine Learning Approaches to Genome-wide association studies

Authors:

D. Enoma; Covenant Univ., Ota, Nigeria

Abstract Body:

Genome-wide Association Studies (GWAS) are conducted to identify single nucleotide polymorphisms (variants) associated with a phenotype within a specific population. These variants associated with diseases have a complex molecular aetiology with which they cause the disease phenotype. The genotyping data generated from subjects of study is of high dimensionality, which is a challenge. The problem is that the dataset has a large number of features and a relatively smaller sample size. However, statistical testing is the standard approach being applied to identify these variants that influence the phenotype of interest. The wide applications and abilities of Machine Learning (ML) algorithms promise to understand the effects of these variants better. The aim of this work is to discuss the applications and future trends of ML algorithms in GWAS towards understanding the effects of population genetic variant. It was discovered that algorithms such as classification, regression, ensemble, and neural networks have been applied to GWAS for which this work has further discussed comprehensively including their application areas. The ML algorithms have been applied to the identification of significant single nucleotide polymorphisms (SNP), disease risk assessment & prediction, detection of epistatic non-linear interaction, and integrated with other omics sets. This comprehensive review has highlighted these areas of application and sheds light on the promise of innovating machine learning algorithms into the computational and statistical pipeline of genome-wide association studies. This will be beneficial for better understanding of how variants are affected by disease biology and how the same variants can influence risk by developing a particular phenotype for favourable natural selection.

PB3500. Machine learning based methods for predicting guide RNA effects on cell fitness and gene expression in CRISPR epigenomic experiments

Authors:

T. Luo¹, W. Mu¹, A. Barrera^{2,3}, L. Bounds⁴, T. S. Klann^{2,3,4}, J. Bryois⁵, G. E. Crawford^{2,3,6}, P. F. Sullivan^{7,8,9}, C. A. Gersbach^{2,3,4}, M. I. Love^{1,8}, Y. Li^{1,8}; ¹Dept. of Biostatistics, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ²Ctr. for Genomic and Computational Biology, Duke Univ., Durham, NC, ³Ctr. for Advanced Genomic Technologies, Duke Univ., Durham, NC, ⁴Dept. of BioMed. Engineering, Duke Univ., Durham, NC, ⁵Roche, Basel, Switzerland, ⁶Dept. of Pediatrics, Div. of Med. Genetics, Duke Univ. Med. Ctr., Durham, NC, ⁷Dept. of Med. Epidemiology and Biostatistics, Karolinska Inst.t, Stockholm, Sweden, ⁸Dept. of Genetics, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ⁹Dept. of Psychiatry, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract Body:

Noncoding cis regulatory elements (CREs) are important in controlling gene expression and governing biological processes. Despite the large number of putative CREs reported, we are still far from comprehensive understanding of the functional regulatory mechanisms that drive complex phenotypes at molecular and cellular levels. CRISPR-Cas9 system and its variants have proven to be powerful tools for performing genetic or epigenetic perturbations. A critical part of a successful CRISPR experiment is the selection of highly efficient guide RNAs (gRNA).

Here we leveraged machine learning methods to predict the impact of gRNAs. Specifically, we utilized data from a whole-genome CRISPR-dCAS9-based epigenomic regulatory element screening (wgCERES), involving >1 million gRNAs targeting >100,000 candidate CREs. We leveraged two methods, XGBoost and Convolutional Neural Networks (CNN), to predict gRNA effects on overall cell fitness (cell survival and proliferation) in K562 cells, and also on expression of nearby genes across multiple cell lines including K562, induced pluripotent stem cells and neural progenitor cells. Although several machine learning models have been developed for gRNA efficiency prediction in CRISPR genetic perturbations, to our best knowledge, ours is the first attempt in the context of CRISPR epigenetic experiments.

We used both gRNA sequence and functional annotations (containing information regarding thermodynamic properties, epigenetic marks, gene essentiality characteristics) as inputs to the prediction models. We built separate models for gRNAs targeting promoter and enhancer regions. For predicting whether a gRNA has a significant effect on cell fitness, we achieved an AUC of 0.817 for promoter regions and 0.723 for enhancer regions on independent test data. For gRNAs having significant effects, we further predicted the effect size (measured by log fold-change) and achieved a Spearman correlation of 0.520 for promoters and 0.342 for enhancers. To identify and rank top features in predicting gRNA effect, we used the Shapley Additive exPlanations (SHAP) method to investigate feature importance in our models; gRNA-DNA hybridization free energy was the most influential feature overall, while epigenetic marks such as H3K27ac and H3K4me3 were critical for gRNAs targeting promoters, whereas gRNA sequence information was critical for enhancer regions. We additionally attempted to predict gRNA effects on gene expression, quantified by single cell RNA-seq, in both whole genome and MHC regions and compared with activity-by-contact model.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3501. Machine learning guided transcriptomic analyses reveal a novel 9-gene module associated with schizophrenia risk

Authors:

F. Guan¹, C. Shen¹, L. Zhu¹, J. Xiao¹, H. Wang¹, W. Zhang¹, Y. Ma¹, H. Gui²; ¹Xi'an Jiaotong Univ., Xi'an, China, ²Henry Ford Hlth.System, Detroit, MI

Abstract Body:

Introduction: Schizophrenia (SCZ) is one of the most severe psychiatric disorders. Machine learning techniques are considered powerful tools for precision medicine in medical applications. However, there are still lacking studies that apply machine learning approaches to transcriptomic or other omics data to classify SCZ.

Methods: RNA-seq data was downloaded from the PsychEncode synapse portal. We integrated traditional bioinformatics analyses, e.g. differentially expressed gene analysis and enrichment pathway analysis, and feature selection with machine learning to mine risk genes that are highly correlated with SCZ. We first systematically characterized risk genes in postmortem dorsolateral prefrontal cortex (DLPFC) tissue of controls and SCZ patients using the available biological background, i.e. pathways known to be highly associated with the disease. Then, we further screened for genes closely associated with disease phenotypes employing efficient feature derivation, e.g. polynomial identity derivation, and signature screening including recursive feature elimination, sequential feature selection, and mutual information methods. Through the joint analysis of multiple machine learning models, i.e. bagging machine learning and ensemble machine learning, these risk genes are then utilized to make a comprehensive assessment of SCZ. We also use polygenic risk score, transcriptome-wide association study (TWAS), and functional genomic data to annotate those genes in the final module. Finally, we verified the differential expression of the final risk biomarkers in the PFC of the SCZ mice model by quantitative real-time PCR (qRT-PCR).

Results: In total 138 different genes were selected by WGCNA and bioinformatics. Among them, a set of 9 genes was identified to best predict SCZ risk (AUC=0.9 in the training dataset and 0.81 in the validation dataset). Among them, only 5 were differentially expressed genes in original datasets. Three of them were also supported by gene-based association tests. The qRT-PCR data showed that eight out of these 9 genes have the same direction of PFC expression changes in the SCZ mouse model.

Conclusion: We develop a novel pipeline of combining traditional bioinformatics analysis with a state-of-the-art machine learning algorithm to explore SCZ omics data. The final gene module contains not only known risk SCZ genes, but also novel ones. We provide proof of principle evidence showing an integrative pipeline not only helps to identify novel risk genes but also improves the prediction power for risk prediction of SCZ.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3502. Machine learning model discriminates false from true CNVs with a 98% accuracy.

Authors:

T. Renne¹, M. Loum², M. Jean-Louis¹, Z. Saci¹, A. Labbé³, G. HUGUET¹, S. Jacquemont¹; ¹Res. Ctr. CHU Sainte Justine, Université de Montréal, Montréal, QC, Canada, ²Université Iba Der Thiam de Thiès, UFR de Sci.s de l'ingénieur, Thies, Senegal, ³Dept. of decision, HEC Montréal, Montréal, QC, Canada

Abstract Body:

Background: Genomic Copy Number Variants (CNVs) are associated with a range of human psychiatric and medical diseases. To understand these associations, CNVs are being investigated in increasingly large cohorts of hundreds of thousands of individuals, which include genotyping array data. Using multiple calling methods and after applying well accepted quality control (QC) criteria (Huguet et al 2018), datasets still include a significant proportion of false CNVs (~ 10%). For example, CNVs calling algorithms performed on good QC GSA Illumina arrays generate a large multigenic CNV in 2% of samples even after applying classic QC methods. Currently, these artifacts have important consequences and delay all downstream analysis. New automated quality control methods like DeepCNV are significant advances, but require large computing resources. Their scalability is problematic and often work only with one CNV caller output.

Knowledge gap: There is currently no automated, efficient and scalable quality control algorithm that applies to multiple CNV callers. Our aim is to develop a machine learning model to discriminate true from false CNVs identified by multiple algorithms on genotyping arrays without the necessity of having access to data on probe intensity.

Methods: We called CNVs using 2 algorithms (PennCNV and QuantiSNP) in 396,000 individuals from 8 cohorts genotyped using Affymetrix and Illumina genotyping array technologies. We manually visualized and classified as true or false approximately 35,000 CNVs (by 3 different experts). The machine learning model was trained on 70% and tested on 30% of the manually curated CNV using multiple features related to the quality of the array (CallRate, Waviness Factor, ...), as well as the characteristics of the CNVs (Probe density, likelihood score, the percentage of overlap between algorithms, ...). To balance the sample sizes of true and false CNVs, we simulated false CNVs using the "imbalanced-learn" package.

Results: Manual curation classified 3,500 of the 35,000 CNVs as false. After training and parameter tuning, the machine learning model could predict CNV class (true vs false) with 98% accuracy. The model classified 99% of true CNVs as true and 80% of false CNVs as false. A pre-trained model can be used directly with new data instantly with no additional training. It was designed to be used with any type of array technology thanks to the feature "Number of probes by technology".

Conclusion: This novel tool, DigCNV, accelerates significantly the processing of large datasets and improves signal-to-noise, especially while analyzing rare non-recurrent CNVs.

PB3503. MagicalRsq: Machine learning based genotype imputation quality calibration.

Authors:

Q. Sun¹, Y. Yang², J. Rosen¹, M. Jiang¹, J. Chen¹, W. Liu¹, J. Wen¹, L. Raffield¹, R. Pace¹, Y-H. Zhou³, F. Wright³, S. Blackman⁴, M. Bamshad⁵, R. Gibson⁵, G. Cutting⁴, M. Knowles¹, D. Schrider¹, C. Fuchsberger⁶, Y. Li¹; ¹Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ²Yale Univ., New Haven, CT, ³North Carolina State Univ., Raleigh, NC, ⁴Johns Hopkins Univ., Baltimore, MD, ⁵Univ. of Washington, Seattle, WA, ⁶EURAC, Bolzano, Italy

Abstract Body:

Whole-genome sequencing (WGS) is the gold standard for fully characterizing genetic variation but is still prohibitively expensive for large samples. To reduce costs, many studies only sequence a subset of individuals or genomic regions, and genotype imputation is used to infer genotypes for the remaining individuals or regions without sequencing data. However, not all variants can be well imputed, and more importantly, the current state-of-the-art imputation quality metric given by imputation software, denoted as standard Rsq, is poorly calibrated for lower frequency variants. Here, we propose MagicalRsq, a Machine learning based imputation quality calibration, by using the eXtreme Gradient Boosted trees method to incorporate various variant-level imputation and population genetics statistics, to provide a better calibrated imputation quality metric. Leveraging WGS data from the Cystic Fibrosis Genome Project (CFGP), and whole exome sequence data from UK BioBank, we performed comprehensive experiments to evaluate the performance of MagicalRsq compared to standard Rsq for partially sequenced studies. We found that MagicalRsq aligns better with true R2 (the squared Pearson correlation between imputed dosages and true genotypes) than standard Rsq in almost every situation evaluated, for both European and African ancestry individuals. Thus, MagicalRsq can serve as an improved post-imputation quality metric. For example, when applying models trained from 1992 sequenced CFGP samples to 3103 independent samples with no sequencing data but with imputation using TOPMed freeze 8 reference panel, compared to the standard Rsq, MagicalRsq improved squared Pearson correlation with true R2 by 2.0% - 56.8% for common variants [minor allele frequency (MAF) > 5%], by 16.3% - 91.7% for low frequency variants (MAF in [0.5%, 5%]) and by 3.0% - 6.2% for rare variants (MAF < 0.5%), across different chromosomes. It also achieved net gains of 1.4 million rare variants, 117k low frequency variants and 18k common variants, where net gains were gained numbers of correctly distinguished variants by MagicalRsq over standard Rsq. Even when trained with only 10k variants, MagicalRsq still provided net gains of 787k rare variants, 94k low frequency variants, and 6k common variants, and such gains were robust to the inclusion of different sets of variants in training models. We anticipate MagicalRsq will benefit downstream analysis by better distinguishing well-imputed variants from poorly-imputed variants. MagicalRsq is freely available from <https://github.com/quansun98/MagicalRsq/>.

PB3504*. MANOCCA : An innovative powerful test to detect predictors of the gut microbiome variability

Authors:

C. Boetto¹, V. Basten Romero¹, E. Patin¹, M. Bredon², D. Duffy¹, L. Quintana-Murci³, H. Sokol^{4,5,6,7}, H. Aschard^{1,8}; ¹Inst. Pasteur, Paris, France, ²Sorbonne Université, Paris, France, ³Pasteur Inst. and Coll. de France, Paris, France, ⁴Hôpital Saint-Antoine, Paris, France, ⁵Inserm, Paris, France, ⁶Paris Ctr. for Microbiome Med., Paris, France, ⁷INRAE Micalis & AgroParisTech, Jouy-en-Josas, France, ⁸Harvard TH Chan Sch. of Publ. Hlth., Boston, MA

Abstract Body:

Multivariate analysis is becoming central in studies investigating high-dimensional omics data. However, some important characteristics of those data have been seldom explored. Here we present MANOCCA (Multivariate Analysis of Conditional Covariance), a powerful method to test the effect of both continuous and categorical predictors on the covariance matrix of a multivariate outcome. The proposed test is by construction orthogonal to tests based on mean (MANOVA) and variance (Levene), and can capture effects missed by both approaches. We first compared the performances of MANOCCA against existing correlation methods (BoxM, Mantel, Fisher Z-score, Jennrich) and show that the latter display severe type I error rate inflation in all simulations mimicking omics data. Only MANOCCA was correctly calibrated. As a case study, we then applied our test to assess the effect of environmental and host genetic predictors on 16S derived gut microbiome covariance matrix, in 1,000 healthy participants from the Milieu Interieur cohort while adjusting for age, sex and BMI. We systematically compared results from our test with standard univariate (linear regression) and multivariate (MANOVA) mean-based tests. MANOCCA strongly outperformed those tests, confirming associations with age and sex but with higher power (in average 200% power increase), and detected additional signals with smoking and appendectomy operation. Host genetic genome wide association study (GWAS) using MANOCCA identified multiple significant associations (P value < 1e-8). This includes a signal with *RGS3*, a gene previously reported associated with blood cell count, as well as a signal with *TCTB* which is known to be associated with cholesterol. In comparison, mean-based methods GWAS screening did not detect any signal. Altogether, these analyses demonstrate the strong capabilities of our novel approach to identify predictors associated with a multivariate outcome covariance matrix, and more generally to detect new signals that cannot be captured by standard mean-based approaches.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3505. MaSk-LMM: a matrix sketching-based fast and scalable linear mixed model for association studies in large biobanks

Authors:

M. Burch¹, A. Bose², P. Drineas¹, L. Parida²; ¹Purdue Univ., West Lafayette, IN, ²IBM T J Watson Res., Yorktown Heights, NY

Abstract Body:

Large-scale biobanks spanning hundreds of thousands of individuals offer unprecedented opportunities to discover novel genetic loci associated with complex human traits and disease risk. Linear mixed models (LMMs) have been widely used in genome-wide association studies (GWAS) to control for population stratification and relatedness. Implementation of LMMs is computationally intensive, particularly in building the genetic relatedness matrix (GRM) and computing the residual maximum likelihood (REML) estimation of genomic variance components. Conventional REML methods involve matrices that are dependent on the number of markers and individuals, thus making LMMs intractable for large biobanks. We developed a fast and efficient LMM method, MaSk-LMM (Matrix Sketching-based LMM), by applying both sample and marker sketching to reduce the dimensions of individuals and markers to speed up the estimation of REML parameters and the GRM computations without too much loss in accuracy. Matrix sketching introduces randomization to the genotype matrix by using a sketching matrix which is significantly smaller than the genotype matrix, but still preserves pairwise distances. We applied MaSk-LMM on a simulated cohort of 100,000 individuals and 600,000 genotypes imitating relatedness and fine-grained population stratification. We set 5% of the genotypes as causal or contributing to the binary or continuous trait of interest. We evaluated three sketching methods (Gaussian, random signs and fast cosine transform) and set the sketching dimensions to 1%, 5%, 10% and 15% of the number of markers and evaluated each scenario ten times to report running times and accuracy. We observed that the proportion of variance explained as the sketching dimension increases, while the false positive rate (FPR) decreases and correlates well with the genomic inflation factor. The p-value for MaSk-LMM increased relative to an exact LMM solution but it was twice as fast as current state-of-the-art (SOTA) methods such as FastGWA and BOLT-LMM. MaSk-LMM can be run in conjunction with grid search as done in Grid-LMM and FastGWA-GLMM and is “embarrassingly parallel,” permitting further gains in computational time. We also applied MaSk-LMM to real phenotypes from UKB such as height, body mass index, LDL cholesterol levels, myocardial infarction, etc. across 456K European samples and reported similar heritability measures and test statistics as in SOTA methods. Thus, sketching-based approaches can be very useful in speeding up intractable LMM computations for large biobanks and accelerate discovery of biomarkers with an efficient, fast, and accurate estimation of the variance components.

PB3506. MATS: A novel multi-ancestry transcriptome-wide association study to account for heterogeneity in the effects of cis-regulated gene expression on complex traits

Authors:

W. Pan, K. A. Knutson; Univ. of Minnesota, MINNEAPOLIS, MN

Abstract Body:

The Transcriptome-Wide Association Study (TWAS) is a widely used approach integrating gene expression and GWAS data to study the role of cis-regulated gene expression (GEx) in complex traits. However, the genetic architecture of GEx varies across populations, and recent findings point to possible ancestral heterogeneity in the effects of GEx on complex traits, which may be amplified in TWAS by modeling GEx as a function of cis-eQTLs. Here, we present a novel extension to TWAS to account for heterogeneity in the effects of cis-regulated GEx which are correlated with ancestry. Our proposed Multi-Ancestry TwaS (MATS) framework jointly analyzes samples from multiple populations and distinguishes between shared, ancestry-specific, and/or subject-specific expression-trait associations. As such, MATS amplifies power to detect shared GEx associations over ancestry-stratified TWAS through increased sample sizes, and facilitates detection of genes with subgroup-specific associations which may be masked by standard TWAS. Our simulations highlight the improved Type-I error conservation and power of MATS compared to competing approaches. Our real-data applications to AD case-control binary phenotypes from the Alzheimer's Disease Sequencing Project (ADSP) and quantitative phenotypes from the UK Biobank (UKBB) identify a number of unique gene-trait pairs which were not discovered through standard and/or ancestry-stratified TWAS. Ultimately, these findings promote MATS as a powerful method for detecting and estimating significant gene expression effects on complex traits within multi-ancestry cohorts, and corroborates the mounting evidence for inter-population heterogeneity in gene-trait associations.

PB3507. mBAT-combo: a gene-based association test to decipher masking effects

Authors:

A. Li¹, S. Liu¹, A. Bakshi², L. Jiang³, W. Chen⁴, Z. Zheng¹, P. Sullivan⁵, P. Visscher¹, N. Wray¹, J. Yang⁶, J. Zeng¹; ¹The Univ. of Queensland, Brisbane, Australia, ²Monash Univ., Melbourne, Australia, ³New York Genome Ctr., New York, NY, ⁴Garvan Inst. of Med. Res., Sydney, Australia, ⁵Univ North Carolina, Chapel Hill, NC, ⁶Westlake Univ., Hangzhou, China

Abstract Body:

Gene-based association tests aggregate multiple SNP-trait associations into sets defined by gene boundaries. Since genes have a direct biological link to downstream function, gene-based test results are widely used in post-GWAS analysis. A common approach for gene-based tests is to combine SNPs associations by computing the sum of chi-squared statistics. However, this strategy ignores the directions of SNP effects, which could result in a loss of power for SNPs with masking effects (i.e., the product of two SNP effects and their genotype correlation is negative). Here, we introduce mBAT-combo a new gene-based test that is better powered than other methods (fastBAT, MAGMA, multiple linear regression model) to detect multi-SNP associations in the context of masking effects. We validate the method through theoretical and empirical simulations and applications to real data. We find that of 35 blood and urine biomarker traits in the UK Biobank, 34 traits show evidence for masking effects in a total of 4,516 gene-trait pairs, implicating a ubiquitous presence of masking effects in complex traits. We further validate the improved power of our method in height, BMI and schizophrenia with different GWAS sample sizes, and show that on average 95.7% (sample size increased by 1.7-fold) of the genes detected only by mBAT-combo with smaller sample sizes can be identified by the single-SNP approach with larger sample sizes. As a more powerful gene-based method, mBAT-combo is expected to improve the downstream pathway or tissue and cell-type enrichment analysis that takes genes identified from GWAS data as input to understand the biological mechanisms of the trait or disease. Despite we focus on mapping genes in this study, the framework of mBAT-combo is general and can be applied to any set of SNPs to refine trait-association signals hidden in complex linkage disequilibrium.

PB3508. Mendelian randomization and colocalization of amino acids in the UK Biobank NMR metabolomic profiles

Authors:

C. Willis, A. Deaton, A. Holleman, L. Krohn, R. Hoffing, P. LoGerfo, M. Plekan, P. Nioi, L. Ward; Alnylam Pharmaceuticals, Cambridge, MA

Abstract Body:

Mendelian randomization (MR) studies offer a theoretically unbiased approach to estimating causal relationships between risk factors and disease outcomes. Studies commonly use protein and expression quantitative trait loci (QTL) as straightforward instruments in MR analysis; however, we sought to characterize and explore the use of metabolite QTLs (metaboQTLs) for target finding and biomarker discovery. We analyzed whole exome sequencing, NMR metabolomic profiling (Nightingale), and disease diagnosis data from the UK Biobank unrelated European ancestry population ($n = 81,112$) to identify disease risks linked to levels of amino acids. We computed LD score regression (LDSC) between 10 amino acids (alanine, creatinine, glutamine, glycine, histidine, phenylalanine, and branched-chain amino acids—leucine, isoleucine, and valine) and 68 disease outcomes revealing nominally significant genetic correlation for 76 metabolite-disease pairs. We performed colocalization and Mendelian randomization analysis on these amino acids and diseases using cis-metaboQTLs to minimize the risk of pleiotropy. Of 222 independent metaboQTLs identified, 18 were cis-acting for nine genes involved in amino acid catabolism. Nine cis-metaboQTLs in BCAT2, HAL, PAH, and SLC1A4 were colocalized ($PP > 0.5$) with at least one disease outcome. MR analysis revealed evidence supporting several causal relationships between amino acids and diseases. Leucine levels (modeled by a metaboQTL at BCAT2 encoding BCAA transaminase 2) were suggested to be an influencing risk for gallstones ($OR = 1.31$, $P = 8.87 \times 10^{-5}$), hyperlipidemia ($OR = 0.86$, $P = 1.84 \times 10^{-4}$), and hypercholesterolemia ($OR = 0.90$, $P = 1.93 \times 10^{-4}$). We also observed a potential protective effect of histidine levels (modeled by a metaboQTL at HAL encoding histidase) on skin cancer ($OR = -0.18$, $P = 5.04 \times 10^{-4}$). Expansion of this study to incorporate additional metabolomic biomarkers could offer vital insights into common disease risks as well as novel drug targets.

PB3509. Mendelian randomization implicates GDF15 blood levels as a causal factor in inflammatory disease.

Authors:

P. Timmers, E. Morgen, K. Fortney, Z. O'Brown, P. Leong, N. Shah; BioAge Labs, Richmond, CA

Abstract Body:

Growth/differentiation factor 15 (GDF15) blood levels are strongly associated with mortality and have been linked to myriad age-related diseases, including cardiovascular disorders, cancers, cognitive impairment, and chronic inflammation. Whether GDF15 plays a causal role in aging or simply functions as a biomarker of disease remains underexplored. Here, we combine three large genetic studies of GDF15 blood protein levels ($N = 60,486$), measured using SomaLogic and Olink technologies, and use phenome-wide colocalization and bidirectional Mendelian randomization to infer causality of GDF15 blood levels across hundreds of complex traits and disease outcomes. We reveal GWAS signals of body mass index and Cystatin C levels colocalize with the *GDF15* locus, but find genetically higher levels of these traits unidirectionally increase GDF15 protein levels and therefore act as confounding variables. We then use Bayesian GWAS to estimate direct genetic effects of GDF15 blood levels independent of these confounders, and find evidence for causal effects of GDF15 on blood levels of 12 proteins in *trans*. Gene set enrichment reveals the genes encoding these proteins are overrepresented in the hallmark IL6 JAK-STAT signaling pathway ($FDR < 0.05$). In addition, GDF15 cis-pQTL are strongly associated with the prevalence of several inflammatory diseases ($P < 1 \times 10^{-10}$), including inflammatory bowel disease and asthma, with moderate confidence for colocalization ($ColocPP > 50\%$). Finally, we find robust evidence that genetically determined GDF15 blood levels are associated with prevalence of prevotella in the gut ($P < 1 \times 10^{-60}$; $ColocPP > 80\%$), highlighting the microbiome for further study. In conclusion, we show phenome-wide bidirectional Mendelian randomization and colocalization can disentangle cause from confounding in a highly complex locus and use these methods to reveal the causal role of GDF15 blood protein levels in inflammatory disease.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3510. Mendelian randomization indicates sex-specific causal effects of estradiol levels on kidney function.

Authors:

M. Nasr^{1,2,3}, C. Schurmann⁴, E. Bottinger^{5,2}, A. Teumer^{1,3}; ¹Univ. Med. Greifswald, Greifswald, Germany, ²Hasso Plattner Inst., Potsdam, Germany, ³DZHK (German Ctr. for Cardiovascular Res.), Partner Site Greifswald, Greifswald, Germany, ⁴Bayer AG, Pharmaceuticals, Berlin, Germany, ⁵Mount Sinai Sch. of Med., New York, NY

Abstract Body:

Chronic kidney disease (CKD) is a public health burden and a leading cause of major cardiovascular disorders as well as a contributor to morbidity and mortality worldwide. Previous research has attempted to identify sexual disparity in CKD observed through sex-associated differences in exposure and prognosis of kidney disease. Epidemiological studies observed an association between sex hormones, including estradiol, and kidney function that may contribute to the different prevalence of CKD in men and women. However, it is difficult to assess the causality of this relationship because it requires randomized controlled trials, which are lengthy and costly. As an alternative approach, we conducted a Mendelian randomization (MR) study to test for a possible causal effect of estradiol on kidney function using observational data and genetic information. We performed unidirectional two-sample MR using published genetic associations results of serum estradiol levels in men (n=4,191 and n=206,927) and women (n=2,607), and of kidney function traits represented by estimated glomerular filtration rate (eGFR, n=567,460), urine albumin-to-creatinine ratio (UACR, n=547,361), and CKD (n=41,395 cases and n=439,303 controls) obtained from the CKDGen Consortium. Additionally, we applied linear mixed models to genome-wide individual-level data from the UK Biobank (n=11,798 men and n=6,835 women) to identify novel genetic associations with estradiol, and subsequently used these variants as instruments in a one-sample MR adjusted for age, body mass index (BMI) and diabetes status. Two-sample MR indicated that genetically predicted estradiol levels are significantly associated with eGFR in women (beta = -0.005, p-value = 0.015). Through the genome-wide association study with UK Biobank data, we identified a single locus at chromosome 14 associated with estradiol levels in men. Using the index variant of this locus (rs7151019, beta = -0.026, p-value = 6E-22) as an instrument in the one-sample MR in 11,798 men with both estradiol and kidney function data available revealed a significant association with eGFR (beta = 0.199, p-value = 0.017). There were no significant causal estimates for UACR or CKD. Based on these results, we conclude that serum estradiol levels may have a causal effect on kidney function characterized by eGFR. Further efforts are needed to identify a strong and reproducible genetic association with estradiol levels in both genders. However, our MR results provide starting points for subsequent studies to develop therapeutic and intervention strategies to reduce kidney diseases and related disorders.

Queensland, Royal Brisbane and Women's Hosp., Brisbane, Queensland, Australia, ¹²Hereditary Cancer Clinic, Prince of Wales Hosp., Randwick, New South Wales, Australia, ¹³Prince of Wales Clinical Sch., UNSW Med. and Hlth., UNSW Sydney, Sydney, New South Wales, Australia, ¹⁴Tasmanian Clinical Genetics Service, Tasmanian Hlth. Service, Royal Hobart Hosp., Hobart, Tasmania, Australia, ¹⁵Sch. of Med. and Menzies Inst. for Med. Res., Univ. of Tasmania, Hobart, Tasmania, Australia, ¹⁶Prince of Wales Hereditary Cancer Ctr., Prince of Wales Hosp., Randwick, New South Wales, Australia, ¹⁷Parkville Familial Cancer Ctr., Peter MacCallum Cancer Ctr. and Royal Melbourne Hosp., Melbourne, Victoria, Australia, ¹⁸Sir Peter MacCallum Dept. of Oncology, Univ. of Melbourne, Melbourne, Victoria, Australia

Abstract Body:

Establishing accurate age-related penetrance figures for the broad range of cancer-types that occur in individuals harbouring a pathogenic variant in *TP53* is essential to determine the most effective risk management strategies in clinical practice. These figures are also needed to allow co-segregation data to be used optimally in the classification of *TP53* variants of unknown significance. However, penetrance estimation can easily be affected by ascertainment, particularly where families have been selected for testing in the past based on Li-Fraumeni syndrome (LFS) clinical criteria.

We performed a maximum likelihood penetrance estimation using full pedigree data from an international multi-centre study of *TP53* positive families identified through dedicated clinics and research studies, incorporating the ability to adjust for the effect of ascertainment and population-specific background cancer risks. The analysis included 163 unique pedigrees from Australia, Spain, and USA, with phenotypic information for 4,899 individuals. In addition to the expected strong associations with classical LFS cancers (breast, osteosarcoma, soft tissue sarcoma, brain cancer, and adrenocortical carcinoma), the analysis also detected a significantly increased lifetime risk for colorectal, lung, and ovarian cancer. Current results show a cumulative risk of any cancer type by age 50 of 44.2% (95% CI 41.9 - 46.3) for males, and 96.6% (95% CI 95.8 - 97.2) for females, higher due to the incidence of breast cancer.

Our findings demonstrate the utility of a MENDEL-modified segregation approach to generate new age-specific cancer risk estimates for *TP53* pathogenic variant carriers. The results confirm the known high lifetime risk for the classical-LFS associated cancer types, and indicate significantly increased lifetime risks for several additional cancer-types where the association with LFS has not been previously established. Accurate cancer risk estimates will help with the refinement of management

recommendations for *TP53* pathogenic variant carriers, and can also be incorporated into *TP53* variant classification modelling.

PB3512. Metabolite prediction models in UK Biobank: A metabolome-wide association study (MWAS)

Authors:

L. Huang¹, A. Tapia², B. Rowland³, J. Rosen^{3,4}, J. Wen⁴, Y. Li^{3,4,5}, L. Raffield⁴; ¹Curriculum in Bioinformatics and Computational Biology, UNC - Chapel Hill, Chapel Hill, NC, ²Dept. of Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA, ³Dept. of Biostatistics, UNC - Chapel Hill, Chapel Hill, NC, ⁴Dept. of Genetics, UNC - Chapel Hill, Chapel Hill, NC, ⁵Dept. of Computer Sci., UNC - Chapel Hill, Chapel Hill, NC

Abstract Body:

As potential disease risk factors, multi-omics readouts including transcripts, proteins, and metabolites are all of interest. High-throughput multi-omics profiling has been recently applied to various cohorts, discovering new disease risk factors and molecular mechanisms. However, due to cost and tissue availability, sample sizes for omics data have severely lagged behind genetic data. To fill this gap, we use genetic and metabolomic data from UK Biobank (UKBB) to perform a metabolome-wide association study (MWAS). Our initial analyses included 101,349 European ancestry participants (EUR) with 161 post-quality control metabolites measured using the Nightingale platform. We identified metabolite quantitative trait loci (mQTL) with a subset of 45,581 individuals, built metabolite prediction elastic net models with these mQTLs ($p < 1e-6$) in an independent subset of 45,466 individuals, and assessed the performance of the prediction models in the remaining 10,302 individuals. Our results showed that a number of metabolites can be reasonably predicted: median testing R^2 0.08, but maximum R^2 0.16, largely consistent with SNP heritability estimates for these metabolites (median H^2 0.18 and maximum H^2 0.24). We then proceeded with our MWAS for the 134 metabolites (testing $R^2 > 0.05$) and tested associations with 29 blood cell traits in the 349,956 EUR UKB samples without measured metabolites. We also tested the associations between measured metabolites and blood cell traits, using the 101,349 samples with measured metabolites. Using either measured or predicted metabolites, we found numerous significant associations. At a Bonferroni threshold of $1.3e-5$, we had an average of 114 (range: 13-133) significant associations per blood cell trait using measured metabolites. Similarly, we had an average of 73 (range: 0-129) significant associations per trait using predicted metabolites. The findings are largely expected because most of the Nightingale metabolites are lipid-related, and lipid traits have well-established relationships with blood cell indices. Association results are reasonably consistent between measured and predicted: 1241 (37.5%) of associations are significant and in the same direction using measured and predicted metabolites. We plan to perform PheWAS with the predicted metabolites, which we anticipate will reveal signals missed by using the much smaller sample size measured metabolites. Although much smaller sample sizes are available, we will also explore MWAS approaches in UKB non-EUR samples. In summary, MWAS in biobank samples can be a powerful approach to reveal molecular mechanisms and discover novel therapeutic targets.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3513. Meta-imputation combining the East Asian and multi-ethnic reference panels enhanced the imputation performance of rare variants for East Asian population

Authors:

Y. Kim¹, M. HWANG¹, N-H. Choi¹, D. Shin¹, K. Yoon¹, H-Y. Park², B-J. Kim¹; ¹Div. of Genome Sci., NIH, Cheongju-si, Korea, Republic of, ²Dept. of Precision Med., NIH, Cheongju-si, Korea, Republic of

Abstract Body:

Genotype imputation has become an essential analysis to enhance association mapping power and discover rare and structural variants which are hardly obtained by most genotyping arrays. Imputation analysis can be more accurate with a population specific reference panel or a multi-ethnic reference panel with a large number of samples. A recent population specific reference panel, the China Metabolic Analytics Project (ChinaMAP, N=10,155), emphasized an importance of a population specific reference panel by showing increased imputation accuracy over the Trans-Omics for Precision Medicine (TOPMed, N=97,256) reference panel, which has about 10 times more multi-ethnic samples. However, it is not feasible to construct a population specific reference panel with a large number of sequenced samples. Alternatively, a meta-imputation approach was developed to comprehensively increase imputation performance by merging imputation results from difference reference panels without assessing individual-level genotype data of the reference panels. Therefore, meta-imputation combining a population specific and multi-ethnic reference panels would be an efficient strategy for accurate imputation of genotypes. In this study, we constructed an East Asian reference panel, the Korean Reference Genome (KRG) panel, from 1,490 whole genome sequenced Korean samples. We analyzed the imputation performance of KRG and further studied an increase in imputation accuracy via meta-imputation. Sequenced reads were aligned and genotypes were called using DRAGENTM. For comparison analysis, three genotype panels of Korean (KOR), Japanese (JPT), and Chinese (CH) were created by selecting variants available in the Korea Biobank Array from 208 whole genome sequenced samples which were not used for the KRG, 104 Japanese and 208 Chinese samples from 1KGP3, respectively. Imputation performance of KRG was compared with previously introduced reference panels of 1,000 Genomes project phase 3 (1KGP3), GenomeAsia Sequencing project (GASP), ChinaMAP, TOPMed, and meta-imputation results using MetaMinimac2 combining KRG and TOPMed (META). For KOR and JPT, KRG showed increased imputation performance (aggregate $R^2 > 0.88$) in overall compared to those of other reference panels ($R^2 < 0.86$). As expected, ChinaMAP showed the best performance for CH. However, for rare variants (Minor Allele Frequency < 1%), META showed enhanced imputation accuracy than other reference panels. This study demonstrated the importance of a population specific reference panel and meta-imputation combining difference reference panels for assessing substantial number of accurately imputed rare variants.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3514. Methods and software for empirical Bayes multivariate multipletesting and effect size estimation

Authors:

Y. Yang¹, P. Carbonetto¹, D. Xie¹, G. David², M. Stephens¹; ¹Univ. of Chicago, Chicago, IL, ²American Univ., Washington D.C., DC

Abstract Body:

The problem of estimating how genetic effects are shared across different conditions or different treatments is an important aspect of many genomic analyses, such as the joint analysis of expression QTL (eQTLs) in multiple tissues. The patterns of sharing in these analyses are often very heterogeneous; for example, different eQTLs may act in different combinations of tissues via distinct mechanisms. To flexibly model these heterogeneous sharing patterns, Urbut et al (2019) recently proposed the multivariate adaptive shrinkage (mash) method to jointly analyze genetic effects across multiple conditions/treatments. However, the question of how to learn these heterogeneous patterns of sharing from data remains unresolved, so here we propose new statistical methods to tackle this question. Our new method is called “Ultimate Deconvolution” because we developed new algorithms as well as implemented the existing Extreme Deconvolution (ED) algorithm of Bovy et al (2011). Compared with ED, UD has two key advantages. First, our new algorithms find better estimates of sharing patterns, and more efficiently, these methods are easy to be applied to large genomic data sets. Second, we address deficiencies of maximum-likelihood estimation in more challenging high-dimensional settings by implementing adaptive regularization for the sharing patterns and cross-validation to control for model complexity. The combination of adaptive regularization, cross-validation, and better algorithms leads to better estimates of sharing in high-dimensional settings with many conditions, and therefore improved accuracy to detect the true underlying effects. We have quantified the benefits of these improvements extensively in simulated genetic data sets. We also illustrate the benefits of these new methods through an analysis of eQTLs in 49 human tissues, using data from the Genotype Tissue Expression (GTEx) project. We have implemented these new methods in an R package, `udr` (“Ultimate Deconvolution in R”), available on GitHub.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3515. MethylPipeR: Multi-omic Prediction of Complex Traits.

