Introduction: Complex Chromosomal Rearrangements (CCR's) are the rare structural chromosomal abnormalities, which involve more than two non-homologous chromosomes with two or more breakpoints. If it is a balanced rearrangement, there will be no significant phenotypic abnormalities detected in the individuals. Many clinical symptoms related with CCR's are congenital malformations, dysmorphism, mental retardation, infertility, recurrent pregnancy loss, bad obstetric history etc. **Material and methods:** A consanguineous (uncle-niece) couple with a history of secondary recurrent pregnancy loss with two spontaneous abortions and the third one was a full-term delivery of female child who died at 7 months of age was referred to institute for genetic analysis. Couple karyotyping revealed a complex chromosomal balanced translocation in female partner with five chromosomes involving five breakpoints with der2,t(2,18)t(4,5,18)t(21,4) karyotype and the male partner karyotype was normal with 46, XY chromosomal constitution. Further, Spectral karyotyping analysis was performed to confirm the CCR. Microarray analysis revealed no gain or loss of chromosomal material in the female partner. The child was presented with dysmorphic features, developmental delay, severe respiratory distress, abdominal pain and hepatomegaly at the time of birth. Her cytogenetic analysis revealed an unbalanced 46, XX, der(2) chromosome and her microarray analysis showed a deletion of 3474.756kbp at cytoband 2q37.3 which was denoted as pathogenic. **Conclusion:** The present case study highlights a novel familial translocation with CCR in a couple having bad obstetric history. The transmission of CCR's in fetus may result in either abortions or child with chromosomal defects and result in congenital anomalies leading to death of the child. To the best of our knowledge this is the first case to be reported with these breakpoints involving 5 different chromosomes from our ethnic group. Hence, the couple was advised for genetic counselling and pre-natal diagnosis in future pregnancies.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2309. Identification of somatic Neurofibromatosis 1 mosaicism using targeted next-generation sequencing of café-au-lait-macules

Authors:

E. Korpershoek¹, R. R. van Minkelen¹, M. Nellist¹, W. N. M. Dinjens², M. van Vliet¹, A. L. Mooyaart², T. J. van Ham¹, Y. van Ierland¹; ¹Erasmus MC, Univ. Med. Ctr. Rotterdam, Dept. of Clinical Genetics, Rotterdam, Netherlands, ²Erasmus MC, Univ. Med. Ctr. Rotterdam, Dept. of Pathology, Rotterdam, Netherlands

Abstract Body:

Purpose Detection of somatic mosaicism in blood can be challenging, even with a sensitive variant detection technique such as Next Generation Sequencing (NGS). For individuals with (segmental) neurofibromatosis type 1 (NF1), mutation analysis of tumors can be an alternative strategy for the identification of somatic NF1 mosaicism, although this is not possible in individuals without syndrome-related tumors. Here we describe a patient with a segmental phenotype, presenting solely with Café-au-lait macules (CALMs) and freckles, in which no NF1 mutation was identified in DNA isolated from peripheral blood. **Methods** DNA isolated from blood and four independent CALMs was investigated by targeted Ion Torrent-based NGS. In addition, cells were cultured from a CALM and from normal skin. RNA isolated from these cultured cells was subjected to transcriptome analysis (RNAseq). **Results** Targeted NGS revealed that three of the four investigated CALMs showed the pathogenic variant NM_000267.3(NF1):c.3916C>T, p.(Arg1306*), which was absent in DNA derived from blood. RNAseq confirmed expression of the NM_000267.3(NF1):c.3916C>T, p.(Arg1306*) variant in RNA from the cultured fibroblasts from a CALM (variant allele frequency of 8%), while no expression was seen in RNA from the cultured fibroblasts from normal skin. **Conclusion** Our results indicate that targeted NGS of independent CALMs can assist in the detection somatic mosaicism in patients with segmental NF1 for whom no variant was identified in peripheral blood DNA.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2311. Importance of the reclassification of the clinical significance of new genetic variants in non-classical mucopolysaccharidosis type IV A

Authors:

R. Gomez, L. Moreno; Univ. Libre, Cali, Colombia

Abstract Body:

In mucopolysaccharidosis IV A, there is a deficiency of lysosomal hydrolase, N-acetylglucosamine-6-sulphate sulphatase enzyme, leading to the accumulation of keratan sulfate and chondroitin-6-sulfate. It affects men and women with equal frequency, the prevalence ranges between 1/40,000 and 1/200,000 births. In Colombia, records are scarce; a frequency of 0.68/100,000 live births is reported. The c.1431G>A variant is the most frequent with 60% of the alleles, followed by the benign p.H36= variants and the intronic variant 634-19G>A with 41% and 34%, respectively. Children have no clinical findings at birth, progressive bone and joint involvement leading to short stature and disabling pain. Spinal cord compression is a common complication that results in neurological deterioration. A male patient with a clinical picture of muscle weakness in the lower limbs and difficulty walking is described. MRI of the spine with alteration in the configuration of the vertebral bodies from T9 to L5 with a tendency to platyspondyly and anterior wedging with a cortical peak at the L2 level. Blood drop collected on GALNS filter paper < 0.03 $\mu\text{mol/l/hr}$ (normal \geq 0.39 $\mu\text{mol/l/hr}$). With subsequent confirmation in leukocyte sample: Galactose-6-sulphate sulphatase: 0.10 (normal = 2.6 - 35.9). Molecular study of the GALNS gene, two variants: One of pathological significance: c.901G>T, Protein change: p. Gly301Cys, heterozygous, Inheritance: autosomal recessive and another variant of uncertain significance: c.1088T>C, Protein switch: p. Ile363Thr: Heterozygous, Inheritance: Autosomal recessive. A bioinformatic study of in silico technology is carried out, including the use of prediction software such as Sorting intolerance from tolerant, mutation taster, UMD-predictor, functional analysis through hidden Markov models, polymorphism phenotyping V2, and protein variation effect analyzer. With a change in clinical significance from a variant of uncertain significance: c.1088T> C to pathogenic. Clinical, paraclinical, enzymatic, and molecular correlation and its phenotype, endotype, and genotype correlation are performed.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2312. Inadequate parental sequencing depth burdens African ancestry patients with inaccurate *de novo* inheritance calls.

Authors:

S. Choi¹, P. White^{1,2}, B. P. Chaudhari^{1,2}; ¹Nationwide Children's Hosp., Columbus, OH, ²The Ohio State Univ., Columbus, OH

Abstract Body:

The rapid genome sequencing (rGS) study is a pilot study which seeks to validate and understand the feasibility of internal rGS compared to standard of care clinical testing (send-out rapid exome or genome sequencing; rES/rGS). The rGS study has enrolled 120 cases including 92 trios (64 clinical rES and 28 clinical rGS comparators). Clinically reported variants and inheritance are compared to research rGS findings to inform test development.

All variants reported as *de novo* on clinical rES were concordant with research rGS (66 variants). When clinical standard of care transitioned to rGS, we noted, in 14 consecutive trios, 8/25 clinically reported *de novo* variants appeared to be inherited from an unaffected parent on research rGS. Sanger sequencing confirmed inheritance in all variants tested (n=6). These variants appeared more commonly in probands of self-reported African (4/5) vs. European (1/9) ancestry (p=0.023, Fisher's exact test). We sought to identify the cause of these inaccurate inheritance calls as well as the apparent inequity by ancestry.

We found that parental depth in clinical rGS was low (median 13.6x, range 5.6x-23.4x) compared to research testing (median 35.6x, range 23.4x-44.8x). We used the distribution of heterozygous, phenotype-related, rare, deleterious variants in genes known to cause autosomal dominant disorders, along with the estimated probability of failing to call the alternate allele in a heterozygous parent, conditional on sequencing depth (assuming a minimum of 3 reads are required to call a variant) to estimate the burden of inaccurate *de novo* inheritance calls when sequencing parents at low depth. At a parental depth of 10x, the positive predictive value (PPV) for phenotype-associated *de novo* variants is estimated at only 47%. At 19x, the PPV becomes >99.9%. The number of rare, phenotype-related, inherited variants in genes known to cause autosomal dominant disorders that could be inaccurately called as *de novo* was significantly greater in those of self-reported African ancestry (median 43, range 29-69) vs. European ancestry (median 20, range 9-25) (p=0.0001, M-W test).

The accuracy of variant calling is directly affected by sequencing depth. Low parental sequencing depth leads to missed variant calls in parents, inaccurate identification of "*de novo*" variants in probands, and, potentially, incorrect variant interpretation. As the absolute number of variants inaccurately called *de novo* is also a function of the number of rare variants, individuals of African ancestry are most affected. Based on our findings, the clinical lab updated their procedures and no incorrect calls of *de novo* inheritance have been reported since.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2313. Increased diagnostic yield from negative whole genome-slice panels using automated reanalysis.

Authors:

S. Berger¹, A. Cohen¹, J. LoTempio², E. Andrew³, G. Mas⁴, S. Marmolejos¹, J. Albert¹, A. Kahn-Kirby⁴, E. Delot⁵, V. Fusaro⁴, E. Vilain⁶; ¹Children's Natl. Med. Ctr., Washington, DC, ²Children s Natl., Washington, DC, ³Children's Natl., Washington, DC, ⁴Invitae, San Francisco, CA, ⁵Children s Natl. Res. and Innovation Campus, Washington, DC, ⁶Children s Natl. Med. Ctr., Washington, DC

Abstract Body:

Purpose: Panel testing, sequencing predetermined lists of genes selected for specific clinical indications, is standard practice in genetic medicine. These tests often are not diagnostic because the relevant gene was not included on the panel. The process to add new genes to traditional hybridization capture panels for clinical use is slow and laborious. Recently, many clinical laboratories have been using next-generation sequencing to offer more flexible panels by validating an exome or whole genome platform and then report on panel regions using bioinformatic analyses. As additional clinical information presents it is possible to reanalyze the existing data without collecting a new sample from the patient or performing additional wet lab work. Typically, the type of genetic test ordered is dictated by clinical guidelines, institutional priorities, payor policies, and patient costs. This often results in ordering the cheapest and smallest panel that meets an immediate diagnostic need. We sought to assess the incremental diagnosis rate for cases lacking a conclusive diagnosis after panel-based testing that was performed using whole-genome sequencing.

Methods: We obtained 15 negative clinically generated whole-genome data cases referred to the Pediatric Mendelian Genomics Research Center, an NHGRI-funded GREGoR site. Previous panel-based testing was performed at Children's National Clinical Molecular Laboratory. Whole-genome variant call files were analyzed with Moon software, an AI phenotype/variant prioritization tool.

Results: In 33% of the cases (5 out of 15) a reportable variant was highly ranked by Moon. Of the five cases, one variant was originally missed, despite having the gene on the original panel, because it was a complex structural rearrangement with deep intronic breakpoints falling outside the reporting regions. In the remaining four cases, actionable variants were discovered in genes not included in the original panel.