Authors:

Y. Cheng; Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract Body:

DNA methylation (DNAm)-based predictors have been developed for a wide range of traits and have shown promise in improving disease prediction. Whilst previous studies have been largely constrained by linear assumptions and the use of CpGs one-at-a-time, we have adopted a more flexible approach based on a range of linear and tree-ensemble survival models for incident disease prediction. Using the Generation Scotland cohort (training $n_{\text{cases}}=374$, $n_{\text{controls}}=9,461$; test set $n_{\text{cases}}=255$, $n_{\text{controls}}=4,546$) we show that the use of CpG DNAm information leads to a significant improvement in the prediction of 10-year T2D incidence (ascertained through linkage to electronic health records) over and above common risk factors ($p=4.2 \times 10^{-12}$). We replicated this finding in an external test dataset (the German-based KORA study). For systematic development of complex trait and incident disease predictors, we have also developed MethylPipeR, an R package with accompanying user interface. MethylPipeR is designed with a focus on reproducibility and is applicable to a wide range of omics data and target traits.

PB3516. Metric projection—AUCs, correlations, and heritability—for biobank scale data: using sparse prediction in the UK Biobank to plug diversity gaps in future biobanks.

Authors:

T. Raben¹, E. Widen^{1,2}, L. Lello^{2,1}, S. Hsu^{1,2}; ¹Michigan State Univ., East Lansing, MI, ²Genomic Prediction, Inc., North Brunswick Township, NJ

Abstract Body:

Sparse machine learning algorithms regularly achieve optimal performance at complex trait prediction when compared to other methods. Additionally, enforcing sparsity can greatly reduce computational memory requirements. Here we discuss *new results* that simple L_1 penalized algorithms regularly perform just as well as, or better than, more widely used methods (Bayesian regression with continuous shrinkage priors, elastic nets, etc.) when error factors and uncertainties are taken into account (both empirical and theoretical uncertainty sources). This is demonstrated for a wide variety of case/control and continuous complex traits in the UK Biobank (UKB) including: breast cancer, asthma, hypertension, type 1/2 diabetes, CAD, lipoprotein a, bilirubin, height, and BMI. Polygenic scores (PGS) for these traits cover a wide range in sparsity from as few as 50 to 25,000 selected SNPs. For all traits, the characteristic phase change behavior of compressed sensing can be identified by measuring performance metrics, variance accounted for, and sparsity. The above methods can now be used to identify where the most predictive signal can be found using the least amount of data. A *novel Monte Carlo method* is used to model the performance metrics (AUC, correlation, etc.) for all of these traits. This leads to projections, with confidence intervals, that can be used to estimate the performance of PGS trained in other biobanks. (1) For a case control trait like asthma, L_1 based PGS leads to an $AUC \sim 0.7$ using only genetic information. (Including covariate contributions—e.g., age and sex—leads to even larger AUCs). For asthma, these projections predict L_1 methods will find an $AUC \sim 0.55$ for African Americans for a predictor trained in the newly available All of Us biobank and an $AUC \sim 0.65$ for individuals of Han Chinese ancestry in the Taiwan Precision Medicine Initiative (TPMI). This TPMI result will surpass that found from predictors trained with European ancestry populations. (2) For a continuous trait such as BMI we find an asymptotic correlation ~ 0.4 . This is competitive with heritability estimates from linear mixed model approximations (e.g., GCTA) and indicates that L_1 methods can capture all of the linear SNP heritability. Similar projections for other traits and ancestry groups are also studied. These predictions will help identify how the largest equity gaps in PGS science can be rectified, for example by helping to determine recruiting targets for diverse biobanks.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3517. miRNA Metabolome - wide association study: A multi-omics integrative approach to Asthma

Authors:

R. Sharma¹, K. Mendez^{1,2}, S. Begum¹, M. Huang¹, A. Tiwari¹, J. Celedon³, C. Clish⁴, S. Weiss¹, J. Lasky-Su¹, M. McGeachie¹; ¹Channing Div. of network Med., Dept. of Med., Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, ²Dept. of Chemistry, Edith Cowan Univ., Perth, Australia, ³Children's Hosp of Pittsburgh of UPMC, Univ. of Pittsburgh, Pittsburgh, PA, ⁴Broad Inst., Cambridge, MA

Abstract Body:

Introduction Both microRNAs (miRNAs) and metabolites have been identified as significant biomarkers for many conditions. Multiple studies have shown that various metabolic stimuli alter miRNA expression. Conversely, miRNAs regulate most cellular processes, impacting metabolism. We postulated that a systems integration of serum miRNAs and metabolites in a large childhood cohort could shed light on the combined synchronized role of miRNAs and metabolites in asthma and in broader metabolomic regulation. **Methods** We performed miRNA sequencing of 1121 serum samples from the Genetic Epidemiology of Asthma in Costa Rica Study (GACRS) and combined these data with targeted LC-MS metabolomic profiling. We performed a global miRNAome-metabolome-wide association (miR-metabo-WAS) analysis using a generalized linear model with adjustment for age, gender, height, and BMI. We applied WGCNA (weighted co-expression network analysis) to identify clusters (modules) of metabolites significantly correlated with miRNA modules and clinical features of asthma. **Results** We identified 2800 significant association between 214 miRNAs and 228 metabolites at 5% FDR. In WGCNA analysis, seven metabolite modules were associated with clinical features of asthma at a 10% FDR (adjusted p-values 8.5×10^{-2} to 2.7×10^{-14}). One of these metabolite modules showed strong significant correlation (P-value: 3.0×10^{-5} to 2.0×10^{-35}) with five miRNAs modules which were also significantly associated with asthma clinical features (adjusted P-value: 8.6×10^{-2} to 4.5×10^{-3}). This module comprised 20 metabolites, including diHOME's, sebacate, and cortisol, that were strongly correlated with six serum miRNAs (mir-143-3p, mir-22-3p, mir-320b/c/d and mir-483-5p) previously reported as asthma-related miRNAs. This module also contained many of the strongest individual miRNA-metabolite associations identified in the miR-metabo-WAS. miRNAs and metabolite modules were associated with airway hyper-responsiveness, airflow obstruction, forced expiratory volume in 1 second, eosinophil count and serum IgE, and asthma-related hospitalizations. **Conclusion** The relatively concentrated effect of miRNAs on metabolite clusters shows that while miRNAs may target and regulate hundreds or thousands of genes, their impact on the resulting metabolome is fairly constrained in asthma. This study of serum miRNA and metabolites demonstrates the value of a combined microRNA-Seq and metabolomics approach to identify meaningful clinical associations and broader genomic regulation of cellular metabolism in Asthma.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3519. MTClass: Identification and annotation of multi-tissue cis-eQTLs using machine learning.

Authors:

R. Li, Z. Qin; Emory Univ., Atlanta, GA

Abstract Body:

Dysregulation of gene expression contributes to the pathophysiology of many human diseases. Mapping genetic variants that affect the expression of one or more genes, termed expression quantitative trait loci (eQTLs), is a growing area of interest. However, to this date, eQTL analysis is typically done one tissue at a time, despite known statistical correlations and biological relationships among tissues. Multi-tissue eQTL mapping identifies variants that affect the expression of the same gene in multiple tissues, thereby potentially recognizing variants with stronger and broader functional impacts that are more likely to lead to phenotypic consequences. However, measuring the effect of a variant on gene expression in multiple tissues is a challenge. To solve this problem, we propose a model-free strategy named MTClass. Instead of calculating a p-value under the statistical testing framework, we attempt to classify vectors of multi-tissue expression values in terms of donor genotype for the variant of interest. We then rank variant-gene pairs based on classification performance. We have tested a support vector classifier and a random forest classifier in this study. We utilized our strategy in a lower-dimensional example (9 tissues, 103 donors) with no missing data and a higher-dimensional example (48 tissues, 948 donors) with missing data. To accommodate missing expression measures in donor-tissue combinations in the latter case, we use multiple imputation with predictive mean matching. We demonstrate in the 9-tissue case that MTClass can identify variants with stronger functional impacts than competing methods such as multi-phenotype association tests. The top 100 and 250 variants identified by MTClass, according to weighted F1 measure, each had 38% more known GWAS SNP hits in their neighborhood according to the GWAS Catalog compared to a competing method. Additionally, we found evidence of biological importance of the top genes identified by MTClass but not by other methods. Using gene set enrichment analysis, we observed that many of these genes serve immune-related functions, especially *HLA-DRB5*, a histocompatibility complex antigen that plays an important role in asthma and allograft rejection. Together, these results emphasize that multi-tissue eQTLs from our method are likely to have functional consequences, and they suggest the value of further pursuing such variants.

PB3520. Multi trait GWAS for diverse ancestry : Mapping the knowledge gap

Authors:

H. Julienne; Inst. Pasteur, Paris, France

Abstract Body:

Approximately 95% of samples analyzed in univariate genome-wide association study (GWAS) are from European ancestry (EUR) individuals. As recently illustrated in the context of polygenic risk scores, existing data in non-European populations, which often present modest sample sizes, can benefit from innovative methods. Here we conducted a multi trait GWAS using JASS (Joint Analysis of Summary Statistics) on blood traits across four super populations.

We detected 357 new genome-wide significant associations in non-European populations (14 in American (AMR), 72 in African (AFR) and 271 in East Asian (EAS)) and conducted an eQTL-informed functional annotation of all lead SNPs. New associations detected represented respectively 7%, 25% and 21% of all associations in the AFR, AMR and EAS populations.

Between EAS and EUR populations, 179 newly detected genes are shared. Many of these shared genes mapped to blood pathways like *MYB* Proto-Oncogene playing a key role in the regulation of hematopoiesis and Neurobeachin Like 2 (*NBEAL2*) involved Gray Platelet Syndrome. Overall, in EAS, top go terms are substantially more enriched when including genes detected with the joint analysis : the enrichment p-value for the term regulation of immune system decreased from 1.5×10^{-4} to 2×10^{-11} .

Interestingly, gene annotation was poorer for the AMR ancestry suggesting a lower multi-trait or eQTLs annotation signal quality which need further elucidation.

Focusing on the AFR population, six new associations mapped to genes annotated for hemoglobin subunit (*HBG1*, *HBG2*, *HBE1*, *HBB* and *HBD*) involved in Beta Thalassemia and Fetal Hemoglobin Quantitative Trait Locus 1 diseases. At least six other newly detected associations for AFR are annotated for blood trait related pathways including Tubulin Beta 1 Class VI (*TUBB1*) expressed in platelets and *CD36* Molecule (*CD36*) gene protein located at the platelet surface.

By applying JASS on non-European ancestries, we mapped 357 new associations and observed a relevant functional annotation for new signals in the EAS and AFR populations. We argue that multi trait GWAS methods can be a valuable tool to narrow the genetic knowledge gap between European and non-European populations.

Abstract Body:

We performed ancestry-specific and sex-specific Phenome Wide Association Studies (PheWAS) analyses to explore traits and disease related outcomes associated with genetically predicted height. We used a Polygenic Score (PGS) for increased height using summary statistics from the latest Genetic Investigation of ANthropometric Traits (GIANT) trans-ethnic meta-analysis for height and assessed its association with a series of phecodes, which are aggregated ICD-10 codes. We examined health-related phecodes from clinical records in more than 700,000 diverse ancestry individuals. We explored data from European ancestry individuals in the UK Biobank (UKB) (N= 330,965), the Million Veteran Project (MVP) (N=217,225), BioVU (N=71,976) and BioMe (N=7,987). We performed a PheWAS meta-analysis (meta-PheWAS) per ancestry, and applied a Bonferroni adjusted significance threshold. The meta-analysis yielded significant associations with 200 phecodes ($p < 4.66E-05$). Height PGS was associated with an increased risk of many circulatory diseases, including atrial fibrillation and flutter (OR = 1.17, 95% CI [1.16, 1.18], $p = 2.87E-212$). We also report that higher height PGS was associated with a higher risk of chronic venous insufficiency (OR = 1.19, 95% CI [1.16, 1.22], $p = 6.01E-53$). We further explored sex-specific meta-PheWAS in the UKB, MVP and BioVU cohorts. 154 and 57 traits reached phenome-wide significance in males and females respectively. Comparing males and females, the meta-PheWAS yielded 110 significant traits only in males and 19 only in females; 95% of the traits were concordant, and their effect sizes were larger for males. Comparing males with the sex-combined meta-PheWAS, 10 traits were found to be significant only in males, specifically, height PGS was associated with a decreased risk of alcoholic liver damage (OR=0.93, 95% CI [0.90, 0.96], $p = 1.05E-05$) and hyperpotassemia (OR=0.95, 95% CI [0.93, 0.97], $p = 8.37E-06$) in males. Comparing females with the sex-combined meta-PheWAS, no traits were found to be significant in females only. We further performed ancestry specific meta-PheWAS analyses. We investigated individuals of African ancestry in the UKB (N= 6,682), MVP (N=57,065), BioVU (N=15,581) and BioMe (N=6,240) cohorts; we identified 17 significant traits. Higher height PGS was associated with a higher risk of osteoarthritis NOS (OR=1.04, 95% CI [1.02, 1.07], $p = 2.75E-05$) in the African meta-PheWAS and presented an attenuated non-significant effect in the European meta-PheWAS. Furthermore, we explored East-Asian ancestry individuals in the UKB (N= 1,936) and MVP (N=4,843) cohorts where no significant traits were identified.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3522. Multi-ancestry polygenic risk scores for venous thromboembolism

Authors:

Y. Jee¹, F. Thibord², C. Kabrhel³, N. Smith⁴, P. Kraft¹, International Network against Venous Thrombosis (INVENT) consortium; ¹Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, ²Div. of Intramural Res., Population Sci. Branch, Framingham, MA, ³Massachusetts Gen. Hosp., Boston, MA, ⁴Univ of Washington, Seattle, WA

Abstract Body:

Venous thromboembolism (VTE) is a significant contributor to morbidity and mortality, with large disparities in incidence rates across ancestry populations. Polygenic risk scores (PRSs) comprised of genome-wide significant variants have been demonstrated to identify European ancestry individuals at the highest risk of VTE. However, there is limited evidence on whether high-dimensional PRS constructed using more sophisticated methods can enhance the predictive ability and their utility in populations of non-European ancestry. We developed PRSs for VTE using summary statistics from the International Network against Venous Thrombosis (INVENT) consortium GWAS meta-analyses of European (71,771 cases and 1,059,740 controls) and African ancestry samples (7,482 cases and 129,975 controls). We used LDpred2, stacked clumping and thresholding, and PRS-CSx to construct multiple PRSs and evaluated their performance in an independent European ancestry sample (2,222 cases and 2,201 controls). LDpred2 trained using European ancestry summary statistics performed the best with OR of 1.51 (95% confidence interval [CI] 1.38-1.67) and area under the curve (AUC) of 0.62 (0.60-0.65). In the European ancestry test set, a multi-ancestry PRS constructed using a linear combination of PRS-CSx scores trained in European and African ancestry populations (AUC=0.60, 0.58-0.63) did not perform better than PRS trained in European ancestry samples (AUC=0.60, 0.58-0.63) or African ancestry samples alone (AUC= 0.58, 0.55-0.60). The highest fifth percentile of the LDpred2 distribution was associated with 2-fold increased risk for VTE (OR=2.04, 1.73-2.40). Results were similar for PRS trained using PRS-CSx in European or African ancestry samples or the multi-ancestry PRS combining European and African scores (OR=1.76 (1.74, 2.42), OR=1.59 (1.67, 2.26), OR=1.87 (1.76, 2.46), respectively). These findings suggest that PRS may be used to identify individuals at highest risk for VTE event and provide guidance for the most effective treatment strategy. We are currently validating these PRSs in African ancestry population.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3523. MultiSuSiE: Multi-population fine-mapping under the sum of single effects model

Authors:

J. Rossen¹, H. Shi¹, M. Kanai², Z. R. McCaw³, L. Liang¹, O. Weissbrod¹, A. L. Price¹; ¹Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, ²Broad Inst. of MIT and Harvard, Cambridge, MA, ³Insitro, South San Francisco, CA

Abstract Body:

Statistical fine-mapping aims to identify biologically causal genetic variants at disease-associated loci. The sum of single effects (SuSiE) model has provided a powerful and versatile approach for fine-mapping causal variants in a single population (Wang et al. 2020 JRSSB) and accommodating functional priors (Weissbrod et al. 2020 Nat Genet). Incorporating data from multiple populations can greatly improve fine-mapping due to differences in patterns of linkage disequilibrium across populations (Schaid et al. 2018 Nat Rev Genet), strongly motivating multi-population methods.

We propose MultiSuSiE, an extension of SuSiE to multiple populations. SuSiE sums across multiple single-effect models (each involving a single causal variant), fitting and residualizing phenotypes for each single-effect model in turn. In MultiSuSiE, each single-effect model still assumes a single causal variant, but effect sizes are allowed to vary across populations via a multivariate normal prior informed by cross-population genetic correlations; MultiSuSiE fits and residualizes phenotypes for population-specific effect sizes of each single-effect model in turn. We additionally adapt the PolyFun framework (Weissbrod et al. 2020 Nat Genet) to multiple populations, integrating genome-wide functional annotations to construct functional priors.

We evaluated MultiSuSiE using simulations involving real genotypes from 93,000 British and 7,000 African individuals from UK Biobank. MultiSuSiE identified 25% more true causal variants with posterior causal probability >0.5 compared to SuSiE applied to 100,000 British individuals, while maintaining correct calibration; MultiSuSiE attained similar improvements relative to existing methods for multi-population fine-mapping. We will present results of applying MultiSuSiE to 49 diseases and complex traits from UK Biobank and incorporating functional priors.

PB3524. Nearest Neighbor Simulated Annealing Cohort Selection for Improved PCA Genome Matching.

Authors:

R. Laboulaye, V. Borda, T. D. O'Connor; Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract Body:

Mining existing genomic data from biobanks to find controls for GWAS can increase study viability and power. These benefits are further pronounced for underrepresented populations such as Latin Americans, whose studies, compared to those of Europeans, typically have smaller sample sizes and whose fine-scale variation in Native American ancestry can be dominated by continental admixture. Prior work on genome matching focuses on finding the optimal genotype embedding space and distance metric, failing to address the construction of an optimal control cohort and instead defaulting to bipartite matching. Our algorithm focuses on not only finding controls that individually match the querying user's cases and controls but also combine into a cohort that reflects the variation exhibited by the query.

Our method employs local search to find the optimal cohort from a set of reasonable candidates. Using the principal components of both the query and potential controls, we use the variance-weighted Mahalanobis distance to find the α ; nearest neighbors of each query genome from the potential controls, which we then merge into a candidate set. Given a desired control cohort size m , we sample m controls from the candidate set and do so β ; times to generate β ; control cohorts. We use the genomic control λ ;, calculated between a control cohort and the query, to evaluate the β ; control cohorts. The λ ; values are then used to select the optimal starting control cohort and a function of their standard deviation is used to initialize our simulated annealing temperature. We perform simulated annealing for n iterations, randomly swapping γ ; genomes between our control cohort and the candidate set at each iteration, evaluating the control cohort by its genomic control λ ;

We evaluate our control cohort selection algorithm on Latin American genomes from 32 dbGAP cohorts, using both the cases and controls as a query. For our biobank, we use the Genetics of Latin American Diversity (GLAD) database, which contains 52,237 genomes. We filter all genomes to a set of 246799 LD-pruned SNPs and embed them in a PCA space. We construct a greedy baseline in which bipartite matching is applied iteratively until a control cohort of size n has been selected. We first evaluate our algorithm on control cohort size $n=500$ and find that it yields an mean improvement (decrease) in the genomic control of 0.252 and a median improvement of 0.0314 when compared with the baseline. We then evaluate our algorithm on values of n from 500 to 3000 incrementing by 500 for our 10 largest PHS cohorts. We find a gradual decline in the improvement over the baseline as n increases, with a median improvement of 0.0125 for $n=1500$ and 0.000152 for $n=3000$.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3525. Network-based cross-phenotype risk scoring models for non-linear compositing multiple disease risks using biobank-scaled PheWAS data

Authors:

Y. Nam, V. Sriram, S-H. JUNG, B. Xiao, M. Shivakumar, A. Verma, D. Kim; Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Background: The polygenic risk score (PRS) can help to identify high-genetic risk by combining individual genetic profiles with single-nucleotide polymorphisms identified through genome-wide association studies. Even though multiple diseases will usually afflict a patient at once or in succession, the conventional PRS focuses on only a single disease of interest. Phenome-wide association studies (PheWAS) can successfully identify associations between multiple phenotypes and genetic variants, allowing us to develop risk scores considering cross-phenotype relationships for index diseases of interest. Genetic associations between phenotypes discovered through PheWAS can be easily implemented through network structure. **Methods:** We developed a network-based cross-phenotype risk score algorithm (netCRS) to predict individual disease risk by utilizing cross-phenotype associations identified from PheWAS. To observe the underlying structure between phenotypes and variants, we designed a multi-layered phenotype-variant relational network using biobank-scaled PheWAS summary statistics. The network consists of a cross-phenotype association network and variant network. Label propagation was applied to predict individual risk scores on the multi-layered network. Individual genetic profiles give initial label information on variant networks, and label propagation diffuses individual genetic profiles into cross-phenotype associations. The final aggregation of propagated results on cross-phenotype association represents a measurement of the possible risk scores across phenotypes focused on an index disease. **Results:** UK Biobank PheWAS summary statistics were used for constructing multi-layered networks, and the individual-level genetic profiles for the European population were collected from the Penn Medicine BioBank. We obtained the netCRS for three dichotomous traits: type 2 diabetes (T2D; 4,400 cases vs. 24,219 controls), obesity (OBS; 4,185 vs. 22,971), and coronary atherosclerosis (CAD; 6,064 vs. 21,900). The number of cross-phenotypes was considered for each trait as follows: 192 phenotypes for T2D, 65 for OBS, and 184 for CAD. To investigate the utility of netCRS, we compared the disease risk prediction between netCRS and PRS (LDpred). The combined model (netCRS + PRS + Sex + Age + PC1~5) achieved an AUC improvement compared to the (PRS + Sex + Age + PC1~5) model; improvement of 3.78% for T2D, 6.57% for OBS, and 3.54% for CAD. **Conclusion:** We expect that using these risk prediction models by incorporating cross-phenotype relationships will allow for the development of prevention strategies and reduction of disease mortality.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3526. New paradigm for uncovering the clinical consequences of genetic variation.

Authors:

M. Xiong¹, R. Fan², L. Luo³, T. Xu⁴, X. Sun⁵, J. Zhao⁶, E. Boerwinkle⁷; ¹Univ Texas Sch. of Publ. Hlth., Houston, TX, ²Georgetown Univ Med Ctr, Washington, DC, ³Univ New Mexico, Albuquerque, NM, ⁴Univ. of Florida, Gainesville, FL, ⁵Univ. of Miami Miller Sch. of Med., Miami, FL, ⁶Univ Florida, Gainesville, FL, ⁷Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX

Abstract Body:

Uncovering the clinical relevance of genetic variants has a great potential to transform healthcare and medicine. Classical methods for mechanical interpretation of variants are association analysis or supervised prediction, based on sparse, imbalanced and noisy clinical labels. Accumulating evidence indicates that a large proportion of association signals is irrelevant to clinical phenotypes. Moreover, the accuracy estimated from the training data may not hold for out-of-training samples. To overcome these limitations, here we propose a new paradigm and analytical pipeline for uncovering clinical consequences of genetic variations with intelligent genomics and causal inference as major tools. We start with sequence evolution and then follow the path: MSA transformer → variational autoencoder (VAE), estimating effects of mutations via grammatical and semantic analysis of sequence embeddings → estimating causal QTL, eQTL scores (assess the causal relationship between genetic variation, gene expression, and phenotypes) → inferring protein structure and function → finally performing multicriteria score optimization and testing the causal role of genetic alterations in disease pathogenesis. The proposed deep latent generative models with nonlinear interactions capture higher-order, context-dependent constraints in sequence evolution. The proposed paradigm is applied to learning the evolution of SARS-Cov-2 variants, forecasting of potential high risk SARS-CoV-2 mutations, and evaluating their fitness potential and immune escape property. We discover numerous virus mutations that increase fitness potential and immune escape capacity. We demonstrate that the proposed paradigm is notably superior to the state-of-art methods in forecasting potentially harmful future SARS-CoV-2 variants and estimating their immune escape ability.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3527. New perspectives in the genetics of persistent opioid use: reexamining candidate gene studies and presenting new results from the Michigan Genomics Initiative

Authors:

A. Annis¹, V. Gunaseelan¹, A. Smith², G. Abecasis³, D. B. Larach¹, M. Zawistowski⁴, C. Brummett¹; ¹Univ. of Michigan, Ann Arbor, MI, ²Univ MICHIGAN, Ann Arbor, MI, ³Regeneron Pharmaceuticals, Tarrytown, NY, ⁴Univ Michigan, Ann Arbor, MI

Abstract Body:

The opioid epidemic is a major health crisis in the United States, with mortality rates from opioid overdoses rising to tens of thousands of deaths each year. Most opioid-related genetic studies focus on addiction and opioid dependence; however, persistent opioid use stemming from opioid prescriptions is common, especially after surgery. Understanding genetic factors contributing to prescription-engendered persistent opioid use would be a huge advance in the apprehension of morbidity and pathways to opioid use disorder and overdose.

In a comprehensive literature review, we collated over fifty genes and genetic loci from sixty-four peer-reviewed publications that posit genetic contributors to opioid-use phenotypes. ~70% of these publications are candidate gene studies (median case count: 303, median control count: 202); of the few studies classified as genome-wide association studies (GWAS), only two of them (Polimanti et al 2020 and Sanches-Roige et al 2021) have sample sizes $\geq 10,000$.

We determined to systematically replicate reported associations for opioid-use phenotypes in the Michigan Genomics Initiative (MGI), which has ~40,000 surgery patients with opioid prescription data. We did association analyses for persistent opioid use with complete data (3,198 cases who filled ≥ 2 opioid prescriptions in the 30 days prior to 180 days after surgery, 36,321 controls) and with opioid naive participants who have no record of prescription opioid exposure in the 120 to 31 days prior to surgery (794 cases, 32,656 controls). Both analyses replicated ($p < 0.05$) known associations in *OPRM1*, the μ -opioid receptor, but did not replicate most other signals, calling into question the validity of small-sample candidate gene studies for opioid use. Importantly, the MGI analyses showed nominal significance for two recently-reported loci, rs640561 ($p = 0.02$) and rs9291211 ($p = 0.04$), which are associated with opioid dependence and problematic opioid use in the Polimanti et al and Sanches-Roige et al GWAS, respectively.

While MGI did not replicate most previously-reported associations, finding signals for known *OPRM1* variants and loci from two sizable GWAS affirms the persistent opioid use phenotype in MGI, gives hope for the tractability of genetic contributors to opioid-use phenotypes, and demonstrates the need for genome-wide association analyses to understand complex traits.

PB3528. Next generation phenotyping of DEGCAGS syndrome.

Authors:

R. Freeman¹, J. Woods²; ¹Valley Children's Hosp., Fresno, CA, ²Valley Children's Hosp., Madera, CA

Abstract Body:

Introduction: Developmental Delay with Gastrointestinal, Cardiovascular, Genitourinary, and Skeletal Abnormalities (DEGCAGS) is a recently discovered, autosomal recessive disorder with a distinct multi-systemic phenotype (MIM # 619488). *ZNF699* has been proposed as an etiology of DEGCAGS, though its function in human development and its role in disease have yet to be elucidated. Fourteen patients with DEGCAGS have been reported in the literature. Herein we report on the fifteenth patient using Next Generation Phenotyping (NGP) for quantitative determination of the core DEGCAGS phenotypes. **Methodology:** Phenotypic data present in pdf files were derived from the patient chart and literature review. These data were imported into R, combined into one file and converted to txt files (pdftools package). The txt files were then processed in ClinPhen for Human Phenotype Ontology (HPO) term extraction. The HPO terms were sorted by frequency according to the HPO hierarchy of terms (ontologyX). A co-occurrence matrix of HPO terms was generated to create an interactive heat map of HPO term co-occurrence frequency (heatmaply). **Results:** A total of 264 unique HPO terms were extracted from the patient record and literature review. The most frequent HPO terms within the top third were hypotonia (19), syndactyly (18), abnormal facial shape (17), microcephaly (12), failure to thrive (6), global developmental delay (6), hearing impairment (5), intellectual disability (5), intestinal atresia (5) and jejunal atresia (5). The count of the top half of HPO systemic hierarchical categories was head (82 HPO terms), heart morphology (48), kidney (25), limb bone deformity (25), cardiovascular system physiology (19), muscle tone (19), hearing abnormality (17) and neurodevelopmental abnormality (17). The top quartile of co-occurring phenotypes were syndactyly/abnormal facial shape (7 co-occurrences), syndactyly/hypotonia (6), hypotonia/abnormal facial shape (5), syndactyly/jejunal atresia (5) and abnormal facial shape/failure to thrive (5). **Discussion:** NGP offers a quantitative approach to phenotyping to generate phenotypic data in an objective and reproducible manner. Co-occurrence matrices provide insight into the core phenotypes associated with disorders. Systemic categorization of phenotypes within the HPO hierarchy provides insights into the biomedical systems involved in disorders that may go unrecognized if only individual phenotypes are reported. NGP methodology may be widely applied to existing and novel genomic disorders to provide systemically sorted quantitative data for those interpreting genomic data within the context of patient phenotypes.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3529. NGS Variant Detection as a Sequence-to-Sequence Modeling Problem

Authors:

B. O'Fallon¹, J. Durtschi², A. Bolia¹, L. Yang¹, H. Best³; ¹ARUP Labs, Salt lake city, UT, ²ARUP, Salt Lake City, UT, ³Univ. of Utah/ARUP Lab., Salt Lake City, UT

Abstract Body:

NGS variant detection tools use many statistical techniques to identify candidate variants, including logistic regression, gaussian mixture models, pair Hidden Markov Models (HMMs), and multiple hand-picked parameter values and heuristic thresholds. Here, we describe an alternative variant detection approach that does not involve any statistical modeling, and instead uses a single deep learning model to directly predict the two germline haplotypes present in the sample. Our model recasts the variant detection problem as a sequence-to-sequence modeling task, akin to language translation, in which the input sequence tokens are the collection of bases aligning to a single reference genome coordinate, and the predicted output sequences are the two haplotypes present in the individual. The model architecture utilizes stacked transformer encoder layers and a simple, fully connected decoder modified to predict two output sequences. We use training data from 17 Genome-in-a-Bottle cell lines sequenced as full genomes on Illumina sequencing instruments, and investigate how model size and training data size affect sensitivity and specificity of the resulting variant calls. We show that our model has the ability to reconstruct haplotypes in regions with complex or ambiguous read mappings, indicating that it learns a HaplotypeCaller-like ability to perform de novo local reassembly of reads. In addition we demonstrate that the model uses local context information when assessing the likelihood of a given variant. Overall, genotyping and phasing accuracy exceeds 99% for most variant classes, indicating that both haplotypes are reconstructed with high accuracy. When compared to HaplotypeCaller, DeepVariant, and Strelka2, our approach yields similar sensitivity for both SNVs and indels, but slightly reduced precision for SNVs.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3530. Non-additive outlier effects of gene expression on anthropometric traits

Authors:

A. Brown¹, T. Dupuis², A. Sartori³, A. Real⁴, D. Davtian¹, E. Pearson¹, E. Dermitzakis⁵, A. Viñuela⁶; ¹Univ. of Dundee, Dundee, United Kingdom, ²Univ. of Dundee, Sch. of Med., Dundee, United Kingdom, ³Université de Genève, Genève, Switzerland, ⁴Univ. of Geneva, Geneva, Switzerland, ⁵GSK, Geneva, Switzerland, ⁶Newcastle Univ., Newcastle, United Kingdom

Abstract Body:

Approaches that use genetic data to produce causal links between molecular phenotypes and disease risk usually assume that additive effects on the molecular trait translate to additive effects on disease risk. However, many complex biological processes involve non-additive mechanisms such as buffering, pathway substitution and feedback loops, which would be expected to reduce the impact of extreme expression phenotypes. In the opposite direction, some rare variants with extreme expression effects are known to cause monogenic disease. By considering combinations of eQTL variants with predicted extreme effects on expression, we test the effect of extreme expression on 6 anthropometric traits. We used eQTLs from DIRECT and GTEx v8 to calculate predicted expression in 44 non-sex specific tissues for 405,719 individuals (UK Biobank). For every gene across all tissues, we defined low (LEEI) and high extreme expression individuals (HEEI) as the persons whose predicted expression levels fell in the bottom or top percentile. We tested for trait differences between these individuals and the rest of the population for 6 traits: systolic and diastolic blood pressure, BMI, grip strength, height, and waist-hip ratio. By controlling for additive effects, we are searching for instances where the combined effects of the variants on the trait, mediated by expression, differs from the sum of the individual variant effects. We found respectively 2, 5, 48, 22, 617 and 35 associations (FDR=0.05) between these traits and the extreme expression of a gene in a tissue. In most cases, genes with non-additive associations between extreme expression and phenotype also showed significant additive correlations (609/729). We observed that extreme expression generally attenuates the contribution of the additive component, suggesting that compensatory mechanisms are in action. We find considerably more evidence for additive expression effects on traits (77,960 total associations), consistent with a dramatically higher power to discover these relationships. However, these non-additive associations provide other insights into how molecular phenotypes affect traits and potentially also provide a way of linking genes to disease with less scope to be confounded by pleiotropy and linkage contamination.

PB3531. Novel Approach to Age Estimation of Rare Variants Enables Prioritization of Functional Variants

Authors:

K. Liao¹, H. Kang², S. Zollner³, Y. Si¹; ¹Univ. of Michigan, Ann Arbor, MI, ²Univ Michigan, Ann Arbor, Ann Arbor, MI, ³Univ Michigan, Ann Arbor, MI

Abstract Body:

Due to the abundance of rare variation, a priori evidence into their functionality is key to developing successful testing strategies for trait associations. However, annotating the consequences of rare variants (especially non-coding variants) based on genomic features is a challenging problem. A piece of evidence into a rare variant's functionality is whether it is undergoing selection. Currently, this is typically considered using conservation scores, which reflect purifying selection over phylogenetic time scales. Evidence of selection within the human population can complement this with more recent signals. A useful proxy for such selection is the age of the variant where variants under selection are typically much younger than other variants of the same allele frequency. Here, we propose a novel method to accurately infer the relative age of a rare variant and highlight how allele age reveals insights into functional consequence.

In this method, we model that carriers of a younger allele also share a more recent common ancestor in the region surrounding the variant site, resulting in longer shared haplotypes nearby. Moreover, due to the more recent common ancestry the density of rare variants on these haplotypes is lower. We leverage these observations to estimate the pairwise time to common ancestor between carrier haplotypes. We combine the pairwise estimates of all carriers to arrive at the age of the variant. As the numerical value of this estimate strongly depends on the population genetic model, we primarily focus on the relative age of a variant. We evaluate our approach in coalescent simulations, using published models of human population history. Across all simulated populations, our approach provides accurate relative allele age estimates with rank correlation above 0.8 with the true ages among variants with the same allele counts. The correlation ranges from 0.86 for doubletons to 0.82 for variants occurring 10 times in the sample in samples between 1,000 and 10,000 individuals. We validate our method in sequencing data by observing that known loss of function variants are younger than synonymous variants of the same allele frequency. We further compare our approach to two recent methods, GEVA and tsdate in both simulation and real data.

Our method is computationally efficient to apply to whole genome sequencing data of >100,000 individuals. These estimated ages provide insights into evolutionary constraints of rare noncoding variants and may thus help identify rare risk variants.

PB3532. Omics profiling in overweight and obese children in the California Bay Area during childhood development and the effects of a multi-modal health intervention program tailored to a majority Latinx community

Authors:

J. Li-Pook-Than¹, E. Wei¹, B. Lee-Mcmullen¹, F. Haydel¹, S. Banuelos¹, T. Robinson¹, M. Snyder²; ¹Stanford Univ., Palo Alto,, CA, ²Stanford Univ., Stanford, CA

Abstract Body:

Childhood development and health risks associated to overweight and obesity stresses are understudied particularly in diverse populations. We describe preliminary multi-omic results of a five-year weight loss intervention program on ~241 overweight and obese children (average 7- 11 year olds) recruited from primarily LatinX communities in the Bay Area of Northern California. Children in the study were randomized into either a community based multi-component, multi-level, multi-setting (MMM) intervention group or active placebo group (control). Using traditional clinical measurements along with comprehensive -omic profiling (including transcriptomes, metabolome and O-link cardiovascular-related proteins) we describe longitudinal changes over the course of the study. Among our findings, are key biological pathways (KEGG) associated to genes that decreased in expression when comparing MMM intervention from control groups (deltas), including genes associated to inflammation (chemokine), insulin, adrenergic signaling in cardiomyocytes, as well as pathways related to cancer and long-term depression. Furthermore, Ingenuity Pathway Analysis (IPA), reveal a crosstalk of networks between these pathways, -omic analytes and components related to childhood development. This unprecedented work also shows that inclusivity and equitable research supports improved precision health science understanding.

PB3533. Omnibus proteome-wide association study (PWAS) method identified 28 novel risk genes for Alzheimer's disease.

Authors:

T. Hu¹, R. L. Parrish¹, A. S. Buchman², N. T. Seyfried³, P. L. De Jager⁴, D. A. Bennett², M. P. Epstein¹, J. Yang¹; ¹Ctr. for Computational and Quantitative Genetics, Dept. of Human Genetics, Emory Univ. Sch. of Med., Atlanta, GA, ²Rush Alzheimer's Disease Ctr., Rush Univ. Med. Ctr., Chicago, IL, ³Dept. of Biochemistry, Emory Univ. Sch. of Med., Atlanta, GA, ⁴Columbia Univ Irving Med Ctr, New York, NY

Abstract Body:

Alzheimer's disease (AD) is a neurodegenerative disorder with polygenic inheritance. The most recent Genome-wide association studies (GWAS) of AD identified 38 risk loci, the majority of which have unknown underlying mechanisms. Proteome-wide association study (PWAS) integrating proteomics data with GWAS summary data has been shown as a powerful tool to identify risk genes associated with AD, with genetic effects potentially mediated through protein synthesis. Combining multiple PWAS methods is expected to improve power by modeling the unknown genetic architectures of protein abundances with multiple models.

Analogous to the transcriptome-wide association study (TWAS), PWAS first trains protein abundance imputation models using nearby SNPs as predictors with a reference dataset, and then tests gene-based association with GWAS summary data taking the estimated SNP effect sizes from the reference data as SNP weights (i.e., pQTL weights). Existing TWAS methods such as PrediXcan (Elastic-Net penalized regression), FUSION, and TIGAR (nonparametric Bayesian Dirichlet process regression) can be easily adapted for PWAS. We applied both PrediXcan and TIGAR to train protein abundance imputation models for 8874 proteins obtained from prefrontal cortex samples of European descent (n=395). We first conducted PWAS using the most recent GWAS summary data of AD (n=762,917) with pQTL weights by PrediXcan and TIGAR, respectively. Next, we used the omnibus aggregated Cauchy association test (ACAT-O) to combine PWAS p-values by PrediXcan and TIGAR, as well as the PWAS p-values using the previously published pQTL weights (by FUSION).

We obtained 6673 protein abundance imputation models by TIGAR/DPR and 1835 by PrediXcan, with 5-fold cross validation $R^2 > 0.5\%$. PWAS by TIGAR detected 11 significant risk genes, and PWAS by PrediXcan detected 7 significant risk genes, with $FDR < 0.05$. The omnibus ACAT-O method identified 32 significant risk genes with $FDR < 0.05$, where 4 genes overlapped with previous PWAS by FUSION (which detected 13 risk genes) and 7 genes were identified by previous GWAS of AD. Interestingly, our identified risk genes *FNBP4* and *CDC42* were reported for general cognitive function; *CCDC86* and *KIF18B* were found involved in the development of neurofibrillary tangles. In conclusion, 28 novel PWAS risk genes were identified for AD, whose genetic effects are potentially mediated through the protein synthesis processes. These results highlight the effectiveness of using existing TWAS methods and the omnibus ACAT-O test for PWAS. This omnibus PWAS method can be applied to study complex polygenic diseases and provide new insights into their genomic architecture.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3534*. On the polygenic trait model in population-based human genetics studies: What is random and what is fixed.

Authors:

Y. Tang, J. D. Storey; Lewis-Sigler Inst. for Integrative Genomics, Princeton Univ., Princeton, NJ

Abstract Body:

The polygenic trait model (PTM) forms the basis of the genetic analysis of complex quantitative traits. The PTM has wide and reliable applications in experimental settings where researchers control the genetics of the experimental units. These scenarios satisfy the assumption of a fixed kinship in the original PTM model. A well-established way to construct the PTM under these conditions is using the sampling distribution to develop a marginal polygenic trait model (mPTM) to conduct inferences based on the marginal likelihood. When the mPTM is utilized in population-based human genetics studies where the kinship is unknown in advance, there is a trend in the literature to use another probabilistic model with fixed genotypes and random genetic effects (FGRE) to perform inference on the mPTM. However, the FGRE adopts a biased kinship estimator and a nontrivially different sampling distribution due to its assumption of fixed genotypes. This results in a different marginal likelihood, thereby affecting the estimation of genetic variance components and heritability. Following the original assumptions of the PTM -- random genotypes and fixed genetic effects (FPTM) -- we describe how to utilize the PTM in population-based studies by equipping the original PTM with a recently developed unbiased kinship estimator. We provide evidence from theory and simulations to suggest that the FPTM yields more accurate estimates of variance components and heritability. Applying the FPTM to the analysis of real data with complex population structures, we found that the FPTM has the ability to modulate the ancestral population when estimating genome-wide heritability. The FPTM also leads to a more accurate characterization of the effects of the choice of ancestral population on statistical power in genome-wide association studies. Our findings may assist in choosing appropriate model assumptions and methods to construct the PTM for human genetics studies with arbitrary population structures, thereby leading to a better understanding of the molecular basis of complex human traits and diseases.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3535. One-sample and two-sample mendelian randomization studies consistently showed that an increase in adiposity raises serum uric acid level in the East Asian populations.

Authors:

S. Lee¹, M. Ryu¹, N. Kim¹, S. Yoon¹, S-H. Jee²; ¹Basgenbio, Seoul, Korea, Republic of, ²Yonsei Univ., Seoul, Korea, Republic of

Abstract Body:

Previous mendelian randomization studies (MR) suggested that the increase in serum uric acid causes adiposity, not vice versa. However, most findings came from the data of the European ancestry. Among East Asian populations, both directions in the causal relationship between adiposity and uric acid have been suggested by observational studies and a few MR studies. Therefore, in this study, two separate MR studies were conducted to test the hypothesis of the causal effect of adiposity, measured by body mass index (BMI), on uric acid in East Asian populations. In the first study, summary statistics from two large, publicly available biobanks from South Korea (72,299 participants in the Korean Genome and Epidemiology Study; KoGES) and Japan (158,284 participants in the Biobank Japan; BBJ) were used to conduct a two-sample MR study. In the second study, a one-sample MR study was conducted using the BBJ only. In both studies, the fixed-effect inverse variance weighted method was the primary analysis, and as sensitivity analyses, leave-one-out analyses, the weighted median method, and the MR-Egger regressions were performed. Twenty-six single nucleotide polymorphisms (SNPs) in the KoGES and 52 SNPs in the BBJ were selected as genetic instruments. In the two-sample MR study using the KoGES and the BBJ, genetically determined BMI had a positive causal effect on uric acid (IVW: β [95%CI] = 0.029 [-0.006, 0.065]; weighted median: β [95% CI] = 0.042 [0.019, 0.065]). While the causal effect estimate from the MR-Egger regression was not statistically significant (β [95%CI] = -0.002 [-0.113, 0.110]), there was also no evidence of horizontal pleiotropy from the MR-Egger regression intercept (β [95%CI] = 0.004 [-0.010, 0.018]). In the one-sample MR study using only the BBJ, the positive causal effect of BMI on uric acid was also observed (IVW: β [95%CI] = 0.197 [0.129, 0.264]; weighted median: β [95% CI] = 0.170 [0.095, 0.244]). Leave-one-out analyses confirmed that the pooled causal effect estimate from various SNPs was not driven by any single SNP. Our findings from the South Korean and Japanese populations are consistent with the causal effect of BMI on uric acid previously found in the European population, suggesting that such pattern may be universal across different populations. When analyzed in both two-sample MR and one-sample MR settings, the causal effect estimates differed in magnitude because the two MR designs tend to be biased in the opposite directions. Nonetheless, the directions of the causal effects were consistent in both studies, increasing the confidence in our findings.

PB3536. OTTERS: A powerful TWAS framework leveraging summary-level reference data

Authors:

Q. Dai¹, G. Zhou², H. Zhao³, U. Vösa⁴, A. Battle⁵, A. Teumer⁶, T. Lehtimäki⁷, O. Raitakari⁸, T. Esko⁹, M. Epstein¹, J. Yang¹; ¹Emory Univ., Atlanta, GA, ²Yale Univ., New Haven, CT, ³Yale Univ. Sch. of Publ. Hlth., New Haven, CT, ⁴Univ. Med. Ctr. Groningen, Groningen, Groningen, Netherlands, ⁵Johns Hopkins Univ., Baltimore, MD, ⁶Univ. Med. Greifswald, Greifswald, Germany, ⁷Tampere Univ., Tampere, Finland, ⁸Univ. of Turku, Turku, Finland, ⁹Univ. of Tartu, Tartu, Tartumaa, Estonia

Abstract Body:

Transcriptome-wide association studies (TWAS) identify genes that influence complex traits through genetic regulation of gene expression. Existing TWAS tools like FUSION require individual-level eQTL reference data from a source like GTEx (n~100s) to impute gene expression in a test GWAS. Therefore, these TWAS tools are not applicable to enormous summary-level reference eQTL datasets like those generated by the eQTLGen consortium (n~32K). Development of TWAS methods that can harness summary-level reference data like eQTLGen is valuable not only to enable TWAS in more general settings but also to permit more powerful analyses, since we expect expression prediction to improve with increasing reference sample size. To fill this important gap, we develop a TWAS framework called OTTERS (Omnibus Transcriptome Test using Expression Reference Summary data) that can use summary-level reference eQTL datasets to perform TWAS. OTTERS adapts a variety of published polygenic risk score (PRS) methods (P+T, lassosum, SDPR, PRS-CS) to train eQTL effect sizes based on a multivariate regression model. For each PRS method, OTTERS uses the estimated eQTL weights to impute gene expression per gene and tests for association between imputed expression and outcome for a GWAS dataset. OTTERS then combines these PRS-based association tests together to create an omnibus TWAS p-value. Simulation studies using real genotype data to simulate expression data illustrated that OTTERS based on summary-level reference eQTL datasets achieved comparable results with FUSION using individual-level reference data. We also demonstrated that TWAS performance based on each of these PRS methods substantially depends on the underlying genetic architecture for gene expression. Since such architecture is unknown a priori in real studies, we believe the omnibus TWAS test implemented in OTTERS will be preferred in practice as this test had near-optimal performance across all of our simulation scenarios. We applied OTTERS to blood eQTL summary-level data (n=31,684) from the eQTLGen consortium and GWAS summary data of cardiovascular disease from the UK Biobank. Comparing OTTERS results to those of FUSION using individual-level GTEx V6 reference data (n=338 for blood tissue), we found that OTTERS revealed 11 potential risk genes missed by FUSION using smaller individual-level reference datasets. In conclusion, our novel OTTERS framework not only provides a practical and powerful tool for TWAS analysis, but also provides the opportunity to leverage other emerging summary-level -omic data, such as methylation, histone marks, and proteins. Free software implementing OTTERS is available on Github.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3537. PathWAS: Combining transcriptomics with proteomics to predict pathway functionality and associations with complex traits

Authors:

S. May-Wilson¹, J. Wilson², N. Pirastu³; ¹Univ. of Edinburgh, Edinburgh, United Kingdom, ²Univ Edinburgh, Edinburgh, United Kingdom, ³Human Technopole, Milan, Italy

Abstract Body:

Rationale: GWAS are a staple in the analysis of complex traits and multifactorial disease. They are often combined with pathway-enrichment analyses to try and elucidate biological mechanisms and relationships, but unfortunately this methodology may miss important individual interactions due to small effect sizes caused by focusing on individual genes acting in isolation. However, combining multiple genes into one broader pathway score may allow us to gain greater insight into the aetiology of complex traits while improving power of discovering novel associations. Our aim was thus to create a statistical framework for creating genetic scores predictive of pathway functionality and then use them to understand the impact of the pathway on complex traits.

Method: PathWAS involves the use of measured protein biochemically at the end of a pathway, as a proxy for pathway functionality. For this we select all available cis-eQTLs for each gene within a pathway from the eQTLgen consortium. We then combine all predicted gene expression in a single pathway score by evaluating the weight of each eQTL on the end-point protein. Overall scores are then derived as the weighted sum of the PRS for each transcribed gene level, where the weights correspond to the MVMR coefficients. For end-point protein summary statistics we used 4907 proteins from the DeCODE proteomics (in 35,000 Icelandic individuals), while pathways were taken from the KEGG database. Finally, each PRS_{pathway} was used for a PheWAS of 60 traits in UK Biobank.

Results: Using the available proteomics data we were able to create 1109 pathway-protein pairs. From these, PheWAS identified more than 3000 significant associations between pathways and different traits (FDR < 0.05). For example, higher activity of the SNAP Receptor (SNARE) interactions pathway increased platelet count while higher activity of NOD-like receptor pathway and reduced BMI.

Conclusion: Our results show that it is possible to use publicly available data to create PRS predictive of pathway functionality and that these can be used to understand their impact on human biology. With the integration of single cell eQTL data which is gradually becoming more widely available it will potentially be possible to create tissue and cell-type specific scores. In conclusion our method extends TWAS analysis to entire pathways increasing power to detect associations. This will be extremely important in understanding the underlying physiology of complex traits while providing potential targets for drug development.

Hosp., Boston, MA, ¹⁶Univ. of Louisville, Louisville, KY, ¹⁷Boston Children's Hosp., Boston, MA, ¹⁸Univ Nevada Sch Med, Las Vegas, NV, ¹⁹Univ Toronto, Toronto, ON, Canada, ²⁰NIH, Bethesda, MD

Abstract Body:

Introduction: Supravalvar aortic stenosis (SVAS), a narrowing of the aorta above the aortic valve, is a characteristic feature of Williams-Beuren syndrome (WBS). SVAS is present in 67% of those with WBS, but severity varies; 21% have SVAS requiring surgical intervention while 46% have milder SVAS and 33% have no SVAS. Finding genetic modifiers contributing to SVAS severity in WBS has been elusive since 1993 when hemizyosity of the ELN locus at 7q11.23 was recognized as the major driver of vascular pathology in WBS.

Methods: We collaboratively phenotyped 473 individuals with WBS and performed the largest whole genome sequencing (WGS) study to date for this condition. Most of statistical packages developed for genome-wide association study (GWAS) require thousands of cases and controls, which is unattainable for most rare disease studies, including WBS. Accordingly, we developed a set of strategies for identifying pathway-level modifiers using WGS data. The strategies start with extreme phenotyping (surgical SVAS vs. no SVAS) and pre-selection of non-synonymous variants with increased predicted functional impact (mild or high CADD score) and an allele frequency (AF) difference between the extreme phenotype groups (5% for common variants and present in at least 1% of one extreme phenotype and 0% in the other extreme for the less frequent variants). These filtered variants account for 1-2% of the total variants. We then identified pathways enriched in common or less frequent variants using the separate allele frequency filters, followed by association testing of SVAS severity with the enriched pathways. We also compared the genes in associated pathways in our analysis to the genes detected from large GWAS studies on aortic related traits/diseases.

Results: The common variant analysis identified key pathways including the extracellular matrix and the innate immune system, while pathways encompassing adaptive immunity, ciliary function, lipid metabolism and PI3KAKT were captured by both the common and less frequent variant analyses. Cell cycle and estrogen responsive pathways were among those identified through the less frequent variant analysis. Eleven genes implicated by this study, including PCSK9 and ILR6, were previously identified in large GWAS assessing aortic traits, suggesting overlapping disease mechanisms. The set of novel strategies presented here were useful for the identification of disease modifiers in WBS and can also be applied to other rare conditions using WGS data.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3539. Pathway analysis using expression factors reveals biological processes underlying genetics of complex traits

Authors:

X. Sun, X. He; The Univ. of Chicago, Chicago, IL

Abstract Body:

GWAS have mapped a large number of loci associated with common human traits. To translate these associations into biological insights, one strategy is to analyze GWAS data of a trait across the genome to identify important gene pathways. The pathway analysis is usually based on enrichment of association signals near genes of a certain pathway. It is often unclear, though, whether the enriched pathways have any causal roles in the trait. For instance, if a large number of genes in a causal pathway of a trait also appear in other pathways, then all these pathways may show enrichment of genetic signals.

We propose a new type of pathway analysis. We hypothesize that genetic variants of a trait may perturb activities of a relatively small number of “core pathways”, which affect the phenotype. This hypothesis is supported by the observations that trait-associated variants may affect expression of many related genes in trans. To map these pathways, we propose to use factor analysis on gene expression data. The factors of genes in a pathway capture correlated expression of these genes, thus can be viewed as a proxy of the pathway activity. Importantly, these factors can be treated as if they were measured data, so that one can test association of variants with these factors, and assess their roles in phenotypes.

We applied this approach to an expression QTL dataset of immune cells. We obtained expression factors of KEGG pathways, and tested association of these factors with all variants in the genome. This test was, however, under-powered. Thus we limited our analysis to variants already associated with phenotypes of interest, blood and immune traits in our case. To assess the role of a pathway in a trait, we tested if the trait-associated variants tend to be associated with the expression factor of this pathway. This analysis revealed numerous significant pathway-trait pairs.

For these pairs, we performed additional analysis to assess possible causal roles of pathways. Borrowing ideas from Mendelian Randomization, we reason that if a pathway factor has a causal effect on a phenotype, then the effect sizes of the variants on the phenotype will be correlated with the effect sizes on the factor. Using this “effect consistency test”, we found 99 pathway-trait pairs. As an example, the top pathway of Crohn’s disease, “Phosphatidylinositol signaling”, has a known role in autoimmune diseases. Interestingly, 55 (53.4%) of these pairs also show enrichment under classic pathway analysis (MAGMA), providing independent support. In conclusion, we have developed a novel approach to pathway analysis of complex human traits. The pathways we found may offer important clues of the etiology of common diseases.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3540*. Performance and accuracy of imputation panels for genetic association studies in sub-Saharan African populations

Authors:

D. Sengupta¹, G. Botha², A. Meintjes², M. Mabiavanga², S. Hazelhurst¹, N. Mulder², M. Ramsay¹, A. Choudhury¹; ¹Univ. of the Witwatersrand, Johannesburg, South Africa, ²Univ. of Cape Town, Cape Town, South Africa

Abstract Body:

Background: The quality of genotype imputation largely relies on the size and genetic proximity of a reference panel to the population for which data are being imputed. Given several fold differences in size and varying degrees of representation of populations from the African continent in the current panels, the selection of an optimal panel is a major challenge for sub-Saharan African (SSA) genome-wide association studies (GWAS).

Methods: A cohort of ~10,900 SSA participants was genotyped using the H3Africa SNP array. This dataset was imputed using five widely used reference panels hosted at the Sanger (African Genome Resource (AGR), KGP and HRC panels), TOPMed and Michigan (KGP) Imputation services and the imputation quality was assessed and compared. High-coverage (>30x) whole-genome sequence (WGS) data from 95 of the SSA samples was used as the "truth-set" to evaluate the accuracy of imputation.

Results: The comparisons show that the two best performing panels, TOPMed and AGR, are able to accurately capture over 75% of the SNPs present in these African genomes. Despite being about 20-fold smaller, AGR not only performs comparably to TOPMed in imputing SNPs (other than extremely rare SNPs, MAF<0.005) but also shows lower discordance with the WGS data (2.2±0.5% for AGR and 3.6±1.9% for TOPMed). Each panel imputed some unique content. TOPMed uniquely imputed ~18M SNPs while AGR uniquely imputed ~9.5M SNPs. Meta-imputation is emerging as an approach to further enhance the quality and quantity of imputation. Our comparisons suggest that such an approach could lead to further improvements in increasing the size of imputed dataset and reducing imputation errors. However, comparison with WGS showed that each panel imputed a considerable number of SNPs (7% for AGR and 9% for TOPMed) that were not observed in WGS, underlining the necessity for cautious scrutiny of results. We observed notable differences in imputation of datasets from three African geographic regions (East, West and South). Characterization of admixture proportions in participants further showed that a considerable portion of the variability was driven by ancestral differences. For instance, individuals with higher Khoe-San ancestry imputed significantly more SNPs than other Southern Africans.

Conclusions: Our results highlight the need for larger reference panels and inclusion of geographically and ancestrally diverse WGS data to improve the imputation of SSA genotype datasets in preparation for GWAS. We also underline the value of developing resources for harmonization and meta-imputation of datasets across platforms/services.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3541. Personality traits are consistently associated with blood mitochondrial DNA copy number estimated from genome sequences in two genetic cohort studies.

Authors:

R. Oppong¹, A. Terracciano², M. Picard³, Y. Qian⁴, T. J. Butler¹, T. Tanaka⁴, A. Z. Moore¹, E. M. Simonsick¹, K. Opsahl-Ong¹, C. Coletta¹, A. Sutin⁵, M. Gorospe¹, S. M. Resnick¹, F. Cucca⁶, S. W. Scholz⁷, B. J. Traynor⁸, D. Schlessinger⁹, L. Ferrucci¹, J. Ding⁴; ¹Natl. Inst. on Aging, Baltimore, MD, ²Dept. of Geriatrics, Florida State Univ., Tallahassee, FL, ³Dept. of Neurology, Columbia Univ., New York, NY, ⁴Natl. Inst Aging, Baltimore, MD, ⁵Florida State Univ., Tallahassee, FL, ⁶IRGB CNR, monserrato, Italy, ⁷NIH, Bethesda, MD, ⁸Natl. Inst Aging, Bethesda, MD, ⁹NIA, Baltimore, MD

Abstract Body:

Mitochondrial DNA copy number (mtDNA_{cn}) in tissues and blood can be altered in conditions like diabetes and major depression and may play a role in aging and longevity. However, little is known about the association between mtDNA_{cn} and personality traits linked to emotional states, metabolic health, and longevity. This study tests the hypothesis that blood mtDNA_{cn} is related to personality traits and mediates the association between personality and mortality. We assessed the big five personality domains and facets using the Revised NEO Personality Inventory (NEO-PI-R), assessed depressive symptoms with the Center for Epidemiologic Studies Depression Scale (CES-D), estimated mtDNA_{cn} levels from whole-genome sequencing, and tracked mortality in participants from the Baltimore Longitudinal Study of Aging (722 participants with complete data, mean age 75 (48 - 100), 48% women). Results were replicated in the SardiNIA Project (587 participants with complete data, mean age 57 (15 - 96), 62% women). We found that mtDNA_{cn} was negatively associated with the Neuroticism domain and its facets and positively associated with facets from the other four domains (Extraversion, Openness, Agreeableness, and Conscientiousness). The direction and size of the effects were replicated in the SardiNIA cohort and were robust to adjustment for potential confounders such as age, sex, platelet count, and white blood cell parameters in both samples. Consistent with the Neuroticism finding, higher depressive symptoms (CES-D) were associated with lower mtDNA_{cn}. Finally, mtDNA_{cn} mediated the association between personality and mortality risk. To our knowledge, this is the first study to show a replicable association between mtDNA_{cn} and personality. It establishes a new connection between mitochondrial biology and emotional traits and states relevant to human health. Furthermore, we found that mtDNA_{cn} mediates the association between personality and mortality risk, thereby providing the first evidentiary support for the hypothesis that mtDNA_{cn} may be a biomarker of the biological process that explains part of the association between personality and mortality.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3542. Phenome-wide Mendelian randomization study of plasma triglycerides and 2,600 disease traits.

Authors:

J. Park¹, S. Bafna¹, I. Forrest¹, A. Duffy¹, C. Marquez-Luna¹, B. Petrazzini¹, H. Vy¹, D. Jordan¹, M. Verbanck², J. Narula¹, R. S. Rosenson¹, G. Rocheleau¹, R. Do¹; ¹Icahn Sch. of Med. at Mount Sinai, New York, NY, ²Université Paris Cité, Paris, France

Abstract Body:

Background: Triglycerides (TG) play vital roles in human physiology, ranging from energy storage and mobilization to inflammation and thrombosis. However, controversy mires whether the relationship between plasma TG levels and disease risk are causal or associative in most human diseases. This topic remains contentious even in atherosclerotic cardiovascular disease (ASCVD), as reflected by the conflicting results of two recent landmark trials, STRENGTH and REDUCE-IT. Establishing causality between TGs and phenome-wide disease risk could inform drug development of the novel repurposing opportunities and adverse effects of approved and emerging TG-lowering therapies, including icosapent ethyl and *APOC3* inhibitors. Clinical trials are currently evaluating TG-lowering therapies targeting *ANGPTL3*, *ANGPTL4* and *APOC3* for dyslipidemias.

Methods: We conducted a phenome-wide, two-sample Mendelian randomization (MR) analysis using an inverse-variance weighted (IVW) estimator to infer the causal effects of plasma TG levels on 2,600 disease traits in the European ancestry population of UK Biobank. We then externally tested 221 nominally significant associations ($p < 0.05$) for replication in an independent population from FinnGen. To account for potential horizontal pleiotropy and the influence of invalid instrumental variables, we performed sensitivity analyses using MR-Egger, weighted median, and MR-PRESSO methods. Finally, we applied multivariable MR controlling for correlated lipid fractions to isolate the independent effects of plasma TG levels.

Results: Our results identified 7 disease traits reaching Bonferroni-corrected significance in both the discovery ($p < 1.92 \times 10^{-5}$) and replication analyses ($p < 2.26 \times 10^{-4}$), supporting a causal relationship between plasma TG levels and ASCVDs, including coronary artery disease (OR 1.33, 95% CI 1.24-1.43, $p = 2.47 \times 10^{-13}$). We also identified 12 disease traits that were Bonferroni-significant in the discovery or replication analysis and at least nominally significant in the other analysis ($p < 0.05$), identifying plasma TG levels as a novel risk factor for 9 non-ASCVD disease traits, including uterine leiomyoma (OR 1.19, 95% CI 1.10-1.29, $p = 1.17 \times 10^{-5}$).

Conclusion: Using a phenome-wide Mendelian randomization approach, we identified 19 disease traits with positive causal associations with plasma TG levels, many of which are outside the context of cardiovascular disease. This suggests rationale for repurposing approved and emerging TG-lowering agents toward novel indications or reveals their adverse side effects.

PB3543. Phenotype integration improves power and preserves specificity in biobank-based genetic studies of MDD.

Authors:

A. Dahl¹, M. THOMPSON², U. An³, K-L. Georgii Hellberg⁴, L. Huang⁵, R. Border⁶, A. Pazokitoroudi⁷, M. Krebs⁴, V. Appadurai⁴, S-A. Bacanu⁸, T. Werge⁴, A. Schork⁹, J. Flint², K. Kendler⁸, S. Sankararaman³, N. Cai¹⁰; ¹Univ. of Chicago, Chicago, IL, ²Univ. of California, Los Angeles, Los Angeles, CA, ³UCLA, Los Angeles, CA, ⁴Inst. of Biological Psychiatry, Copenhagen, Denmark, ⁵Helmholtz Pioneer Campus, Munich, Germany, ⁶Univ. of California Los Angeles, Los Angeles, CA, ⁷UCLA, LA, CA, ⁸Virginia Commonwealth Univ, Richmond, VA, ⁹Inst. for Biological Psychiatry, Copenhagen, Denmark, ¹⁰Helmholtz Zentrum München, Neuherberg, Germany

Abstract Body:

Biobanks play an increasing role in human genetics because their large size substantially increases power to detect genetic associations. Biobanks often contain several phenotypes relevant to a given disorder, and researchers face complex trade-offs between shallow phenotypes (high sample size, low specificity) and deep phenotypes (low sample size, high specificity). Here, we focus on an extreme case: Major Depressive Disorder (MDD) in UK Biobank. Previous studies found that shallow and deep MDD phenotypes have qualitatively distinct genetic architectures, but it remains unclear which are optimal for scientific study or clinical prediction. We propose a new framework to get the best of both worlds by integrating information across MDD-relevant measures phenome-wide. First, we use phenotype imputation to increase sample size for deep MDD phenotypes, which dramatically improves GWAS power (increases #loci ~10 fold) and PRS accuracy (increases R² ~2 fold). Further, we find that the genetic architecture of the imputed deep MDD phenotypes remains highly specific to MDD by (1) validating our results using data from PGC, iPSYCH, and ATLAS and (2) leveraging recent and novel measures of pleiotropy based on GWAS summary statistics or PRS. We also develop a reciprocal approach to improve MDD-specificity of GWAS on shallow MDD phenotypes by adjusting for phenome-wide PCs. Finally, we study phenotype integration at the level of GWAS summary statistics, which improves GWAS and PRS power but introduces non-MDD-specific signals. Our work provides a simple and scalable recipe to improve genetic studies in biobanks by combining the large sample size of shallow phenotypes with the power and specificity of deep phenotypes, which addresses a crucial barrier to characterizing the etiology of heterogenous complex disorders.

PB3544. Phenotypic and genetic relationships between physical activity, sleep, and brain health.

Authors:

Y. Guo, B. Zhao, P. Paschou; Purdue Univ., West Lafayette, IN

Abstract Body:

Lifestyle choices are associated with brain structure, function, and health. Physical activity and sleep, two essential aspects of lifestyle, can be easily intervened and have been under clinical practice to prevent the incident or slow the progression of various brain dysfunctions. In addition, changes in brain correlates of mental health can potentially affect sleep regularity, willingness to physical activity, and physical performance. Using multiple data types from the UK Biobank, we aim to examine the phenotypic and genetic relationships between sleep, physical activity, and brain health. We expect to identify brain regions and networks that are strongly associated with the variation in physical activity and sleeping habits. We also seek to quantify possible genetic correlation and causality between physical activity, sleep, and brain health. In general, we hope this study can contribute to the current knowledge of the genetic architecture and biological networks involved in the beneficial effects of developing physically active and balanced lifestyle behaviors on brain health.

PB3545*. Phenotypic subtyping via contrastive learning reveals heterogeneity in the genetic architecture of traits.

Authors:

A. Gorla¹, J. Mefford², V. Ravi³, Y. Di^{4,5}, J. Wang³, T. Zhu^{4,5}, A. Alwan³, E. Halperin^{6,7,8,9}, J. Flint¹⁰, N. Zaitlen¹¹, E. Rahmani¹²; ¹Bioinformatics InterDept.al Program, Univ. of California, Los Angeles, Los Angeles, CA, ²Dept. of Neurology, Univ. of California, Los Angeles, Los Angeles, CA, ³Dept. of Electrical and Computer Engineering, Univ. of California, Los Angeles, Los Angeles, CA, ⁴CAS Key Lab. of Behavioral Sci., Inst. of Psychology, Beijing, China, ⁵Dept. of Psychology, Univ. of Chinese Academy of Sci., Beijing, China, ⁶Dept. of Computer Sci., Univ. of California, Los Angeles, Los Angeles, CA, ⁷Dept. of Computational Med., Univ. of California, Los Angeles, Los Angeles, CA, ⁸Dept. of Anesthesiology and Perioperative Med., David Geffen Sch. of Med. at UCLA, Los Angeles, CA, ⁹Dept. of Human Genetics, Univ. of California, Los Angeles, Los Angeles, CA, ¹⁰Dept. of Psychiatry and Biobehavioral Sci., Brain Res. Inst., Univ. of California, Los Angeles, Los Angeles, CA, ¹¹Ctr. for Neurobehavioral Genetics, Semel Inst. for NeuroSci. and Human Behavior, Univ. of California, Los Angeles, Los Angeles, CA, ¹²Dept. of Electrical Engineering and Computer Sci., Univ. of California, Berkeley, Berkeley, CA

Abstract Body:

BACKGROUND: Unmodeled phenotypic heterogeneity reduces statistical power and reproducibility in GWAS, and it has been posited as a possible explanation for small observed effect sizes. Existing phenotype subtyping methods primarily rely on clinically observed heterogeneity or metadata clustering. However, these approaches are typically unsuccessful in mapping phenotypic variation to heterogeneity in the genetic basis of traits.

OBJECTIVE: We aimed to develop a method to define *de novo* phenotypic subtypes that are more likely to reveal genetic heterogeneity.

METHOD: We introduce Phenotype Aware Component Analysis (PACA), a novel model-based contrastive learning algorithm. Given case-control data of any modality that may harbor meaningful sub-phenotypic signals, PACA learns a gradient of variation unique to cases, while accounting for variation and imbalances of biological/technical confounders between cases and controls.

RESULTS: We compared PACA to several commonly used dimensionality reduction and contrastive learning algorithms. To do so, we pooled individuals with different traits from the UK Biobank and evaluated the methods in discriminating the presence of subtypes. We found that PACA is the only method that is both well-powered to capture phenotypic heterogeneity and calibrated in reporting no heterogeneity under the null. We then verified that PACA can be applied to data modalities other than genetics. Using the PsychENCODE data (N=1,321), we grouped transcriptomes from bipolar (BP) and schizophrenia (SZ) cases. PACA, which was blind to the BP/SZ labels, isolated a gradient that differentiates BP from SZ ($r=0.3$, $p=2.7e-14$) and reflects heterogeneity in the genetic architecture ($p=1.4e-6$, Subtest). Finally, we used PACA to define subtypes for traits in which heterogeneity is suspected but has not so far been demonstrated. Applying PACA to voice recordings of women with recurrent major depressive disorder (MDD; N=6,142) we identified two MDD subtypes. A regression analysis, conditioned on 10 genetic principal components, geographic location and age, demonstrated that the variation between the putative subtypes is associated with psychiatric illness and handedness. A follow up GWAS on one of the subtypes revealed an association with rs1430259 ($p=4.5e-07$), an intronic variant in *CNTNAP5*; importantly, neither this variant ($p=0.66$) nor any other was revealed in a standard case/control GWAS of MDD.

CONCLUSION: PACA is a calibrated and well-powered modality-agnostic method for learning sub-phenotypic variation that reflects genetic heterogeneity.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3546. PheWAS-based clustering of Mendelian Randomization instruments reveals distinct mechanism-specific causal effects between obesity and educational attainment.

Authors:

L. Darrous^{1,2}, Z. Kutalik^{1,2,3}; ¹Univ. Ctr. for Primary Care and Publ. Hlth., Lausanne, Switzerland, ²Swiss Inst. of Bioinformatics, Lausanne, Switzerland, ³Dept. of Computational Biology - Univ. of Lausanne, Lausanne, Switzerland

Abstract Body:

Motivation:

Mendelian Randomization (MR) is a statistical method that estimates the causal effect between risk factors and common complex diseases using genetic variants as instruments. It has several assumptions, some of which are prone to violation when the genetic variants are pleiotropic. For example, within-sibling MR analysis reveals a small negative causal effect estimate between body mass index (BMI) and educational attainment (EDU) (-0.05 [95% CI: $-0.09, -0.01$]), however, MR analysis based on GWAS of unrelated samples yields a substantially larger estimate (-0.19 [$-0.22, -0.16$]) possibly due to confounding and pleiotropy.

Methods:

We investigated pleiotropic effects of the BMI-associated instruments across 407 traits in the UK Biobank and grouped these SNPs using K-means clustering based on their association profile. We then used MR to estimate the cluster-specific causal effects of BMI on EDU. Enrichment analysis enabled meaningful labelling of the obtained clusters. As a complementary approach, we also systematically scanned the 407 traits for potential confounders and mediators (via bi-directional MR) and included them in a stepwise multivariable MR (MVMR) to obtain the multivariable causal effect of BMI on EDU.

Results:

The clustering of 322 BMI-associated genetic instruments yielded six groups with distinct causal effect estimates on EDU. Notably, a cluster strongly enriched for socio-economic status (SES)-related traits (job type, time spent outdoors) yielded the largest BMI-on-EDU causal effect estimate (-0.48 [$-0.55, -0.41$]) whereas the cluster enriched for largest impact on lean-mass had the smallest estimate (-0.09 [$-0.13, -0.05$]), agreeing with within-sibling MR results. Repeating the analysis using a proxy trait for childhood BMI revealed four clusters with homogenous near-null causal effects on EDU. Reassuringly, none of these clusters were enriched for SES traits. Our follow-up analysis uncovered 19 potential confounder traits (including time spent watching television and past tobacco smoking). Four of these traits survived in the stepwise MVMR, massively attenuating the causal effect estimate of BMI on EDU (from -0.19 to -0.01).

Conclusion:

Well-powered GWAS studies have not only revealed wide-spread pleiotropy, leading to biased MR estimates, but also enabled us to identify and annotate subsets of exposure instruments with similar functions. Using our approach (of instrument clustering and MVMR with systematic confounder search), we have uncovered distinct causal effects and the presence of confounders of the BMI-educational attainment relationship.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3547. PLEIOVAR - Assessing Pleiotropic Effects of SNPs on Traits in Genome-wide Association Studies.