Conclusion: Whole-genome or exome-based panels offer the ability to improve diagnostic yield by performing reanalysis as guidelines are updated or as new phenotypic information becomes available. As whole-genome sequencing costs continue to decrease, we anticipate this will become a more tractable option for clinical laboratories.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2314. Increased Diagnostic Yield With Long Read Sequencing In Patients With Undiagnosed Neurodevelopmental Disorder

Authors:

S. Jamuar¹, J. Goh¹, J. Teo², A. Wang¹, S. Ng³, M. Chin⁴, K. Chua⁵, S. Au⁴, X. Chan⁴, J. Lim³, S. Kam³, H. Law¹, A. Wenger⁶, W. Lim²; ¹KK Women's and Children's Hosp., Singapore, Singapore, ²SingHealth.Duke-NUS Inst. of Precision Med., Singapore, Singapore, ³KK Women's and Children's Hosp., Singapore, Singapore, ⁴Pacific BioSci.s, Singapore, Singapore, ⁵PacBio, Singapore, Singapore, ⁶Pacific BioSci.s, Menlo Park, CA

Abstract Body:

Background: Singapore Undiagnosed Disease Programme, established in 2014, has performed whole exome/genome sequencing using short read technology in over 600 patients so far, achieving a diagnostic yield of 38.8%. In a sub-cohort of 82 patients with neurodevelopmental disorder, we achieved a diagnostic yield of 43%.

Aim: Given the limitations of short read sequencing in detecting structural variants, repeat expansion disorders, etc., we aimed to study the potential increase in diagnostic yield in our cohort with the use of long read sequencing.

Method: We identified 10 families where a genetic disorder was strongly suspected. This included a personal history of severe developmental delay/ intellectual disability and/or presence of growth abnormalities and/or multiple malformations; or a family history of affected relative(s). We performed HiFi long read sequencing using Sequel IIe system on high molecular weight genomic DNA extracted from peripheral leucocytes. We performed de novo assembly to identify structural variants, as well as alignment to human reference genome for variant calling using established bioinformatic pipelines. Variants were reviewed at a multidisciplinary team meeting, and candidate variants were selected for validation through orthogonal technologies.

Results: Out of the 5 samples analysed so far, we have identified a candidate variants in 2 (40%) of these families. One is a 1.83kb deletion of exon 1 of DYRK1A (MIM# 600855) in a child with global developmental delay and facial dysmorphism. In another child with progressive neurodegenerative disorder, gaze palsy and ataxia, a 7kb repeat expansion in BEAN1 gene (MIM# 612051), associated with spinocerebellar ataxia 31, was identified. Analysis on the remaining 5 samples is ongoing.

Conclusion: Our initial pilot of long read sequencing on patients with undiagnosed neurodevelopmental disorder further increased our diagnostic yield by identifying variants that are typically missed on traditional short read sequencing.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2315. Increasing global access to clinical whole genome sequencing for under-resourced undiagnosed individuals

Authors:

S. Terry¹, J. L. Ortega¹, R. J. Taft^{2,1}, S. Moosa³, J. Green¹, V. Rajan¹; ¹Genetic Alliance, Damascus, MD, ²Illumina Inc, San Diego, CA, ³Stellenbosch Univ., Cape Town, South Africa

Abstract Body:

Background: The search for a diagnosis by individuals with undiagnosed conditions, sometimes called the diagnostic odyssey, is burdensome for individuals, families, communities, and society. This burden is compounded when the resources necessary to end the diagnostic odyssey are not available, as is the case in the majority of low and middle-income countries (LMICs). Genetic Alliance's iHope™ Genetic Health (iGH) is a global program designed to help patients from LMICs and/or low- and moderate-income households achieve a diagnosis through clinical whole genome sequencing (cWGS), education, and support. Leveraging contributions from Illumina, AWS, LunaPBC, and others, iGH connects patients and their clinicians with laboratories offering cWGS free of charge. **Objective:** Genetic Alliance issued a Request for Information (RFI) to determine needs of patients, laboratories, clinical sites that care for rare disease patients. We aimed to understand the opportunities and challenges for cWGS for under-resourced individuals and their clinicians, the global capacity for cWGS, and identify novel care pathways. **Methods:** Genetic Alliance created an RFI with questions tailored to various stakeholder groups, including laboratories, researchers, clinicians, families, and advocacy organizations. The RFI was sent by direct email to genetic testing labs, professional societies, and academic and patient organizations. In addition, it was distributed through Genetic Alliance's social media channels. Responses were collected during March 2022. We reviewed the responses and synthesized a summary categorized by major stakeholder groups. **Results:** We received 28 responses from the stakeholder groups from nine countries. The overall themes from all stakeholders are similar: the main barriers to providing cWGS are cost, coverage policies and reimbursement, and clinician and patient education. Cost: the high costs of cWGS make routine utilization difficult. Reimbursement: cWGS is rarely covered by payors. Education: patients require cultural-background appropriate genomic education, particularly prior to testing; medical practitioners are often unaware of both the availability and potential impact of genomic testing; and the availability of specialist staff, including medical geneticists, genetic counselors and bioinformaticians, is limiting uptake and availability. **Discussion:** This information has helped define iGH's near-term goals and enable resource investment where it will have the most impact. iGH will release its first round of RFPs in 2022, with initial disbursements of grants to participating laboratories in LMIC shortly thereafter.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2316. Infinium Global Screening Array for CNVs detection.

Authors:

L. Vieira¹, G. Carvalho¹, Y. Gasparini², V. Almeida¹, B. Wolff¹, A. Nascimento¹, L. Kulikowski³; ¹Faculdade de Med. da Univ.e de São Paulo, São Paulo, Brazil, ²Univ.e de Sao Paulo, Sao Paulo, Brazil, ³Univ.e de Sao Paulo, São Paulo, Brazil

Abstract Body:

Copy number variations (CNVs) play important role in the development of many complex phenotypic traits. Cytogenomic CNVs analyses using Infinium CytoSNP-850K bead chips (Illumina) providing comprehensive genome-wide coverage across a screen of 850,000 probes and commonly applied at routine laboratories. However there are other platforms for genotyping assays, such as the Global Screening Array BeadChip (GSA), which uses the same beadarray technology to detect single-base polymorphisms (SNP) with 650,000 probes. In this sense, we compared the effectivity of CNVs detection by GSA platform with CNVs results obtained from with samples previously genotyped by the gold standard Infinium CytoSNP-850K techniques and also Multiplex Ligation-dependent Probe Amplification (MLPA) assays. We studied 21 samples previously evaluated by gold standard platforms for CNV detection, 7 by MLPA assays and 14 by CytoSNP-850K. All samples were submitted to the GSA assay and analyzed by the CNV partition plug-in of the Genome Studio software provided by Illumina. The genomic results were associated with the clinical phenotypes. The CNVs obtained by both platforms, GSA and CytoSNP, were fully compatible, showing only expected variations in breakpoints at regions with different probe coverage. The GSA assay showed higher resolution compared with samples genotyped by MLPA, as the coverage of probes in deleted and/or duplicated regions is greater than that of MLPA probes. Thus enabling to suggest the breakpoints of the deletions and the amount of genes affected. In addition to the CNVs, it was possible to visualize clinically relevant regions such as the ROH regions. Therefore, the GSA assay is effective for the detection of CNVs when compared with MLPA assays for genome screening, despite its lower resolution. The use of GSA can also represent an excellent cost-benefit compared to CytoSNPs, especially considering the search for pathogenic CNVs in the laboratory routine.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2317*. Integrating population-scale data into structural variant visualization

Authors:

M. Chowdhury, R. Layer; Univ. of Colorado, Boulder, CO

Abstract Body:

Structural variation (SV) has been linked to various diseases, but use of SV information remains low in the clinical setting which relies mainly on short-read sequencing. The main barrier to adoption is the overabundance of false positive calls made by SV detection tools. Given the uncertainty of SV callers, many tools have been developed to help validate SV calls by visualizing the genomic regions around potential SVs.

Visualization tools are of great importance in the validation of SV callsets. It is often possible to accept or reject a potential SV by examining the sequence alignments in and around the reported genomic region. Viewing raw alignments in a tool like IGV is difficult and time consuming, however. To alleviate this issue we developed Samplot, a tool for visualizing genomic regions that contain an easy to understand view of genomic coverage as well as a compact representation of paired/split read alignments. To enhance the utility of these images for manual SV curation, we developed SVPlaudit, a cloud based framework for collaborative annotation of putative SV callsets. Given the ease of human based curation with Samplot images, we developed Samplot-ML, a machine learning model trained to classify Samplot SV regions, to enable automated filtering of potential false positive SVs.

We now seek to extend the utility of Samplot into the realm of population level data using our recently developed structural variant index (STIX). STIX extracts discordant/split read alignments (often used by short read SV callers to make their predictions) from huge cohorts of whole genome sequencing data and allows one to determine the density of SV evidence across the indexed population given a simple interval query. The new integrated visualization displays the original sample level information with a population view of discordant/split read alignments returned from a STIX query of the SV breakpoints. This enables us to visually compare sample level alignments in a genomic region against the background distribution in one or more STIX populations. For example: if we are interested in calling somatic SVs in a tumor sample, we can use the presence of STIX evidence in a normal tissue cohort to reject a SV as likely germline.

We see the development of our visualizations and automated curation tools as an important two-pronged approach to the SV problem. Determining elements of useful visualizations has informed the development direction of tools like Samplot-ML and vice versa. We foresee this new integrated view of sample and population level data will help improve the quality of SV callsets in the short term and serve as a base for future automated SV curation tools.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2318*. Investigating the frequency of parental gonosomal mosaicism in Neurodevelopmental Disorder cohorts to improve the genetic diagnostic rate

Authors:

N. Sandran^{1,2}, D. Webber¹, K. Harper², J. Berry¹, M. Corbett^{1,2}, A. MacLennan², J. Gecz^{1,2}, C. van Eyk^{1,2}; ¹Neurogenetics Res. Program, Adelaide Med. Sch., Univ. of Adelaide, Adelaide, Australia, ²Australian Collaborative Cerebral Palsy Res. Group, Robinson Res. Inst., Univ. of Adelaide, Adelaide, Australia

Abstract Body:

Neurodevelopmental disorders (NDDs) are a heterogeneous group of predominantly genetic disorders like intellectual disabilities (ID), autism spectrum disorders (ASD), epilepsy or cerebral palsy (CP), among others. Exome or genome sequencing fails to resolve up to 70% of select NDDs. We have identified parental mosaicism as one of the possible factors, not yet systematically investigated, which can increase NDD diagnostic rates. We consider parental mosaicism to be either (i) germ line restricted, i.e. germline mosaicism (GeM), or (ii) gonosomal (GoM), i.e. present in a subset of somatic tissues plus germ cells. Our study focuses on GoM present at <0.3 variant allele frequency (VAF) in an unaffected or mildly affected parent which may lead to filtering of that variant from the subsequent analysis/prioritisation, i.e. false negative finding. We hypothesised that the detection of parental GoM from the start of the trio analyses could resolve a proportion of unresolved individuals with NDDs. We investigated the Australian Cerebral Palsy (CP) Biobank (discovery cohort, n=155 parent-child trios) and Simons Simplex Collection exome datasets (replication cohort, n=200 parent-child trios) and developed a pipeline incorporating multiple variant callers (Mutect2, MosaicHunter and MosaicForecast) to detect GoM variants in parents prior to confirming the presence of those variants as constitutional germline variants in the affected child. Our preliminary analyses of the CP cohort show that, on average, each parent carries 56 suspected mosaic variants, and transmits two (approximately 4% of total mosaic variants). Therefore, each individual carries two constitutional germline variants which were transmitted from a GoM parent (average: 2.12 maternal variants, 2.14 paternal variants). These GoM variants are present at an average 0.25 VAF in the parents. Approximately 10% of GoM variants in our cohort are rare deleterious (gnomAD population frequency < 1x10⁻⁴, CADD phred >=20) exonic or canonical splicing variants and we have prioritised seven potentially disease-causing variants. While preliminary, our approach and supporting data show that considering parental mosaicism at the outset of trio exome or genome studies have the potential to discover a sizeable fraction (~ 4 variants/affected child) of otherwise undetected variants which may explain at least a proportion of the unexplained NDDs

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2319*. Is 22q11.2 deletion syndrome truly less common in African American patients?