Authors:

O. Meirelles, L. Launer, D. Li, K. Tsai, D. Schlessinger; Natl. Inst. on Aging, Baltimore, MD

Abstract Body:

Genome-Wide Association Studies (GWAS) explore associations between individual DNA variants, usually single nucleotide polymorphism (SNPs), and a trait. Analyses have recently been extended to assess association between multiple SNPs and a trait, or between a single SNP and multiple traits. With “PLEIOVAR”, we add analyses for pleiotropic effects between groups of SNPs, defined for each gene region, and multiple traits. Using principal component analysis (PCA) of multiple SNPs vs. multiple traits, associations are assessed by a summary statistic for each gene, and its significance efficiently evaluated by the chi-squared distribution. We applied the program to analyses of levels of lipids -- LDL, HDL and triglycerides (TG) -- in 6,289 participants in the SardiNIA population study and replicated the results for the lipid traits in the Coronary Artery Risk Development in Young Adults (CARDIA) study (2,726 individuals) and the InCHIANTI cohort (1,151 individuals). Computational speed is fast, taking under 5 minutes on a single CPU to run SardiNIA on the three lipid traits and on 22,397 genes. After meta-analysis of all cohorts, PLEIOVAR identified a total of 40 significant gene associations, with 23 previously reported by GWAS (14 of them pleiotropic) and 13 candidate novel gene associations, mostly involving lipid metabolism and cardiovascular disease. Finally, we used our method as a novel way to score gene networks from Gene Ontology (GO) to effectively detect pleiotropic enriched gene networks, generating association scores more significant than GO and other gene network databases, which like GO, also base their p-values on Fisher’s exact test.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3548*. Polygenic prediction across populations is influenced by ancestry, genetic architecture, and methodology

Authors:

Y. Wang^{1,2}, M. Kanai^{2,1,3,4}, T. Tan⁵, M. Kamariza³, K. Tsuo^{3,1,2}, K. Yuan^{1,2}, W. Zhou^{1,2}, Y. Okada^{4,6}, the BioBank Japan Project, H. Huang^{1,2}, P. Turley⁷, E. Atkinson⁵, A. Martin^{1,2}; ¹Massachusetts Gen. Hosp., Boston, MA, ²Broad Inst. of MIT and Harvard, Cambridge, MA, ³Harvard Univ., Cambridge, MA, ⁴Osaka Univ., Suita, Japan, ⁵Baylor Coll. of Med., Houston, TX, ⁶RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, ⁷Univ. of Southern California, Los Angeles, CA

Abstract Body:

With large-scale efforts underway to increase diversity in genomics research, there is an urgent need to understand how best to leverage such resources to reduce gaps in polygenic risk score (PRS) performance between ancestries. However, few studies have comprehensively investigated how various factors, such as the ancestry composition and trait genetic architecture, affect the generalizability of PRS built from multi-ancestry GWAS (PRS_M). In this study, we analyze large-scale simulated and empirical data to investigate this issue.

Specifically, we simulated 560K individuals from European (EUR), East Asian (EAS), and African (AFR) ancestry, respectively. We used 365K EUR and 155K EAS from UK Biobank (UKBB) and Biobank Japan (BBJ) for real data analyses, including anthropometric and blood-panel traits. We constructed single-ancestry PRS (PRS_S) using GWAS with varying numbers of individuals from each ancestry and PRS_M using meta-analyzed EUR and EAS or AFR GWAS with various ancestry compositions. We also constructed local ancestry-based PRS using GWAS from the Tractor method on 4K African American from UKBB to utilize resources from recently admixed populations. PRS was initially built using P+T and evaluated in understudied non-EUR populations using partial R^2 relative to covariates only.

Using simulated data, we find that PRS_M including individuals of the target ancestry, outperform PRS_S. Notably, such accuracy gain is saturated at a lower proportion of target ancestry for less polygenic traits compared to more polygenic traits. We observe similar findings using real data. First, we find that using substantially smaller sample sizes (20%-80% fewer) in BBJ can achieve comparable accuracy to 320K EUR in UKBB. Second, we observe a significant improvement of average accuracy across traits of PRS_M over PRS_S using GWAS from EUR (0.027 vs. 0.021) and EAS (0.026 vs. 0.016), respectively. We note that such improvement is not always seen (~14% comparisons) especially when EAS only accounts for a relatively small proportion in the multi-ancestry GWAS. Finally, we find that local ancestry-based PRS can improve performance compared to using large-scale EUR-based PRS (0.025 vs. 0.010) especially for less polygenic traits when there are variants with large ancestry-specific effects.

Overall, our study provides insights into how ancestry composition and genetic architecture impact polygenic prediction across populations. With the benefits of leveraging understudied populations when constructing PRS using different strategies, we highlight the necessity of increasing genetic diversity to close the gap and achieve equitable use of PRS across ancestries.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3549. Polygenic risk scores for coronary heart disease in diverse populations using population-specific optimization.

Authors:

J. Smith¹, C. Tcheandjieu², O. Dikilitas¹, S. Clarke³, A. T. Hilliard⁴, S. Koyama⁵, K. M. Lee⁶, J. Lynch⁷, K. Ito⁸, K-M. Chang⁹, S. Kanoni¹⁰, P. Tsao¹¹, M. Kosel¹, D. Schaid¹, T. Assimes¹², I. Kullo¹; ¹Mayo Clinic, Rochester, MN, ²Gladstone Inst.s, San Francisco, CA, ³Stanford University, Stanford, CA, ⁴VA Palo Alto Hlth.care System, Palo Alto, CA, ⁵Broad Inst., Cambridge, MA, ⁶U.S. Dept. of VA, Bedford, MA, ⁷Salt Lake City VA Med. Ctr., Salt Lake City, UT, ⁸RIKEN Ctr. for Integrative Med. Sci., Yokohama City, Japan, ⁹Corporal Michael J Crescenz VA Med. Ctr., Philadelphia, PA, ¹⁰Queen Mary Univ. of London, Cambridge, United Kingdom, ¹¹VA Palo Alto Hlth.Care System/Stanford Univ., Palo Alto, CA, ¹²Stanford Univ Sch Med., Palo Alto, CA

Abstract Body:

Introduction: The performance of polygenic risk scores (PRSs) for coronary heart disease (CHD) varies across populations with the lowest performance observed among African (AFR) ancestry individuals. **Methods:** To improve CHD PRS performance across diverse populations, we used pruning and thresholding (P+T) to construct population specific as well as multi-population PRSs from GWAS summary statistics of European (EUR), African (AFR), Hispanic (HIS) and East Asian (EAS) populations including nearly a quarter of a million cases of CHD from the Million Veterans Program (MVP), the UK Biobank, Cardiogram+C4D, and Biobank Japan. The PRSs were tested and validated within each population using independent samples from the Million Veterans Program (MVP), the electronic Medical Records and Genomics (eMERGE) Network, and several NHLBI cohorts with data available through dbGaP. PRS performance was assessed using logistic regression analyses adjusted for age, sex, and principal components. The best performing PRS for each population was identified based on the point estimate of the highest OR observed per standard deviation (SD) increase in the PRS. These ORs were compared to the ORs obtained with the prior best performing PRS in Europeans (metaGRS). We also compared the predictive ability of P+T PRS with a multi-population PRS using a continuous shrinkage method implemented in PRS-CSx. **Results:** Population-specific P+T PRSs outperformed the metaGRS and the multi-population PRS with ORs (95% CI) of 1.24 (1.16-1.33) for AFR, 1.35 (1.31-1.40) for EUR, and 1.49 (1.27-1.40) for HIS populations in the MVP. However, confidence intervals of the multi-population P&T PRS and the population specific PRS had substantial overlap. Additional validation in multiple independent cohorts involving all populations combined, EUR, AFR, HIS, EAS, and South Asian (SAS) populations resulted in ORs (95% CI) per SD of 1.43 (1.40-1.47), 1.60 (1.55-1.66), 1.18 (1.13-1.22), 1.39 (1.25-1.54), 1.69 (1.61-1.76), and 2.75 (2.41-3.14), respectively. The analysis using the single multi-population PRS-CSx for CHD was also validated in AFR, EUR, and HIS populations with ORs (95% CI) of 1.20 (1.14-1.27), 1.41 (1.37-1.44), and 1.54 (1.35-1.75). **Conclusions:** Our population-specific CHD PRS outperformed metaGRS for AFR individuals, but the gap in predictive performance compared to EUR remains. Our work highlights the need for more diverse population representation at each stage of PRS development.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3550. Polygenic scores enable discovery of widespread genetic interactions associated with quantitative traits in the UK Biobank.

Authors:

L. Ferreira¹, S. Hu², S. Myers¹; ¹Univ. of Oxford, Oxford, United Kingdom, ²Novo Nordisk Ltd., West Sussex, United Kingdom

Abstract Body:

Although a huge number of human genetic associations have been discovered, genetic predictions overwhelmingly use additive polygenic scores (PGS) which ignore interactions between loci. Such interactions are expected based on evidence from model organisms but human examples are limited, with the vast number of potential interactions hampering discovery power.

We developed an approach to overcome this lack of power by testing for interactions between a SNP and *groups* of other variants, such as those in the PGS, and applied this to quantitative traits in the UK Biobank. We are motivated by functional networks, where a SNP altering behaviour of one gene can have downstream effects on many others. Our approach is robust to false positives due to nonlinear additive effects or locally clustered associations and is initialised by iteratively building a PGS accounting for all linear associations.

We find many distinct interaction signals: 148 loci interacting with the PGS for 53 traits. These include variants driving pathogenesis for diverse diseases at genes including *APOE*, *FTO*, *G6PC2*, *HFE*, *HLA-G*, *IL33*, *LDLR*, *PNPLA3*, *PRDM1*, *SHGB*, *TCF7L2* and *UBD*. As well as their well-studied direct impacts, our analysis therefore reveals that these SNPs also modify effects at other loci. Strikingly, some SNPs show no direct association with a trait but instead alter the predictive power of its PGS.

We developed a test to identify, at each variant interacting with the PGS, the subset of SNPs driving that interaction, revealing networks of interacting loci. This identified a known interaction between an *ABO* variant and a *FUT2* stop-gain mutation impacting alkaline phosphatase, and novel mutations involved in this interaction at *FUT6*, *TREH*, *PIGC*, *ASGR2* and *ZNF678*. A second highlight is an interaction between a variant upstream of *IL33* and a missense variant in *ALOX15* affecting eosinophil count. This may shed light on the aetiology of asthma: a recent study in mice found a role for *ALOX15* in reducing *IL33*-induced airway eosinophilic inflammation. Finally, we see interactions involving distinct traits (LPA and alanine aminotransferase) and distinct coding mutations at *APOE* that drive strongly reduced, and increased, Alzheimer's disease risk, respectively, and are interesting given recent suggestions of a link between Alzheimer's and liver function.

Our results challenge the paradigm of simply adding effect sizes across mutations and provide examples of functionally connected variants for many traits. They offer potential to improve PGS performance using non-linear terms and their cross-population transferability by identifying determinants of performance variability.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3551. Polygenic scores for insulin resistance are associated with brain volumes in the NHLBI Trans-Omics for Precision Medicine (TOPMed) Program.

Hosp., Boston, MA, ¹⁰Harvard Pilgrim Hlth.Care Inst., Boston, MA, ¹¹Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ¹²Boston Children's Hosp., Harvard Med. Sch., Boston, MA, ¹³Univ. of Texas Rio Grande Valley Sch. of Med., Brownsville, TX, ¹⁴Univ. of Kentucky, Lexington, KY, ¹⁵Univ. of Massachusetts Med. Sch., Worcester, MA, ¹⁶Lundquist Inst., Harbor-UCLA Med. Ctr., Torrance, CA, ¹⁷Univ. of Virginia, Charlottesville, VA

Abstract Body:

Background: Insulin resistance (IR) is a major risk factor for Alzheimer's Disease (AD) and has been associated with cognitive impairment, dementia, and neurodegeneration. Though the association between IR and AD has been explored genetically, the proportion of variance explained (PVE) by the IR genetic instruments has been limited, due to few genetic loci identified in genome-wide association studies (GWAS) of IR. **Methods:** We constructed polygenic scores (PSs) for fasting insulin (FI) based on the Trans-Omics for Precision Medicine (TOPMed) Freeze 9 whole-genome sequencing (WGS) data. We used PRS-CSx (Ruan *et al.*, *Nat Genet.* 2022) to generate ancestry-specific PSs (European, African, and Hispanic/Latino), with weights derived based on ancestry-specific UK Biobank reference panels and FI GWAS summary statistics adjusted for body mass index (BMI) (Chen *et al.*, *Nat Genet.*, 2021). We used MetaSubtract (Nolte *et al.*, *Eur J Hum Genet.* 2017) to remove the effect of TOPMed studies from the FI meta-analyses. We generated a multi-ancestry PS_{FI} by fitting a linear combination of the standardized ancestry-specific PSs that most accurately predicted HOMA-IR in five TOPMed cohorts (validation set, N~17k participants [34% European, 28% African, 38% Hispanic] without diabetes), adjusting for BMI. We then evaluated the association of the multi-ancestry PS_{FI} with HOMA-IR, AD, dementia, general cognitive function, and four brain volumes in eight TOPMed cohorts (testing set, ~14k participants [66% European, 22% African, 11% Hispanic]). Association analyses were performed using logistic or linear mixed-effect models adjusted for age, sex, study, 11 genetic principal components, and accounting for relatedness using a genetic relationship matrix. General cognitive function and brain volumes analyses were additionally adjusted for education and intracranial volume (ICV) respectively. We used a threshold of $P < 0.05 / N_{\text{traits}} / N_{\text{tests}} = 0.05 / 7 / 4 = 0.002$ to define an association as significant. **Results:** The multi-ancestry PS_{FI} was strongly associated with HOMA-IR (PVE_{Joint}=12%). No significant or suggestive association was detected for the multi-ancestry, the African, or the Hispanic PS_{FI} with any of the neurological outcomes. The European PS_{FI} was significantly associated with ICV ($P=7E-07$), and suggestively associated with lateral ventricular ($P=0.004$) and total brain volumes ($P=0.05$). **Conclusion:** By leveraging multi-ancestry and WGS data, we increased the PVE of the genetic instruments for IR and

ASHG 2022 Annual Meeting Poster Abstracts

confirmed the association of IR with brain volumes. The identified European-specific associations require further investigation. **Funding:** NIH K99AG066849-02

Kyung Im³; ¹University of California San Diego, La Jolla, CA, ²Vanderbilt Univ. Med. Ctr., Nashville, TN, ³Univ. of Chicago, Chicago, IL, ⁴Univ. of California San Diego, La Jolla, CA, ⁵Scripps Res. and UC San Diego, San Diego, CA, ⁶Univ. of California, San Diego, San Diego, CA, ⁷Univ. at Buffalo, Buffalo, NY, ⁸Med. Coll. of Wisconsin, Milwaukee, WI, ⁹Univ. of Michigan, Ann Arbor, MI, ¹⁰Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN, ¹¹Washington Univ. Sch. of Med., St. Louis, MO, ¹²Univ. of California Davis, Davis, CA, ¹³Univ. of Colorado, Aurora, CO, ¹⁴Wake Forest Univ., Winston-Salem, NC

Abstract Body:

Genome-wide association studies have demonstrated that most traits are highly polygenic; however, translating these polygenic signals into biological insights remains difficult. A lack of satisfactory methods for translating polygenic results across species has precluded the use of model organisms to address this problem. Here we explore the use of polygenic transcriptomic risk scores (PTRS) for translating polygenic results across species. Unlike polygenic risk scores (PRS), which rely on SNPs, PTRS use imputed gene expression for prediction, which allows cross-species translation to orthologous genes. We first developed RatXcan, which is a framework for transcriptome-wide association studies (TWAS) in outbred rats. Leveraging predicted transcriptome and genotype data from UK Biobank, and the genetically trained gene expression models from RatXcan, we scored more than 3,000 rats using human-derived PTRS for height and BMI. Strikingly, we found that these human-derived PTRS significantly predicted analogous traits in rats ($r = 0.08$, $P = 8.57 \times 10^{-6}$; $r = 0.06$, $P = 8.51 \times 10^{-4}$, respectively). The genes included in the PTRS were enriched for biological pathways including skeletal growth and metabolism and were over-represented in tissues including pancreas and brain. This approach facilitates experimental studies in model organisms that examine the polygenic basis of human complex traits and provides an empirical metric by which to evaluate the suitability of specific animal models and identify their shared biological underpinnings.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3553. PopMLvis: A Tool for Analysis and Visualization of Population Structure in Genome-Wide Association Studies

Authors:

M. Elshrif¹, K. Isufaj¹, K. Kunji¹, M. Saad²; ¹Qatar Computing Res. Inst. - Hamad Bin Khalifa Univ., Doha, Qatar, ²Qatar Computing Res. Inst., HBKU Research Complex, QCRI, Qatar

Abstract Body:

Background: Population genetics aims to analyze genetic differences within and among groups of individuals. These analyses are carried out using a variety of algorithms that assign an individual to a given population group based on its genetic background. Although there are several tools that perform population genetic analysis, there is a lack of a framework that allow an interactive visualization of several clustering and multi-dimension reduction tools such as Principal Component Analysis (PCA), t-Distributed Stochastic Neighbor Embedding (t-SNE), Admixture, PC-air, and K-means.

Methods: We propose *PopMLvis*, a user-friendly platform that offers a complete environment to interactively visualize population structure analysis of Genome-Wide Association Studies (GWAS) data. In particular, *PopMLvis* allows users to visualize their PCA and Admixture data combined, make interactive cluster inference, and outlier detection (e.g., Isolation Forest, Local Outlier Factor, and OneClassSVM). It also allows running a PCA that accounts for genetic relatedness between individuals (PC-air). *PopMLvis* supports dimensionality reduction (PCA and t-SNE), fuzzy C-means, and hierarchal clustering, as well as outlier detection algorithms. Figures and text files can be downloaded with all exploratory results and clustering inference with great flexibility. *PopMLvis* was mainly written in Python with the addition of the R package PC-air.

Availability: *PopMLvis* is freely available and can be accessed online from any web browser at <https://popmlvis.qcri.org>. In addition, for data privacy issues, the source code of *PopMLvis* can be downloaded and installed from GitHub, where a standalone version can run on user laptops or servers.

PB3554. Population diversity in global reference genome cohorts

Authors:

V. Skrahina¹, G. Oprea¹, N. Ameziane¹, H. Cheema², A. Rolfs^{1,3}; ¹Arcensus, Rostock, Germany, ²Childrens' Hosp., Lahore, Pakistan, ³Univ. of Rostock, Rostock, Germany

Abstract Body:

Whole Genome Sequencing (WGS) is the most comprehensive genetic test available with the highest diagnostic yield. The major diagnostic challenge is the “uniformity” of the currently used human genome reference (hg38), being mainly Caucasian- based, the genomic diversity is restricted to the European population (>85%).

To increase the diagnostic yield, we have gathered under-represented genomic and clinical datasets, especially originating from consanguineous families. We have analysed more than 1200 Pakistani (71%), Albanian (10%) and Saudi Arabian (19%) probands by WGS. In both cohorts, at least 93% of the patients are younger than 18 years and the most predominant symptom are neurodevelopmental delay, seizures, and intellectual disability.

A high diagnostic rate (pathogenic and/or likely pathogenic variants) was achieved for the Pakistani (78%), Saudi Arabia (66%) and Albanian cohort (65%), with the following percentage of autosomal recessive disorders 85%, 56% and 26%, respectively. The most frequently diagnosed diseases are metabolic disorders (14%), intellectual neurodevelopment disorders (9%) and epileptic encephalopathy (6%). The remaining disorders are representing a highly diverse group of more than 450 different diseases. Importantly, for most frequent diseases (affected genes: *BTD*, *GALT*, *ATP7B*, *CDKL5*, *NAGLU*) causative treatments exist. 4-10% of all patients from these ethnicities are suffering from two or more monogenic disorders.

Studying consanguineous cohorts speeds up the identification and characterization of novel genes, indicating clinically relevant or irrelevant genomic regions, and contribute simultaneously to the global genome reference setup by including genomic diversity. Interestingly, for our cohorts more than 20% of the clinical genome is represented by novel variants (not described elsewhere), of which 4.9% predicted to impact protein function. 80% of variants that impact protein structure are frequent in our Pakistani and Saudi-Arabia population and classified therefore as benign or likely benign. Without this valuable information, these patients would have been misdiagnosed.

The application of WGS as a routine first-line molecular diagnostic approach has a significant impact on clinical management of patients and if treatment is not available, the inclusion of such patients in ongoing clinical trials, will speed drug development. Understanding the global human genome diversity leads to increased knowledge about the genetic variants causing diverse phenotypes and those being part of the global “variome”.

PB3555*. Power Window: a power-based sliding window method to identify the rare and novel variants underlying gene-based association signals

Authors:

A. Bolze¹, K. Barrett¹, J. Grzymalski², W. Lee¹, N. Washington¹, E. Cirulli¹; ¹Helix, San Mateo, CA, ²DRI, Reno, NV

Abstract Body:

Systematic determination of which rare genetic variants are pathogenic for a given phenotype remains a major challenge, even when there is an established association between the phenotype and rare variants in the gene. We have developed Power Window, a novel technique to identify the regions of the gene where rare variants are statistically significantly associated with a trait using population-scale clinico-genomic datasets. Power Window is a sliding window technique for rare variants that slides not by the number of variants or the number of nucleotides, but rather by the number of variant carriers—and thus the statistical power. The method can be used to focus on specific types of variants, such as loss of function (LoF) or coding, or specific parts of the gene, such as those expressed in different tissues. It can also identify regions within a gene that have opposite directions of effect on a phenotype.

We use Power Window to build regional LoF and coding models for well-established gene-level disease associations in a training set of 300k exomes from the UKBiobank (UKB). We then test our models in two additional cohorts: an unrelated set of 128k exomes from the UKB and 30k exomes from the Healthy Nevada Project (HNP). Importantly, the variants tested in these replication datasets include novel variants that were not observed in the training set, but that occur in the same set of regions implicated in the training set. We find that 99% of these models show the same direction of effect in the test set, and 57% demonstrate statistically significant replication. The significant models retain a mean of 54% of the variant carriers in the gene (range 2-98%) and often drive a dramatic improvement in the effect size, especially for coding variants: 50% of the significant coding models for quantitative traits saw their effect size improve by at least 40% over the effect size observed when rare variants were aggregated across the whole gene; for binary traits, 50% of the significant coding models more than doubled the associated odds ratio. Power Window showcases that even in the absence of family data or functional tests, in some cases computational predictions alone can determine, with high accuracy, which novel coding variants will have high penetrance in a population, unlocking new potential for population genetic screening.

PB3556. Practical screening for differences in predictive value of polygenic scores across the phenotypic range

Authors:

J. Mefford¹, M. Smullen², F. Zhang¹, R. Border¹, A. Dahl³, N. Zaitlen¹; ¹Univ. of California Los Angeles, Los Angeles, CA, ²UMass, Worcester, MA, ³Univ. of Chicago, Chicago, IL

Abstract Body:

Polygenic scores (PGS) show promise as tools for basic and translational science. Genetic risk predictions for heritable diseases may finally bring knowledge gained from large genetic association studies to the clinic with personalized disease screening and care management. PGS have also been used as instruments in social science to help identify causal connections between biological or social factors and outcomes such as educational attainment.

An underlying assumption of applications of PGS is the uniformity of predictive accuracy across the phenotypic range. We demonstrate with simulations and analytic derivations how G×E and G×G affect PGS predictive value. For example, we know that height is quite heritable, and we can make PGS that are well correlated with height. However, if a portion of a target population faces food insecurity, the severity of under-nutrition may strongly affect height and limit PGS predictability - particularly in the low end of the height range. PGS with such variable predictability will bias downstream applications.

Quantile regression followed by trend tests of quantile-specific effect sizes has been used to test for non-uniform PGS accuracy. We show that such tests of trends or non-uniformity can be inflated under a range of analyses. Instead, we focus on the magnitude of differences in PGS predictive value. We use bootstrap confidence intervals and 1-sided significance tests to identify traits where quantile-specific PGS predictions have substantially different accuracy than the mean PGS accuracy.

We conduct a comprehensive survey of PGS predictability for traits in the UK Biobank and observe that this issue is severe and widespread, with 46% of traits having ratios of quantile specific to mean PGS predictability significantly greater than 1.2 ($p < 0.05$) and 54% of traits having quantile specific predictability significantly less than 1/1.2.

We see a number of qualitative patterns of PGS effect sizes across covariate adjusted phenotype quantiles. Some traits like BMI have a wide range of PGS predictability, with relative effects - ratios of quantile specific PGS effects to the standard, mean PGS effect - ranging from 0.38 (95% CI 0.36, 0.58) at the 0.05 BMI quantile to 1.90 (1.73, 2.34) at the 0.95 BMI quantile. That is, predicting BMI is much less accurate for lower BMI individuals than for higher BMI individuals using a global BMI PGS.

Such non-uniformity of PGS predictability could result in inequitable disease risk assessment or biased PGS-based research in health and social sciences. Our approach provides a straightforward routine screening for the magnitude of the non-uniformity of PGS effect sizes in current and future studies.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3557. Predicting cancer risk from germline next-generation sequencing data using a novel context-based variant aggregation approach.

Authors:

Z. Guan, C. B. Begg, R. Shen; Mem. Sloan Kettering Cancer Ctr., New York, NY

Abstract Body:

Twin studies have shown that most common cancer types have a substantial heritable component. However, known risk variants (SNPs from GWAS and pathogenic variants in known cancer predisposition genes) explain only a limited proportion of the estimated heritability of cancer. It has been hypothesized that much missing heritability lies in rare variants not captured by SNP arrays. Rare variants need to be aggregated to achieve sufficient statistical power for detection. We propose a novel context-based variant aggregation approach for extracting signals from rare variants detected through germline whole-exome and whole-genome sequencing. Many studies have shown that the distributions of the genomic, nucleotide, and epigenetic contexts of somatic variants in tumors are informative of cancer etiology and site of origin. Recently, a new direction of research has focused on extracting signals from the contexts of germline variants and evidence has emerged that patterns defined by the nucleotide contexts of germline variants are associated with oncogenic pathways, histological subtypes, and prognosis. It remains an open question whether aggregating germline variants based on these contexts can improve cancer risk prediction. Using germline whole-exome sequencing data from over 200,000 individuals from the UK Biobank and whole-genome sequencing data from over 2,000 individuals from the Pan-Cancer Analysis of Whole Genomes Consortium, we investigate the predictive value of meta-features aggregating rare variants based on their genomic, nucleotide, and epigenetic contexts for distinguishing cancer cases from controls and for predicting tumor subtypes (such as homologous recombination deficiency). We compare the performance of risk models based on known risk variants and risk models that additionally include the meta-features.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3558*. Predicting ExWAS results from GWAS data: A shorter path to causal genes.

Authors:

K. Liang, Y. Chen, S. Yoshiji, J. Farjoun, V. Forgetta, B. Richards; McGill Univ., Montreal, QC, Canada

Abstract Body:

Genome-wide association studies (GWAS), have identified thousands of loci associated with susceptibility to disease, yet the causal genes within these loci are largely unknown. Identifying these causal genes is necessary to enable for deeper understanding of the disease and for genetics-based drug development. Several algorithms have been developed to address this problem, such as the Effector Index (Ei), Locus-2-Gene (L2G), Polygenic Prioritization score (PoPs), and the Activity-by-Contact score (ABC). However, their efficacy as compared to the more expensive, but more precise Exome-wide Association Study (ExWAS) is unclear. Here, we quantified the performance of these algorithms by evaluating their ability to identify ExWAS significant genes in nine traits. We found that Ei, L2G and PoPs can identify ExWAS significant genes with an area under the precision recall curve much greater than their respective baselines (Ei: 0.53 vs 0.06, L2G: 0.46 vs 0.07, PoPs: 0.21 vs 0.06, ABC: 0.18 vs 0.08). Furthermore, we found that for every 1SD increase in the normalized scores, there is an associated 1.4-4.3 fold increase in the odds of a gene reaching exome-wide significance (Ei: 4.3, L2G: 2.7, PoPs: 2.1, ABC: 1.4). Overall, we see that Ei, L2G, and PoPs can accurately anticipate ExWAS results, making these promising techniques for drug target discovery when well-powered ExWAS data are not readily available. In addition, because these gene prioritization metrics do not rely on ExWAS data, they can serve as an independent source of evidence that can complement ExWAS results when they are available. These metrics are therefore cost-effective ways to use the large collection publicly available GWAS data to obtain additional evidence regarding the causality of a gene and help identify potential drug targets.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3559. Predicting how our genetic variants regulate splicing and impact human phenotypes.

Authors:

H. Jacobs¹, C. Burge¹, H. Finucane²; ¹MIT, Cambridge, MA, ²Massachusetts Gen. Hosp., Boston, MA

Abstract Body:

A fundamental goal of human genetics is to predict which genomic variants impact molecular phenotypes to better understand disease etiologies. One molecular phenotype is pre-mRNA splicing, a process that determines which RNA sequences will be encoded into protein. Despite much progress, the functional impact of variants on splicing is under-studied compared to other molecular phenotypes, such as gene expression.

Here, we leverage fine-mapped splice quantitative trait loci (sQTLs) (Barbeira et al 2021) in the Genotype-Tissue Expression (GTEx) Consortium and construct a predictor that differentiates between SNPs with high vs low posterior probability of causally impacting splicing. This predictor, which we call splice modifier score (SMS), utilizes features such as epigenetic marks, conservation, evidence of splicing factor binding, splice site strength (via MaxEnt), and distance to nearest GTEx splice site. SMS predicts a held-out test set with an AUROC of 0.94. We find distance to nearest GTEx splice site greatly improves recall, while additional features generally improve precision, suggesting sQTL variants interact locally with core splicing machinery. Using SMS rather than sQTL PIP improves colocalization with UKBB GWAS variants. Using a probability cutoff of 0.6 (precision: 0.7), SMS prioritizes 57 putatively causal variants ($PIP \geq 0.5$, excluding protein truncating variants) in the UK Biobank (UKBB) as likely splice-modifying variants, compared to 43 identified by sQTL colocalization with the same probability cutoff. We also compared splice sites identified in GTEx with splice sites from reference transcript annotations (GENCODE). In GTEx, we determine there are ~450k biologically interpretable splice sites, of which ~170k do not exist in GENCODE. GTEx-specific splice sites have a similar distribution of MaxEnt scores to GENCODE splice sites. These novel splicing events tend to be both tissue-specific and rare in the GTEx population: 20% of GTEx-specific splice sites are unique to a single person in GTEx, compared to 5% of splice sites shared between GTEx and GENCODE. Incorporating GTEx-specific splice site annotations improves recall of UKBB high PIP ($PIP \geq 0.9$) variants in splice sites by 1.2x. GTEx splice sites intersect with high PIP UKBB variants in many tissues, demonstrating that leveraging more RNAseq data from the human population can help uncover splicing relevant to complex traits. This work demonstrates the utility of studying splicing to interpret non-coding variants in disease.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3560. Prediction of atrial fibrillation and stroke using machine learning models.

Authors:

A. Papadopoulos¹, D. Harding¹, G. Slabaugh¹, P. Deloukas², E. Marouli³; ¹Queen Mary Univ. of London, London, United Kingdom, ²Queen Mary Univ. London, London, United Kingdom, ³Barts and The London Sch. of Med. and Dentistry Queen Mary Univ. of London, London, United Kingdom

Abstract Body:

We employed machine learning (ML) approaches to evaluate 2,716 clinical features and disease phenotypes available in the UK Biobank as predictors for Atrial Fibrillation (AF) risk. After quality control, 308 features were selected for analysis in 23,095 prospective AF cases and equal number of controls. Different ML methods were employed, including LightGBM, XGBoost, Random Forests (RF), Deep Neural Networks (DNN,) and Logistic Regression with L1 penalty (LR). In order to eliminate the "black box" character of the tree-based ML models, we employed Shapley-values (SHAP), which are used to estimate the contribution of each feature to AF prediction. The area-under-the-curve (AUC) values and the 95% confidence intervals (CI) per model were: 0.751 (0.742, 0.759) for XGBoost, 0.750 (0.742, 0.759) for LightGBM, 0.740 (0.731,0.749) for SVM, 0.739 (0.730, 0.748) for LR, 0.725 (0.716, 0.734) for RF and 0.669 (0.659, 0.678) for DNN. Considering the running time, memory and stability of each algorithm, XGBoost was the best performing among those examined. De-Long's test showed that there is statistically significant difference in the AUCs between XGBoost and the non-tree-based models. The two most important features identified for XGBoost, using SHAP analysis, are the genetic risk score (GRS) of AF and age. As expected, the AF GRS had a positive impact on the model output, i.e. a higher AF GRS increased AF risk. Similarly, age also had a positive impact increasing AF risk. Secondary analysis was performed for the individuals who developed stroke after AF diagnosis, employing 322 features in 3,219 prospective cases of people who developed stroke after AF, and equal number of controls in UK Biobank. The AUC values and the 95% CI per model were: 0.618 (0.593, 0.643) for SVM, 0.613 (0.585, 0.638) for LightGBM, 0.611 (0.584, 0.637) for RF, 0.602 (0.576, 0.629) for XGBoost, 0.571 (0.544, 0.598) for DNN, 0.544 (0.517, 0.571) for LR. De-Long's test showed that there is evidence for statistically significant difference between the SVM and the LR models. Using SHAP analysis for the tree-based model that performed best, LightGBM, the two most important features are cystatin C and systolic blood pressure. De-Long's test showed that there is evidence for statistically significant difference between LightGBM and the current clinical tool for stroke prediction in AF patients, CHA2DS2-VASc, which has AUC and 95% CI of 0.608 (0.581, 0.634).

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3561. Prediction of congenital heart disease subgroups associated with copy number variants using a multinomial machine learning-based classifier.

Authors:

J. S. Penaloza^{1,2}, B. Moreland¹, B. J. Landis³, L. R. Elmore³, G. C. Geddes³, J-h. Lin⁴, S. Yatsenko⁴, C. W. Lo⁴, S. Wechsler⁵, S. R. Lalani^{6,7}, V. Garg^{1,2}, J. C. Hodge³, S. Ware³, K. L. McBride^{1,2}, P. White^{1,2}; ¹Nationwide Children's Hosp., Columbus, OH, ²Ohio State Univ. Coll. of Med., Columbus, OH, ³Indiana Univ. Sch. of Med., Indianapolis, IN, ⁴Univ. of Pittsburgh, Pittsburgh, PA, ⁵Emory Univ. Sch. of Med., Atlanta, GA, ⁶Baylor Coll. of Med., Houston, TX, ⁷Texas Children's Hosp., Houston, TX

Abstract Body:

Congenital Heart Disease (**CHD**) is a global health burden that is a major cause of infant mortality. Copy number variants (**CNV**) are a common cause of CHD. Some recurrent CNVs are associated with specific CHD, but frequently, patients who have the same CHD are diagnosed with distinct CNVs whose contribution to CHD pathogenesis remains unclear. To address this challenge, in this study we functionally annotated clinically validated CNVs associated with isolated CHD by applying machine learning.

Here we leveraged our access to data from the Cytogenomics of Cardiovascular Malformations (**CCVM**) Consortium, including information on demographics, diagnosis, and clinical chromosomal microarray analysis of 1353 patients with CHD. The isolated CHD subgroups we focused on are (Ventricular/Atrial Septal Defect (**VSD/ASD**), Right Ventricular Obstruction (**RVOTO**), Left Ventricular Outflow Tract Obstruction (**LVOTO**), Heterotaxy (**HTX**), Conotruncal Defect (**CTD**), Atrioventricular Septal Defect (**AVSD**), and Anomalous Pulmonary Venous Return (**APVR**).

We developed a multinomial machine learning classifier to identify CNV patterns, both distinct and shared, between isolated CHD subgroups, among features such as genomic region, biological processes related to genes within the CNV, and other attributes. Three tree-based algorithms were compared: decision trees, random forests, and XGBoost. The Random Forest (**RF**) model performed the best, attaining a F1 score of 0.60, which is 5X higher than the baseline performance threshold of 0.125 for an 8-way balanced classification. We used Shapley Additive Explanation (**SHAP**) values to analyze the features that most contribute to the classification of the CHD subgroups. From the global SHAP plots we found CNV type, brain related processes, cell migration, and cell adhesion are important parameters determining the overall classification. Class-specific SHAP plots, illustrate the positive and negative impact each attribute has on predicting a CHD subgroup. As an example, according to our RF model, CNVs that appear with HTX tend to involve CNV duplication, and impact to cell adhesion and cell projection with distinguishing features in tissue morphogenesis and positive regulation of intracellular signaling transduction. In contrast, for the VSD/ASD subgroup, we see larger weight placed on central nervous system development and neurogenesis biological processes. The class-specific features vary in their impact on the model with respect to the CHD subgroup, amongst a combination of shared and distinct attributes. These findings demonstrate machine learning is an effective tool for functional annotation of CNVs associated with CHD.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3562. Prioritization of causal genes from genome-wide association studies by Bayesian data integration across loci.

Authors:

Z. Mousavi¹, M. Arvanitis¹, T. Duong¹, J. Brody², A. Battle¹, N. Sotoodehnia³, A. Shojaie³, D. E. Arking⁴, J. S. Bader⁵; ¹Johns Hopkins Univ., Baltimore, MD, ²Univ of Washington, Seattle, WA, ³Univ. of Washington, Seattle, WA, ⁴Johns Hopkins Univ Sch. of Med., Baltimore, MD, ⁵Johns Hopkins Univ, Baltimore, MD

Abstract Body:

Genome-wide association studies (GWAS) have been effective in identifying genetic variants, usually single-nucleotide polymorphisms (SNPs) associated with human traits, including disease and disease risk. The variants identified by GWAS, or causal variants in linkage disequilibrium with the variants, often affect the regulation of nearby genes or the activity of their protein products. A GWAS locus can span many genes; however, and prioritizing which gene or genes in a locus are most likely to be causal remains a challenge. Better prioritization and prediction of causal genes could reveal disease mechanisms and suggest interventions. We describe a new Bayesian inference method to prioritize candidate genes across loci identified by large-scale GWAS. This method prioritizes genes as causal by integrating information about individual loci, including existence of Mendelian genes or expression quantitative trait loci (eQTL) in the region, and network connectivity as provided by protein-protein and gene regulatory interaction data. Our analysis of recent GWAS data for well-studied traits such as cardiovascular electrophysiology and cancer predisposition suggest that for 70-80% of genome-wide significant SNPs, the closest gene is most likely to be causal. For the remaining loci, our predictions improve upon the naive choice of the closest gene, assessed by better enrichment for relevant biological annotations, and provide predictions for loci that lack eQTL or other informative features. A strength of the method is the ability to prioritize genes based on cross-locus information at loci where there is no evidence for colocalization. Examples in which the gene is selected based on cross-locus information rather than distance to the SNP or colocalization include NKX2-5 for cardiovascular electrophysiology, and MRKN1 for breast cancer predisposition.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3563. Prospective analysis of disease incidence and progression with genetic, clinical and lifestyle risk factors

Authors:

W. Wang, N. Eriksson, M. McIntyre, R. Bagur Quetglas, 23andMe Research Team, A. Auton, S. Shringarpure; 23andMe, Sunnyvale, CA

Abstract Body:

Large and diverse databases and improved methodology allow advanced understanding in prediction of disease incidence and progression with genetic, clinical and lifestyle risk factors.