Authors:

D. McDonald-McGinn^{1,2}, T. Crowley¹, D. McGinn³, K. Gaiser^{1,2}, V. Giunta¹, L. Lairson¹, O. Tran¹, M. Share⁴, K. Valverde², S. Pastor¹, B. Emanuel^{1,2}, E. Zackai^{1,2}; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Perelman Sch. of Med. of the Univ. of Pennsylvania, Philadelphia, PA, ³Children's Hosp. of Philadelphia and Hosp. of the Univ. of Pennsylvania, Philadelphia, PA, ⁴ECRI Inst., Philadelphia, PA

Abstract Body:

Background: In 2005, our Center reported underrepresentation of African Americans in our 22q11.2DS cohort (45/379 [12%]) compared with our hospital population (42%) postulating a paucity of dysmorphic features as a possible explanation and expressing concern that late/missed diagnoses impacted remediation and recurrence risk counseling. 17 years later only 11% of our patients (172/1620) are Black, suggesting that, as has been inferred when examining 22q11.2 low copy repeats (LCRs), the 22q11.2DS is truly less common in Blacks. Here we examined associated features and geocodes to determine if Black patients are being identified. **Methods:** We performed a retrospective IRB approved chart review on 1620 patients with 22q11.2DS. Deletion size, age at diagnosis, indication for testing, congenital anomalies particularly presence, absence, and severity of congenital heart disease (CHD), additional co-morbidities, demographics including geocodes, familial status, and year of birth were abstracted for analysis to compare patients self-reported as Black or White. In addition, Face2Gene technology was used to compare recognizable facial features in 125 Black patients with 22q11.2DS (Mean age 2.5 years) compared with White control patients with 22q11.2DS. **Results:** The mean age at diagnosis (MAAD) was 5.1 years for the entire cohort (N=1620); 5.4 years for White patients (N=1228); 5.2 years for Black patients (N=172); 3.7 and 2.6 years for White and Black probands respectively. Controlling for presence and type of CHD: MAAD where there was no CHD was 6.7 and 7.9 years; simple CHD was 4.3 and 1.5 years; moderate CHD was 2.6 and 1.8 years; complex CHD was 2.6 and 0.2 years, for White and Black patients respectively. Additional co-morbidities did not change MAAD but geocodes were found to be significant. Familial deletions were identified in 8% and 16% of White and Black probands respectively. Face2Gene identified 22q11.2DS associated craniofacial features in both cohorts. **Conclusions:** Controlling for CHD, timing of 22q11.2DS diagnoses for Black and White patients was similar. Co-morbidities were minimally different. Geocodes revealed significantly lower MAAD for White and Black patients traveling >100 miles to our Center (3.8 and 1.3 years respectively). White patients were more likely to travel (47% v 16%). Familial deletions were significantly more common in Black patients (16% v 8%). Face2Gene successfully recognized 22q11.2DS in both Black and White patients, suggesting the lack of craniofacial features is not a limiting diagnostic factor. Thus, we believe 22q11.2DS is truly less common in Black Americans perhaps explainable by differences in 22q11.2 LCRs.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2320. *KANSLI*, mosaic or not?

Authors:

M. I. A. Weerts¹, M. A. van Slegtenhorst¹, M. Alders², K. E. Stuurman¹; ¹Dept. of Clinical Genetics, Erasmus MC, Univ. Med. Ctr. Rotterdam, Rotterdam, Netherlands, ²Dept. of Clinical Genetics, Amsterdam Univ. Med. Ctr., Amsterdam, Netherlands

Abstract Body:

Background: Koolen-De Vries syndrome (OMIM #610443) is caused by heterozygous pathogenic variants - including 17q21.31 microdeletions and sequence variants - in the *KANSLI* gene. The syndrome is a clinically heterogeneous multisystemic condition with characteristic facial features, developmental delay, intellectual disability, hypotonia, epilepsy and congenital malformations. Here we present a patient with clinical features of Koolen-De Vries syndrome, where a common benign copy number variant complicated molecular confirmation of the clinically suspected diagnosis. **Case presentation:** A 9-year old girl presented with an IQ of 57, selective mutism, hearing loss and craniofacial features including a course face, brachycephaly, low frontal hairline, upslant of the eyes, broad mouth with widespread teeth, lowset ears, and long and slender hands and feet including broad first digits. Although clinically the diagnosis of Koolen-De Vries was suspected, genetic testing by microarray analysis and whole exome sequencing using a gene panel for intellectual disability did not confirm the suspected diagnosis. Subsequent whole exome analysis with extra emphasis on the *KANSLI* gene revealed a *de novo* pathogenic frameshift variant in exon 2 of the *KANSLI* gene (NM_001193466.1:c.1213_1216dup) with a skewed allele frequency of 20% - confirmed by Sanger sequencing analysis - suggesting mosaicism. Because the clinical presentation did not fit mosaicism, additional genetic testing was performed. Re-evaluation of the microarray data showed that the skewed allele frequency of the sequence variant was likely to be caused by a common benign copy number gain including *KANSLI* exons 1-3. Episignature analysis revealed a methylation profile distinct for Koolen-De Vries syndrome, confirming the clinical suspicion and pathogenicity of the sequence variant. It was concluded that the pathogenic frameshift variant NM_001193466.1:c.1213_1216dup in the *KANSLI* gene was present in a non-mosaic state and the molecular confirmation of the full clinical phenotype of Koolen-De Vries syndrome in this girl. **Discussion:** Our case highlights the pitfall of neutral copy number variants complicating genetic testing, the added value of Episignature methylation profile analysis to further interpret genetic findings, and the importance of clinical phenotyping.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2321. Leveraging genomic advances to ascertain the cause of congenital limb defects in Indian subcontinent.

Authors:

N. Langeh¹, M. Ansari¹, S. Khan¹, M. Faruq², M. Chowdhury¹, M. Kabra¹, N. Gupta¹; ¹All India Inst. of Med. Sci. (AIIMS), New Delhi, India, ²CSIR Inst. of Genomics and Integrative Biology (IGIB), New Delhi, India

Abstract Body:

Introduction: Limb reduction defects can range in severity from missing fingers to the partial or complete absence of a limb. The genetic etiology and pathogenesis for approximately one-third of limb reduction defects remain unidentified till date. In the present study, we explored the genomic variants involved in the pathogenesis of longitudinal limb defects: radial ray defect (RRD), and split-hand/foot malformation (SHFM). The aim of this study was to better define the strategy for genetic testing of limb defects and genotype-phenotype correlations in the Indian cohort. **Method:** Patients with clinical features suggestive of either RRD or SHFM were recruited. Following clinical and radiological evaluation, targeted Sanger sequencing of the gene was carried out for known syndromes. Genomic evaluation was performed using Chromosomal microarray (CMA) alone; CMA followed by whole exome sequencing (WES) analysis; WES analysis alone based on the clinical phenotype and a negative targeted molecular testing. **Results:** Ninety-one of the 144 subjects with radial ray defect (n=62) and split-hand/foot malformation (n=29) were recruited for genomic evaluation. Of 91, 16% (15/91) had consanguinity and 10% (9/91) had a positive family history. Extensive phenotyping suggested known syndromes including Holt-Oram syndrome (14/62) and thrombocytopenia-absent radius syndrome (4/62). Out of 91, genomic results (CMA in 38; WES in 43; targeted Sanger sequencing in 2) were available for 73 families with a global diagnostic yield of 23% (17/73). The yield of CMA in 18 SHFM and 20 RRD was 17% (3/18) and 20% (4/20) respectively, whereas the diagnostic yield of WES was 19% (3/16) SHFM and 15% (4/27) RRD. Monoallelic, novel pathogenic variant in *TBX3*, and biallelic, novel pathogenic variants in *CEP57*, *ROR2*, and *ESCO2* were found. **Conclusion:** Limb defects are commonly encountered; however, the overall yield of genomic evaluation remains low. We provide a preliminary basis resulting in the delineation of causative genes and improved molecular diagnosis of limb defects in clinical practice. Our study supports the importance of screening copy number variants in the diagnostic testing of SHFM.

PB2322. Long-read HiFi genome sequencing reveals a 2.7 kilobase intronic insertion in *NR5A1* as a cause of 46,XY disorder of sexual development

Authors:

G. Del Gobbo¹, X. Wang¹, M. Couse², C. Lambert³, S. Zhang³, S. Dhillon³, C. Fanslow³, W. Rowell³, C. Storer³, C. R. Marshall⁴, K. D. Kernohan^{5,1}, K. M. Boycott^{6,1}; ¹Children's Hosp. of Eastern Ontario Res. Inst., Univ. of Ottawa, Ottawa, ON, Canada, ²Ctr. for Computational Med., The Hosp. for Sick Children, Toronto, ON, Canada, ³Pacific BioSci.s of California, Inc, Menlo Park, CA, ⁴The Hosp. for Sick Children, Toronto, ON, Canada, ⁵Newborn Screening Ontario, Ottawa, ON, Canada, ⁶Children's Hosp. of Eastern Ontario, Ottawa, ON, Canada

Abstract Body:

Short-read exome and genome sequencing have shown immense utility in diagnosing rare genetic disorders, however nearly two-thirds of rare disease patients still remain without a molecular diagnosis following sequencing and analysis. While short reads provide highly accurate detection of small variants, their application to detect complex structural variants and variation in highly repetitive or GC-rich regions of the genome is limited. Long-read genome sequencing addresses these limitations and enables accurate detection of structural variation, tandem repeat expansions, and improved sequencing in regions typically inaccessible by short reads.

We used long-read genome sequencing to investigate a family with a multigenerational autosomal dominant 46,XY disorder of sexual development where extensive clinical and research-based genetic testing had failed to identify a diagnosis. This condition was limited to males, incompletely penetrant, and showed phenotypic variability, with external genitalia abnormalities ranging from mild hypospadias to female genitalia, dysgenic testes, and reduced fertility. Previous testing included karyotyping, microarray, targeted *NR5A1* and *DHH* sequencing, and short-read exome, genome, and RNA-sequencing.

DNA from four affected family members was sequenced on the Sequel IIe system, generating PacBio HiFi reads, as part of the Care4Rare Canada research project. All four individuals were found to carry a heterozygous 2,752 bp insertion in intron 4 of *NR5A1*. *NR5A1* is located at 9q33.3, and pathogenic loss-of-function variants in this gene are associated with autosomal dominant 46,XY disorders of sexual development. The insertion is absent from control databases and segregates with the disorder in the family. Functional studies in fibroblasts derived from affected gonadal tissue support reduced *NR5A1* expression, and RNA-sequencing shows significant allele-specific expression of coding variants on the haplotype without the insertion.

This study provides a promising example of the utility of long-read sequencing in the context of unexplained rare diseases and highlights the contribution of undiscovered non-coding variation to Mendelian disorders.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2323. Low-level paternal mosaicism of novel pathogenic *DNMIL* variant confirms EMPF1 diagnosis in proband, highlighting importance of deep sequencing when parental carrier status is ambiguous.

Authors:

G. Akler^{1,2,3}, V. Dolgin⁴, O. Birk^{4,5}, S. Glover⁶; ¹TOVANA Hlth., Houston, TX, ²Geneyx Genomex Ltd., Herzliya, Israel, ³Precision Med. Insights, P.C., Great Neck, NY, ⁴The Morris Kahn Lab. of Human Genetics, Natl. Inst. for Biotechnology in the Negev and Faculty of Hlth.Sci., Beer-Sheva, Israel, ⁵Soroka Med Ctr, Beer-Sheva, Israel, ⁶Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract Body:

Encephalopathy due to defective mitochondrial and peroxisomal fission-1 (EMPF1) is caused by biallelic pathogenic variants in *DNMIL*, encoding dynamin 1-like, a key regulator of mitochondrial fission or division. EMPF1 is characterized by variable phenotype, onset and severity, the main features of which include delayed psychomotor development or neurodevelopmental regression, dystonia or hypotonia, and refractory seizures consistent with epileptic encephalopathy, with some reported cases leading to death. Herein we report on the case of a boy affected by neurodevelopmental delay and regression, one sided hypotonia, involuntary movements, optic atrophy, hereditary alpha tryptasemia and immunological dysfunction, carrying two likely pathogenic compound heterozygous novel *DNMIL* variants: c.270C>G (p.Asn90Lys) and c.1393G>A (p.Val465Ile). Segregation analysis using Sanger sequencing showed maternal carrier status of the c.1393G>A variant, but no parental source of the c.270C>G variant. Suspicion of low-level mosaicism of the father was entertained given the classic symptoms of the proband. Deep sequencing was performed on multiple tissue types collected from the father with findings demonstrating mosaic carrier status of the father (7% in saliva, 12% in dermal fibroblast tissue, 5% in blood WBC), confirming the diagnosis in the proband. The findings emphasize the importance of follow-up studies using deep sequencing in cases with high index of suspicion for a genetic diagnosis despite inconsistent results in segregation analysis, enabling unraveling of parental mosaicism.

PB2325. Minimizing false negatives in NGS-based diagnostic testing by optimizing variant filtering strategy

Authors:

B. Guan, A. Naik, E. Ullah, D. McGaughey, A. Agather, B. P. Brooks, R. Hufnagel; Natl. Eye Inst., NIH, Bethesda, MD

Abstract Body:

Minimizing false-negative variant calling and filtering in next-generation sequencing (NGS) is critical for diagnostic testing and, ultimately, patient care. Sources of false-negative findings from variant calling are well-recognized, including insufficient coverage of certain medically relevant genes and failed identification of structural variants by short-read technologies. However, the contribution of variant filtering strategies toward false negatives is less well-understood. Variant allele frequencies (AF) and maximum subpopulation AF (popmax AF) in the general population are often used to filter out variants considered too common to cause a rare disease in a “hard-filtering” process. However, the allele frequencies are known to vary among different public population databases. We thus hypothesized that the widely disparate AFs in public reference databases could lead to false negatives in NGS-based genetic testing. We first examined the extent of AF differences for the variants located in the OMIM Gene Map in the gnomAD v2.1.1 exome and genome datasets. Among these 4701 disease-relevant genes, we found 6991 variants in 2977 genes with popmax AF < 0.01 in one dataset but > 0.01 in the other, whose overall AFs were 1.5 to ~1e5 fold higher in one dataset than the other. Of these, 48 are predicted loss of function (pLOF) variants. We thus established a variant filtering strategy that considers possibly pathogenic variants observed with AF > 0.05 in reference databases. As a result, from an exome cohort of 220 patients with inherited retinal dystrophies, we identified two likely-pathogenic variants in *CEP164* in a patient that were not reported in genetic testing by two clinical laboratories, despite the gene being included in the analysis. One *CEP164* exonic variant (gnomAD exome: AF, 0.064, popmax AF, 0.069; gnomAD genome: AF, 0.001, popmax AF: 0.002) in a homopolymer region was classified as benign by two clinical laboratories as reported in the ClinVar database. Detailed examination of other 47 pLOF variants with substantial AF differences in gnomAD exome and genome datasets implicates such variants in medically relevant genes may have frequent false negative NGS calls, such as variants in *MYO15A*, *NFI*, and *RNPC3*. This type of error from hard-filtering can be remedied by incorporating variant filter flags for low quality calls, coupled with relaxing AF cutoffs in the analysis pipeline. We expect that this strategy to address the false-negatives resulting from disparate AFs in reference databases and to resolve missing inheritability in a substantial number of patients in NGS-based genetic testing.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2326. Mitochondrial variants and short tandem repeat expansions detected by clinical whole genome sequencing

Authors:

K. Schulze¹, L. Vossaert¹, P. Liu¹, C. Qu², V. Nguyen², M. Santana², L. Meng², C. Eng¹, H. Dai¹, F. Xia¹; ¹Baylor Coll. of Med., Houston, TX, ²Baylor Genetics Diagnostic Lab., Houston, TX

Abstract Body:

Whole genome sequencing (WGS) allows the detection of many different types of genetic variation that have traditionally been evaluated by other tests and methodologies. Aside from genomic single nucleotide, copy number, and structural variants, WGS can also detect mitochondrial variants and short tandem repeat (STR) expansions. We have reviewed the mitochondrial variants and STR expansions reported in our laboratory among all clinical WGS cases.

Using PCR-free WGS, we reported 7 mitochondrial variants, found in 6 individuals, that had $\geq 1,000\times$ read coverage, $\geq 1.5\%$ heteroplasmy, and were classified as pathogenic, likely pathogenic, or variant of unknown significance favoring pathogenic. The average depth of these variants was 3,663.6 reads (range 1,601-5,412 reads) with mean heteroplasmy of 22.8% (range 1.8%-100%). All variants occurred only once, with the exception of m.14453G>A, which was reported twice. In addition, we reported 2 STRs with expansions that were within the range of a full mutation, one in the *DMPK* gene and another in the *PHOX2B* gene. Of note, our validation studies have shown that the accuracy of calling STR repeat expansions by WGS decreases as the true number of repeats increases; this means that while WGS can detect STR expansions beyond the normal range for most repeat expansion disorders, the short read technology often limits the determination of the exact number of expanded repeats. In summary, we have encountered multiple examples of pathogenic mitochondrial variants and STR expansions in our experience with clinical WGS and can confirm the wide scope of genetic variation that can be detected by WGS.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2327. Molecular characterization of a rare case of chromosome 20p duplication syndrome in an Egyptian male patient with multiple congenital anomalies

Authors:

S. Abd Allah, M. K. Mekkawy, E. Asem, A. M. Mohamed, S. Ismail, A. Kamel; Natl. Res. Ctr., Cairo, Egypt

Abstract Body:

Introduction Chromosome 20p duplication syndrome is a rare chromosomal disorder that occurs due to duplication of variable segments of the short arm of chromosome 20. The severity and manifestations of the condition depend on the size and location of the duplication and if it is associated with another chromosomal abnormality. Very few cases of chromosome 20p duplication have been reported with no recurrent breakpoints. The majority have partial duplications and have occurred as part of a translocation (along with a deletion in another chromosome). Precise genotype-phenotype correlations remain elusive due to the small number of patients and heterogeneity of breakpoints. The clinical manifestations reported in people with chromosome 20p duplication are markedly variable ranging from completely normal individuals to severe clinical disability. Symptoms and signs include intellectual disability (ID), developmental and speech delay, poor coordination, dental problems, spinal bone abnormalities, distinctive facial features, and heart defects. **Case Report** A male patient presented to the Human Genetics Clinics at the National Research Centre, Cairo, Egypt with dysmorphic features and developmental delay. He was 7 years old of a non consanguineous parents. Detailed clinical examination revealed distinctive facial dysmorphic features, mild scoliosis, delayed language development and mild intellectual disability with poor coordination. Pelvic ultrasonography showed hydronephrosis and urethral duplication, while brain MRI showed ventriculomegaly. Pedigree analysis revealed similar clinical manifestations in two family members. Karyotyping for the patient and his parents was performed using GTG banding technique on peripheral blood lymphocytes and showed 46,XY,der(14) in the patient resulted from a balanced paternal translocation: 46,XY,t(14;20) (p11.1;q11.1), while the mother had a normal karyotype (46,XX). Molecular characterization of the breakpoints was conducted for the patient using Affymetrix Genome-Wide Human SNP Array 6.0 and identified duplication of the whole short arm of chromosome 20 without associated abnormalities in chromosome 14 : arr[GRCh38]20p13q11.1 (80927_30190264)x3 Fluorescent insitu hybridization (FISH) was performed for the patient and his father using whole chromosome paint probes for chromosomes 14 and 20 and confirmed the origin of the add material in the proband and the balanced translocation in the father. **Conclusion** We report the first Egyptian patient with rare pure 20p duplication, inherited from a balanced paternal carrier with molecular characterization and phenotype/ genotype correlation.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2328. Monozygous twins with distal 5p duplication: a case report.

Authors:

D. Contreras, **R. Lebel**, J. Black; SUNY Upstate Med. Univ., Syracuse, NY

Abstract Body:

Duplications of the short arm of chromosome 5 are very rare, and their severity is highly variable. The few patients reported with duplication distal to 5p13.3 had milder psychomotor delays and short stature compared to those with duplications proximal to 5p13.3, the latter group being characterized by developmental delays, failure to thrive and seizures.

We saw monozygotic diamniotic twin girls born to a 25-year-old primigravida mother and 28-year-old father for developmental delays, behavioral concerns, and multiple malformations (umbilical hernia, loose jointed fingers, pectus excavatum and Duane anomaly). SNP arrays revealed 2.9Mb duplication of 5p15.33p15.32 in both girls. In the DECIPHER database and one previously published case report, one finds similar duplications (ranging 1.07 to 2.42 Mb) that overlap in five genes: *MRPL36*, *NDUFS6*, *IRX4*, *IRX2* and *IRX1*. Though all patients have global developmental delays, the twins uniquely present with pectus excavatum and Duane anomaly. Their duplication exclusively contained the genes *LSINCT5* and *C5orf38*. Further, their family history suggests inheritance with incomplete penetrance. In conclusion, the overlapping five genes in all these cases may be related to their phenotype.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2329*. Multiple molecular diagnoses identified by clinical whole genome sequencing in an international cohort of more than 1,200 individuals

Authors:

E. Thorpe, A. Malhotra, T. Kalista, D. Perry, R. Taft; Illumina, San Diego, CA

Abstract Body:

Clinical whole genome sequencing (cWGS) is increasingly utilized to support the molecular diagnosis of patients with rare genetic disorders. From June 2016 to May 2022, 1,233 individuals with a suspected rare genetic disease pursued cWGS through the Illumina iHope Program, a philanthropic effort to provide cWGS to children with resource limitations impeding access to molecular testing. Here, we describe individuals who received multiple molecular diagnoses (MMD).

A positive test outcome (PTO) was reported in 491 individuals (39.8%), defined by at least one reported variant consistent with the indications for testing (IFT), found in the molecular state expected to cause disease, and classified as pathogenic or likely pathogenic by ACMG variant classification criteria. MMD were reported in 46 individuals (3.7% of cases; 9.4% of positive reports). Molecular diagnoses were associated with two (n=42 individuals), three (n=3 individuals) or four (n=1 individual) distinct conditions. MMD were specific to the IFT in 39% (18/46), related to the phenotype in addition to a secondary finding in one of 59 genes as defined by ACMG v2.0 in 20% (9/46), or in addition to an incidental finding (IF) in a gene outside of ACMG recommendations but which met laboratory reporting criteria due to clinical guidelines or actionability criteria in 41% (19/46).

Across the 46 MMD reports, 114 variants were reported. A majority (65%) were SNVs, which included two mitochondrial SNVs, followed by small indels (18%) and CNVs (17%), which included two chromosomal aneuploidies and one UPD. Eight cases had multiple variant types contributing to the MMD on a single report.