We constructed two non-overlapped cohorts, discovery cohort and prospective cohort, from 23andMe, Inc. research-consented participants, a large cohort of research-consented individuals with genotype data obtained via a direct-to-consumer product and phenotypic data obtained from online self-report surveys. We built polygenic risk score (PRS) models across multiple populations in the discovery cohort, and then compared cumulative incidence rates among different genetic risk groups for multiple phenotypes (12 in European population, 9 in Latino population and 3 in African American population) in the prospective cohort. We also investigated the interplay of PRS with clinical and lifestyle risk factors in disease incidence of type 2 diabetes (T2D) and coronary artery disease (CAD).

The cumulative incidence rates, in the first follow-up year, were higher in participants at high genetic risk compared to all participants across multiple populations. Among participants with clinical risk, we observed that those at high genetic risk had higher disease incidence rates. We also found that low lifestyle risk was associated with reduction in disease incidence among participants at high genetic risk. Take the first follow-up year incident T2D as an example, the cumulative incidence rate was 1.19% (95% CI [1.12%, 1.27%]) in participants within the top 10% PRS risk and 0.48% (95% CI [0.46%, 0.50%]) among all participants in European population; 1.18% (95% CI [1.04%, 1.32%]) in participants within top 20% PRS and 0.56% (95% CI [0.52%, 0.61%]) among all participants in Latino population; 1.52% (95% CI [1.20%, 1.85%]) in participants within top 20% PRS and 0.95% (95% CI is [0.83%, 1.06%]) among all participants in African American population. Among the participants who reported with high blood sugar in European population, the T2D incidence rate was 7.27% (95% CI [6.44%, 8.17%]) in the high genetic risk group, compared to 5.29% (95% CI [4.97%, 5.60%]) in the overall high blood sugar group. Within the high genetic risk group, participants at low lifestyle risk had a lower incidence rate, 0.42% (95% CI [0.31%, 0.53%]), compared to the overall incidence rate, 1.19% (95% CI [1.12%, 1.27%]), in European population.

In this study, we found that our PRS model predicted disease incidence across multiple populations, and could identify individuals with higher risk of disease progression. The analysis also provided insights on potential disease risk modifications based on lifestyle.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3564. Protecting privacy in polygenic risk score calculation by homomorphic encryption

Authors:

H. Kim¹, C. Kim¹, B. Han²; ¹Seoul Natl. Univ., Seoul, Korea, Republic of, ²Seoul Natl. Univ. Coll. of Med., Seoul, Korea, Republic of

Abstract Body:

Genome-Wide Association Studies (GWAS) have revealed many small effects of genetic variants on common complex diseases and opened an opportunity for calculating polygenic risk score (PRS) of individuals from their genotype data. Many individuals now have access to their genotype data due to the prevalent direct-to-customer genetic test, and numerous health companies are providing PRS calculation services conditioned on that the users upload their genetic data. However, this trend raises serious privacy and security concerns. Even if the genotype data is encrypted during transmission, the uploaded genetic data must ultimately be decrypted in order to calculate PRS. If the decrypted genotype data is hacked, disastrous situations can occur, such as the individual being uniquely identified. To overcome this privacy issue, we developed SecurePRS (Secure Polygenic Risk Score), a systematic framework to calculate PRS using homomorphic encryption technique. In our framework, even the PRS service provider needs not decrypt the data and does not have access to the PRS results, thereby providing a full privacy protection. For better performance, we applied four representative linear PRS models (PRScs, SBLUP, LDpred and P+T) in an unencrypted state and used the estimated weights to calculate PRS in an encrypted state.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3565. Proteome-Wide Association Analysis in the Women's Health Initiative Study

Authors:

B. Chen¹, C. Lee¹, A. Tapia¹, A. Reiner², H. Tang³, C. Kooperberg⁴, Y. Li⁵, L. Raffield⁶; ¹Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ²Univ of Washington, Seattle, WA, ³Stanford Univ. Sch. of Med., Stanford, CA, ⁴Fred Hutchinson Cancer Res. Ctr., Seattle, WA, ⁵Univ North Carolina, Chapel Hill, NC, ⁶UNC - Chapel Hill, Chapel Hill, NC

Abstract Body:

Studying the genetically regulated component of protein abundance can improve our knowledge of molecular mechanisms underlying cardiovascular diseases (CVD). In Proteome-Wide Association Studies (PWAS), genetic variants near the protein-coding gene (± 1 Mb), also known as *cis* or local SNPs, are used to predict the protein level. These predicted protein levels are then associated with phenotypes of interest. However, proteins can be regulated through variants outside of the local region. Thus, we propose an intermediate GWAS step to identify protein quantitative trait loci (pQTL) throughout the genome and select variants for consideration in PWAS model training. This allows for the inclusion of *trans* or distal SNPs in protein level prediction models. We here assess prediction of 552 proteins measured using targeted Olink panels in 1,002 individuals from the Women's Health Initiative (WHI) with complete proteomics data across all panels and whole genome sequencing data from TOPMed freeze 9. We split the individuals equally into a GWAS set (for identification of pQTL), elastic net training set using all nominal pQTLs genome-wide ($p < 0.0001$), and a testing set, for comparison of predicted and inferred protein levels. We compared the correlation between inferred and predicted protein level in held out testing set data (testing r^2) using this proposed approach, which incorporates both local and distal SNPs, to the testing r^2 using only local SNPs in elastic net model training (in two thirds of the total sample size, instead of one third, since there is no need for an initial GWAS to detect pQTLs genome-wide). The two approaches resulted in similar testing r^2 's for most proteins (despite the increased sample size for model training using local SNPs only), but some proteins showed a noticeable increase in testing r^2 with our method compared to using local-only SNPs. For example, for Cartilage Acidic Protein 1 (CRTAC1) the testing r^2 increased from 0.101 to 0.351 due to several large effect distal pQTLs. In total, 160 proteins have a testing $r^2 > 0.05$ in this relatively modest sample size, with a max testing r^2 of 0.71. In the future, we aim to assess associations of predicted proteins with CVD outcomes and quantitative phenotypes in WHI participants with sequencing data only, assess whether predicted protein associations are driven by local and distal SNPs or just local SNPs, and work to replicate our results using other datasets, such as UK Biobank.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3566. Publicly Available Privacy-preserving Benchmarks for Polygenic Prediction

Authors:

M. Witteveen, E. Pedersen, F. Privé, D. Speed, B. Vilhjalmsón; Aarhus Univ., Aarhus, Denmark

Abstract Body:

In recent years, many different approaches for creating polygenic scores have been proposed and this trend shows no sign of abating. Most of these new polygenic score methods claim to outperform previously proposed methods, making it confusing for users to choose an appropriate PRS approach. This apparent performance paradox is due to challenges in properly determining what approaches are superior, because different datasets, quality control, and preprocessing steps are used to determine performance. As shown previously, these steps can have a significant impact on the overall prediction accuracy for polygenic score methods (Privé et al., bioRxiv 2022), and thus lead to an incomplete comparison of PRS methods.

In the related field of Machine Learning this problem has been addressed by the introduction of publicly available benchmark datasets, which allow for fair comparison between approaches, which has been vital to the advancement of the field. However the creation of such publicly available benchmark datasets in genetics has, until now, proved challenging because of privacy concerns.

As a solution, we present a privacy-preserving and publicly available benchmark for polygenic prediction, which allows researchers to both train and test polygenic prediction methods using only linkage disequilibrium (LD) information and summary statistics from genome-wide association studies, thus preserving privacy.

Using UK biobank data and a diverse set of 8 external summary statistics, we show that with our approach we estimate the squared correlation prediction accuracy almost perfectly. The method only requires linkage disequilibrium (LD) information and genome-wide association summary statistics, and no individual level data. We further used the benchmark data to compare a variety of polygenic scoring methods including PRS-CS, LDpred2, and SBayesR and observe a remarkable concordance, with perfect recovery of model rankings and almost perfect correlation of model performance measures.

This new benchmark for PRS model development and comparison will be made publicly available for researchers to download. We believe this benchmark can be used as a clear and unbiased standard for future polygenic score methods to compare against.

PB3567. PUMICE-S: Prediction Using Models Informed by Chromatin conformations, Epigenomics and Summary Statistics

Authors:

L. Wang; Penn State Coll. of Med., Hershey, PA

Abstract Body:

Transcriptome-wide association studies (TWAS) has gained popularity in many complex trait studies. TWAS first create gene expression models from an eQTL dataset that measures both gene expression and genetic variants. It then predicts gene expression in a GWAS dataset and correlates predicted gene expression with phenotypes of interest. The power of TWAS critically depends on training sample size for deriving gene expression prediction models. The largest available eQTL datasets are only available as summary statistics, such as eQTLGen. It is important to extend current TWAS approaches and use summary statistics to predict gene expression levels. Here, we present a new method PUMICE-S (Prediction Using Models Informed by Chromatin conformations, Epigenomics, and Summary statistics). PUMICE-S can take advantage of summary-statistics from a much larger dataset. It also integrates 3D genomic data to properly define cis-regulatory regions and uses epigenetic annotation to prioritize causal variants. To illustrate the advantage of PUMICE-S for analyzing large eQTL summary statistics, we applied PUMICE-S to eQTLGen summary statistics with $N=31,684$ and compare it with classical methods, including PrediXcan, TIGAR and UTMOST, trained on GTEx individual-level data. Because of the large sample size, we observed PUMICE-S results in an average 76.8%, 55.6%, and 41.8% increase of in the number of significant prediction models, where the predicted and measured gene expressions are significantly correlated. It will also lead to 99.7%, 81.7%, and 41.3% improvement in prediction accuracy. To illustrate the advantage of incorporating 3D genome and epigenetic data, we compared with two polygenic risk score methods based on summary statistics, including lassosum and LDpred2-inf. PUMICE-S resulted in an average of 47.6% and 76.2% improvement in imputation accuracy and an average gain of 20.6% and 46.4% more significant imputed models. To further identify significant gene-level associations, we applied our methodology to 37 multi-ancestry genome-wide association studies in immune-related traits and showed that PUMICE-S identified 179%, 92%, 30%, 163%, 111% more significant gene-trait pairs compare to that of PrediXcan, TIGAR (trained on DGN), UTMOST (trained on GTEx multi tissues), Lassosum, LDpred2-inf (trained on eQTLGen), respectively. Based on that, we performed a comprehensive downstream analysis, including cell type enrichment analysis and computational drug repurposing, and identified significant enrichment for cell types and bioactive small molecules capable of reversing the expression profile of clinically relevant trait-associated genes.

PB3568. Quantifying portable genetic effects and improving cross-ancestry genetic prediction with GWAS summary statistics

Authors:

J. Miao¹, H. GUO², G. Song¹, Z. Zhao¹, L. Hou², Q. Lu¹; ¹Univ. of Wisconsin-Madison, Madison, WI, ²Tsinghua Univ., Beijing, China

Abstract Body:

Polygenic risk scores (PRS) calculated from genome-wide association studies (GWAS) of Europeans are known to have substantially reduced predictive accuracy in non-European populations, limiting its clinical utility and raising concerns about health disparities across ancestral populations. However, existing methods to address this problem have several critical limitations (e.g., most methods require some individual-level data that are independent from input GWAS; these data rarely exist in practice), and the improvement in predictive performance has been incremental. Here, we present a novel statistical framework named X-Wing with three main innovations to improve PRS performance in ancestrally diverse populations. First, we introduce and estimate cross-population local genetic correlation which directly quantifies correlated (portable) genetic effects between multiple ancestral populations. Second, we introduce a novel Bayesian method to incorporate local genetic correlation annotation into multi-population PRS modeling, where annotation-dependent statistical shrinkage amplifies the effects of annotated variants (*i.e.*, variants with correlated effects between populations). Finally, we propose an innovative strategy to combine multiple PRS trained in various populations into an omnibus score with improved prediction accuracy using GWAS summary data alone as input. The entire X-Wing procedure only requires GWAS summary data, which is a major advance compared to existing approaches. Through extensive benchmarking using numerous GWAS datasets including UK Biobank, Biobank Japan, and Population Architecture using Genomics and Epidemiology Consortium study, we demonstrate that X-Wing pinpoints portable genetic effects and substantially improves PRS performance in non-European populations. Applied to 31 traits in East Asians, cross-population genetic correlations using X-Wing-annotated SNPs are substantially higher than the genome-wide genetic correlation estimates, while correlations in the remaining genome are consistently lower. X-Wing PRS achieves 31.0%-96.1% gain in predictive R^2 compared to state-of-the-art methods based on GWAS summary statistics. Followed up on 13 traits in admixed Americans, X-Wing also shows a substantial improvement in prediction accuracy, with the R^2 increase ranging from 18.7%-122.1%. Overall, X-Wing introduces several methodological innovations that will likely have broad and impactful applications and provides an accurate and privacy-preserving method to construct PRS in ancestrally diverse populations.

PB3569. Quantifying the causal impact of modifiable risk factors and biomarkers on total healthcare burden via Mendelian randomization

Authors:

J. Lee¹, S. Jukarainen², P. Dixon³, N. Davies⁴, G. Davey Smith⁴, P. Natarajan⁵, A. Ganna²; ¹Broad Inst. of MIT and Harvard, Finnish Inst. for Molecular Med., Cambridge, MA, ²Inst. for Molecular Med. Finland, Helsinki, Finland, ³Nuffield Dept. of Primary Care Hlth.Sci., Univ. of Oxford, Oxford, United Kingdom, ⁴MRC Integrative Epidemiology Unit, Univ. of Bristol, Bristol, United Kingdom, ⁵Broad Inst. of MIT and Harvard, Cambridge, MA

Abstract Body:

Background Public health aims to reduce the burden of modifiable risk factors to improve population health and decrease healthcare burden. Previous studies have attempted to quantify the total healthcare burden (e.g. total healthcare expenditure) associated with certain modifiable risk factors such as adult body mass index (BMI), systolic blood pressure (SBP), or waist circumference (WC). However, such studies are based on observational data or single disease clinical trials. Thus, they are likely to suffer from confounding or ignore the impact of modifiable risk factors on broader healthcare burden, which is mediated by multiple disease states.

Methods Here, we linked outpatient, hospital, and medication registries to the FinnGen Study to quantify the total healthcare costs for 373,460 Finnish individuals. We performed Mendelian randomization for 15 modifiable risk factors and biomarkers to identify their causal impact on healthcare expenditure using exposures from the UK Biobank and outcomes from the FinnGen Study. Costs were standardized to costs at 2017 and converted from euros to dollars.

Results For 373,460 individuals (56% female, mean age = 61, SD age = 18), the total healthcare expenditure was \$1.08B, or a mean and median of \$2,905 and \$1,409, respectively (SD = \$11,605). We estimated that a standard deviation increase in WC, adult BMI, and SBP was increased annual total healthcare costs by 22.9% [95% CI: 18.9%-27.1%], 13.6% [10.3%-17.1%], and 13.2% [9.0%-17.7%] per person, respectively. We estimated a \$217 annual increase in healthcare costs per person for 10 cm of WC, \$191 for 5 kg/m² of adult BMI, and \$90 for 10 mmHg of SBP. This is the first comprehensive, genetically-informed quantification of modifiable risk factors.

Conclusion Taken together, we used genetic information to quantify the causal impact of modifiable risk factors and biomarkers on healthcare burden and found a substantial effect on total annual healthcare costs ranging from \$90 to \$217 per person.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3570*. Quantifying the effects of high-dimensional cross-trait assortative mating on complex trait genetic architectures

Authors:

R. Border¹, G. Athanasiadis², A. Buil³, A. Schork⁴, N. Cai⁵, A. Young⁶, T. Werge⁷, J. Flint¹, K. Kendler⁸, S. Sankararaman¹, A. Dahl⁹, A. L. Price¹⁰, N. Zaitlen¹; ¹Univ. of California Los Angeles, Los Angeles, CA, ²Univ. of Barcelona, Barcelona, Spain, ³Mental Hlth.Sct Hans Hosp., Roskilde, Denmark, ⁴Res. Inst. for Biological Psychiatry, Roskilde, Denmark, ⁵Helmholtz Zentrum München, Neuherberg, Germany, ⁶Univ. of California, Los Angeles, Los Angeles, CA, ⁷Univ. of Copenhagen, Copenhagen, Denmark, ⁸Virginia Commonwealth Univ, Richmond, VA, ⁹Univ. of Chicago, Chicago, IL, ¹⁰Harvard Sch Pub Hlth, Boston, MA

Abstract Body:

Though the potential impacts of assortative mating on genetic architecture have been understood for over a century, researchers have only recently begun to characterize its impact on commonly used methods in statistical genetics, nearly all of which assume mating is random. The results of these investigations have been striking, particularly with respect to cross-trait assortative mating (xAM): xAM inflates genetic correlation estimates, even in the absence of pleiotropy, and breaks the assumptions required for Mendelian randomization to produce valid causal inferences. Still, investigations of xAM so far have considered at most two traits at a time, a simplification undercut by empirical evidence demonstrating widespread, phenome-wide cross-mate similarity. Here, we present the first analysis of high-dimensional xAM and its implications for polygenic methods.

First, we solve the problem of simulating complex mating patterns involving an arbitrary number of traits by establishing its equivalence to a fundamental combinatorial optimization problem in operations research, enabling forward-time simulations that accurately reflect the complexity of realistic human mating patterns. Then, utilizing empirical estimates of cross-mate correlations among a broad array of traits ($n \leq 500,000$), we characterize the impact of high-dimensional xAM on multiple widely-used methods for interrogating genetic architecture. We find that the large number of phenotypes involved in xAM leads to substantial upward bias in genetic correlation estimates and polygenic prediction metrics. For example, in the complete absence of pleiotropy, five generations of bivariate xAM across ADHD and Schizophrenia would yield LDSC genetic correlation estimates 74.6% as large as published estimates; simultaneously modeling cross-mate correlation across five psychiatric phenotypes increases this to 101.1%. These findings imply that not only do xAM-induced biases likely distort our understanding of pleiotropy, but that only considering two traits at a time is insufficient for disentangling causal biology from structure in complex populations.

Finally, to address the consequences of high-dimensional xAM, we introduce random-regressor-random-slope (RRRS) regression, a novel statistical framework for decomposing genetic covariation into components reflecting pleiotropy versus xAM-induced structure by explicitly modeling the joint distribution of causal variants and their effects. We present simulations demonstrating that RRRS delivers unbiased genetic correlation estimates under xAM, and describe current progress toward implementation at biobank-scale.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3571. Rapid identification of clusters of multi-level colocalized traits within hundreds of candidate traits and in the presence of multiple causal variants.

Authors:

Z. Kuncheva¹, C. Foley^{1,2}, H. Runz³, B. Sun^{3,4}; ¹Data Sci. and Engineering, Res. and Dev., Optima Partners, Edinburgh, United Kingdom, ²Sch. of Clinical Med., Univ. of Cambridge, Cambridge, United Kingdom, ³Biogen, Cambridge, MA, ⁴BHF Cardiovascular Epidemiology Unit, Dept. of Publ. Hlth. and Primary Care, Univ. of Cambridge, Cambridge, United Kingdom

Abstract Body:

Thousands of genomic regions affecting complex diseases have now been identified. However, elucidating the causal genes and mechanisms involved remains an outstanding biological and computational challenge. By assessing shared genetic aetiology across multiple related traits (e.g., molecular traits, metabolic pathways, complex diseases and conditions), statistical colocalization attempts to unravel causal pathways and pinpoint risk variants. Insights from current approaches are limited owing to a computational bottleneck: screening for complex patterns of colocalization across hundreds of traits simultaneously is prohibitive and costly, rendering analyses to at most around ten traits. Consequently, biological information shared between potentially hundreds of related traits is unexplored.

Here we present Coloc-clust, a novel and efficient clustering algorithm, tool and online portal. Coloc-clust ingests GWAS summary statistics to detect clusters of colocalized traits within a vast set of candidate traits simultaneously, e.g., 100 traits can be jointly analysed in seconds. Moreover, Coloc-clust does this in the presence of an arbitrary number of causal variants. We demonstrate the accuracy and impact of Coloc-clust by performing a genome-wide multi-trait, multi-causal variant colocalization analysis of cardiovascular disease (CVD) and many related traits: revealing complex and rich patterns of clustered colocalized traits across CVD related traits. For ease of interpretation and use, we summarise findings in knowledge-graphs, with helpful prioritisation statistics, for target validation, pathway identification and safety assessment.

Coloc-clust provides a user-friendly and significant contribution to the post-GWAS in-silico toolkit, helping to extend the utility of GWAS outcomes toward functional insights and to generate new biological hypotheses.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3572. Rare variation analyses of over 6,900 ALS cases in a multi-ethnic population.

Authors:

T. Pottinger, J. Motelow, G. Povysil, Z. Ren, The New York Genome Center ALS Sequencing Consortium, GTAC Investigators, D. Goldstein, M. Harms; Columbia Univ. Irving Med. Ctr., New York, NY

Abstract Body:

Hypothesis: Rare genetic variation will impact the diagnosis of amyotrophic lateral sclerosis (ALS) found through the analysis of whole genome sequencing data. Gene region analyses will further help to uncover variants that play a significant role in disease manifestation for disorders, such as ALS, determined by single gene mutations. **Background:** ALS is a neurodegenerative disease affecting approximately 5 persons per 100,000 in the general US population of adults. It is characterized by the progressive decline of the nervous system that leads to the weakening of muscles and impacts physical function. While environmental factors such as smoking and environmental toxin exposure is known to contribute to ALS, 5 to 10% of persons with this disease have genetic factors that contribute to the progression of disease. Because of the known contribution of inheritance to ALS, it is vital to examine ALS manifestations in ethnically diverse and genetically defined populations. **Approach:** For these analyses, we included 6,970 individuals who were diagnosed with ALS and 22,524 controls. We utilized regional collapsing scores that have been described previously in conjunction with gene based collapsing approaches to conduct collapsing analyses to identify rare variants that associate with ALS. **Results:** A gene-based protein truncating variants collapsing model showed a significant association with *NEK1* and *TBK1*, genes that have previously been shown to be associated with ALS. Both gene and domain based functional variants collapsing models showed significant associations with *SOD1*, *TARDBP*, and *TBK1*. However, the domain-based model removed variants found in controls in the *TARDBP* gene increasing observed associations in comparison to the gene-based model. These genes have been previously associated with ALS. **Conclusions:** In one of the largest ALS rare variation studies to date, we identified rare variants in genes that have been previously associated with ALS utilizing gene and domain-based collapsing techniques.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3573. Rare-variant aggregation analysis reveals new genes involved with IgG glycosylation.

Authors:

L. Klaric¹, A. Landini¹, P. R. H. Timmers^{1,2}, A. Frkatovic³, I. Trbojevic-Akmacic³, F. Vuckovic³, G. Tzoneva⁴, Regeneron Genetics Center, O. Polasek^{5,6}, C. Hayward¹, A. R. Shuldiner⁷, G. Lauc³, J. F. Wilson^{1,2}; ¹MRC Human Genetics Unit, Inst. of Genetics and Cancer, Univ. of Edinburgh, Edinburgh, United Kingdom, ²Ctr. for Global Hlth.Res., Usher Inst., Univ. of Edinburgh, Edinburgh, United Kingdom, ³Genos GlycoSci. Res. Lab., Zagreb, Croatia, ⁴Regeneron Pharmaceuticals, Tarrytown, NY, ⁵Algebra Univ. Coll., Zagreb, Croatia, ⁶Dept. of Publ. Hlth., Sch. of Med., Univ. of Split, Split, Croatia, ⁷Regeneron Genetics Ctr., tarrytown, NY

Abstract Body:

Genome-wide association studies (GWAS) have identified thousands of loci associated with human complex traits and diseases. However, most of these variants are common with small effect size and found in noncoding regions, posing a challenge for uncovering their functional impact on the phenotype. On the other hand, variants having a disruptive effect on the protein, such as predicted loss of function (pLOF) and missense variants, may help identify genes with a clear biological link to the phenotype of interest. Using multiple gene-based aggregation tests, we investigated rare (MAF < 5%) pLOF and missense variants from whole exome sequencing that associate with the N-glycome of serum transferrin (N=1907) and IgG (N=4912). Overall, we identified 18 significant gene-based associations for transferrin (p-value < 8.06x10⁻⁸) and 41 for IgG glycan traits (p-value < 1.19x10⁻⁷), of which 3 and 33, respectively, were independent from sentinel SNPs identified in GWAS using imputed genotypes. Glycome-associated rare pLOF and missense variants are located in genes already known to have a biological link to protein glycosylation (*FUT6*, *FUT8* for transferrin; *FUT8*, *MGAT3* and *ST6GAL1* for IgG) but also in genes which have not been previously reported (eg, *ARHGAP45*, *PDZRN3* and *RFXPAP* for IgG). While the former show that common and rare variants act in concert to regulate protein glycosylation pathways, the latter expand our knowledge about the wide network of genes involved in protein glycosylation. In summary, variant aggregation analyses discovered both known and novel genes involved in the regulation of protein glycosylation.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3574. Rare-variant association studies: When are aggregation tests more powerful than single-variant tests?

Authors:

D. Bose¹, C. Fuchsberger^{2,1}, M. Boehnke¹; ¹Dept. of Biostatistics and Ctr. for Statistical Genetics, Univ. of Michigan, Ann Arbor, MI, ²Inst. for Biomedicine, Eurac Res., Bolzano, Italy

Abstract Body:

Although single-variant tests have been remarkably successful in identifying association in common variant GWAS, their power is substantially less for rare variants. This led to the development of aggregation tests, which have been shown in some situations to have more power for rare variants. Still, in most studies to date that have employed both types of tests, single-variant tests have yielded more associations, even for rare variants. The continued use of these methods warrants a better-informed investigation of the range of genetic models and sample sizes for which aggregation tests can be expected to be more powerful than single-variant tests.

We consider a normally distributed continuous trait in n independent study participants following an additive genetic model with c causal out of v total rare variants in an autosomal gene/region having heritability h^2 . First, we calculate analytically the power of single-variant (SV), burden, and SKAT tests to detect associations under the assumption of independent variants. With stricter assumptions of all variants having the same minor allele frequency (MAF), and causal variants having the same effect size and direction, we show that power for all three tests depends on nh^2 , c , and v . Second, to account for linkage disequilibrium, we perform simulations based on 378,215 unrelated exome-sequenced White British UK Biobank participants. Aggregation tests require us to choose which rare variants in the gene to include in the gene mask for the test with the aim to include causal variants and exclude non-causal ones. We set effect sizes of causal variants proportional to $\log(\text{MAF})$ which assigns larger effect sizes to rarer variants and Beta(1,25) weights for burden and SKAT tests to upweight rarer variants in the mask. We focus on the mask, which includes only rare protein-truncating (PTV) and missense variants in a gene, for all 1,154 genes in Chromosome 2 having at least two rare PTVs and/or missense variants. Type-I error is well controlled by all tests. When heritability=0.1% is concentrated in only a small proportion of variants in a gene (e.g., <10%) and $n=100,000$, average power for the SV test (>76%) is much higher than that of aggregation tests (<30%) for all the 1,154 genes considered. In contrast, when heritability=0.1% is split among a larger proportion of variants in a gene (e.g., >50%), average power for burden (>86%) and SKAT (>64%) tests beats that of SV test (<48%). We will extend these results to other variant masks, sample sizes, and heritabilities to more specifically answer the question of when SV tests are more powerful.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3575*. Reaching 95.0 years of age: The genetic association in the elderly Croatian population

Authors:

Ž. Celinščak, M. Setinc, A. Stojanovic Markovic, T. Skaric-Juric; Inst. for Anthropological Res., Zagreb, Croatia

Abstract Body:

Human longevity is influenced both by genetic and non-genetic factors, and genetic variability accounts for approximately 25% of variation in life expectancy. Genes that can positively influence lifespan and the ageing process are known as longevity genes. We aimed to elucidate single nucleotide polymorphisms (SNPs) that are significantly related to longevity as defined by the cut-off age of 95.0 (the threshold age for extreme longevity) in a sample of elderly persons of European origin. The study sample comprised of 314 unrelated individuals from Croatia who were above 85.0 years of age when the data were collected. As the sample of long-lived individuals was gathered in the period between 2007 and 2009, the age at death for each individual has been determined from the national mortality register 10 years after the initial sampling. This enabled us to differentiate between truly long-lived individuals that had survived beyond 95 years of age, and those that died before reaching 95 years, thus elucidating which SNPs are a key component for extreme longevity in the Croatian population. Genotype data were obtained for 42 SNPs from 28 putative longevity genes, which were selected due to strong and/or replicated association to human longevity and their role in different signalling pathways of cellular ageing and senescence. Univariate and multivariate logistic regression were performed with genotypic data coded as: 2 = longevity allele homozygotes; 1 = heterozygotes; 0 = non-longevity allele homozygotes. Out of the initial 42 SNPs, 10 SNPs that reached the inclusion criteria of having a p-value of $p < 0.2$ in univariate logistic regression entered the series of multivariate logistic regressions. The best model, explaining 9.3% of the variance for the survival to the age of 95.0, consisted of five SNPs. Three SNPs that were significantly (at $p < 0.05$ level) associated with reaching 95.0 years of age are PTPN1 rs6067484, PAPPB rs4837525, and TP53 rs1042522. Two remaining SNPs were marginally significant (APOE rs429358; $p = 0.053$) or not significant (IRF4 rs12203592) but they both contribute to the strength of the model. Although the best model explains a considerable proportion of variance for surviving up to the 95-years-of-age phenotype, the modest associations of particular SNPs warrant replication in more powered studies. (CSF grant IP-01-2018-2497: HECUBA)

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3576*. REGENIE v3: more efficient analysis of rare genetic variation with an extended set of gene-based tests.

Authors:

J. Mbatchou¹, A. Ziyatdinov², J. Marchini³, Regeneron Genetics Center; ¹Regeneron Genetics Ctr., TARRYTOWN, NY, ²RGC, Regeneron Pharmaceuticals, White Plains, NY, ³Regeneron Genetics Ctr., Tarrytown, NY

Abstract Body:

Large-scale biobanks worldwide have gathered vast amount of genetic and phenotypic data derived through electronic health care records and self-reported information. This has provided researchers unique opportunities to find new targets as well as uncover new indications for existing therapies. As analyzing such large data sets can incur a high computational burden, we had proposed REGENIE has a tool to address this limitation. REGENIE (1) uses an efficient whole genome regression framework to capture population structure, relatedness and polygenicity; (2) incurs low memory costs by reading and storing the genetic data in chunks; (3) can efficiently analyze multiple phenotypes in parallel; (4) can process both quantitative and binary traits, including highly unbalanced binary traits; (5) includes gene-based burden tests to study rare variation using functional annotation information. We have extended the tool, in REGENIE v3, to be more suitable for analyses involving rare variants, such as with whole exome sequencing. We have added a wider range of gene-based tests extending beyond the burden test, including the variance component tests SKAT and SKAT-O, which are less prone to power loss from single variants having different direction of effects, the Cauchy combination tests ACAT-V and ACAT-O, as well as a novel Non-Negative Least Squares test which combines variable selection with significance testing imposing a same-effect direction constraint. These can be applied to both quantitative as well as binary traits including those with high case-control imbalance. Furthermore, REGENIE v3 enables to perform conditional analyses, such as to determine whether a rare variant signal is driven by a nearby common variant signal. Through simulations studies as well as real data applications in UK Biobank with sample sizes up to 408K, we demonstrate the computational efficiency of REGENIE v3 compared to existing approaches including with compute time and memory usage, as well as illustrate the performance of the different gene-based tests on several quantitative and binary traits with various case-control ratios.

London, London, United Kingdom, ¹⁵Inst. of Cardiovascular Sci., Faculty of Population Hlth., Univ. Coll. London, London, United Kingdom

Abstract Body:

Genotyping arrays provide an efficient, economical way to address specific traits or diseases, focusing on specific variants or genomic regions. However, rare variants present particular challenges for reliability, largely due to difficulties with algorithmic interpretation of clustering. This has led to problems of false-positive genotyping results for rare variants using the previous UK Biobank Axiom and UK BiLEVE microarrays in the UK Biobank. Here we present the design and performance of a custom genotyping array focusing on obesity and diabetes to determine the overall efficiency and performance of the Axiom myDesign genotyping array by ThermoFisher for analysing rare variants. Genotyping performance was assessed through the inclusion of duplicate samples and previously exome sequenced samples along with the standard Axiom genotyping array quality control samples. A total of 2,112 samples were genotyped and the overall quality of both samples and markers was high in standard QC. As expected, the quality of genotyping for common variants was high. We used version 5.1 of the Axiom Analysis Suite Software, which executes a Rare Het Adjusted (RHA) algorithm, to improve on the previous software version (AxiomGT1). We found that the updated version provides reliable data for rare variants: the average concordance rate between rare variants in sequenced and genotyped samples was 96% and the average concordance rate in duplicated samples was 99%. Our data suggest that an array-based approach could be efficient and cost-effective for rare variant analysis and increase confidence that the results are reliable.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3578. sCLC: a Novel Statistical Method for Association Studies of Multiple Phenotypes and Genetic Variants based on GWAS Summary Statistics

Authors:

M. Wang, X. Cao, S. Zhang, Q. Sha; Michigan Technological Univ., Houghton, MI

Abstract Body:

There is strong evidence showing that joint analysis of multiple phenotypes in genome-wide association studies (GWAS) can increase statistical power when detecting the association between genetic variants and human complex traits. We previously developed the Clustering Linear Combination (CLC) method and a computationally efficient CLC (ceCLC) method to test the association between multiple phenotypes and a genetic variant. Although CLC and ceCLC perform very well, especially for phenotypes that have natural grouping, both CLC and ceCLC require individual-level genotypes and phenotypes that are often not easily accessible due to privacy concerns and some logistical considerations. Recently, a vast majority of GWAS summary statistics obtained from single-trait tests are publicly available. In this research, we develop a novel statistical method for association studies of multiple phenotypes and genetic variants based on GWAS summary statistics. This new method is called sCLC, the CLC method based on GWAS summary statistics. We use the LD score regression to estimate the phenotypic correlation matrix among phenotypes, then use this correlation matrix to cluster multiple phenotypes into different number of clusters and test the association between phenotypes in each cluster and a genetic variant. Finally, we consider all possible numbers of clusters among the phenotypes and apply the Cauchy combination to integrate p-values for each cluster. The overall test statistic of sCLC has an approximate Cauchy distribution whose p-value can be obtained from the cumulative density function. We perform a variety of simulation studies and compare sCLC with other commonly used methods. Simulation results show that sCLC can control the Type I error rates well and has the highest power in most scenarios. Moreover, we apply the newly proposed method to the UK Biobank GWAS summary statistics from the XIII category with 70 related musculoskeletal system and connective tissue phenotypes. The results demonstrate that sCLC can detect the most number of significant SNPs, and most of these identified SNPs can be matched to genes that have been reported to be associated with those phenotypes. Furthermore, sCLC also identifies some novel signals that were missed by standard GWAS, which provide new insight into the potential genetic factors of the musculoskeletal system and connective tissue phenotypes.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3579. SDPRX: A statistical method for cross-population prediction of complex traits

Authors:

G. Zhou¹, C. Tianqi¹, H. Zhao²; ¹Yale Univ., New Haven, CT, ²Yale Univ. Sch. of Publ. Hlth., New Haven, CT

Abstract Body:

Polygenic risk score (PRS) has demonstrated its great utility in biomedical research through identifying high risk individuals for different diseases from their genotypes. However, the broader application of PRS to the general population is hindered by the limited transferability of PRS developed in Europeans to non-European populations. To improve PRS prediction accuracy in non-European populations, we develop a statistical method called SDPRX that can effectively integrate genome wide association study summary statistics from different populations. SDPRX automatically adjusts for linkage disequilibrium differences between populations, and characterizes the joint distribution of the effect sizes of a variant in two populations to be both null, population specific or shared with correlation. The prior assumption made by SDPRX is more general than current methods such as XPASS and PRS-CSx. Unlike SDPRX, XPASS assumes that the genetic architecture is polygenic and all SNPs have non-zero effect sizes. SDPRX differs with PRS-CSx in two aspects. First, it explicitly allows SNPs to have both population specific and shared effect sizes whereas PRS-CSx assumes all SNPs are shared. Second, SDPRX directly incorporates the cross-population genetic correlation into the model for better estimation of shared effect sizes.

We first evaluated the prediction performance of SDPRX, PRS-CSx, LDpred2 and XPASS via simulations across different genetic architectures and training sample sizes. We found that jointly modeling EUR and non-EUR GWAS can improve the prediction accuracy in non-EUR populations if non-EUR GWAS alone was not well powered and SDPRX outperformed the other methods in most cases.

We next compared the performance of SDPRX with PRS-CSx, LDpred2 and XPASS in predicting 15 quantitative traits and 2 binary traits for EAS individuals in UK Biobank using external summary statistics. For each method, one can derive a linear combination of the estimated effect sizes of two populations to further optimize the performance in the target population. The average improvement of SDPRX over PRS-CSx, LDpred2 and XPASS was 14%, 49% and 43% without the linear combination, and 15%, 26% and 34% after the linear combination. For AFR individuals, the performance was compared with 6 quantitative traits and 1 binary trait due to the limited number of publicly available summary statistics. The average improvement of SDPRX over PRS-CSx, LDpred2 and XPASS was 15%, 13% and 39% without the linear combination, and 14%, 31% and 44% after the linear combination.

PB3580. Sensitive detection of within-species contamination from low-pass whole genome sequencing data

Authors:

A. Liu¹, M. Gibson¹, L. Flagel¹, J. Pickrell², J. Li²; ¹Gencove Inc., Long Island City, NY, ²Gencove, New York, NY

Abstract Body:

The accurate detection of DNA sample contamination is an essential aspect in the quality control process of whole genome sequencing. Even moderate levels of sample contamination can lead to a substantial increase in erroneous genotype calls, and may lead to false positive associations when conducting GWAS. Currently, existing methods primarily rely on high coverage sequence data in order to accurately infer deviations from expected allele frequencies, which might be indicative of contaminating reads from another individual.

For applications using low-coverage sequencing (such as in the context of ancient DNA studies and cell-free DNA), there are few existing methods in the literature, most of which are appropriate only for very particular applications.

Here, we introduce a method that leverages known haplotype frequencies from a reference panel such as the 1000 Genomes in order to make accurate estimates of contamination in samples which are sequenced to extremely low (<1x) coverages. Our method uses a maximum likelihood framework which compares the expected and observed linkage disequilibrium between pairs of markers that overlap with distinct sequence reads. Under this framework, an observed deviation from expected haplotype frequencies indicates the presence of contaminating reads from another individual. To accurately represent the individual's haplotype frequencies, we adjust population haplotype frequencies to reflect the inferred ancestry of the target sample.

We show that our low-coverage contamination method estimates contamination more accurately at low coverages (<1x) than existing methods tuned for high-coverage samples, particularly for low levels of contamination (1%- 5%). Furthermore, we show that our method can resolve biased contamination estimates that may arise from admixed individuals or mis-specified haplotype frequencies from the reference panel. Our work emphasizes the importance of quality control metrics tailored to low-pass sequencing as applications in this area become increasingly popular.

PB3582. Sex-stratified vs. sex-combined analysis in the presence of genetic effect heterogeneity.

Authors:

B. Lin, L. Sun; Univ. of Toronto, Toronto, ON, Canada

Abstract Body:

The effect of a genetic variant on a complex trait may differ between male and female, e.g. genetic effects may be sex-specific for testosterone levels. In the presence of genetic effect heterogeneity between female and male, sex-stratified analysis is often used, which provides easy-to-interpret sex-specific effect size estimates. However, from power of association testing perspective, sex-stratified analysis may not be the best approach. As sex-specific genetic effect implies SNP-sex interaction effect, jointly testing SNP main and SNP-sex interaction effects may be more powerful than sex-stratified analysis or the standard main-effect testing approach. When individual data are not available, it is then of interest to study if the interaction analysis can be derived from sex-stratified summary statistics. We considered several different sex-combined methods and evaluated them through extensive simulation studies. We observed that a) the joint SNP main and SNP-sex interaction analysis is most robust to a wide range of genetic models, and b) this joint interaction testing result can be obtained by quadratically combining sex-stratified summary statistics (i.e. squared sex-stratified summary statistics). We then provide theoretical justification for the equivalence between these joint interaction test and quadratically combined omnibus test. Finally, we provide additional supporting evidence by applying the methods to GWAS of testosterone levels in the UK Biobank data.

PB3583. Shared genetic etiology and causality between COVID-19 and venous thromboembolism: evidence from genome-wide cross trait analysis and bi-directional Mendelian randomization study

Authors:

Z. Liu^{1,2}; ¹Univ. of Hong Kong, Hong Kong, Hong Kong, ²Columbia Univ., New York, NY

Abstract Body:

Venous thromboembolism (VTE) occurs in up to one third patients with COVID-19. VTE and COVID-19 may share a common genetic architecture, which has not been clarified yet. To fill this gap, we leveraged summary-level genetic data from the latest COVID-19 host genetics consortium and UK Biobank and examined their shared genetic etiology and causality. The cross-trait analysis identified 8, 11, and 7 shared loci between VTE and severe COVID-19, COVID-19 hospitalization, SARS-CoV-2 infection respectively, in 13 genes involved in coagulation and immune function and enriched in the lung. Co-localization analysis identified eight shared loci in ABO, ADAMTS13 and FUT2 genes. Bi-direction Mendelian randomization suggested that VTE was associated with higher risks of all COVID-19 related traits, and SARS-CoV-2 infection was associated with higher risk of VTE. Our study provided timely evidence and novel insights into the genetic etiology between COVID-19 and VTE.

PB3584. Shared genetic etiology between Alzheimer's disease and stroke: A large scale genome-wide cross-trait analysis

Authors:

Z. Wang, X. Han, J. Li, IGAP Consortium, MEGASTROKE Consortium, L. Liang; Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA

Abstract Body:

Alzheimer's disease (AD) and stroke are the leading causes of death worldwide and common comorbidities in the elderly population. There are many shared risk factors between the diseases, which could possibly be driven by shared genetic factors. With GWAS summary statistics obtained from IGAP and MEGASTROKE consortiums, we performed a cross-trait analysis between AD and stroke to investigate the genetic correlations, common genetic factors, shared GWAS risk loci, and causal effects between the two diseases. Results showed significant genetic correlations between AD and all strokes (AS), as well as cardioembolic stroke (CES). Based on the Mendelian Randomization (MR) methods, we evaluated the diseases' causal effects and concluded that the observed genetic correlations are not causal between the diseases. Meta-analysis revealed shared genes and risk loci, including *CELF1* and *MTCH2*. We then performed causal inference between 338 CSF metabolites and the diseases to investigate the biological mechanisms behind the genetic correlations we observed. Based on MR, we identified the shared metabolites and pathways including cholesterol, ascorbate, 2-hydroxybutyrate, which may contribute to blood-brain barrier dysfunction, oxidative stress, and other risk factors. Lastly, to investigate the similarity between AD and SVS metabolite profiles, we conducted genome-wide association analyses for 6 MRI markers using UK Biobank data, which is currently the largest in scale. With the GWAS summary statistics, we examined the genetic correlations and causal effects between MRI markers and complex diseases. Results show a strong causal effect from fractional anisotropy (FA) to CES, and causal effects from AD to FA, mean diffusivity (MD), and total volume of white matter hyperintensities (TVWMH). The results suggest the shared pathology between AD and stroke is mainly related to the white matter. In conclusion, the observed genetic correlations between AD and stroke are likely due to the non-causal effects, which are explainable using shared risk loci, shared metabolites & pathways, and MRI markers.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3585. Shared Genetics Drive Mate Selection.

Authors:

K. Burghardt¹, E. Arpawong², J-L. Ambite¹; ¹USC Information Sci. Inst., Marina del Rey, CA, ²Univ. of Southern California, Los Angeles, CA

Abstract Body:

People often use the expression "they were born to be together" when referring to their relationships, but how do the factors from birth---namely genetics---play a role in mate selection? Prior work in this area has focused on using polygenic scores to assess genetic correlations between one's polygenic scores and spouse phenotypes, focused on specific areas of similarity in the genome, or on European ancestry samples only. We expand this work by studying a racially/ethnically diverse subsample of older adults to analyze data across the genome from 2,424 participants who form 1,214 marriage pairs, which is our proxy of mate selection. In preliminary analysis, we find that principal components, extracted using principal component analysis (PCA) across all participants who shared their genetic sequences, are the dimensions that explain the most data variance, and reflect genetic ancestry. We then develop methods to determine genetic associations with mate selection throughout the genome. First, we use a model to find the genetic segments that associate with marriage, by comparing pairwise-shared segments between married participants with segments shared by random pairs of subjects. Then, we find the phenotypic covariates that mediate these associations. We find that a small set of genetic slices are significantly associated with marriage, but these slices are mediated by preferences for partners with similar ethnicity, religion, and birthplace, and (to a lesser extent) education. After controlling for these covariates, we find that some genetic slices are significantly associated with marriages. Next, we show an overall quantitative approach of scoring slices together. We calculate pairwise genetic risk scores, which we call Slice Polygenic Risk Scores (SliPRS) and find significant correlations between high SliPRS and the probability of marriage between participant pairs. These results offer new insight into the genetics and mediating factors driving mate selection.

Ctr. for Motor Neuron Disease Res., Sydney, Australia, ²Population Hlth. and Immunity Div., The Walter and Eliza Hall Inst. of Med. Res., Melbourne, Australia, ³Dept. of Med. Biology, The Univ. of Melbourne, Melbourne, Australia, ⁴Brain and Mind Ctr., The Univ. of Sydney, Sydney, Australia, ⁵Sch. of Med. Sci., Faculty of Med. and Hlth., Univ. of New South Wales, Sydney, Australia, ⁶SA Pathology, Women's and Children's Hosp., Adelaide, Australia, ⁷Dept. of Clinical Med., Faculty of Med. and Hlth. Sci., Macquarie Univ., Sydney, Australia, ⁸Dept. of Neurology, Royal Prince Alfred Hosp., Sydney, Australia, ⁹Brain and Mind Ctr., The Univ. of Sydney, Sydney, Sydney, Australia, ¹⁰Dept. of Neuropathology, Royal Prince Alfred Hosp., Sydney, Australia

Abstract Body:

Introduction: Short tandem repeats (STRs) are tracts of repetitive DNA present throughout the human genome. Pathogenic expansions of STRs cause more than 20 neurodegenerative diseases. Historically, to assess STRs in individuals, targeted laboratory-based screening of single STRs was performed. However, the development of bioinformatic tools that detect STRs in whole-genome sequencing (WGS) data enables simultaneous assessment of multiple STRs in large disease cohorts.

Objective: To systematically assess known STR expansions in sporadic amyotrophic lateral sclerosis (sALS) and sporadic frontotemporal dementia (sFTD) patients using WGS data.

Methods: 21 STR expansions known to cause motor and neurodegenerative diseases were screened in WGS data from 608 Australian sALS and 68 Australian sFTD patients, and 4,703 European controls. PCR genotyping was performed to validate expansions.

Results: We identified and validated 162 pathogenic and/or intermediate repeat expansions in 152/676 (22%) sALS and sFTD patients across 9 genes: *C9orf72* (ALS/FTD), *ATXN1* (spinal cerebellar ataxia type 1, SCA1), *ATXN2* (SCA2), *ATXN8* (SCA8), *TBP* (SCA17), *HTT* (Huntington's disease, HD), *DMPK* (myotonic dystrophy 1, DM1), *CNBP* (DM2) and *FMRI* (Fragile-X site A, FRAXA).

Pathogenic expansions were identified in *C9orf72* (n=41), *ATXN8* (n=6), *CNBP* (n=3), *ATXN1* (n=1), *DMPK* (n=1) and *FMRI* (n=1).

Intermediate expansions were identified in *ATXN1* (n=89), *ATXN2* (n=12), *ATXN8* (n=2), *HTT* (n=2), *TBP* (n=1) and *FMRI* (n=3). Expansions in *C9orf72*, *ATXN2* and *HTT* were 37, 3 and 2.5 times more prevalent in patients than controls, respectively.

Conclusion: STR expansions that are causal for neurodegenerative diseases are present in up to 25% of sporadic ALS and FTD patients. This further supports the concept of a common genetic spectrum of neurodegenerative diseases.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3587. Simple phenotype transformations help elucidate genetic architecture in the tails of biomarker distributions.

Authors:

N. Baya^{1,2,3}, D. Palmer¹, S. Myers³, C. Lindgren¹; ¹Big Data Inst., Univ. of Oxford, Oxford, United Kingdom, ²Wellcome Ctr. for Human Genetics, Oxford, United Kingdom, ³Dept. of Statistics, Univ. of Oxford, Oxford, United Kingdom

Abstract Body:

We can better understand the genetic underpinning of complex disease by studying the genetic architecture of related biomarkers. A genetic predisposition to being in the tail of a biomarker distribution may be relevant to related diseases. We sought to discover variants associated with being in the tails of a biomarker distribution (tail status) that are overlooked in standard biomarker genome-wide association studies (GWAS).

Tail status for 33 biomarkers was defined in 185,506 European ancestry samples from the 200k UK Biobank whole exome sequencing data release. Samples residing in either tail of a biomarker distribution were considered cases in a GWAS.

We were particularly interested to determine whether any variants are more significantly associated with tail status than the biomarker viewed as a continuous trait. We hypothesized that there would be a higher proportion of rare variant associations in the tail status GWAS than the continuous trait GWAS because we expect samples in the tails to have a greater accumulation of rare, high effect variants.

We found 458 exome-wide significant ($p < 3.45e-7$, Bonferroni-corrected using number of variants tested, $n=144,561$) variant associations across 19 traits for the 'either-tail' GWAS. Among these associations, the rare variant (MAF<0.01) proportion ($60/458=13\%$) was larger than the proportion of rare variants with significant associations in the continuous trait GWAS ($480/11807=4\%$). Within the either-tail GWAS significant associations, we found 66 variants that were more significant in the either-tail GWAS than the continuous trait GWAS. Of these, 40 were significant only in the either-tail GWAS. Evidence of non-monotonic trends in average allele frequency across the continuous biomarker distribution was found in 10 of 66 variants, suggesting a complex non-linear architecture underlying the effects.

To assess whether the 458 significant either-tail associations are driven by lower-tail or upper-tail associations, we performed two additional lower-/upper-tail GWAS per biomarker, either defining cases as individuals residing in the lower tail or residing in the upper tail. Among the variants significantly associated with either-tail status, 52% (236/458) had upper-tail GWAS p-values that were more significant than the lower-tail GWAS p-values.

Our results show that by using simple phenotype binarization we can uncover variant effects that are significantly associated with tail status that would not be found in a standard GWAS on the continuous trait. We expect these associations to provide clues to aid in our understanding of the genetic architecture of biomarkers and related diseases.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3588. Single cell RNA-seq data analysis of the Huntington's disease cerebellum using the interactive webserver, ICARUS.

Authors:

A. Jiang¹, E. Mears¹, R. Handley¹, V. Hawkins¹, C. McLaughlan², S. Bawden², S. Rudiger², J. Kelly², P. Verma², R. Faull¹, H. Waldvogel¹, L. You³, K. Lehnert¹, R. Snell¹; ¹The Univ. of Auckland, Auckland, New Zealand, ²South Australian Res. and Dev. Inst., Adelaide, Australia, ³Fudan Univ., Shanghai, China

Abstract Body:

Huntington's disease (HD) is a debilitating neurodegenerative genetic disorder caused by an expanded polyglutamine (CAG) trinucleotide repeat in the Huntingtin (HTT) gene resulting in a triad of behavioural, cognitive, and motor defects. Current knowledge of disease pathogenesis remains unclear and no disease modifying interventions have been discovered. We present the results of our cerebellar single cell RNA-seq data performed on 5 human HD cases and 5 controls. We will also present the analysis of striatal samples taken from 6 year-old HD sheep (*OVT73*) and 6 controls. The datasets reveal further supporting evidence for neuroinflammation, excitotoxicity and mitochondrial dysfunction in the HD brain.

The dataset was analysed with ICARUS, a new web server tool designed and implemented to enable users without experience in R to undertake single cell RNA-seq analysis. The focal point of ICARUS is its intuitive tutorial-style user interface, designed to guide logical navigation through the multitude of pre-processing, analysis and visualization steps (Available here, <https://launch.icarus-scrnaseq.cloud.edu.au/>). In summary, we will present our latest findings incorporating both the sheep model and the human results.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3589. Single-cell transcriptomic landscape in Alzheimer's disease

Authors:

V. Swarup, E. Miyoshi, S. Morabito, E. Head; Univ. of California Irvine, Irvine, CA

Abstract Body:

The gene-regulatory landscape of the brain is highly dynamic in health and disease, coordinating a menagerie of biological processes across distinct cell-types. Understanding these regulatory programs requires a holistic experimental and analytical approach. Here, we present a single-cell study of 380,000 nuclei in late-stage Alzheimer's Disease (AD) using parse biosciences whole transcriptome kit, profiling gene-expression in thousands of genes and uncovering vast neuronal and glial heterogeneity in late-stage AD. We introduce a co-expression network analysis strategy for single-cell data (hd-WGCNA) to perform a systems-level meta-analysis of AD transcriptomics to uncover underlying regulatory architecture. hd-WGCNA is based on a meta-analytical approach to jointly form co-expression networks in metacells constructed from the integrated snRNA-seq dataset as well as bulk-tissue RNA-seq data of the human cortex, where each edge in a co-expressed module is supported by both bulk RNA-seq data and snRNA-seq data. Finally, this work, provides an unbiased single-cell atlas of transcriptomic regulation of AD in distinct brain regions.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3590. Smoking-informed methylation QTLs in human nucleus accumbens

Authors:

M. Carnes¹, B. Quach², L. Zhou¹, R. Tao³, A. Deep-Soboslay³, L. Bierut⁴, B. Maher⁵, A. Jaffe³, T. Hyde³, J. Kleinman³, E. O. Johnson⁶, D. Hancock⁷; ¹RTI Intl., Durham, NC, ²RTI Intl., Research Triangle Park, NC, ³Lieber Inst. for Brain Dev., Baltimore, MD, ⁴Washington Univ Sch Med, St Louis, MO, ⁵Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, ⁶RTI Intl., Duluth, MN, ⁷RTI Interntional, Durham, NC

Abstract Body:

Smoking is a leading cause of preventable morbidity and mortality. Smoking is heritable, and hundreds of genome-wide significant variants are associated with smoking behaviors (initiation, age of initiation, cigarettes per day, and cessation), as identified by the GWAS and Sequencing Consortium of Alcohol and Nicotine use (GSCAN). Most are noncoding variants with unknown neurobiological effects. To evaluate their regulatory potential, we used genome-wide genotypes and DNA methylation (DNAm) data in postmortem human nucleus accumbens (NAc) from the LIBD Human Brain Repository to identify cis-methylation quantitative trait loci (mQTL) and investigate epistatic interactions by cigarette smoking. Active smokers (European ancestry N= 26; African ancestry N= 26; total N=52) and nonsmokers (European ancestry N= 75; African ancestry N= 93; total N=168) were defined based on cotinine and next-of-kin reporting. We used the joint 2df method to simultaneously test variant and smoking-by-variant interaction effects on DNAm, adjusting for biological and technical covariates. We accounted for multiple testing using a two-stage approach based on eigenMT and Bonferroni corrections. We found >2 million significant mQTLs (padj<0.05) representing 41,695 unique CpGs after filtering (MAF>0.05 and missingness <0.10 in both ancestries). Most of the unique CpGs (67%) lie within a gene body or in a known gene regulatory region. Results were largely driven by main effects, as 95% of significant CpGs were also identified in baseline mQTL analyses that did not account for an interaction. We assessed mQTLs among 371 overlapping GSCAN-identified variants. Of these, 229 variants (62%) were significant mQTLs, all driven by main effects of the variant on DNAm with no evidence of interaction with smoking. Of the 229, the top mQTLs overlapped with GSCAN-identified variants that were annotated to *HLA-G*, *BRWD1*, *ZNF207*, and *SLC25A20* (all p<1e-50). The most significant of which, rs3115418-cg04567952 (punadj=1.9e-101), was identified by GTEx as a NAc eQTL for the *TYW5* gene. We present the first genome-wide mQTL map in the human NAc and report enriched overlap with genetic variants of smoking behaviors, suggesting that regulation of DNAm levels in the brain may help explain the neurobiology underlying smoking GWAS loci.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3591. Specific HLA risk alleles associated with the highly variable region of T cell receptors (TCRs) in Leukemia, Melanoma and COVID-19 patients.

Authors:

J. Han; Seoul Natl. Univ. Coll. of Med., Seoul, Korea, Republic of

Abstract Body:

[Background] Human leukocyte antigen (HLA) genes are highly polymorphic and strongly affect diverse disease risks including immune-related diseases. The peripheral hypothesis is that HLA risk alleles are encrypted to proteins that may increase presenting critical autoantigens and lead to autoimmunity. In this hypothesis, the event arises in the peripheral tissues and lymph nodes. There is another non-mutually exclusive hypothesis, the central hypothesis. In the central hypothesis, HLA risk alleles influence primary lymphoid organ selection and ultimately affect the increasing number of T cell receptors (TCRs) having autoreactivity. In this hypothesis, the key event arises in the primary lymphoid organ, thymus and bone marrow selection. Nowadays, human autoimmunity researchers assert some evidence supporting the central hypothesis rather than the peripheral hypothesis. [Study design] We wanted to study the interaction between TCRs and modified patients' cells from the perspective of the central hypothesis in non-autoimmune diseases. We investigated several non-autoimmune disease categories that may be related to the HLA-TCR interaction, which are cancer diseases by the mutagen (leukemia and melanoma) and infectious diseases by the virus (COVID-19). Here we investigated the effect of HLA alleles on TCRs' highly diverse regions (e.g. complementarity determining region 3, CDR3) which have an important role in antigen recognition. We analyzed which HLA risk alleles affect TCRs' region characteristics in the patients and compared the association pattern to the healthy control, from the perspective of the central hypothesis. [Results] We found a number of associations between HLA alleles and TCR region in non-autoimmune diseases. We observed that some HLA alleles and amino acid positions affect TCR in multiple diseases. In addition, the TCR's highly diverse region involved by the HLA risk alleles were different in patients from in healthy people. In summary, these investigations show that HLA risk alleles may lead to the bias of TCR's highly diverse regions on an individual level, which can differ by an individual's disease status.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3592. ssCTPR: summary statistic based cross-trait penalized regression

Authors:

M. Weidmann, J. Rossen, L. Liang; Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA

Abstract Body:

The arrival of large-scale genome-wide association studies (GWAS) in recent years has allowed the development of polygenic risk scores (PRS) for genetic risk prediction. However, current sample sizes are often still inadequate to accurately estimate the effects of variants with minor genetic effects. GWAS summary statistics provide access to effect estimates for individual variants on many traits without needing individual-level data. By leveraging shared causal variants from genetically-related traits, it is possible to improve the effect estimates and overall accuracy of PRS. Here, we propose summary-statistic-based cross-trait penalized regression (ssCTPR). ssCTPR uses GWAS summary statistics for the primary traits as well as from multiple genetically-related traits. The summary statistics for the secondary traits can be generated from either the same or a separate set of subjects. Our cross-trait penalty function utilizes information from secondary traits that could be useful to improve the causal effect estimation for the primary trait of interest while discarding non-useful information. Our method can take advantage of precomputed linkage disequilibrium (LD) matrices based on a large reference panel to better estimate independent causal genetic effects. We also developed an efficient search algorithm to ensure convergence and optimization of the tuning parameters. We used genotype data from 330,000 British individuals from UK Biobank to simulate a range of genetic architectures for continuous traits. Using a preliminary implementation of the method, ssCTPR attained a 6% increase in out-of-sample r^2 compared to single trait PRS based on LassoSum. We further extend the method by implementing a gradient-descent algorithm to rapidly search the 3-dimensional space for tuning parameters. We will also discuss criteria to ensure gradient descent algorithm convergence when candidate SNPs are in LD. Our method shows that adding GWAS summary statistics from related traits can boost the prediction accuracy of PRS compared to PRS generated using summary statistics of only the primary trait. We compute and make publicly available the PRS models using UK Biobank diseases and traits.

PB3593*. Subcontinental Admixture in Individuals with European Ancestry and Implications for Genetic Epidemiology Studies

Authors:

M. Gouveia, A. Adeyemo, C. N. Rotimi, D. Shriner; NIH, Bethesda, MD

Abstract Body:

Admixed populations are commonly thought to have resulted from recent interbreeding between continentally separated populations. European-ancestry populations are recognized as stratified but not as admixed, so genetic epidemiology studies including Europeans or European Americans do not fully control for potential confounding effects of local ancestry. We analyzed a large genome-wide data collection of over 18,000 European-ancestry individuals, including 1,216 individuals across 79 European populations and 17,684 European Americans from five genetic epidemiology cohorts in the US (ARIC, CARDIA, FHS, GENOA, and MESA). We found that the 1000 Genomes and Human Genome Diversity Projects provided incomplete coverage of European ancestries, so we generated a new reference panel to capture the breadth of European ancestral diversity. We inferred a three-way admixture profile in Europeans, with genetic variation significantly correlated ($p < 1.2 \times 10^{-13}$) with North-to-South ($\rho = 0.72$) and West-to-East ($\rho = 0.84$) geographic origin. We also identified population structure in European Americans, with this structure due to admixture rather than discrete subpopulations. We replicated the classical false-positive association between height and lactase persistence (rs4988235) when models were not fully adjusted for ancestral population structure. In a GWAS of height, we observed systematically better fits and smaller genomic inflation factors when models were adjusted for principal components (PCs) derived from projection of European Americans onto our reference panel, rather than for PCs derived from study-specific unsupervised analysis. Overall, we provide evidence of subcontinental admixture in Europeans and European Americans, which if not properly accounted for can produce false positives in genetic epidemiology studies.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3594*. Supervised modeling on CRISPR gene regulatory screening and cell-type-specific gene regulatory landscapes to prioritize GWAS Targeted Genes

Authors:

M-J. Tsai^{1,2}, S. Reppe³, T. Sato⁴, M. Wein⁴, K. Gautvik³, Y-H. Hsu^{1,5,2}; ¹Hinda and Arthur Marcus Inst. for Aging research, Boston, MA, ²Dept. of Med., Beth Israel Deaconess Med. Ctr. and Harvard Med. Sch., Boston, MA, ³Oslo Univ. Hosp., Oslo, Norway, ⁴Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, ⁵Broad Inst. of MIT and Harvard, Cambridge, MA

Abstract Body:

Background: More than 95% of disease-linked genetic variants reside in the dark genome, and most of these non-coding variants have no function due to historical technical barriers. Significant efforts have been made to characterize human non-coding genomic regions, and advanced approaches have been developed to identify causal variants and prioritize targeted genes in non-coding GWAS loci. But it remains a significant challenge to connect causal variants to their target genes across cell types. **Methods:** To overcome such challenges, we apply supervised machine learning algorithms to develop a prediction method, EPFinder, to predict enhancer-gene mapping and prioritize the target genes in GWAS loci. We generated human cell-type-specific high-resolution chromatin-interaction (Hi-C seq), open chromatin regions (ATAC-seq), histone marks (ChIP-seq), and transcriptome (RNA-seq). These data were then used as input features with ensemble machine learning models to learn the patterns of 4,072 enhancer-gene pairs in human K562 Leukemia Cells obtained from the CRISPR-FlowFISH dataset. We apply this model to predict known disease genes under GWAS loci for type 2 diabetes (T2D), height, and osteoporosis GWAS to benchmark and validate model performance. **Results:** EPFinder has an area under the precision-recall curve (AUPRC) of 90.08% (AUPRC range from 87.6% to 90.3%) for different cell types, outperforming existing methods for predicting CRISPR datasets. To validate the performance of targeted genes prediction in GWAS loci, we selected the well-known T2D, height, and bone genes. For model prediction, we used cell-type-specific Hi-C, ATAC-seq, RNA-seq, and ChIP-seq from disease-relevant primary cell types. We estimated prediction ability by odds ratio (OR) of the positive prediction rate among those well-known targeted genes. Our model improved targeted prediction ability from OR = 21.1 ($p = 7.8 \times 10^{-13}$) to OR = 41.1 ($p = 3.3 \times 10^{-49}$) compared to identifying target genes using Hi-C and ATAC-seq along. **Conclusion:** With human primary cell-type-specific 3D genome architecture and gene regulatory landscapes as input, our model allows us to prioritize targeted genes in GWAS loci with traits relevant to the cell types of the input data. Machine learning to predict cell-type-specific enhancer-gene mapping enables us to accurately identify affected cell types, potential causal variants, and causal genes, especially in non-coding GWAS loci.

PB3595. Supervised multiset sparse partial least squares discriminant analysis in multi-omics data integration.

Authors:

K. Su¹, A. M. Alam¹, C. qiu¹, J. Greenbaum¹, Q. Tian¹, Z. Luo¹, L. Wu¹, L. Zhao¹, H. Shen^{2,1}, H-W. Deng^{2,1}; ¹Tulane Ctr. for BioMed. Informatics and Genomics, New Orleans, LA, ²Tulane Univ., New Orleans, LA

Abstract Body:

Multi-omics (MO) studies exploring the interrelationships of various biological factors have provided newfound opportunities to discover biomarkers and characterize biochemical consequences of genetic variation. However, the heterogeneous data types and high dimensionality of the data introduce extraordinary challenges for developing analytical methodologies to integrate MO datasets. Current methods integrated MO datasets without considering traits and therefore provide irrelevant results for disease outcomes. We propose a multiset sparse Partial Least Squares Discriminant Analysis (msPLSDA) method to simultaneously extract phenotype-relevant features from thousands of heterogeneous biological elements and predict phenotype status in a unified supervised MO framework.

The msPLSDA consists of three essential components. The first is a PLS method, which is well suited for handling multicollinearity issues; the second is an elastic net penalization technique incorporated into the PLS modeling that enables feature selection; and the third is a multi-block technique, which can incorporate prior biological knowledge, such as functional gene modules or pathway information. Numerical simulation experiments were conducted to demonstrate the performance in feature selection and discrimination for the proposed method. As a real data application, msPLSDA was applied to the transcriptome, methylome, and metabolome from Louisiana Osteoporosis Study for bone-related biomarker identification.

The implementation of the proposed method for feature selection indicated that high selection accuracy is achieved by increasing sample size (suggested at least 80 samples for three categorical outcomes). The high differences of features among outcome groups and lower covariances among features also contribute to the accuracy of feature selections. In the LOS dataset, the trained msPLSDA model reached a high accuracy discrimination rate (95% confidence interval: 0.96 ~ 1) and identified more significant biomarkers in terms of bone-associated pathways, such as osteoclast differentiation (KEGG, p-value: 0.0037 and odd ratio: 6.77).

Overall, msPLSDA revealed phenotype-related features from each omics type. The generated results will assist in providing interpretable outputs, which can then be used for further downstream bioinformatic analyses, such as pathway analysis to identify molecular functionalities, network analysis to estimate molecular interactions and causal inference. This method will help pave the way toward a better understanding of disease pathogenesis in translational medicine.

Abstract Body:

Coronary artery disease (CAD) is a leading cause of death and disability worldwide and represents a common complex disease with genetic and environmental determinants. GWAS of CAD from international consortia, including the CARDIoGRAMplusC4D Consortia, and analysis of UK Biobank data have identified over 150 independent variants associated with the risk of CAD. In this study, we leverage multiple sources of molecular 'omics data from the NHLBI Trans-Omics for Precision Medicine (TOPMed) program to examine prior findings with (a) overlap of GWAS with eQTL/pQTL, and (b) network structure. Our study leveraged transcriptomic data obtained from peripheral blood mononuclear cells (PBMCs) and plasma proteomics from participants in the Multi-Ethnic Study of Atherosclerosis (MESA). We performed Bayesian colocalization using R/coloc to identify the molecular targets implicated by GWAS. Support for hypothesis 4 (both the QTL and GWAS are associated with the region and share a single causal variant) used a posterior probability threshold of 0.8 for Bayesian colocalization. To investigate the relationship of the colocalized genes and proteins with subclinical atherosclerosis, we conducted Bayesian colocalization using the results of GWAS for coronary artery calcium (CAC) and carotid artery intima-thickness (cIMT), focusing on those genes identified in our initial analyses of CAD. We performed weighted gene co-expression network analyses (WGCNA) to identify the modules of highly correlated genes and calculated the module membership (MM threshold of 0.8) to identify the hub genes for each module. We examined the association of the hub genes with CAC in MESA using linear regression with adjustment for age, sex, and study site to identify the CAC-related hub genes for each module. Based on our Bayesian colocalization, we identified 224 putative genes and 78 putative proteins by integrating eQTL and pQTL from TOPMed MESA with summary statistics from the prior GWAS of CAD (van der Harst and Verweij, 2018). Among these, we observed additional colocalization with subclinical atherosclerosis traits for *ILRUN* (cIMT), *GGCX* (CAC), and *RNF114* (CAC). Using WGCNA on the TOPMed RNA-seq data from MESA PBMCs, we constructed 30 modules of highly correlated genes and further identified the CAC-related hub genes for each module. We found *AHCYL1* to be a CAC-related hub gene from the “dark green” module, also located within the region of the lead variant on chromosome 1 from the GWAS of CAD. Our study identified multiple candidate genes at GWAS loci that are supported by molecular QTL and further showed the value of network analysis to highlight the core role of some genes implicated by GWAS.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3597. The effect of CA and D vitamins on the course of COVID 19 from the plasma osmolality perspective in a Turkish Cohort.

Authors:

A. Ulgen¹, H. Sivgin², S. Cetin³, W. Li⁴; ¹Dept of Biostatistics, Faculty of Med., Girne American Univ., Karmi, Cyprus, ²Tokat State Hosp., Dept. of Internal Med., Tokat, Turkey, ³Dept. of Biostatistics, Faculty of Med., Tokat Gaziosmanpasa Univ., Tokat, Turkey, ⁴The Robert S. Boas Ctr. for Genomics and Human Genetics, The Feinstein Inst. for Med. Res., Manhasset, NY

Abstract Body:

Osmolality, concentration of solute particles, can be estimated from the measurement of three other blood test variables (sodium, glucose, and urea), and was rarely used for prognosis for COVID-19. As a result of the analysis of the data obtained from COVID-19 patients, we found osmolality to be an excellent prognostic biomarker for both mortality and hospitalization. On the other hand, both hypocalcemia and vitamin-D deficiency are also significantly associated with a higher mortality rate in our data, while only calcium and not vitamin D is associated with a higher hospitalization rate. Different types of tests, including logistic regression, t-test, Wilcoxon test, lead to the same conclusion. After conditioning on osmolality in a multiple logistic regression, calcium level remains to be significantly associated with both mortality and hospitalization (p-val <0.001). However, vitamin D loses its association with mortality when conditioning on osmolality (significant only at 0.05 level).

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3598. The effect of mental diseases on chronic kidney disease: a bidirectional Mendelian randomization study

Authors:

S. Yu; Sichuan Univ., Chengdu, China

Abstract Body:

Background:

It has been released that the association between chronic kidney disease (CKD) and mental diseases such as bipolar disease (BIP), major depressive disorder (MDD), anxiety disorder (AD), attention deficit/hyperactivity disorder (ADHD), and schizophrenia (SCZ). the prevalence of depression in CKD patients varies from 22.8 to 39.3%. Therefore, psychiatric patients have 1.5-3 times more hospitalization compared to patients having only CKD. However, there was insufficient evidence on whether these psychiatric traits causally lead to CKD and vice versa, owing to possible residual confounding and reverse causation bias in observational research. Methods:we performed various MR studies including inverse-variance weighted method and MR-Egger, **latent** causal variable (LCV) model, Causal Analysis Using Summary Effect Estimates (CAUSE), using genome-wide significant single-nucleotide polymorphisms (SNPs) up to 5,890,484 participants, retrieved from large-scale genome-wide association studies (GWAS), as instrumental variables (IVS) to assess the associations of the risk of renal function and mental disease with five renal variables, including BUN (Blood Urea Nitrogen), EGFR (Estimated Glomerular Filtration Rate) of creatine, EGFR of cysteine, UACR (Urine Albumin-Creatinine Ratio), and urate.

Result: For forward MR,the LCV and CAUSE shows that MDD was associated with EGFR of creatine[GCP: -0.268, 0.417, p = 0.001], BIP was associated with UACR [GCP: 0.024, 0.476, p = 0.04].For reversed MR, Two-sample MR provided evidence that BIP was associated with higher odds of EGFR of cysteine [beta:0.001, 95%CI: 0.001, 0.002, p = 0.027]. While MDD was associated with lower BUN [beta: -0.003, 95%CI: -0.005, -0.001, p = 0.011] and higher EGFR of creatine [beta:0.001, 95%CI: 7.776, 0.002, p = 0.037] Conclusion:Our study provides further evidence that MDD is causally associated with higher odds of EGFR of creatine and lower BUN. Our results showed evidence of non-linear causal association between MDD and CKD; BIP and CKD

PB3599. The effects of demographic-based selection bias on GWAS results in the UK Biobank

Authors:

T. Galama¹, S. van Alten², B. Domingue³, A. Marees², J. Faul⁴; ¹Univ. of Southern California, Los Angeles, CA, ²Vrije Univ.it Amsterdam, Amsterdam, Netherlands, ³Stanford, Stanford, CA, ⁴Univ. of Michigan, Ann Arbor, MI

Abstract Body:

The implications of selection bias due to volunteering (*volunteer bias*) for studies of genetic associations are poorly understood. Because of its large sample size and breadth of phenotypes, the UKB is included in almost all large GWASs as one of the largest cohorts, yet is known to be highly selected. In this paper, we develop inverse probability weighted GWAS (IPWGWAS) to estimate GWAS summary statistics in the UKB that are robust against volunteer bias. IPWGWAS results in effect sizes that are more predictive and reduces the odds of false positive results. Using IPWGWAS, we find (1) substantial increases in heritabilities for behavioral phenotypes (e.g., educational attainment, BMI, and age at first birth), (2) differences in genetic correlations between various behavioral phenotypes, and (3) show that some biological annotations estimated by GWAS are false positives that are driven by volunteer bias. For example, we show that the finding that SNPs associated with age at first birth are mainly expressed in the brain cerebellar hemisphere and the brain cerebellum, is entirely the result of volunteer bias. Further, we will assess whether volunteer bias can explain the surprisingly low within-sibship heritabilities of educational attainment and household income that are common in the literature. Our findings are useful for understanding the extent to which a particular phenotype is prone to volunteer bias in GWAS, and correction using IPWGWAS provides an alternative when population-representative cohorts are not available for GWAS analyses.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3600. The hidden factor: the importance of accounting for covariate effects in power and sample size computation when analyzing a binary trait.