Variants related to the IFT were associated with 78 unique diseases, each reported in a single individual except for Cornelia de Lange syndrome (n=3), *CACNA1A*-related disorders (n=2) and *TRAF*-related syndrome (n=2). Twenty-six (33%) disorders related to the IFT followed dominant or X-linked inheritance associated with heterozygous or hemizygous *de novo* variants, with an additional 12 (15%) suspected to be *de novo* but both parents were not available for testing. Eighteen (23%) disorders related to the IFT followed autosomal recessive inheritance. Disorders reported as a secondary finding all followed dominant inheritance with a majority inherited from a parent. Nearly half (9/19) of IFs were associated with dominant cancer predisposition syndromes, although glucose-6-phosphate dehydrogenase deficiency was the single most common IF (n=5).

In summary, identification of MMD was observed in nearly 10% of positive reports, which supports the benefit of comprehensive testing approaches, including cWGS, in rare disease cohorts.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2330. Mutation Spectrum of Polycystic Kidney Disease-Toronto Genetic Epidemiology Study

Authors:

A. Haghghi^{1,2}, I. Bari², S. Khowaja², N. He², I-A. Iliuta², X. Song², M. Lanktree³, A. Paterson⁴, J. Lerner-Ellis⁵, Y. Pei²; ¹Brigham and Women's Hosp., Harvard Med. Sch., Boston, MA, United States, Boston, MA, ²Toronto Gen. Hosp., Univ. Hlth. Network, Univ. of Toronto, Toronto, ON, Canada, ³St. Joseph's Hlth.care Hamilton, Hamilton, ON, Canada, ⁴SickKids Res. Inst., Toronto, ON, Canada, ⁵Mount Sinai Hosp., Sinai Hlth., Toronto, ON, Canada

Abstract Body:

Background: Autosomal dominant polycystic kidney disease (ADPKD) is the most common hereditary kidney disease worldwide. Mutations in *PKD1* and *PKD2*, respectively, account for 85% and 15% of the genetically resolved cases in clinical series enriched with high-risk patients. Here, we report the ADPKD mutation spectrum of a large cohort of relatively unselected patients from a single geographical region. **Methods:** We performed mutation screening in 2,171 patients from 1,606 different families from the Greater Toronto Area (population 6.8 million) using NGS targeted sequencing and multiplex ligation-dependent probe amplification of *PKD1* and *PKD2*, as well as NGS of a panel of 50 cystic disease genes. Standard algorithms for sequence alignment, base calling, and QC filtering were applied to identify rare (MAF \leq 1%) deleterious variants as predicted by multiple algorithms. **Results:** We detected *PKD1* and *PKD2* mutations in 1205 (75%) families, non-*PKD1* and *PKD2* (i.e. *ALG8*, *ALG9*, *PKHD1*, *GANAB*, *PRKCSH*, *SEC63*, *LRP5*, *WFS1*, *TSC1-2*, *COL4A1*, and *COL4A3-5*) rare putative pathogenic variants in 120 (10%) families, with no mutations detected in 281 (15%) families. Among the *PKD1* and *PKD2* genetically resolved families, 916 (76%) and 289 (24%) were due to mutations in *PKD1* and *PKD2*, respectively. Adjusted for exon size across all 46 exons in *PKD1*, we found an enrichment of truncating mutations in exon 44. We also found over 100 recurrent mutations in \geq 2 different families (haplotype analysis in progress). **Conclusion:** We found extensive genetic and allelic heterogeneity in ADPKD with a higher prevalence of *PKD2* mutations than reported in the clinical series. We also found non-*PKD1* and non-*PKD2* cystic disease mutations in 10% of families, while 15% of the families remained genetically unresolved.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2331. Non-invasive detection of *TEK* mutations in a cohort of children with isolated venous malformations using cell-free DNA

Authors:

N. Au^{1,2}, D. M. Jensen¹, V. Dmyterko¹, T. Cook¹, K. Zenner³, J. Perkins^{4,3}, J. T. Bennett^{1,5}; ¹Seattle Children's Res. Inst., Seattle, WA, ²Univ. of Washington, Seattle, WA, ³Dept. of Head and Neck Surgery, Univ. of Washington Sch. of Med., Seattle, WA, ⁴Seattle Children's Hosp., Seattle, WA, ⁵Div. of Genetic Med., Dept. of Pediatrics, Univ. of Washington Sch. of Med., Seattle, WA

Abstract Body:

Venous malformations (VeM) are the result of abnormal vascular morphogenesis. VeM are caused by post-zygotic activating mutations within *TEK*, a tyrosine kinase receptor within the *PI3K-MTOR-RAS-MAPK* pathway. *TEK p.L914F* is among the most common pathogenic variant in VeM, contributing to ~45% of cases. Currently, molecular diagnosis of VeMs requires surgically resected tissues because these somatic variants are present in a small fraction (1-20%) of cells in the lesion. Cell-free DNA (cfDNA) is an emerging diagnostic analyte that is already in use in cancer diagnosis and prenatal genetic screening. The critical role mutant endothelial cells play in the development of VeM and their proximity to blood led us to ask whether plasma-based cfDNA could be used to detect the mutant variant. We detected *TEK* mutations in the cfDNA from 7/19 patients with isolated VeM using droplet digital polymerase chain reaction (ddPCR). Plasma obtained directly from lesions was more likely to have a mutation detected (3/4) than peripherally derived plasma samples (2/15). Mutations were detected in plasma-derived cfDNA but not in the blood genomic DNA. Our results will reduce the need for invasive procedures and the time required to determine the pathological variant in VeM patients, improving their chances for targeted pharmacologic therapies.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2332. Novel potential biomarkers for *DICER1* syndrome

Authors:

M. Wu¹, R. D. Lopez², M. Warren^{3,4}, R. Shah^{1,4}, P. Neviani⁵, J. F. Amatruda^{1,4}; ¹Div. of Hematology-Oncology, Cancer and Blood Disease Inst., Children's Hosp. Los Angeles/Univ. of Southern California, Los Angeles, CA, ²Children's Hosp. Los Angeles/Univ. of Southern California, Los Angeles, CA, ³Dept. of Pathology and Lab. Med., Children's Hosp. Los Angeles, Los Angeles, CA, ⁴Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA, ⁵Saban Res. Inst., Children's Hosp. Los Angeles, Los Angeles, CA

Abstract Body:

MicroRNAs (miRNAs) are small RNA molecules that play a critical role in regulating gene expression. The *DICER1* enzyme is a key component of the microRNA biogenesis pathway. Reflecting this central role, patients who inherit or acquire mutations in the *DICER1* gene have an increased risk of developing a spectrum of benign and malignant tumors —thereby earning the recognition as a pediatric cancer predisposition syndrome known as *DICER1* syndrome (OMIM 601200). *DICER1* syndrome is definitively diagnosed by DNA sequencing demonstrating presence of a loss of function mutation on one copy of *DICER1* plus a “hotspot” mutation on the other copy of *DICER1*. As tumor and germline DNA sequencing can pose logistical and/or cost difficulties, a complementary diagnostic method based on marker expression is valuable for both diagnostics and surveillance. Biomarkers that are candidate therapeutic targets are also appealing as these may offer a more tailored approach for therapy. As there are no approved biomarkers for identification of *DICER1*-associated tumors, we performed RNAseq and miRNAseq in an engineered murine mesenchymal cell model that incorporates a specific *DICER1* hotspot mutation to identify candidates. We validated candidate biomarkers at the RNA (*Eya2*, and miR-30d-3p) and protein (*Eya2*) levels *in vitro*, to provide proof of principle data for their eventual clinical utility. The miRNA candidate biomarkers levels were evaluated in both total and small extracellular vesicle-enriched fractions. These novel data pave the way for additional tools for diagnosis and surveillance in patients with *DICER1* syndrome.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2333. Optical genome mapping and whole genome sequencing in a case of multiple chromosomal rearrangements

Authors:

J. Levy¹, M. Rachid¹, C. Dupont², A. Rapinat³, D. Gentien³, A. Verloes⁴, Y. CAPRI⁵, A-C. Tabet⁵; ¹AP-HP, Paris, France, ²APHP-Hosp. Robert Debre, Paris, France, ³Inst. Curie, Paris, France, ⁴Robert-Debré Univ. Hosp., Paris, France, ⁵Robert Debré Univ. Hosp., Paris, France

Abstract Body:

Few studies have shown the potential of using short-reads whole-genome sequencing (WGS) approaches and optical mapping (OM) for the detection of clinically relevant structural variants (SVs) in neurodevelopmental disorders. We presented a 7-year-old female patient with macrocephaly (+3.5 SD), moderate valvular stenosis with patent foramen and developmental delay. SNP array analysis revealed several genomic rearrangements: a paternal uniparental isodisomy (UPD)pat of the 11pter region and four *de novo* duplications: a 800 kb-3q23 duplication; a 730kb-12q13.12 duplication, a 256 kb-15q15.1 duplication and a 342 kb-19q13.42 duplication. Whereas (UPD)pat explained the macrocephaly, the 4 duplications were considered as variations of uncertain significance. WGS allowed specifying that the 3q23 and 15q15.1 duplications were in tandem and revealed structural variants involving both chromosomes 12 and 19. Short-reads WGS could not map precisely any of the rearrangement's breakpoints and position that lie within SVs. We used optical genome mapping (OGM) to determine the orientation and the position of the duplicated segments at 12q13.12 and 19q13.42, allowing us to propose a mechanism and classify this rearrangement. This study highlights the complementarity of techniques for the detection of clinically relevant structure variants.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2334. Optical genome mapping identified a likely pathogenic *POLR3B* variant in an undiagnosed male with ataxia, hypotonia, and cerebellar atrophy

Authors:

A. Ortega¹, J. Yu¹, A. Baxter¹, J. Rosenfeld², K. Worley², S. Ketkar², D. A. Scott², Undiagnosed Diseases Network, A. Hastie¹, A. Chaubey¹; ¹Bionano Genomics, San Diego, CA, ²Baylor Coll. of Med., Houston, TX

Abstract Body:

Recent advances in genomic technology have significantly increased the identification of causative variants in subjects with genetic disorders. However, a large portion of subjects with a suspected genetic etiology remain undiagnosed after numerous advanced genetic tests. Here we describe a research case referred to a Bionano postnatal clinical study through the Undiagnosed Diseases Network (UDN). The subject was a 6-year-old male presenting with a normal early development, who then presented with neurological symptoms including ataxia, hypotonia, cerebellar atrophy and speech delay beginning at one and a half years of age. Prior genetic tests including chromosomal microarray, ataxia panel, and whole-exome sequencing (WES) were not diagnostic. Using optical genome mapping (OGM), the subject's ultra-high molecular weight (UHMW) genomic DNA was isolated, labeled, and imaged across nanochannel arrays. An automated bioinformatics pipeline was then used to identify structural variations in the genome. In this case, we identified a heterozygous 5.5 kilobase (kb) deletion located in *POLR3B* which is associated with autosomal recessive leukodystrophy (MIM: 614381). This 5.5kb deletion is within a 17.9kb window (chr12:106,446,738-106,464,666, hg38) including exons 20 to 23 and is likely to affect one of the coding exons of *POLR3B*. Importantly, the subject's prior WES data identified a maternally inherited likely pathogenic missense variant (c.1244T>C; p.Met415Thr) in *POLR3B*. After reviewing trio WES data (subject and his parents), a paternally inherited exon 20 deletion was suspected. In addition, the subject's RNA sequencing data showed exon 20 skipping in some *POLR3B* transcripts, supporting the finding of an exon 20 deletion. Biallelic missense and deletion variants in the proband were later confirmed by whole-genome sequencing and targeted Sanger sequencing. In conclusion, we used OGM in combination with other genetic testing technologies to identify likely pathogenic, biallelic *POLR3B* variants in a previously undiagnosed subject with ataxia, hypotonia, and cerebellar atrophy. This case demonstrates the challenges and limitations of current genetic analysis tools and highlights the need to use complementary technology, like OGM and NGS sequencing, to comprehensively identify candidate disease-causing variants and provide comprehensive answers in research on rare disease.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2335*. Optical genome mapping identifies double parental paracentric inversions as risk factor for atypical monocentric recombinant chromosomes in offspring