Authors:

Z. Zhang, L. Sun; Univ. of Toronto, Toronto, ON, Canada

Abstract Body:

Accurate power and sample size estimation are crucial to the design and analysis of genome-wide association studies (GWAS). It is well known that replication studies with underestimated sample sizes can result in false negatives, missing truly associated SNPs. In GWAS of a binary trait via logistic regression, important covariates such as age and sex are typically included in the model. However, their effects are rarely properly considered, for example, in power or sample size computation for a successful replication study. Unlike when analyzing a continuous trait, the power of association analysis of a SNP with a binary trait also depends on covariate effects, even under the assumption of gene-environment (G-E) independence. Earlier methodological work recognizes this phenomenon but implemented methods are not flexible. We thus propose and implement a generalized method to honestly calculate the power of an association study, and correctly estimate the sample size necessary for a successful association study of a binary trait. The proposed method a) accommodates different types of non-genetic covariate E, b) deals with different types of G-E relationships, and c) is computationally efficient thus applicable to GWAS. Extensive simulation studies show that the proposed method is accurate and computationally efficient for both prospective and retrospective sampling designs with various covariate structures and G-E dependency. A proof-of-principle application to the UK Biobank data focused on the understudied $n = 3,460$ self-reported African participants; $n = 2,512$ after population principal component analysis. The application showed that ignoring covariate age effect led to significantly overestimated power (hence underestimated replication sample size) when analyzing the binary hypertension trait. In contrast, the computation for the continuous blood pressure trait is invariant to the covariate effect, as expected based on the analytical and simulation results. The R package *SPCompute* that implements the proposed method can be found at <https://cran.r-project.org/web/packages/SPCompute>.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3601*. The impact of 22q11.2 copy number variants on human traits in the general population.

Authors:

M. Zamarioli^{1,2}, C. Auwerx^{2,3,4,5}, M. Sadler^{4,2,3}, A. van der Graaf², K. Lepik², M. Moyses-Oliveira¹, A. Dantas¹, M. Melaragno¹, Z. Kutalik^{2,3,4}; ¹Univ.e Federal de São Paulo, São Paulo, Brazil, ²Univ. of Lausanne, Lausanne, Switzerland, ³Swiss Inst. of Bioinformatics, Lausanne, Switzerland, ⁴Univ. Ctr. for Primary Care and Publ. Hlth., Lausanne, Switzerland, ⁵Ctr. for Integrative Genomics, Univ. of Lausanne, Lausanne, Switzerland

Abstract Body:

Phenotypic consequences of 22q11.2 copy number variants (CNVs) have been demonstrated in clinical cohorts but have remained understudied in the general population. To address this gap, we performed a phenome-wide association scan in 405,324 unrelated UKBB participants using CNV calls from the genotyping array. To restrict the investigated traits, we mapped 236 Human Phenotype Ontology terms linked to any of the 90 genes encompassed by the region to 170 UKBB traits using cross-ontology mapping and web-scraping followed by manual curation. We then assessed the association between the copy-number state of 504 SNP-array probes in the region and 152 binary and 18 continuous traits using logistic and linear regression, respectively. Four association models were investigated: deletion-only, duplication-only, mirror (i.e., duplications and deletions have opposing effects) and U-shape (i.e., duplications and deletions have the same effect direction). We assessed the causal effect of the expression level of 39 testable (i.e. instrumentable) 22q11.2 genes on associated traits with transcriptome-wide mendelian randomization (TWMR). We also performed multivariable Mendelian randomization (MVMR) to assess the relationship among associated traits and infer if the pleiotropic effect of CNVs are vertical (indirect) or horizontal (genuine). Among the investigated participants, 1127 were duplication carriers and 694 had deletions within 22q11.2 low copy repeats A-D, with variable sizes. We found eight continuous and nine binary traits associated under different models revealing distinct impacts. Eight traits associated under the U-shape model, e.g. body-mass index (BMI; $\beta = 0.33 \text{ kg/m}^2$; $P = 4.9 \times 10^{-10}$), while three did so under the mirror model, e.g. mean platelet volume (MPV; $\beta = -0.54 \text{ femtolitres}$, $P = 1.3 \times 10^{-18}$). TWMR showed that increased expression of *ARVCF* increases BMI ($P = 10^{-4}$), concordantly with its encompassing CNV. Similarly, increased *DGCR6* levels causally reduced MPV ($P = 0.001$), in line with the corresponding CNV effect. Finally, cross-trait MVMR suggested a predominant role of horizontal pleiotropy. We have further showed that CNV probes in genes linked to a given HPO term are 15 times more likely ($P < 6 \times 10^{-9}$) to show significant association with the corresponding UKBB continuous trait. Our findings show that within the general population, 22q11.2 CNVs are associated with traits previously implicated by genes in the region, with duplications and deletions acting similarly or in opposite directions upon different traits. We also showed that gain or loss of distinct segments within 22q11.2 may impact a trait following different association models.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3602. The impact of genetic variation on hearing acuity variability

Authors:

J. Duran, L. Jorde; Univ. of Utah, Salt Lake City, UT

Abstract Body:

Although considerable research has been done on the genetics of deafness, relatively little is known about the genetics of normal variability in hearing acuity. We have analyzed genetic data from multigenerational families to assess the impact of genetic variation on hearing acuity variability at seven frequencies (250Hz, 500Hz, 1000Hz, 2000Hz, 4000Hz, 6000Hz, 8000Hz). Air conduction hearing acuities are measured as the lowest threshold (volume) at which an individual can hear a tone. We used a family-based methodology to estimate heritability and identify genetic variants that may be responsible for hearing acuity variability. The cohort consists of thirty-four large three- and four-generation Utah CEPH families who have been whole-genome sequenced (WGS) and screened for over 100 quantitative phenotypes. Using the SOLAR software package, we show that hearing acuity heritability ranges from 30% for 250hz and steadily decreases to 18% for both 6000Hz and 8000Hz. Hearing acuity is known to be impacted by environmental factors and may be the reason for decreased heritability at higher frequencies. Most twin studies estimate the heritability of hearing loss as 35% to 60%. A twin study measuring hearing acuity of individuals at least 65 years old estimated average hearing acuity heritability at 40%. Twin studies tend to overestimate heritability, so our family-based estimates are likely to be more accurate. Utilizing the WGS of the Utah CEPH cohort, we employed quantitative trait loci (QTL) mapping, which identifies loci predicted to be associated with changes in phenotypic variability. Our analysis uses single nucleotide polymorphisms (SNP)s as the variants of interest and accounts for covariates to predict QTLs. We identified 27 significant (Bonferroni-corrected $p < 0.05$) SNPs predicted to impact hearing acuity. In addition, chromosomes two, nine, and twelve are enriched for significant QTLs across the lower frequencies (250Hz, 500Hz, 1000Hz, and 2000Hz). When analyzing significant QTLs, we identified two SNP alleles segregating through two generations in at least one family. Further assessment of the identified QTLs is required to identify families that carry these alleles and whether they affect hearing acuity and segregate through families. We have identified approximately 15,000 individuals with hearing acuity assessment in the UK Biobank as a replication cohort to validate our findings.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3603. The impact of rare regulatory variation from epigenetics to protein

Authors:

T. Li¹, N. Ferraro², M. Cirnigliaro³, S. Arteaga³, L. Pérez-Cano⁴, J. Lowe³, B. Strober⁵, B. Ni⁵, NHLBI TOPMed Consortium, D. Geschwind³, S. Montgomery², A. Battle⁵; ¹Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ²Stanford Univ., Stanford, CA, ³Univ. of California, Los Angeles, Los Angeles, CA, ⁴Stalicia DDS, Barcelona, Spain, ⁵Johns Hopkins Univ., Baltimore, MD

Abstract Body:

Any individual genome has thousands of rare genetic variants (RVs) and determining the subset that influence traits remains a key challenge due to the lack of a known regulatory code. We previously demonstrated that incorporating transcriptomic data can prioritize functional RVs as individuals with outlier gene expression are more likely to carry a nearby candidate RV. However, the transcriptome captures only a part of the regulatory cascade from genotype to phenotype, and it is unknown how RVs underlying other omic signals such as epigenetic changes or proteomics are related to disease risk. Here, we analyzed transcriptomic, methylomic, proteomic, and whole genome sequencing (WGS) data from 1,319 individuals in the TOPMed Multi-Ethnic Study of Atherosclerosis (MESA). We observed strong enrichment of RV burden nearby outlier signals in each molecular phenotype, where multimodal outliers show even stronger enrichments. We extended Watershed, a Bayesian hierarchical framework incorporating genomic annotations and observed outlier status for RNA expression and splicing to include methylation and protein expression levels to prioritize RVs. The multiomic Watershed model learned features corresponding to known variant biology and outperformed genomic annotation models in predicting regulatory status of pairs of individuals who share the same RVs nearby the same gene. When trained on European samples and evaluated on other populations, prediction accuracy remained similar (area under precision-recall curve for Europeans between [0.05, 0.14] and others [0.03, 0.16]), suggesting cross-population portability. Each omics signal prioritized a distinct set of variants which showed significantly larger effects on complex traits such as height, rheumatoid arthritis, Alzheimer's disease, and schizophrenia.

To further demonstrate the capability of Watershed to inform trait associations, we analyzed WGS data from 192 brain samples with paired transcriptomic data from the PsychENCODE UCLA Autism Spectrum Disorder (ASD) dataset. Watershed posteriors for splicing and protein signals significantly distinguishes individuals with idiopathic ASD from controls for SFARI Category I genes, suggesting that the multiomic Watershed model can be transferred to other tissues and disease contexts. Lastly, we observed that individuals with ASD harbor a higher number of brain-specific RVs prioritized by Watershed, demonstrating its ability to identify causal rare variants and mechanisms in ASD. Overall, our work presents a framework to integrate multiomic data and improve gene-trait prioritizations and genetic risk prediction through rare variants.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3604*. The largest deep-coverage whole genome seq meta-analysis on osteoporosis identified novel GWAS loci

SPH, Boston, MA, ²¹Hebrew SeniorLife Inst. for Aging Res., Ha, Boston, MA

Abstract Body:

Osteoporosis is common in the elderly characterized by systematically reduced bone mineral density (BMD) and poor bone quality, which increases the risks of osteoporotic fracture, especially at hip and spine. Osteoporosis is diagnosed by BMD measured from DXA machines. Previously, we reported the largest common-variant GWAS analyses on estimated BMD from heel ultrasound (N~400K). However, the identified loci only explained ~20% variance of estimated BMD, comparing to the 85% heritability of DXA-derived BMD in twins. Thus, the current common-variant-based GWAS approach only detects a small fraction of genetic heritability. To explain the missing heritability, WGS has been incorporated to provide comprehensive enumeration of sequence variation. To identify less common, rare and structural variants that are associated with DXA BMD, we utilized the deep-coverage WGS (30X coverage) in 50k Caucasians (~40K from the UK Biobank study and ~10K from the NHLBI TOPMed Program) with clinical defined BMD derived from DXA at lumbar spine (LS) and femoral neck (FN) skeletal sites. From single variant association analysis, we identified 60 GWAS loci associated with FN BMD and 68 GWAS loci associated with LS BMD ($p < 5E-8$). Among them, the lead SNPs on 20 GWAS loci are missense variants. A subset of these variants was also associated with osteoporotic fracture in the same study samples. The most significantly associated locus with FN BMD was for SNP rs6886306 located in the intron of MEF2C (MAF=0.51, $\beta = -0.085$, $p = 9.26E-39$). The most significantly associated locus with LS BMD was for an Indel variant, SNP rs60521551, located in the intergenic region on chr13q14.1 locus (MAF=0.53, $\beta = 0.125$, $p = 3.94E-76$). For rare variant gene-based association analyses (MAF< 0.5%), we performed SKAT-O gene-based analysis to test the joint effect of the predicted to be functional variants annotated to protein-coding genes with the following variant filtering criteria: high-confidence loss-of-function variants, or missense variants with predicted pathogenicity. 18 genes were found to be genome-widely associated with either LS BMD or FN BMD ($p < 5E-6$), among which BCAS3, LRP5, and TMEM41B have been found to be associated with bone-related phenotypes; and the other 13 genes are novel association findings. These novel associated genes/loci are underway with CRISPR gene-editing experiments in the zebrafish model. The WGS provides fine resolution of sequence variation to further reveal the underlying genetic mechanism of less common/rare, structural, and missense variants involved in bone loss pathophysiological mechanisms and provided important clinical insight into osteoporosis treatment.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3605. The nature of nurture is not in the parents' genes: estimating indirect genetic effects from parents using imputed grandparental genotypes

Authors:

A. Young^{1,2}, R. Cheesman³, M. Lehtovirta⁴, G. Hatem⁵, J. Guan², S. Moeen Nehzati², H. Jayashankar⁶, L. Hakaaste⁴, T. Tuomi^{4,5}, A. Okbay⁷, D. Cesarini^{6,8,9}, D. Benjamin^{1,2,6}, R. Prasad^{4,5}, E. Ystrom^{3,10}; ¹Human Genetics Dept., UCLA David Geffen Sch. of Med., Los Angeles, CA, ²UCLA Anderson Sch. of Management, Los Angeles, CA, ³PROMENTA Res. Ctr., Dept. of Psychology, Univ. of Oslo, Oslo, Norway, ⁴Inst. for Molecular Med. Finland (FIMM), Univ. of Helsinki, Helsinki, Finland, ⁵Lund Univ. Diabetes Ctr. (LUDC), Malmö, Sweden, ⁶Natl. Bureau of Economic Res., Cambridge, MA, ⁷Dept. of Economics, Sch. of Business and Economics, Vrije Univ.it Amsterdam, Amsterdam, Netherlands, ⁸Dept. of Economics, New York Univ., New York, NY, ⁹Res. Inst. of Industrial Economics (IFN), Stockholm, Sweden, ¹⁰Dept. of Mental Disorders, Norwegian Inst. of Publ. Hlth., Oslo, Norway

Abstract Body:

Genetic associations are often interpreted as the result of direct genetic effects, i.e. effects of alleles in an individual on that individual. However, indirect genetic effects (IGEs) from relatives can also lead to genetic association: for example, if alleles in parents affect offspring through the environment, a phenomenon termed 'genetic nurture'. Previous work has suggested that IGEs from parents explain around 1/3rd of the association between educational attainment (EA) and polygenic predictors (PGSs) of EA. These studies have relied on fitting models that include the proband (phenotyped individual) and parents' PGSs. Because the variation in the proband PGS that is independent of the parents' PGSs is due to random segregations of genetic material in the parents, these models can isolate the component of the association between phenotype and PGS that is due to direct genetic effects. However, these studies are not able to isolate the component of the association due to IGEs from parents: the estimates are confounded due to the parental PGSs being correlated with other environmental and genetic factors due to population structure and assortative mating. While some studies have attempted to adjust for assortative mating, these adjustments rely upon strong assumptions that may not be valid. In this study, we extend the two generational model (proband and parents) to a three generational model including grandparents. Just as the two generation model can isolate the component of association due to direct effects, the three generation model can also isolate the component due to IGEs from parents. To overcome the lack of probands with genotyped parents and grandparents, we extend recently developed imputation methods to impute PGSs of ungenotyped grandparents from the observed grandparental genotypes and the genotypes of parents and their sibling(s). We apply our method to an educational attainment PGS derived from a 3 million person genetic association study, isolating the component of association due to IGEs from parents using data from the Norwegian Mother, Father and Child Cohort Study (MoBa) and Generational Scotland (GS). The standardized indirect genetic effect (i.e. partial correlation coefficient) estimate from MoBa is 0.01 (S.E.=0.037) and from GS is -0.02 (S.E.=0.068), compared to a standardized direct genetic effects of 0.23 (S.E.=0.010) in MoBa and 0.259 (S.E.=0.040) in GS. Our results show that IGEs likely explain only a small fraction of the association between EA and EA PGSs, implying that assortative mating and population stratification explain most of the apparent indirect genetic effect previously found.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3606. The relationship between kinship and heritability estimation accuracy

Authors:

D. Chen, J. Storey; Lewis-Sigler Inst. for Integrative Genomics, Princeton Univ., Princeton, NJ

Abstract Body:

Heritability, a quantity that captures the proportion of phenotypic variation explained by genetics, is fundamental to the study of the inheritance of human traits. Genome-wide association studies involving densely genotyped SNPs have made it possible to estimate heritability in population-based studies using linear mixed models (LMMs). Typically, heritability estimation fits a LMM utilizing a covariance based on a matrix of estimated kinship values, making the estimation of kinship values critical in this process. There are several approaches to estimating kinship. The accuracies of previous kinship estimates depend on the underlying structure and relatedness of the population, while the recently developed Ochoa-Storey estimator is suitable for arbitrary population structures. Here, we develop a framework to characterize the accuracy of genetic variance components and heritability estimation based on the accuracy of the kinship estimate. From this framework, we are able to characterize heritability estimation accuracy utilizing the standard kinship estimate as well as the recently developed Ochoa-Storey kinship estimate. We specifically show that (1) the standard kinship estimate results in downwardly biased heritability estimation, determined by the average of the true kinship coefficients and (2) the Ochoa-Storey kinship estimate results in nearly unbiased heritability estimation. We demonstrate our results on simulated and real data, including admixed populations.

PB3607. The role of sleep in human brain and heart health: an investigation using 40,000 brain and cardiac magnetic resonance images from the UK Biobank

Authors:

Z. Fan¹, Y. Li¹, X. Yang¹, J. Lin², Q. Wang³, J. Xie¹, P. Paschou¹, P. Drineas¹, T. Li⁴, H. Zhu⁴, B. Zhao¹; ¹Purdue Univ., West Lafayette, IN, ²Yale Univ., New Haven, CT, ³Peking Univ. Sixth Hosp., Beijing, China, ⁴Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract Body:

Increasing evidence indicates that poor sleep is a modifiable risk factor for various cardiovascular diseases and brain disorders. However, sleep's association with cardiac and brain structure and function, as well as their genetic overlapping, is not well understood. Here we present a systematic investigation of sleep-brain/heart connections using seven sleep traits and multi-modality cardiac and brain imaging data from over 40,000 subjects in the UK Biobank. Sleep conditions were phenotypically and genetically associated with heart structure, heart function, brain grey matter, brain white matter, and brain functional architectures. We prioritized important brain regions and functional networks associated with sleep and identified sleep-associated genomic loci that were colocalized with imaging measures of cardiovascular and brain systems. Mendelian randomization shows potential causal links between sleep traits and brain functional connectivity. In conclusion, biobank-scale imaging genetic data provides insights on the role of sleep in human health from a multi-organ perspective. An interactive web browser was developed to facilitate exploring our results.

PB3608*. The unusual suspects: genome-wide significant sex-difference in minor allele frequency in gnomAD v3.1.2 whole genome sequence via a novel population-aware retrospective regression

Authors:

L. Sun¹, Z. Wang², A. D. Paterson³; ¹Univ. of Toronto, Toronto, ON, Canada, ²Natl. Univ. of Singapore, Singapore, Singapore, ³Hosp. for Sick Children, Toronto, ON, Canada

Abstract Body:

Recently, a non-negligible proportion (~2%) of X chromosomal SNPs have been reported to have genome-wide significant sex-difference in minor allele frequency (sdMAF), through the analyses of high-coverage whole genome sequence in multiple populations and datasets, including the non-Finnish Europeans and African/African Americans from gnomAD v3.1.2 (Zhong et al., 2022).

The existing sdMAF test is intuitive, contrasting the MAF between female and male, but it is conservative when applied to multiple populations. Additionally, not all gnomAD populations nor the whole genome were analyzed.

We have developed a novel regression-based sdMAF testing framework, applicable to multiple populations, and to both the X chromosome and autosomes. Unusually, the proposed regression model is retrospective, regressing genotype on sex, population and sex-population interaction. Unusually, the regression model is linear despite the discrete nature of genotype data. Unusually, the variance of the regression is covariate-dependent (i.e. sex- and population-specific) to account for the potential MAF differences between sexes and populations.

When there is only one population, testing the regression coefficient of sex results in a Wald test that coincides with the existing sdMAF test. In the presence of multiple populations, different tests can be derived from the proposed multivariate retrospective regression model, depending on the scientific question. For example, to test for the presence of sdMAF in any population, one can jointly test the regression coefficients of the sex and sex-population interaction. To test for the difference in sdMAF between populations, one can test the coefficient of sex-population interaction. Additionally, the proposed test incorporates population-aware Hardy-Weinberg disequilibrium correction factors, making the test not conservative. Finally, if other factors (e.g. age and fine-scale population structure) are deemed important in sdMAF analysis, such factors can be readily incorporated in the proposed regression model as covariates.

We apply the proposed method to gnomAD v3.1.2, focusing on n~75,000 from seven populations with population-specific n>1000. We perform both population-stratified and -combined analyses, across the whole genome. We demonstrate a) genome-wide significant sdMAF predominantly is a X chromosomal phenomenon, b) there is a striking consistency across the populations among many SNPs with significant sdMAF, and finally c) there are some SNPs with notable differences in sdMAF between populations. These sdMAF findings potentially impact down-stream association analyses.

PB3609. The use of population-based common controls in GWAS of infectious diseases can result in biased association signals

Authors:

D. Duchon¹, C. Vergara¹, C. Thio², P. Kundu¹, N. Chatterjee¹, D. Thomas², G. Wojcik¹, P. Duggal¹; ¹Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, ²Johns Hopkins Sch. of Med., Baltimore, MD

Abstract Body:

Genome-wide association studies (GWAS) involving population-based common controls from biobanks, national cohorts, and large consortiums have identified genes and variants for a range of complex diseases. Utilizing population-based common controls can drastically increase sample size and statistical power with available genetic and phenotypic data. However, the use of these population-based common controls can also result in non-differential misclassification of the outcome attenuating true effect sizes. There has been increased attention to genetic studies of infectious diseases, like COVID-19, and the use of convenient population-based global controls. However, there has been concern about a lack of phenotypic or pathogen exposure information on these controls and what effect that may have on the results. Through simulation, we show that infectious disease outcomes that use population-based common controls with unknown pathogen exposure can result in biased effect estimates and spurious signals of genome-wide significance. We demonstrate that the magnitude of this bias depends upon the strength of the association between a locus and pathogen exposure and also the prevalence of the pathogen in the community. For example, in simulated comparisons between 20,000 cases and 20,000 pathogen exposed controls or common controls, no spurious associations are observed for a locus strongly associated with pathogen exposure when cases are compared to well-characterized controls regardless of pathogen prevalence or common controls when pathogen exposure is universal. However, when prevalence is rare (5%) or common (50%), >99% and >20% of simulated replicates, respectively, result in spurious associations ($P < 5 \times 10^{-8}$) between a locus strongly associated with pathogen exposure and the outcome. We also compare the results of an empirical GWAS of hepatitis C Virus (HCV) clearance using well-characterized persistently infected controls to population-based controls from the UK Biobank. We find biased effect estimates for known HCV clearance-associated loci and potentially spurious associations. These findings suggest that the use of population-based common controls may be inappropriate for outcomes that are conditional upon environmental exposure, including infectious diseases, and that results from infectious disease GWAS involving common controls be interpreted with caution.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3610*. Tissue-specific impacts of aging and genetics on gene expression patterns in humans.

Authors:

R. Chung¹, R. Yamamoto², J. Vazquez¹, H. Sheng¹, P. Steinberg¹, N. Ioannidis¹, P. Sudmant¹; ¹Univ. of California, Berkeley, Berkeley, CA, ²Univ. of California, Los Angeles, Los Angeles, CA

Abstract Body:

Age is the primary risk factor for many common human diseases including heart disease, Alzheimer's dementias, cancers, and diabetes. Determining how and why tissues age differently is key to understanding the onset and progression of such pathologies. Here, we set out to quantify the relative contributions of genetics and aging to gene expression patterns from data collected across 27 tissues from 948 humans. We show that age impacts the predictive power of expression quantitative trait loci across several tissues. Jointly modelling the contributions of age and genetics to transcript level variation we find that the heritability (h^2) of gene expression is largely consistent among tissues. In contrast, the average contribution of aging to gene expression variance varied by more than 20-fold among tissues with 5 tissues having a larger proportion of age-related gene expression than heritable gene expression. We find that the coordinated decline of mitochondrial and translation factors is a widespread signature of aging across tissues. Finally, we show that while in general the force of purifying selection is stronger on genes expressed early in life compared to late in life as predicted by Medawar's hypothesis, a handful of highly proliferative tissues exhibit the opposite pattern. These non-Medawarian tissues exhibit high rates of cancer and age-of-expression associated somatic mutations in cancer. In contrast, gene expression variation that is under genetic control is strongly enriched for genes under relaxed constraint. Together we present a novel framework for predicting gene expression phenotypes from genetics and age and provide insights into the tissue-specific relative contributions of genes and the environment to phenotypes of aging.

PB3611. Tools for efficient manipulation and meta-analysis of summary statistics from multi-exposure, genome-wide, gene-environment interaction studies

Authors:

K. Westerman; Massachusetts Gen. Hosp., Boston, MA

Abstract Body:

Summary statistics from genome-wide association studies enable valuable downstream analyses such as heritability estimation, enrichment testing, and meta-analysis. Genome-wide interaction studies (GWIS), are increasingly being performed to generate similar summary statistics describing environmental modification of genetic effects. Our recently published software program, GEM, enables GWIS models with multiple interaction exposures (for increased power), and adjustment for gene-covariate interactions (to avoid hidden confounding). However, the software infrastructure does not yet exist to harmonize and meta-analyze GWIS summary statistics in the context of these more complex analytical designs. Here, we introduce methods and associated tools for efficient manipulation of multi-exposure summary statistics based on a single GWIS run: REGEM enables the assessment of alternative model configurations (partitioning exposures into interactions, interaction covariates, and standard covariates) using only summary statistics, and METAGEM performs meta-analysis allowing for multiple exposures. We deployed these tools to conduct a multi-ancestry analysis of genetic interactions influencing waist-hip ratio (WHR), incorporating multiple exposures (both sex and body mass index [BMI]). In six ancestry groups from the UK Biobank (N = 381,089), we conducted both ancestry-stratified and pooled GWIS with individual-level data for common, autosomal genetic variants using GEM. Next, using REGEM and METAGEM with these multi-exposure summary statistics, we derived equivalent results corresponding to single-exposure tests (sex or BMI only), and conducted multi-exposure, multi-ancestry meta-analysis. First, we found that GxAcestry interaction covariates were necessary to control genomic inflation of interaction estimates due to population stratification in the pooled analysis. Second, the pooled analysis found the same set of loci as meta-analysis; this comparison was enabled by the multi-exposure meta-analysis capability of METAGEM and indicates the potential for more inclusive and powerful pooled GWIS with multiple ancestries. Third, the derivation of corresponding single-exposure summary statistics (e.g., sex-only GEI estimates) for comparison to the multi-exposure results required only 0.65 CPU-hrs rather than the 350 CPU-hrs required to re-run the equivalent individual-level GWIS. Our suite of tools, GEM, REGEM and METAGEM, provides key software infrastructure for maximizing the utility of summary statistics from ancestrally diverse and analytically complex GWIS studies.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3613*. Tradeoff between prediction accuracy and transferability in the design of polygenic risk scores.

Authors:

A. Dominguez¹, Y. Zhang¹, C. Pato², S. McCarroll³, M. Boehnke¹, L. Scott¹, S. Zollner¹; ¹Univ. of Michigan, Ann Arbor, MI, ²Rutgers Univ., Newark, NJ, ³Harvard Med. Sch., Boston, MA

Abstract Body:

Polygenic risk scores (PRS) are commonly used to estimate individual risk for a given complex trait. PRS include each marker's marginal association with the trait by using summary statistics from genome-wide association studies (GWAS). However, most GWAS participants are of European (EUR) descent, which biases risk estimates for non-EUR populations. The bias depends on the construction of the PRS, but how parameters such as number of markers affect this bias is not well understood. In this study, we investigate the influence of markers on predictive accuracy and transferability of PRS of bipolar disorder (BPD).

Using clumping & p-value thresholding and summary statistics from the Psychiatric Genomics Consortium (PGC), we calculate PRS for 3,334 African Americans from InPSYght (1,224 cases/2,110 controls) and 5,670 EUR Americans from Prechter Bipolar Study (909 cases) & Michigan Genome Initiative (1,186 cases/3,575 controls) (PMGI). We combine our sample's genomic data with 1,000 Genomes Project (1KGP) and perform principal component analysis to obtain continuous measures of ancestry. To assess predictive performance of PRS, we use logistic regression models to calculate Nagelkerke's R-Squared (R^2) in InPSYght and PMGI separately while adjusting for sex and first five principal components (PCs). We observe increasing predictive accuracy with more markers and maxima at threshold $p < 0.9$ ($R^2 = 2.4\%$) for InPSYght and $p < 10^{-3}$ for PMGI ($R^2 = 4.1\%$).

To assess the impact of ancestry PCs on PRS, we use linear regression models to calculate R^2 while adjusting for sex and affection status. For thresholds near $p < 10^{-6}$, PRS are broadly independent of PCs in both samples ($R^2 < 2\%$). For thresholds between $p < 0.05$ and $p < 0.9$, PCs explain much more variance in PRS for InPSYght ($R^2 > 3\%$) and PMGI ($R^2 > 16\%$). Furthermore, the mean PRS for InPSYght is consistently larger than PMGI and the difference increases with more markers.

To evaluate whether our findings are exclusive to BPD, we calculate PRS for our sample and 1KGP for three additional traits: height (GIANT), schizophrenia (PGC), and type 2 diabetes (DIAGRAM/GERA/UKB). We observe substantial differences in mean PRS across all traits which are exacerbated with larger thresholds, indicating systematic differences in allele frequencies between populations for the underlying variants. Lastly, variance explained by PCs increases as PRS are constructed with less stringent thresholds.

Our findings establish a tension between having complex, informative PRS with more markers and their susceptibility to population structure. This results in more accurate PRS for individuals with EUR ancestry but biased PRS for more diverse ancestries.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3614. Transcript-aware gene burden analyses in the UK Biobank reveal isoform-specific compositions and functions

Authors:

D. Jakubosky, G. McInnes, A. Leverentz, Z. Romer, B. Gonzalez, N. Karra, B. Cajés, S. Bruse, O. Gottesman; Empirico Inc., San Diego, CA

Abstract Body:

A commonly utilized method for rare variant association analysis involves aggregating carriers of predicted-deleterious coding variants in a given gene. So-called gene burden tests have become increasingly necessary with the availability of large-scale biobanks comprising whole exome and whole genome sequencing data linked to rich phenotypic information, such as the UK Biobank, where protein-altering sequence variants are often too rare to be tested individually. Previous studies have generally focused on burdens that aggregate variants across all protein-coding transcripts of a gene in a single test. However, alternative splicing of genes is an essential part of gene regulation and transcript isoforms are expressed in a tissue-specific and context-specific manner, a process that has a critical role in both development and disease. Sequence variants may therefore only be present in, or have an impact on, one (or a subset) of protein-coding transcripts; and in cases where transcripts have distinct biological functions, the performance of a pan-transcript burden test may suffer. We utilized whole exome sequencing data from the UK Biobank to generate transcript-specific deleterious variant burdens, representing 19,037 protein-coding genes, derived from a set of 3,761,661 variants (MAF <0.05) observed in 421,226 individuals. Among the represented genes, more than 70% had multiple protein-coding transcripts with unique sets of variants in their transcript-specific burdens. We further evaluated the similarity of all pairs of transcript-specific burdens within genes. Depending on the stringency of deleteriousness predictions for variants included, approximately 50% of tested genes had at least one highly-divergent pair of transcript-specific burdens, characterized by a transcript having at least 5 unique variants that account for at least 50% of variants linked to that transcript. Transcript-specific burdens were tested for association with thousands of binary and quantitative phenotypes, revealing a substantial number of associations that would not have been detected using traditional pan-transcript gene burden tests and suggesting a high prevalence of transcript isoforms with distinct functions. This study provides important insight into the relevance of both composition and function of gene isoforms when conducting gene burden analyses, and highlights the value of deriving transcript-aware gene burdens to maximize the utility of rare variant association analysis in large-scale biobanks. This research has been conducted using the UK Biobank Resource under Application Number 34229.

PB3615. Transcriptome and GWAS identified disease-specific eosinophilia-pathways and their upstream regulators in primary biliary cholangitis.

Authors:

K. Ueno¹, Y. Hitomi¹, Y. AIBA², O. Gervais³, Y. Kawai¹, S-S. Khor⁴, M. Kawashima⁵, N. Nishida⁶, K. Kojima⁷, M. Nagasaki⁸, K. Tokunaga¹, M. NAKAMURA⁹; ¹Natl. Ctr. for Global Hlth.and Med., Tokyo, Japan, ²Nagasaki Med. Ctr., Omura, Japan, ³Kyoto Univ., Mishima, Japan, ⁴Natl. Ctr. for Global Hlth.and Med., Tokyo, Tokyo, Japan, ⁵Japan Sci. and Technology Agency, Chiyoda-ku, Japan, ⁶Natl. Ctr. for Global Hlth.and Med., Ichikawa, Chiba, Japan, ⁷Tohoku Univ., Sendai, Japan, ⁸Kyoto Univ., Kyoto-City, Japan, ⁹NHO Nagasaki Med. Ctr., Omura, Nagasaki, Japan

Abstract Body:

Primary biliary cholangitis (PBC) is a chronic cholestatic liver disease presumably by autoimmune mechanism. Our recent transcriptome analysis has identified that mRNA expression associated with eosinophilia is increased in PBC as compared to chronic hepatitis C (CHC). The aim of this study is to investigate the molecular mechanisms of eosinophilia in PBC. Firstly, we identified 256 genes that are significantly increased in PBC as compared to CHC by mRNA-microarray of liver samples. Downstream analysis with Ingenuity Pathway Analysis (IPA) of these 256 genes revealed that top 3 pathways are associated with eosinophilia and 11 genes (*CLC*, *IFNG*, etc) were categorized in eosinophilia. The analysis of upstream regulators by IPA of these 11 genes revealed that *IFNG* was the top regulator. The mRNA expression of *IFNG* was significantly correlated with the mRNA expression of six genes such as *BCL2A1* indicating that *IFNG* plays a central role in eosinophil infiltration in PBC as compared to CHC. Secondly, we investigated the cause of eosinophilia using two GWAS datasets from European and Japanese populations. We identified one locus *CLC* which was significantly associated with eosinophil counts in the peripheral blood in GWAS. *CLC* is abundantly expressed in eosinophils and in silico analysis identified *rs2238678* in *CLC* locus as a causal variant and its effector gene was also identified as *CLC* in GTEx. Subsequent analysis indicated that *rs2238678* is a functional SNP. G allele of this SNP was associated with increased number of eosinophils in the two GWAS. These results indicated that genetic polymorphism of eosinophil-constituents has some role in eosinophil differentiation. Thirdly, transcription factors were predicted from the three gene datasets (a transcriptome data and two GWAS data). As a result, androgen receptor was predicted as the most significant common upstream regulator. We also utilized the expression data from peripheral blood of PBC and extracted 102 genes whose expression was significantly correlated with *CLC* expression. Three genes (*IL4*, *IL5*, and *GATA2*) which are well known major factors in differentiation of eosinophil were predicted as the top regulators, indicating that differentiation and activation of eosinophil might occur in peripheral blood of PBC. In conclusion, the mechanisms of eosinophilia in PBC are a complex phenomenon which involve activation of *IFNG* pathway in the liver, activation of *IL4*, *IL5*, *GATA2* pathways in the peripheral blood, the genetic polymorphism of eosinophil-constituents such as *CLC*, and regulation by sex hormone such as androgen. Further studies are needed to clarify the role of eosinophilia in the pathogenesis of PBC.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3616*. Transcriptomics-based drug-repurposing screen discovers potential novel therapies for primary open-angle glaucoma.

Authors:

K. Duchinski^{1,2,3}, J. Rouhana^{2,4,3}, S. Huggett^{5,6}, A. Segre^{2,4,3}; ¹Dept. of BioMed. Informatics, Harvard Med. Sch., Boston, MA, ²Ocular Genomics Inst., Dept. of Ophthalmology, Massachusetts Eye and Ear Infirmary, Boston, MA, ³Broad Inst. of Harvard and MIT, Cambridge, MA, ⁴Dept. of Ophthalmology, Harvard Med. Sch., Boston, MA, ⁵Behavioral Genetics of Addiction Lab., Emory Univ., Atlanta, GA, ⁶5AM Ventures, Cambridge, MA

Abstract Body:

Primary open-angle glaucoma (POAG), a heritable neurodegenerative eye disease, is the second leading cause of irreversible blindness worldwide. In POAG, gradual degeneration of the optic nerve that transmits visual stimuli from the retina to the brain, results in vision field loss. Increased intraocular pressure (IOP) is the main risk factor for POAG. Current treatments attempt to delay POAG progression via IOP-lowering medications. However, up to 40% of POAG patients do not have elevated IOP. We devised a drug-repurposing approach that searches for drugs whose perturbational gene expression profiles anti-correlate with genetically-determined expression profiles associated with disease risk. Such compounds may exert protective or therapeutic effects on disease. We used the LINCS L1000 project that measured the effects of 1,796 FDA-approved and experimental small molecules on the expression of 12,328 genes in >80 human cell lines. We statistically inferred expression changes associated with POAG risk by applying S-PrediXcan, a transcriptome-wide association study (TWAS) method, to the summary statistics of a trans-ancestry POAG genome-wide association study (GWAS) meta-analysis of 34,179 cases and 349,321 controls (International Glaucoma Genetics Consortium), using a transcriptome prediction model trained on 403 peripheral retina RNA-seq and imputed genotype data (Ratnapriya et al., 2019). We next computed the heritability-weighted Pearson correlation between POAG TWAS z-scores and 38,479 independent LINCS drug perturbation signatures ($R^2 < 0.8$) across 910 compounds for 184 genes with significant TWAS p-values ($P < 0.01$). We applied a multi-level meta-regression model of the correlation coefficients as a function of drugs, adding cell line as a random effect. We identified 38 small molecules, including anti-inflammatory and anti-cancer drugs, whose perturbation signatures were significantly anti-correlated with gene expression associations with POAG ($P < 1E-06$). Literature review of the top small molecules' gene targets revealed promising links to POAG. Future work will entail building POAG expression profiles based on relevant GTEx tissues. To validate our approach, we analyzed a GTEx aorta TWAS of a cross-ancestry systolic blood pressure (SBP) GWAS (Million Veterans Program). The leading result for SBP was the widely-used antihypertensive drug amlodipine. This work suggests novel POAG treatments for experimental follow-up and presents a promising genetically and transcriptionally-driven approach for identifying new treatments, which can be applied to any complex disease with available GWAS summary statistics.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3617. Transferability of polygenic scores for anthropometric traits to the Native Hawaiian population

Authors:

Y-C. Lo¹, S. Jeon¹, L. Wilkens², L. Le Marchand², C. Haiman¹, C. Chiang^{1,3}; ¹Ctr. for Genetic Epidemiology, Dept. of Population and Publ. Hlth.Sci., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA, ²Epidemiology Program, Univ. of Hawai'i Cancer Ctr., Univ. of Hawai'i, Honolulu, HI, ³Dept. of Quantitative and Computational Biology, Univ. of Southern California, Los Angeles, CA

Abstract Body:

Polygenic scores (PS) are promising in predicting or stratifying individuals based on the genetic susceptibility to common diseases or complex traits. However, as large-scale genome-wide association studies (GWAS) are heavily biased towards European-ancestry individuals, there are concerns that PS models trained largely in European-ancestry populations would not transfer well to populations of different ancestries. This poor transferability has been demonstrated for a number of ethnic minority populations, but have not been evaluated for Native Hawaiians, who makes up 0.5% of the U.S. population and is the second-fastest-growing ethnic minority in the U.S. Native Hawaiians are largely admixed, having ancestry components from both European and East Asian ancestry, among others. It is therefore also unclear whether the admixture alleviates some of the transferability issues of PS observed in other ethnic populations. Using height and BMI as examples of highly polygenic human traits, we evaluated the transferability of PS to Native Hawaiian populations. We obtained the summary statistics from currently largest GWAS for each anthropometric traits from Europe-ancestry cohorts and East Asian-ancestry cohorts. We trained a genome-wide PS model for each trait using the pruning-and-thresholding approach and evaluated each model in an out-of-sample cohort of Japanese, White, and Native Hawaiian individuals from the Multiethnic Cohort (MEC). For PS models trained with GWAS summary statistics from Europe-ancestry cohorts (the GIANT consortium and UK Biobank), the models can predict better in out-of-sample MEC non-Latino white individuals (partial $r^2 = 0.31$ and 0.097 for height and BMI, respectively) compared to Native Hawaiians (partial $r^2 = 0.18$ and 0.081) or Japanese (partial $r^2 = 0.15$ and 0.064). Moreover, PS model trained with GWAS summary statistics from East Asian-ancestry cohorts (Biobank Japan) can predict BMI approximately similarly in MEC Japanese individuals (partial $r^2 = 0.025$) compared to Native Hawaiians (partial $r^2 = 0.036$). Our results thus confirm a degree of loss of transferability of PS models to Native Hawaiians for highly polygenic traits, although admixture from European and East Asian-ancestry components in Native Hawaiians may also have helped with prediction based on PS trained in GWAS datasets from other ancestries. Nevertheless, increasing representation of Native Hawaiians in genetic studies, better modeling of the differences in ancestry or linkage disequilibrium patterns, or further incorporating of non-genetic risk factors will be helpful to improve risk predictions.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3618. Transformer generative adversarial networks and variational autoencoder for causal analysis of genetic variation in the presence of unobserved confounding

Authors:

J. Zhao¹, T. Xu¹, M. Xiong²; ¹Univ Florida, Gainesville, FL, ²Univ Texas Sch. of Publ. Hlth., Houston, TX

Abstract Body:

Despite significant progress in genetic association studies (GWAS), the signals identified by association analysis may not have specific pathological relevance to diseases so that a large fraction of disease-causing genetic variants is still hidden. Association signals provide limited information on the causal mechanism of diseases. The use of association analysis as a major analytical platform for genetic studies of complex diseases is a key issue that may hamper discovery of disease mechanisms, calling into the questions the ability of GWAS to identify loci-underlying diseases. It is time to move beyond association analysis toward techniques, which enables the discovery of the underlying causal genetic structures of complex diseases. To achieve this, we develop transformer generative adversarial networks and variational autoencoder as a general framework for uncovering causal clinical relevance of genetic variation in the presence of unobserved confounding. Proxy variables such as omics or imaging data can be used to approximate the unobserved confounding. Deep latent variable models and representation learning with proxy variables will be developed to uncover the unobserved confounding. Deep learning-based classifier two sample test will be developed to rigorously test causation of the genetic variant with the disease. Large simulations will be performed to calculate type I error rates and power of the proposed method for testing causation. The proposed method will be applied to genetic studies of Alzheimer's disease. We anticipate that our analysis will stimulate serious discussion of paradigm shift from association to causation.

The X chromosome is enriched for genes functioning in the brain and has many links to brain physiology and development. However, the X chromosome is also an often overlooked chromosome in analysis of the genetic etiology of diseases. We performed analysis of the X chromosome in the Vanderbilt University Medical Center biobank samples, called BioVU, across neurodegeneration phenotypes. Genome-wide association analysis (GWAS) was performed for each neurodegeneration phenotype within BioVU. GWAS results were then used in a combined polygenic risk score analysis within BioVU for neurodegenerative traits using existing brain phenotype GWAS as training sets. Finally, predicted expression of each gene on the X chromosome was calculated from models using elastic net from the Genotype-Tissue Expression (GTEx) consortium data. The models were then applied to all samples in BioVU and transcriptome-wide association analysis (TWAS) was performed on all neurodegenerative phenotypes. Results of these analyses will be presented and the function of implicated genes will be discussed.

PB3620. Uncovering ancestry-specific differences in genetically driven transcriptomic dysregulation in schizophrenia and bipolar disorder.

Authors:

D. Mathur¹, S. Venkatesh¹, T. Bigdeli², K. Therrien¹, D. Burstein¹, A. Fanous³, P. Harvey⁴, G. Voloudakis¹, P. Roussos¹; ¹Icahn Sch. of Med. at Mount Sinai, New York, NY, ²SUNY Downstate Hlth.Sci. Univ., Brooklyn, NY, ³Washington VA Med. Ctr., Washington, DC, ⁴Miami VA Hlth.care System, Miami, FL

Abstract Body:

Genome-wide association analyses (GWASs) identify genetic variants associated with disease; however, translating genetic findings to downstream applications is challenging since most variants reside in non-coding regions. Transcriptome-wide association studies (TWASs) leverage tissue-specific molecular profiling data (for the construction of transcriptomic imputation models) to bridge this gap by converting genetic risk variation into transcript-level dysregulation. However, the current status quo as it pertains to the use of TWAS for gene discovery is limited to the usage of GWAS and transcriptomic imputation models of European (EUR) ancestry. Here, we explore the shared and unique components of genetically driven transcriptomic dysregulation between EUR and African (AFR) ancestry for schizophrenia and bipolar disorder.

We leverage molecular profiling data (genotypes and gene expression) from CommonMind Consortium dorsolateral prefrontal cortex brain samples comprising 925 EUR and 276 AFR individuals to train ancestry-specific transcriptomic imputation models. To compare power, an additional EUR imputation model is generated using 276 individuals matched in terms of sample size, age, sex, and disease status to the individuals making up the AFR model. We assess the trans-ancestry predictive performance of the EUR transcriptomic imputation model to predict observed AFR expression and vice versa. We then perform cis-ancestry summary-level schizophrenia and bipolar disorder TWAS for EUR and AFR. Finally, using the cis-ancestry TWASs as ground truth, we (1) explore shared and unique gene and pathway dysregulation in these disorders and (2) perform trans-ancestry TWASs to evaluate the loss of power when using models of different ancestry.

We find greater convergence of gene expression dysregulation at the gene and pathway level in schizophrenia than in bipolar disorder between ancestries. Trans-ancestry TWASs exhibit significant loss of power but overall maintain moderate correlation in top genes.

Abstract Body:

Epstein Barr virus (EBV) infects ~95% of the population worldwide and is known to cause adverse health outcomes such as Hodgkin's, non-Hodgkin's lymphomas, and multiple sclerosis. There is substantial interest and investment in developing infection-preventing vaccines for EBV. To effectively deploy such vaccines, it is vital that we understand the risk factors for infection. The current literature, describes complex, often conflicting webs of intersecting factors- sociodemographic, clinical, genetic, environmental- rendering causality difficult to decipher. We aimed to use Mendelian Randomization (MR) to overcome the issues posed by confounding and reverse causality to determine the risk factors for the acquisition of EBV. We mapped the complex evidence from the literature on factors associated with EBV serostatus (as a proxy for infection) into a causal diagram to determine putative risk factors for use in our study. Using data from the UK Biobank of 8,422 individuals genomically deemed to be of white British ancestry between the ages of 40 and 69 years at recruitment between the years 2006 and 2010, we performed a genome wide association study (GWAS) of EBV serostatus, followed by a Two Sample MR to determine which putative risk factors were causal. Our GWAS identified two novel loci associated with EBV serostatus (rs71449058, rs1210063). In MR analyses, we confirmed shorter time in education, an increase in number of sexual partners, and a lower age of smoking commencement, to be causal risk factors for EBV serostatus. Given the current interest and likelihood of a future EBV vaccine, our findings on causal factors for EBV acquisition are informative for future vaccine development and deployment. Knowing these risk factors aids the determination of who to prioritise when a vaccine is introduced. We also highlight the power and value of MR for untangling infectious disease risk factors.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3622. Unravelling the genetic contributions to gestational duration in Autism Spectrum Disorder individuals: results from the SPARK sample.

Authors:

C. Chatzigeorgiou, M. Janecka; Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Autism spectrum disorder (ASD) is a highly heritable neurodevelopmental disorder with complex etiology. While previous epidemiological studies have identified prematurity as a risk factor for the disorder, the mechanisms underlying potential causal effects of this exposure remain unknown. Given that the duration of pregnancy in the general population is influenced by fetal and maternal genetic and non-genetic factors, and our earlier work demonstrating phenotypic differences between ASD cases born term and pre-term, we investigated systematic genetic differences between ASD cases born term and pre-term. Utilizing a sample of ASD cases with and without the exposure allowed us to (1) uncover variants which potentially exert their effects through interacting with other genetic/non-genetic factors enriched in ASD, and (2) elucidate potential molecular differences in ASD associated with this early-life exposure. We first conducted a genome wide association study (GWAS) using 993 ASD cases born pre-term (cases) and 7,464 unrelated cases of ASD born term (controls) identified in the Simons Foundation Powering Autism Research for Knowledge (SPARK) dataset. Polygenic risk scores (PRSs) for pre-term birth were calculated based on Liu *et al*, summary statistics using PRSice-2. We observed an association between pre-term birth in ASD cases. To advance biological insight among the set of significant variants and map them to a smaller set of disease-relevant genes and pathways, functional genomic resources were used to functionally annotate variants and map them to genes (<https://fuma.ctglab.nl/>). These analyses revealed 76 possible causal genes identified by positional mapping and expression quantitative trait locus mapping, including top hits *PTPRD* ($p=1.09 \times 10^{-13}$, previously shown to interact with maternal stress to increase the risk of pre-term birth), *PCDH15* ($p=2.97 \times 10^{-12}$ previously associated with neuropsychiatric disorders) and *DLGAP1* ($p=1.95 \times 10^{-12}$ previously linked to schizophrenia and other brain disorders). MAGMA tissue expression analysis identified enrichment across brain tissues and blood vessels. In conclusion, our findings revealed possible causal genes underlying the phenotypic presentation in the pre-term ASD cases. As the top hit identified in our analyses *PTPRD* has been associated with pre-term when interacting with maternal stress, the analyses are ongoing to validate potential interactive nature of this gene, and other ones identified in our analyses, and their relevance to ASD etiology.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3623. Unsupervised representation learning significantly improves genomic discovery for lung function and respiratory disease prediction.

Authors:

T. Yun¹, B. Behsaz¹, J. Cosentino², A. Carroll³, C. Y. McLean¹, F. Hormozdiari¹; ¹Google Res., Cambridge, MA, ²Google Res., San Francisco, CA, ³Google Res., Palo Alto, CA

Abstract Body:

High dimensional clinical data (e.g. time series, images) provide a unique opportunity in genetic studies of complex traits; however, we lack statistical methods to fully utilize them in association studies. We introduce a novel method to discover associations between genotypes and high dim phenotypes by learning low dimensional, nonlinear representations with unsupervised deep learning. Using variational autoencoders (VAE) incentivized to learn encodings that have uncorrelated coordinates, separable biological factors can be better captured in each coordinate. We perform GWAS on each coordinate to study the genetics of the underlying phenotype, agnostic to manually defined labels.

We demonstrate this approach on spirometry tests for lung function, and generate synthetic phenotypes we call spirogram encodings (SPINCs) and residual spirogram encodings (RSPINCs). SPINCs use a standard convolutional VAE, while RSPINCs use a novel VAE modified to admit 5 widely used spirometry features (FEV1, FVC, FEV1/FVC, PEF, FEF25-75%) in the encodings, encouraging remaining coordinates to capture residual signals not represented by those 5 manual features (MFs).

From GWAS on just 2 RSPINCs in UK Biobank (n=325K), which carry substantial heritability ($h^2 = 0.161 \pm 0.011, 0.045 \pm 0.003$), we discover 74 additional genome-wide significant (GWS) loci, in addition to 724 GWS loci from GWAS on 5 MFs. With SPINCs (dim=5) we discover 634 GWS loci, 141 of which are novel with respect to GWAS on 5 MFs. We also compare SPINCs (dim=5) to 5 principal components (PCs) of raw spirogram values. GWAS on SPINCs generate 22% more GWS loci than PCs (634 vs 521) and 3.28 \times more novel loci (141 vs 43).

We also construct a set of polygenic scores (PGS) on (R)SPINCs as general genetic predictors of lung function. To study their predictive capacity, we consider two lung diseases, asthma and COPD, and evaluate the accuracy of a linear model on PGS in a held-out set in 3 metrics: prevalence in the top PGS decile, AUC, AUPRC. We observed a 9% increase in asthma prevalence in top PGS decile by using 5 SPINCs PGS instead of 5 MF PGS, and a 6% increase by adding 2 RSPINCs PGS to 5 MF PGS ($p < 0.05$ for the differences). In fact, 5 SPINCs PGS outperforms 5 MF PGS in all metrics for both diseases ($p < 0.05$ for asthma). With RSPINCs, adding 2 RSPINCs PGS to 5 MF PGS again improves upon using just the 5 MF PGS in all metrics for both diseases ($p < 0.05$ for all but COPD prevalence). This general set of PGS can be used for any trait associated with spirometry, especially when direct GWAS is underpowered due to insufficient labels. We believe our approach can become a standard method for using high dim phenotypes for GWAS and prediction.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3624. Using external reference panel and meta-analysis summary statistics for rare-variant aggregation tests.

Authors:

B. Ryan¹, R. Welch¹, M. Boehnke¹, C. Fuchsberger²; ¹Univ. of Michigan, Ann Arbor, MI, ²Eurac Res., Bolzano, Italy

Abstract Body:

Genome-wide association studies (GWAS) have identified hundreds of thousands of associations between common genetic variants and a wide range of human diseases and traits. These studies are often of low power to identify associations with rare genetic variants, which are thought to contribute to the heritability of many common diseases and traits. Aggregation tests pool the genetic signal across multiple variants in a gene or other region of the genome to test the cumulative effect of these variants on a disease or trait. These aggregation tests can increase the power to detect rare variant genetic association. To further increase power, meta-analysis is employed to pool information across studies via summary statistics such as effect sizes and p-values. To perform proper aggregation test meta-analysis, accurate estimates of the covariances for the single-variant test statistics also are needed. Covariance files are often too large to be shared and estimation of the covariances requires access to individual level data for each of the participating studies. Unfortunately, individual-level genetic data often cannot be shared due to privacy concerns. In this study, we apply a previously proposed method of estimating single-variant test statistic covariance from an external reference panel to perform aggregation tests on a variety of traits from the UK Biobank. The method uses correlation between variants in the reference panel and allele frequencies from the meta-analysis studies to estimate the test statistic covariance. We propose a two-stage approach by first filtering genes using a null covariance where covariance between all variants is set to zero to perform aggregation tests, and in stage two testing only those genes passing a p-value threshold. Using the null covariance generally overestimates significance of genes, allowing us to confidently exclude non-significant genes in the first stage. Using this approach we are able to reproduce known associations such as for *APOB* with LDL cholesterol and *LPL* with HDL cholesterol. When p-values on the log scale produced using individual-level data and our method are compared, Pearson correlation coefficients are close to one across various traits. This approach allows for substantial memory cost improvements and will be a useful tool for collaboration between studies.

PB3625. Using genetic associations from shared clustered genetic predictors to infer causation

Authors:

F. Batool¹, A. Patel¹, D. Gill², S. Burgess¹; ¹Univ. of Cambridge, Cambridge, United Kingdom, ²Univ. of London, London, United Kingdom

Abstract Body:

Genetic variations are driver of phenotypic diversity and provide evidence on nature of causal relationship through associations among complex traits and diseases. Genome-wide association studies have shown a large number of genetic variants association with complex diseases, that governs the mechanism of these complex diseases with each variant having a very small effect size. For the gene region that contains a cluster of genes that controls the gene expression resulting in gene product such as risk factor, it is difficult to determine which proteins are causal risk factors. Often, selection of genetic variants from whole genome is made through strict pruning to a near independence threshold. When genetic variants are highly correlated, inclusion of too many highly correlated variants lead to ill-conditioning, and strict pruning on variants lead to imprecise estimates. To disentangle complex cis-gene regions, causal inference method is developed for complex traits that perform statistical dimensionality reduction as an alternative to traditional pruning methods to extract genetic proxies (instrumental variables) to avoid problems of collinearity. This method is illustrated using circulating levels of cytokines, namely, MCP-1, MCP-3, eotaxin for the variants from gene in CCL2 region with stroke which is the third leading cause of death worldwide. CCL2 that encodes these cytokines is located in gene region that also includes genes CCL7 and CCL11. Previously these cytokines were shown to draw associations on single exposure trait in a uni-variable MR setting. To discover the most likely casual risk factor, data for genetic associations of strokes (ischemic and cardioembolic) from MEGASTROKE consortium, genetic association of cytokines from GWAS of eQTL, for the variants from gene in CCL2 region. The correlations were taken from UK Biobank for European ancestries.

PB3627. Validation of large-scale Hispanic S-PrediXcan findings by independent Hispanic RNA-Seq data analysis confirms novel lipid-associated genes.

Authors:

L. Petty^{1,2}, H-H. Chen², W. Zhu¹, C. G. Downie³, M. Graff³, M. Lee⁴, K. E. North³, J. B. McCormick⁴, S. P. Fisher-Hoch⁴, J. M. Mercader⁵, H. M. Highland³, J. E. Below², Hispanic Lipids Consortium; ¹Vanderbilt Univ., Nashville, TN, ²Vanderbilt Univ. Med. Ctr., Nashville, TN, ³Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ⁴Univ. of Texas Hlth.Sci. Ctr. at Houston, Brownsville Regional Campus, Brownsville, TX, ⁵Broad Inst. of MIT and Harvard, Cambridge, MA

Abstract Body:

Background: Most genetically regulated gene expression imputation models have been derived from reference data that is primarily of European ancestry, and the utility of these models for disease gene discovery in non-European ancestry populations remains largely unexplored. Additionally, Hispanic/Latino populations have both higher prevalence of cardiometabolic disease (CMD) and are drastically underrepresented in genetic studies of CMD traits relative to non-Hispanic whites. To help address both knowledge gaps, we applied GTEx project-derived S-PrediXcan models to our Hispanic Lipids Consortium meta-genome wide association study (GWAS) results. We compared top findings to RNA-Seq association results in an independent Hispanic cohort.

Methods: We first completed a meta-GWAS of blood lipid/lipoprotein traits (high-density lipoprotein cholesterol [HDL-C], low-density lipoprotein cholesterol [LDL-C], total cholesterol [TC], and triglycerides [TG]), comprising up to 63,185 Hispanic/Latino individuals. The meta-analysis was performed using MR-MEGA and included two study-level principal components to capture ancestry differences. Then, we used MR-JTI GTEx v8 S-PrediXcan models to test the association of genetically regulated expression with each trait and performed Mendelian randomization to assess causality of all identified associations. Next, we tested association of whole blood expression between each of our S-PrediXcan-identified genes and the trait of interest in 880 Mexican American individuals from the Cameron County Hispanic Cohort (CCHC). Finally, we tested if genes associated with each CMD trait using gene expression were enriched in those genes associated with each CMD trait using S-PrediXcan.

Results: We identified strong enrichment of genes associated with measured gene expression in the S-PrediXcan findings (Kolmogorov-Smirnov $p_{\text{HDL-C}} < 2.2 \times 10^{-16}$, $p_{\text{LDL-C}} = 1.39 \times 10^{-3}$, $p_{\text{TC}} = 7.13 \times 10^{-6}$, $p_{\text{TG}} = 2.51 \times 10^{-9}$). In addition to the overall enrichment, our measured gene expression association analyses validated two of the novel genes discovered in our S-PrediXcan analyses, *NEDD9* for HDL-C and *GOLGA8A* for LDL-C.

Conclusion: Inclusion of diverse populations in RNA-Seq reference data to is necessary to realize the full potential of genetically regulated expression analyses in all populations. Despite low representation, here, we demonstrate that GTEx S-PrediXcan models have utility for identification of dysregulated genes associated with CMD in Hispanics/Latinos. In addition, we are constructing Hispanic expression prediction models in our RNA-Seq and genotype data, and will make these models publicly available.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3628. Variants in *CRY2* and *MTNR1B* influence the diurnal variability of blood glucose levels

Authors:

S. Jones¹, N. Sinnott-Armstrong^{1,2,3,4}, J. K. Pritchard^{2,5}, H. M. Ollila^{1,2,3,6}; ¹Inst. for Molecular Med. Finland, HiLIFE, Univ. of Helsinki, Helsinki, Finland, ²Dept. of Genetics, Stanford Univ., Stanford, CA, ³Broad Inst. of Harvard and MIT and Ctr. of Genomic Med., Massachusetts Gen. Hosp., Boston, MA, ⁴Fred Hutchinson Cancer Res. Ctr., Seattle, WA, ⁵Dept. of Biology, Stanford Univ., Stanford, CA, ⁶Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA

Abstract Body:

Introduction Circadian rhythms coordinate not only the timing of sleep and wakefulness, but also a wide range of homeostatic processes in the body. Environmental cues including light, temperature, feeding and exercise contribute to diurnal variation in gene homeostasis and expression. In particular, diurnal rhythms play a role in regulating the timing of glucose metabolism. Conversely, a disrupted metabolism manifesting, for example, as high glucose levels or even type-2 diabetes mellitus (T2DM) is associated with insomnia, later chronotype and short sleep in both epidemiological and genetic studies.

Early genetic associations with glucose levels and T2DM were discovered at the *MTNR1B* (a melatonin receptor) and *CRY2* loci that are also known canonical regulators of circadian rhythms. Yet the biological mechanisms behind the associations with glucose levels are not understood. We hypothesized that the circadian coordination of glucose levels may be under genetic control.

Methods In data from ~335,000 unrelated European-ancestry UK Biobank participants, we assessed whether genetic variants were associated with glucose timing, as well as glucose levels. We performed a "diurnal variability" GWAS of blood glucose levels. In the analysis, we assumed a cosine glucose profile, including terms relating to genotype interaction with the sine and cosine of blood-draw time, in addition to the standard additive genotype and covariate terms. For variants showing genome-wide significant interaction with the sine and cosine terms, we validated the results by applying a generalized additive model that does not assume a specific diurnal glucose profile.

Results We identified significant associations with both amplitude and phase of glucose levels at *MTNR1B* (rs10830963, $P=4.8 \times 10^{-8}$, $\text{beta}[\text{se}]=0.0076[0.0014]$) and *CRY2* variants (rs11605924, $P=1.7 \times 10^{-8}$, $\text{beta}[\text{se}]=0.0070[0.0012]$). This effect was notable since the levels are antiphase in the morning vs. the evening for the *MTNR1B* variant. Furthermore, the *CRY2* variant carriers showed a phase shift in glucose levels (of ~1 hour) compared to non-risk allele carriers. These effects were independent of diurnal preference (morningness/eveningness) with the variants showing stronger effects than an individual's diurnal preference.

Conclusion Our findings suggest that there are variants involved in coordinating the timing of blood glucose levels over the course of the day, and implicate *MTNR1B* and *CRY2* in the regulation of both overall glucose levels and glucose timing in humans. We are continuing to develop the methodology to allow more general application to other phenotypes and analysis with mixed-model approaches.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3629. Whole-exome sequencing in 545,835 individuals implicates 27 genes in eosinophil biology

Authors:

C. Sidore, L. Gurski, M. Suci, K. Siminovitch, Regeneron Genetics Center, GHS-RGC DiscovEHR Collaboration, G. Abecasis, M. Ferreira; Regeneron Genetics Ctr., Tarrytown, NY

Abstract Body:

Background. Eosinophils play a key role in immune responses to parasites, bacteria and allergens. Previous GWAS of peripheral blood eosinophil counts have identified over 500 loci with common variant associations, but the genes which underlie the observed associations are largely unknown. Analysis of rare coding variation provides an independent approach to identify genes involved in the regulation of eosinophil numbers in peripheral blood.

Methods. We sequenced the exomes of 545,835 individuals from the UK Biobank and Geisinger Health System (GHS) cohorts, and tested the association between eosinophil counts and rare (MAF<1%) non-synonymous variants in 19,411 genes, individually and in aggregate through gene burden and SKAT-like tests. We also performed a GWAS using imputed TOPMed data in the same individuals and tested if the rare variant associations were independent of common variant signals.

Results. We analyzed the association between eosinophil counts and 8M rare variants from exome sequencing, performing single variant and gene-based tests. We found significant ($P < 5 \times 10^{-8}$) associations with rare coding variants in 38 genes located in 28 loci. Of these, the association with 27 genes remained significant after accounting for 950 common variants (average effect size 0.023 SD, range 0.008-0.14) identified in the TOPMed GWAS. These include 25 genes for which the strongest association was with a burden of predicted loss-of-function (pLOF) variants (7 genes; average effect 0.255 SD, range 0.085-0.442) or deleterious missense variants (18 genes; average effect 0.192 SD, range 0.055-0.615). Twelve genes were the closest gene to a GWAS signal, and therefore are the likely effector genes of the common variant signals. For 5 genes (SLC27A3, ARHGAP25, RASGRP2, SRSF2, RASAL3) we found evidence for association with rare variants from exome sequencing but not with common variants from GWAS; the association with SRSF2 was explained by rare somatic mutations. Overall, 5 genes (SLC27A3, CISH, IL33, HABP2, ALOX15) had suggestive associations ($P < 5 \times 10^{-4}$) with allergic disease (159,544 cases vs. 321,114 controls), while 2 genes (ARHGAP25, RASGRP2) have not been previously implicated in eosinophil biology. We also tested for associations with a burden of rare non-coding variation in gene enhancers using imputed TOPMed data, but found no convincing novel associations.

Conclusions. We demonstrate that analysis of rare coding variation from exome sequencing can help pinpoint likely effector genes underlying common variant associations with eosinophil counts, identify new gene associations missed by GWAS and illuminate novel associations for allergic disease.

Statistical Genetics and Genetic Epidemiology Posters - Wednesday

PB3630*. Winner's curse in rare variants association analysis: bias depends on effect direction and the pooled methods used

Authors:

D. Soave^{1,2}, S. Kokic¹, L. Sun³; ¹Wilfrid Laurier Univ., Waterloo, ON, Canada, ²Ontario Inst. for Cancer Res., Toronto, ON, Canada, ³Univ. of Toronto, Toronto, ON, Canada

Abstract Body:

Rare variants (RVs) may explain a large portion of genetic heritability, however, studies involving RVs inherently have low power to detect associations with SNPs individually. Gene and set-based tests aggregate across multiple SNPs to improve power by jointly testing for association between a trait and a group of SNPs. A common approach to effect estimation for the group of SNPs is the average genetic effect (AGE), where the parameter corresponds to the effect of a single collapsed genotype variable. The inclusion of non-causal SNPs or SNPs with effects in opposite direction may lead to a downward bias of the effect size estimate. On the other hand, hypothesis testing and effect estimation performed using the same sample will lead to an upward bias, due to the phenomenon known as selective inference or winner's curse. A modified bootstrap correction to AGE estimation for the rare variants context may provide good biased-reduced AGE estimates, however, it is not clear (1) if the individual estimates for each of the causal variants suffers equally from the winner's curse (i.e. with the same amount of upward bias) regardless of true effect size or effect direction, and (2) if the bias estimation/correction depends on the type of tests used (e.g. burden/linear- versus SKAT/quadratic-type tests). To investigate these questions, we conducted a simulation study using the Genetic Analysis Workshop 17 data (real human sequence data from the 1000 Genomes Project). We examined the implications of the competing winner's curse and heterogeneity of individual effects under both the linear and quadratic testing classes. We observed that both the modified bootstrap method and likelihood method effectively reduce the winner's curse in the AGE estimate under both the unidirectional and bidirectional scenarios. Under the unidirectional model, each individual naïve effect estimate has upward bias. However, the amount of bias differs between rare variants, depending on the MAF and its true effect. Furthermore, under the bidirectional model when not all effects have the same direction, the individual estimates can be downward biased depending on the test used. The pooling of rare variants is clearly an issue for effect size estimation for individual variants. The situation becomes even more complicated as we consider the possibility of including causal variants with bidirectional effects. Unfortunately, the usefulness of our ability to quantify genetic effects and the missing heritability due to rare variants remains in question as a deeper understanding of the consequences of pooling/grouping variants with heterogeneous effects is warranted.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3631. Machine learning-based phenotyping significantly improves power for genetic discovery in NAFLD and NASH

Authors:

B. Ungun¹, F. Casale², **H. Sominen**³, K. Sandor¹, S. Modi¹, M. Albert⁴, S. Satapati¹, T. Karaletsos¹, T. Soare³, P. Palmedo¹, D. Koller¹; ¹insitro, South San Francisco, CA, ²Dept. of Informatics, Technical Univ. of Munich, Munich, Germany, ³insitro, Boston, MA, ⁴Precision Immunology NewCo, South San Francisco, CA

Abstract Body:

Genetically supported drug targets are at least twice as likely to be approved; however, large human cohorts are required to catalog genetic associations for complex traits. Assembling large datasets with gold-standard clinical diagnosis is difficult, particularly for diseases such as nonalcoholic fatty liver disease (NAFLD) or nonalcoholic steatohepatitis (NASH) due to the invasive nature of the liver biopsy. Here, we used a machine-learning (ML) algorithm to quantify NAFLD- or NASH advanced (F4) fibrosis-risk in the UK Biobank, and leveraged it to drive genetic discovery. We trained an ML classifier using age, sex, and 37 blood measurements and anthropometric markers to predict ground truth cases (n=1,774) and controls (n=2,209), and then applied the ML model to estimate the risk of NAFLD in 275,727 Europeans in the UK Biobank (individuals meeting our inclusion criteria). Within individuals with known or ML-imputed NAFLD, we specifically identified a high risk subset (n = 77,086), i.e. individuals who were predicted to have NAFLD with “high confidence” by the above classifier (20% false positive rate), and then trained a binary classifier using 15 biomarkers of fibrosis with consistent literature support to predict ground truth cases (n=97 with an ICD-10 code for F4 fibrosis) from simple steatosis (n=1,246), and used it to estimate the risk of NASH F4 fibrosis. ML-based risk scores of NAFLD and NASH F4 fibrosis predicted ICD-10 codes with high accuracy within the UK Biobank dataset (AUC=0.87±0.01 for NAFLD and 0.81±0.03 for NASH F4 fibrosis, on held out sets). A genome-wide association study of these ML-derived traits identified > 100 genome-wide significant loci across both traits, significantly expanding our understanding of the genetic architecture of these complex diseases (P < 5 x 10⁻⁸). Amongst these loci were well known associations, including HSD17B13, PNPLA3, TM6SF2 and GCKR, confirming established biology. In addition, we replicated published associations using proxy phenotypes by other groups (e.g. liver fat quantified from ML of abdominal MRI data or chronic elevation of alanine aminotransferase), including TRIB1, COBLL1 and MAST3. Overall, these findings demonstrate the value of leveraging ML-based trait predictions to identify novel genetic associations.

Statistical Genetics and Genetic Epidemiology Posters - Thursday

PB3633. A unifying statistical framework to discover disease genes from GWAS

Authors:

J. McManus, R. Lovelett, D. Lowengrub, S. Christensen;
Kallyope, Inc., New York, NY

Abstract Body:

Genome-wide association studies (GWAS) identify genomic loci associated with complex traits, but it remains a major challenge to systematically pinpoint the specific genes underlying the association signals. In the biotechnology and pharmaceutical industries, the difficulty in ascertaining disease genes from GWAS has hampered the use of human genetics in drug discovery. We therefore developed a computational framework to rigorously discover the genes dysregulated by causal variants, without restricting ourselves to given cell types or relying on assumptions from biological networks. In particular, we extend the equations of statistical fine-mapping, to compute the probability that each gene in the human genome is effected by a causal variant, given a particular trait. Previously, statistical fine-mapping has been applied to compute the probability that particular genetic variants mediate disease risk. We show how to compute analogous probabilities of association for genes, which are the basis for drug development. Furthermore, we demonstrate that genes targeted by causal variants can be confidently identified, even when the causal variants themselves cannot be pinpointed. Our computations are enabled by several key innovations. First, we partition the genome into optimal linkage disequilibrium blocks, enabling genome-wide detection of trait-associated genes. Second, we unveil a comprehensive mapping that associates genetic variants to the target genes they affect. The combined performance of the map on high-throughput functional genomics and eQTL datasets supersedes the state of the art. Lastly, we describe an algorithm which learns, directly from GWAS data, how to incorporate prior knowledge into the statistical computations, significantly improving their accuracy. We validate each component of the statistical framework individually and in combination. Among methods to identify genes targeted by causal variants, this paradigm rediscovers an unprecedented proportion of known disease genes, without sacrificing precision. Moreover, it establishes human genetics support for many genes previously implicated only by clinical or preclinical evidence, and it discovers an abundance of novel disease genes with compelling biological rationale.

Pharmacogenomics Posters - Thursday

PB3634. Local ancestry stratified GWAS identifies pharmacogenomic variants associated with metformin glycemic response in African American individuals with type-2 diabetes

Authors:

S. Xiao¹, B. Wu¹, S. Yee², F. Xu³, S. Sridhar³, M. Yang¹, S. Hochstadt¹, W. Cabral¹, D. Lanfear¹, M. Hedderson³, K. Giacomini², K. Williams¹; ¹Henry Ford Hlth., Detroit, MI, ²Univ. of California San Francisco, San Francisco, CA, ³Div. of Res., Kaiser Permanente Northern California, Oakland, CA

Abstract Body:

Metformin is considered first-line therapy in treating type-2 diabetes (T2D), yet little is known regarding the genetic underpinnings of drug response. African Americans are disproportionately affected by T2D, and in earlier work, we observed differences in metformin treatment response by race-ethnicity. Unfortunately, African Americans have been understudied in most genomic and pharmacogenomic studies to date, and the studies that have been performed do not fully account for the effects of underlying population structure. Here we performed the first local-ancestry informed genome-wide analysis for pharmacogenomic variants associated with metformin treatment response. Our discovery population included African American participants from the Diabetes Multi-omic Investigation of Drug Response (DIAMOND) cohort, a study of health plan members from metropolitan Detroit. The replication cohort consisted of African American participants who received care at Kaiser Permanente Northern California (KPNC). Pharmacy claims were used to calculate an average daily drug exposure among individuals on metformin monotherapy. Among individuals continuously exposed to greater than or equal to 425mg of metformin daily, we evaluated for genetic variants associated with a change in blood glycated hemoglobin (HbA1c) levels. A unique aspect to our approach was that we evaluated variant effect sizes only at locations unambiguously homozygous for African ancestry. In this way, our discovery and replication analyses were not affected by an averaging of effect sizes across ancestral groups, and the effect of population group differences in linkage disequilibrium were also minimized. Our analysis revealed a genome-wide significant signal in the DIAMOND cohort at variant *rs143276236* located in an intronic region of the gene *ARFGEF3* ($P=9.4E-9$) on chromosome 6. Re-evaluation in KPNC demonstrated an association with consistent direction ($P=0.021$). The meta-analyzed results showed a $P=8.6E-9$. Functionally, this gene has been previously predicted to have role in the regulation of glucose homeostasis through its effect on insulin secretion. Our study demonstrates the potential power and importance of using an ancestry-informed association approach when seeking to identify pharmacogenomic variants in admixed populations.