Authors:

P. Kuentz¹, A. Vitobello², Y. Duffourd³, M. Chevarin⁴, B. Keren⁵, C. Schluth-Bolard⁶, D. Sanlaville⁷, M. Rossi⁸, A-L. Mosca⁴, N. Marle⁴, C. Thauvin-Robinet⁴, L. Faivre⁴, P. Callier⁹; ¹CHU BESANCON, BESANCON, France, ²CHU Dijon Bourgogne, Dijon, France, ³CHU DIJON - INSERM U1231, DIJON, France, ⁴CHU Dijon, Dijon, France, ⁵APHP, Paris, France, ⁶CHU Strasbourg, Strasbourg, France, ⁷HCL, CBPE, BRON Cedex, France, ⁸CHU Lyon, Lyon, France, ⁹CHU Le Bocage, Dijon, France

Abstract Body:

Individuals with heterozygous paracentric inversions are not thought to have a higher risk of abnormal offspring as compared to the general population so that prenatal diagnosis should not be offered systematically. Using a combination of conventional, molecular and next-generation cytogenetics, we characterized atypical unbalanced recombinant monocentric chromosomes identified in three unrelated individuals with syndromic intellectual disability, arisen from parents with balanced double paracentric inversions. In the affected individuals, chromosomal microarray identified a common pattern composed of an interstitial gain, a variable copy-neutral region and an interstitial loss in all affected individuals. Optical mapping (OM) revealed that the duplicated segment was inserted in an inverted orientation within the deleted region. In parents, OM identified large paracentric inversions (ranging from 17.1 to 23.6 Mb) encapsulating, in two out of three cases, a smaller inversion (of 1.8 and 4.8 Mb), corresponding to the neutral regions found in the affected individuals. In the third case, neither technique could identify an inversion in the copy-neutral region because of its small size (16.4 Kb) and of its composition in segmental duplications. Finally, using OM and fluorescent in situ hybridization, we demonstrated that at least in one case, the two encapsulated inversions were in cis. Overall, our data support either a double inversion loop or U-type exchange as possible meiotic mechanisms as a cause of the atypical rearrangements identified in affected kindred. Our observations may guide future recommendations for genetic counseling in case of known parental paracentric inversions.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2336. Optical genome mapping improves clinical interpretation of constitutional copy number gains.

Authors:

G. Raca, J. Han, C. Fong, J. Ji, R. Schmidt, A. Dharmadhikari; Children's Hosp. Los Angeles, Los Angeles, CA

Abstract Body:

Genomic location and orientation of copy number gains, which are critical for their clinical interpretation, cannot be determined from chromosomal microarray (CMA) data. Consequently, copy number gains detected by CMA are often classified as variants of uncertain clinical significance. Sequencing studies have shown that the majority of copy number gains are positioned head-to-tail (in direct orientation) adjacent to the original locus, likely preserving the reading frame of the affected gene. If this structural information was readily available, most copy number gains could be classified as likely benign, thus avoiding clinician and patient concern and costly follow up parental studies. In contrast, those gains that are inverted, triplicated, or inserted into a distant locus can disrupt or fuse genes in a manner that is not revealed by CMA, resulting in missed diagnoses. Optical genome mapping (OGM) allows genome-wide detection of CNVs with the resolution that supersedes most clinically used CMA platforms, but it also provides detailed structural information about altered chromosome regions. We hypothesized that OGM will allow improved interpretation of the functional and clinical significance of copy number gains as compared to CMA. By retrospectively searching our clinical database we identified 22 cases in which CMA testing detected copy number gains that included either the 5' or the 3' portion of a disease-associated gene. In all the cases the gains were reported as variants of uncertain clinical significance. OGM not only detected the same copy number gains detected by CMA, but also provided information about their genomic location and orientation. Gains involving the following genes implicated in autosomal dominant or X-linked genetic disorders were found to represent direct in situ duplications that preserved an intact copy of the coding region: *PAFAH1B1*, *MID1*, *PLCB4*, *PDK3*, *EXT1*, *TRIP12*, *RAD51*, *TTC21B* and *SLC6A1*. In contrast, more complex rearrangements were identified involving the *GLI3* and *HCNI* genes. The structural information obtained by OGM allowed to predict the effect of the detected gains on gene function, and to reclassify the gains as likely benign or likely pathogenic. Our study demonstrates that OGM not only shows concordant results to CMA, but that it also represents a superior assay for constitutional CNV testing since it allows improved interpretation of the clinical significance of copy number gains.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2337. Pallister-Killian syndrome: Characterization of the isochromosome 12p by fluorescent in situ hybridization: A Case Report.

Authors:

S. Lavu, L. Vemulakonda, F. Shakil, H. Islam, C. KUMAR; Westchester Med. Ctr., Valhalla, NY

Abstract Body:

Pallister-Killian syndrome (PKS) is a rare sporadic developmental disorder usually with a tissue-specific mosaic distribution of an additional isochromosome 12p [i(12p)] without gender predilection. Typically, children with this diagnosis are characterized by craniofacial dysmorphism, hypotonia, intellectual disabilities, skin pigmentation, seizures, heart defects, diaphragmatic hernia, sparse hair and other phenotypic features. As such, it can be detected as early as in utero or in infancy and childhood. The signs and symptoms of PKS vary in severity. Here, we present a case of 4-day old male baby born to a 37-year-old at 34 weeks with a left sided congenital diaphragmatic hernia (CDH) found on prenatal ultrasound. He also had dysmorphic craniofacial features and a slight dextrocardia possibly shifted secondary to the CDH. The baby also presented with respiratory distress, bilateral cryptorchidism and bronchopulmonary dysplasia. On echocardiography, he had moderately dilated right ventricle with moderate tricuspid valve insufficiency with tricuspid regurgitation. He had evidence of persistent pulmonary hypertension secondary to pulmonary hypoplasia. Due to his phenotypic abnormalities, the cytogenetic and chromosomal microarray investigations were indicated. Chromosome analysis performed on GTG banded metaphases prepared from cultured lymphocytes revealed a mosaic male karyotype as: 47,XY,+i(12)(p10)[3]/46,XY[47]. Three out of 50 cells had 47 chromosomes with an extra isochromosome 12p resulting in the tetrasomy of 12p. The rest of the 47 cells were normal. The Fluorescence in situ hybridization (FISH) tests were performed by using two chromosome 12 specific FISH probes (Abbott Molecular Inc.), CEP 12 and LSI ETV6/RUNX1 to characterize the extra isochromosome. The FISH analysis revealed the presence of two signal patterns for CEP 12 probe (2 and 3 copies) and ETV6/RUNX1 probes (2 and 4 copies for ETV6 (12p13.2) gene and normal 2 copies for RUNX1 (21q22) gene) confirming the presence of an extra isochromosome 12p. The microarray analysis performed on peripheral blood identified the presence of a 34.7 megabase mosaic triplication (two additional copies) of short arm of chromosome 12 (from 12p13.33 to 12p11.1 region). The cytogenetic, FISH and microarray results confirmed the presence of a mosaic cell population with an abnormal cell line with an extra isochromosome 12p resulting in the tetrasomy of 12p in the peripheral lymphocytes of this newborn. This is consistent with a diagnosis of mosaic Pallister-Killian syndrome. This abnormality occurs in de novo. However, presence of germline mosaicism in one of the parents could not be ruled out.

Matsumoto¹; ¹Yokohama City Univ., Yokohama, Japan, ²Juntendo Univ., Tokyo, Japan, ³Inst. da Crianca, Faculdade de Med., Univ. de Sao Paulo, Sao Paulo, Brazil, ⁴Yokohama City Univ. Med. Ctr., Yokohama, Japan, ⁵Juntendo Univ. Urayasu Hosp., Urayasu, Japan

Abstract Body:

RNA sequencing is a technique used to determine the sequences of all transcripts derived from target tissues, and it enables the identification of deep-intronic variants that create a cryptic exon by pipelines for detecting aberrant splicing events. However, RNA sequencing analysis of neurodevelopmental disorders is limited by difficulties in obtaining appropriate RNA derived from target neural tissues. Recent studies suggest that transcript isoforms significantly overlap (approximately 60%) between brain tissue and Epstein-Barr virus-transformed lymphoblastoid cell lines (LCLs). Interestingly, 14 cohesion-related genes with variants that cause Cornelia de Lange Syndrome (CdLS), a rare neurodevelopmental disorder with dysmorphic features, are highly expressed in brain and LCLs. Among 66 CdLS families, we previously found either pathogenic single nucleotide variants (SNVs) or copy number variants (CNVs) in 46 families (46/66 = 69.7%), but not in the other 20 families. In this context, we first performed RNA sequencing of LCLs from 22 solved (with pathogenic variants) and 19 unsolved (with no confirmed variants) CdLS cases, and 106 healthy controls in the Genotype-Tissue Expression (GTEx) Biobank. RNA sequencing pipeline was developed using 22 solved CdLS cases and 105 healthy controls with two different methods: short variant analysis (for single nucleotide and indel variants) and aberrant splicing detection analysis. Then, 19 unsolved CdLS cases were subsequently applied to our pipeline, and four pathogenic variants in *NIPBL* (one inframe deletion and three intronic variants) were newly identified. Two of three intronic variants were located at *Alu* elements in deep-intronic regions, creating cryptic exons. As a result, the total diagnostic rate was increased from 69.7% (46/66) to 75.8% (50/66). RNA sequencing with LCLs was useful for identifying hidden variants in exome-negative cases.

PB2339. Positive Findings in Clinical Mitochondrial Genome Testing by NGS

Authors:

J. Yang¹, C-Y. Kao¹, J. Dong¹, J. Lattier¹, H. DAI², L. Meng², F. Xia², E. Schmitt¹, S. Peacock¹, J. Lattier¹, W. Craigen³, L-J. Wong³, C. Eng², Y. Wang²; ¹Baylor Genetics, Houston, TX, ²Baylor Coll. of Med./Baylor Genetics, Houston, TX, ³Baylor Coll. of Med., Houston, TX

Abstract Body:

Background: Genetic disorders lead to a wide spectrum of human disease. In addition to the nuclear-encoded DNA, maternally inherited mitochondrial DNA plays an important role in human health. The mitochondrial genome is a 16569bp double helix loop and encodes 37 genes. Pathogenic variants on the mitochondrial DNA are associated with human diseases including mitochondria myopathy, maternally inherited diabetes mellitus and deafness (MIDD), Leber's hereditary optic neuropathy (LHON), Leigh syndrome and many others. **Methods:** Baylor Genetics has established a robust platform to sequence the whole mitochondrial genome using Next Generation Sequencing (NGS) technology. Long-range PCR is used to amplify the mitochondrial DNA and exclude nuclear DNA. NGS is applied to sequence the samples in a high throughput manner. NGS data are processed to call single nucleotide variants (SNV) and large deletions in the mitochondrial genome. Variants can be confidently called at heteroplasmic levels as low as 1.5%. We retrospectively analyzed positive findings from cases tested consecutively but without selection based on clinical indications. **Results:** We detected pathogenic or likely pathogenic SNV in 709 cases and large deletions of mitochondrial genomic regions in 600 cases. 27 cases were positive for both SNV mutations and large deletions. The majority of samples were extracted from blood. Other sample types were urine, bone marrow, fibroblasts, amniocytes, buccal swabs, previously extracted DNA and affected tissues, including liver, skeletal muscle and others. The ages of test subjects ranged from prenatal to 89-year-old adults. The pathogenic variant m.3243A>G in the tRNA Leucine gene associated with MELAS syndrome was the most prevalent mutation, which was detected 186 times. It was heteroplasmic in all cases, ranging from 1.5% to 94.9%. **Conclusion:** Mitochondrial genome sequencing is a robust and efficient means of molecular diagnosis for human mitochondrial genome disorders.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2340. Potentially noteworthy intronic variants in the *COL5A1* and *COL5A2* genes in patients with classical Ehlers-Danlos syndrome: The necessity for RNA study and genetic diagnostic approaches

Authors:

W. Heo, J-H. Jang; Samsung Med. Ctr., Seoul, Korea, Republic of

Abstract Body:

The Ehlers-Danlos syndromes (EDS) are clinically and genetically heterogeneous disorders characterized by abnormal collagen production, mainly involving joints, skin, vasculature, and other hollow organs. Among 13 subtypes of EDS classified by the 2017 international classification of the EDS, classical Ehlers-Danlos syndrome (cEDS, OMIM#s 13000, 130010) also known as EDS type I/II has a prevalence of 1 in 20,000-40,000 which is the second most common subtypes of EDS followed by hypermobile EDS. It is an autosomal dominant disorder and 90% of cases result from variants in the *COL5A1* and *COL5A2* genes, which encode the type V collagen, the $\text{pro}\alpha 1$ (V) and $\text{pro}\alpha 2$ (V) chains respectively. Collagen V proteins consist mostly of the triple-helical region containing the repetition of [Gly-Xaa-Yaa] and are heterotrimers (two $\text{pro}\alpha 1$ and one $\text{pro}\alpha 2$). It is known that the in-frame deletion had more severe clinical manifestations than the null variant due to these characteristics of the collagen structure. There were patients without a genetic diagnosis in approximately 10% of cEDS patients. Since functional studies including RNA studies on non-canonical intronic variants have scarcely been conducted, there has room for improving the diagnostic yields of EDS. With the expansion of the test method through massively parallel sequencing, access to deep intronic variants has become easier than before, and since whole-transcriptome analysis is also possible, the technical basis for actively testing splicing alteration has been established. For these reasons, despite the skin biopsy is required to obtain cultured fibroblasts for RNA study of *COL5A1/2*, it is well worth performing. Here, we predicted potential pathogenic variants among non-canonical intronic variants (± 50 nt from closest exon/intron junction without canonical splice-site) in *COL5A1/2* using SpliceAI scores and known variants listed in the Human Gene Mutation Database 2022.1. Our results demonstrate that there was a total of 2,412 intronic variants (1,170 variants of *COL5A1*; 1,242 variants of *COL5A2*) with potentially splicing alteration. We suggest that these variants could be needed in the RNA study of fibroblasts culture when the patient's phenotype is strongly suspected of cEDS. If this method is not available, whole-genome sequencing could be an alternative option for discernment of necessities of the RNA study in limited circumstances.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2341. Rapid whole genome sequencing in the neonatal intensive care unit of Brazilian hospitals.

Authors:

M. Migliavacca; DASA, São Paulo, Brazil

Abstract Body:

The rapid pace of advancement in understanding the molecular basis of genetic diseases has led to a growing appreciation of the impact of genetic diagnosis on provision of medical care. Provision of optimal clinical care for affected children depends on timely ascertainment of the underlying genetic cause, facilitating a shift from empiric treatment to precise management of an identified disorder. Previously, the long turnaround time for genetic test results precluded their real-time application to critical care medicine. Recently, whole genome sequencing (WGS) coupled with a focused phenotype-driven analysis of WGS data, became available as an option for rapid molecular diagnosis. Thus, applicability of WGS to critical care medicine may no longer be hindered by time constraints. Studies have shown that early molecular diagnoses improve outcomes and reduce healthcare costs. Nevertheless, provisioning rapid and affordable genomic testing strategy within a national healthcare service in order to deliver equity of access is challenging. Traditionally, a series of genetic tests are used step wise for the cytogenetic or molecular diagnosis of these diseases. Mainly in low- and middle-income countries, the access to these tests is difficult, they are very expensive and the results are frequently delayed. Because of that precise timely diagnoses are not made and opportunities for prevention, anticipatory guidance, and treatment are missed or delayed. To address these difficulties related to performing multiple genetic tests we will perform rapid WGS on 100 neonatal patients (and their parents) being treated in the neonatal intensive care units (NICU) of Brazilian hospitals (Sabará Hospital Infantil and Hospital de Clínicas de Porto Alegre) with suspected rare Mendelian diseases that fit a pre-established selection criteria. WGS libraries will be sequenced on the NovaSeq 6000 platform at DASA laboratory. The final report will be returned in 15 days and will include the analysis of CNVs, indels, SNVs and a number of selected non-coding variants known to cause rare diseases. Some studies such as the one by Chung CCY et al. (2020) concluded that rapid exome sequencing in a pediatric clinical setting is feasible, has high diagnostic and clinical utility, and reduces healthcare utilization costs. With this project, we hope to shorten the time for accurate diagnosis of neonatal patients with rare Mendelian disease and critical medical conditions. We expect that timely accurate diagnoses will improve the management and treatment of these patients and lower costs to the overall health care system.

PB2342. Recombinant chromosome with proximal 14q duplication in two sibs with mental retardation and facial dysmorphism due to maternal translocation t(14q21;21p11).

Authors:

S. Tayel^{1,2}, A. Abd Rabuh²; ¹Alexandria Univ., Faculty of Med., Alexandria, Egypt, Egypt, ²Genetics Unit, Alexandria Regional Ctr. for Women's Hlth.and Dev., Alexandria,, Egypt

Abstract Body:

Introduction: Rearrangements involving the proximal segment of the long arm of chromosome 14 (14q) are rare. Clinical phenotypes of duplications 14q vary and genotype-phenotype correlation is difficult due to insufficient data. Material and Methods: Conventional cytogenetic analysis by GTG- banding and Fluorescence in situ Hybridization (FISH) using pre-labeled centromeric and telomeric probes for chromosomes 14 and 21 were performed on peripheral blood metaphase spreads of the different family members of the study. Results: We report two children with severe mental retardation, developmental delay, dysmorphic faces, microcephaly, cleft palate, and fingers and toes anomalies due to proximal duplication 14q (14q10;q21). They had the 47,XY,+mar karyotype. This marker was a small supernumerary chromosome sSMC resembling a small acrocentric one. GTG chromosome banding of the mother (who had 3 early abortions as well) and her sister (who had 4 neonatal deaths) revealed balanced translocation t(14;21) with the karyotype of: 46,XX,t(14;21)(q21.3;p11.2) 46,XX,t(14;21)(14pter→14q21.3::21p11.2→21pter;21qter→21p11.2::14q21.3→14qter). FISH analysis confirmed the cytogenetic finding and delineated the sSMC as a derivative chromosome 14. Conclusions: Carriers of Robertsonian translocations can give rise to unbalanced gametes through adjacent segregation in meiosis I. This family study adds to the specification of the genotype-phenotype correlation of proximal 14q duplications and addresses the importance of the proper complicated genetic counseling of Robertsonian translocation carriers prior to IVF, ICSI and PGD.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2343*. Return of incidental genetic findings to pediatric patients: considerations and opportunities from experiences in genome sequencing

Authors:

K. Bowling^{1,2}, M. Thompson², S. Scollon³, A. Slavotinek⁴, B. Powell⁵, B. Kirmse⁶, L. Hendon⁶, K. Brothers⁷, B. Korf⁸, G. Cooper², J. Grealley⁹, A. Hurst⁸; ¹Washington Univ. Sch. of Med., Saint Louis, MO, ²HudsonAlpha Inst. for Biotechnology, Huntsville, AL, ³Baylor Coll. Med., Houston, TX, ⁴Univ. of California San Francisco, San Francisco, CA, ⁵Univ North Carolina at Chapel Hill, Chapel Hill, NC, ⁶Univ. of Mississippi Med. Ctr., Jackson, MS, ⁷Univ. of Louisville, Louisville, KY, ⁸Univ Alabama at Birmingham, Birmingham, AL, ⁹Albert Einstein Coll. of Med., Bronx, NY

Abstract Body:

The uptake of comprehensive clinical and research genetic testing (e.g. exome/genome sequencing) has introduced unexpected testing results (incidental findings) that have become a major challenge for both testing laboratories and providers. While the American College of Medical Genetics and Genomics has outlined guidelines for laboratory management of clinically actionable secondary findings, debate remains as to whether incidental findings should be returned to patients, especially those representing pediatric populations. The Sequencing Analysis and Diagnostic Yield working group in the Clinical Sequencing Evidence-Generating Research Consortium has collected a cohort of pediatric patients found to harbor a genomic sequencing-detected incidental finding. The incidental variants were not thought to be associated with the indication for testing and were disclosed to patients and families. In total, 24 incidental findings were detected across 23 pediatric patients. These findings span four different research studies/laboratories and demonstrate management heterogeneity across study sites. We summarize specific cases to highlight core considerations that surround detection and return of unexpected findings (uncertainty of disease onset, disease severity, age of onset, clinical actionability, and personal utility), and suggest that interpretation of incidental findings in pediatric patients can be difficult given evolving phenotypes. Further, return of unexpected results can benefit patients and providers, but do present challenges. While there may be considerable benefit to return of incidental genetic findings, these findings can be burdensome to providers and present risk to patients. It is important that laboratories conducting genomic testing establish internal guidelines in anticipation of detection. Heterogeneity in policies related to these findings across clinical labs and research studies underscores the need and potential benefit for shared guidelines. However, future discussion is required to determine whether cohesive guidelines or policy statements are warranted.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2344. Review of Cytogenetic Findings of patients with Turner Syndrome and its variants among Filipinos from 1991 to 2020

Authors:

E. Maceda, C. Calalo, M. Abadingo, E. Salonga, J. Oblefias, C. Padilla; Univ. of the Philippines Manila, Manila, Philippines

Abstract Body:

A review of the karyotyping results of the Cytogenetics Laboratory of the Institute of Human Genetics, National Institutes of Health, University of the Philippines Manila showed that Turner Syndrome accounted for 2.64% of all samples received from 1991-2020. For 30 years, the most common karyotype in Turner syndrome was the classical Turner syndrome or the standard monosomy 45,X. It was noted in 195 patients, which is 37.69 % of all patients diagnosed with Turner syndrome. Mosaicism with a normal female karyotype was noted in 50 patients (9.62%). For the Turner syndrome variants, the most common is isochromosome Xq seen in 125 patients (24%). This is followed by Turner syndrome with marker chromosome in 55 patients (10.58%). Deletion Xp and deletion Xq were noted in 22 patients (4.23%) and 20 patients (3.85%), respectively. From this review, it can be noted that chromosomal analysis or standard karyotyping is a vital and useful diagnostic tool in Turner syndrome. The information obtained from it may be useful in clinical decision-making of families and healthcare providers. Its importance in providing adequate genetic counseling cannot be overemphasized.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2345. Somatic Mutational Landscape of Extracranial Arteriovenous Malformations and Phenotypic Correlations

Authors:

M. Eyries¹, F. EL SISSY¹, M. WASSEF², B. FAUCON³, D. SALVAN³, S. NADAUD⁴, F. COULET¹, H. ADLE-BIASSETTE², F. SOUBRIER⁴, A. BISDORFF⁵; ¹. Sorbonne Université, Département de génétique, Assistance Publique-Hôpitaux de Paris, Hôpital Pitié-Salpêtrière, PARIS, France, ². Dept. of Pathology, Lariboisière Hosp., Assistance Publique-Hôpitaux de Paris, Univ. of Paris, Faculty of Med., PARIS, France, ³. Dept. of Otorhinolaryngology, Lariboisière Hosp., Assistance Publique-Hôpitaux de Paris, PARIS, France, ⁴. Sorbonne Université, INSERM UMR_S1166, Unité de recherche sur les maladies cardiovasculaires, le métabolisme et la nutrition, ICAN, PARIS, France, ⁵. Dept. of Neuroradiology, Lariboisière Hosp., Assistance Publique-Hôpitaux de Paris, PARIS, France

Abstract Body:

Arteriovenous malformations (AVMs) are rare congenital fast-flow vascular anomalies characterized by a direct connection between arteries and veins, with the absence of a capillary network. Most AVMs arise in the brain, but they can occur anywhere in the body, with a predilection for the head and neck and are so-called extracranial AVMs. Somatic genetic variants may be the cause of extracranial AVMs, but few studies have explored these genetic anomalies, and no genotype-phenotype correlations have been identified. This study included twenty-three patients with extracranial AVMs that were confirmed clinically and treated by surgical resection, and for whom frozen tissue samples were available. Targeted next-generation sequencing analysis was performed using a gene panel that included vascular disease-related genes and tumor-related genes. We identified a pathogenic variant in 17 out of 23 samples (73.9%). Pathogenic variants were mainly located in *MAP2K1* (n=7) and *KRAS* (n=6), and more rarely in *BRAF* (n=2) and *RASAI* (n=2). *KRAS* variants were significantly ($p<0.005$) associated with severe extended facial arteriovenous malformations, for which relapse after surgical resection is frequently observed, while *MAP2K1* variants were significantly ($p<0.005$) associated with less severe, limited arteriovenous malformations located on the lips. Our study highlights a high prevalence of pathogenic somatic variants, predominantly in *MAP2K1* and *KRAS*, in extracranial arteriovenous malformations. In addition, our study identifies for the first time a correlation between the genotype, clinical severity and angiographic characteristics of extracranial AVMs. The *RAS/MAPK* variants identified in this study are known to be associated with malignant tumors for which targeted therapies have already been developed. Thus, identification of these somatic variants could lead to new therapeutic options to improve the management of patients with extracranial arteriovenous malformations.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2346. Statistical method for detection of uniparental disomy using SNP microarray or NGS technologies

Authors:

M. Roytman; Bionano Genomics, San Diego, CA

Abstract Body:

Uniparental disomy (UPD), or the inheritance of two paired chromosomes from the same parent, is challenging to detect given that it does not affect chromosome number or structure. However, UPD can cause human disease, due to disturbance of imprinted regions. Knowledge of the parent of origin for the UPD event is important, as maternal and paternal UPD can have significantly different phenotypic expression. Karyotyping and aCGH microarrays cannot detect UPD since there is no copy number change. In contrast, SNP microarrays and sequencing (at a depth sufficient to detect SNP genotypes) can be used to detect presence of UPD with provision of data from at least one parent. Here, we present a statistical approach using a Hidden Markov Model (HMM) to infer stretches of UPD in a patient-derived sample when provided genotypes for at least one parent. This method can detect both heterodisomy, in which both parental homologues are present, as well as isodisomy, in which two copies of one parental homologue are present. In addition, the approach can discriminate between UPD and absence of heterozygosity (AOH) caused by common stretches of DNA inherited from both parents (as in case of closely related parents). The HMM algorithm is built on a model which defines the likelihoods of observing a trio of genotypes, given each possible inheritance mode to include both maternal and paternal inheritance for the isodisomy and heterodisomy types. The HMM can detect both whole-chromosome and segmental UPD patterns, and outputs the parent of origin for UPD events. Results of the algorithm are seamlessly visualized and include color coding of individual SNP probes based on parent of origin, alongside existing copy number and allelic event calls so they can be interpreted in a holistic and whole-genome context.

PB2347. Strategies to Reduce Inconclusive Genetic Testing Results for Inherited Cardiomyopathies: Perspectives from a Clinical Diagnostic Laboratory

Authors:

L. Bronicki^{1,2}, C. Boswell-Patterson¹, C. Chisholm¹, L. Little¹, M. Ghani³, A. Smith⁴, L. Huang¹, G. Mettler¹, K. Boycott⁴, J. Rutberg¹, J. Richer¹, O. Jarinova¹; ¹CHEO, Ottawa, ON, Canada, ²Univ. of Ottawa, Ottawa, ON, Canada, ³The Children's Hosp. of Eastern Ontario, Ottawa, ON, Canada, ⁴Children's Hosp. of Eastern Ontario, Ottawa, ON, Canada

Abstract Body:

Cardiomyopathies harbour a strong genetic component and can substantially increase the risk of sudden death. Cardiomyopathies, including hypertrophic cardiomyopathy (HCM), dilated cardiomyopathy (DCM) and arrhythmogenic right ventricular cardiomyopathy (ARVC), are groups of disorders affecting the structure and function of the heart. Advancements in our understanding of the genetic causes of cardiomyopathies are rapidly evolving, with an increasing number of associated genes emerging every year. This, in turn, causes strain on genetic diagnostic laboratories, which are expected to keep pace with advancements in the field while providing cost-effective testing services with the highest possible analytical and clinical validity. At the CHEO Genetics Diagnostic Laboratory (GDL), we have implemented workflows that facilitate keeping our cardiomyopathy next-generation sequencing (NGS) testing relevant and accurate, without severely depleting resources. Two of these recent workflows include biennial revisions of our cardiomyopathy NGS testing menus and implementing current gene- and disease-specific variant interpretation guidelines. Both workflows are derived from internal and published data, and guidelines and recommendations set by the Clinical Genome Resource (ClinGen), an organization comprising of international clinical, laboratory and research experts in genetic diseases. Following these workflows for our pan cardiomyopathy, HCM and ARVC NGS tests reduced the number of genes or total sequence (base pairs) offered from 45 to 30, 19 to 12 and 7 to 7, respectively. We also implemented changes to variant interpretation guidelines, such as decreasing the general population allele frequency thresholds and criteria for interpreting truncating and missense variants in *TTN*. In addition to increasing efficiencies in the laboratory, these changes decreased the number of inconclusive results significantly, including by ~62% for HCM cases. Our data reaffirm that workflows aimed at updating gene testing menus and variant interpretation guidelines lead to improved analytical and clinical validity. These strategies ultimately allow us to continuously provide up-to-date testing services to patients, in a cost-effective and responsible manner.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2348*. The perplexing 22q11.2 duplication syndrome: an important cause of congenital anomalies, medical conditions, cognitive deficits, and behavioral phenotypes - or nothing at all

Authors:

D. McGinn^{1,2}, T. Crowley¹, K. Gaiser^{1,3}, V. Giunta¹, L. Lairson¹, M. Unolt⁴, M. Digilio⁵, B. Emanuel^{6,3}, E. Zackai^{6,3}, N. S. Philip⁷, S. Garcia-Minaur⁸, D. Heine-Suner⁹, A. Bassett¹⁰, A. Swillen¹¹, D. McDonald-McGinn^{6,3}; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Perelman Sch. of Med. of the Univ. of Pennsylvania, Philadelphia, PA, ³Perelman Sch. of Med. of the Univ. of Pennsylvania, Philadelphia, PA, ⁴Sapienza Univ. of Rome, Rome, Italy, ⁵Ospedale Bambino Gesù, Rome, Italy, ⁶Children's Hosp. of Philadelphia, Philadelphia, PA, ⁷Hosp d'Enfants de la Timone, Marseille Cedex 5, France, ⁸Hosp. Univ. rio La Paz, Madrid, Spain, ⁹Hosp. Univ. ri Son Espases, Palma de Mallorca, Spain, ¹⁰Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada, ¹¹KU Leuven, Leuven, Belgium

Abstract Body:

Background: The chromosome 22q11.2 duplication syndrome (22q11.2DupS) is expected to be as common as the 22q11.2 deletion syndrome (22q11.2DS) resulting from meiotic non-allelic homologous recombination in patients with *de novo* CNVs. 22q11.2DupS and 22q11.2DS have been identified in 1 in 850 and 1 in 992 unselected fetuses respectively. Despite this prevalence, few 22q Centers have experience with 22q11.2DupS while families are seeking anticipatory guidance. Here we report findings on 295 patients with 22q11.2DupS including etiology (familial v. *de novo*), CNV size, and associated features in probands and affected relatives. **Methods:** Records were retrospectively reviewed under IRB approval on 295 individuals diagnosed between 20 weeks-gestation and 68 years. 211 were members of 133 families followed in Philadelphia, including 3 parents of children with 22q11.2DS. 84 patients were followed at 9 international collaborating sites including Leuven (36), Madrid (9), Mallorca (7), Marseilles (16), Rome (11), and Toronto (5). 53% and 59% of Philadelphia and international patients respectively were male. Mean age at diagnosis (MAAD) was 9.4 years and 10.4 years for Philadelphia and international cohorts respectively. However, MAAD was 4.3 years for probands and 24 years for affected relatives. **Results:** Of the Philadelphia and international cohorts, 78% and 72% were familial respectively. When familial, the diagnosis in the parent was often a surprise as several had advanced degrees. 22 siblings were also ascertained. Most probands were referred for developmental delay or autism: 53% and 12% in Philadelphia and 58% and 11% internationally. Associated medical features overlapped with 22q11.2DS, although frequencies were overall reduced. 55% of Philadelphia and 58% of international patients had a standard LCR22A-LCR22D duplication. **Conclusions:** Probands with 22q11.2DupS have features overlapping with 22q11.2DS including structural anomalies/medical conditions (cardiac, endocrine, ENT, GI, immune, neurologic, palate, and skeletal), neurocognitive and behavioral differences - but the overall frequency is reduced. Familial cases of 22q11.2DupS (72%-78%) are more common than 22q11.2DS (~10%) leading to identification of previously undiagnosed relatives with significant genetic counseling implications. Nested duplications (42%-45%) are frequent compared with 22q11.2DS (~15%). MAAD (9.4-10.4 years) is considerably greater than for 22q11.2DS (3.7 years) often sending families on a protracted diagnostic odyssey. While families look to 22q Centers for guidance, these findings offer important insights, but many discussion points remain.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2349. The power of whole genome sequencing: Identification of an undocumented homozygous partial gene deletion in a patient with a neurological phenotype.

Authors:

G. Fischer¹, F. XU², A. Dennis³, A. Yang⁴; ¹PreventionGenetics, Marshfield, WI, ²Prevention Genetics, Marshfield, WI, ³Oregon Hlth.& Sci. Univ., Portland, OR, ⁴Oregon Hlth.and Sci. Univ., Portland, OR

Abstract Body:

A nineteen-year-old male presenting with seizures, intellectual disability and regression, microcephaly, and various developmental features underwent whole genome sequencing (WGS) after an extensive previous genetic work-up. Previous testing included echocardiogram, metabolic and methylation studies; all collectively unremarkable. Sequence variants reported via epilepsy multi-gene panel, mitochondrial DNA, and whole exome sequencing were subsequently determined to be inherited, reducing the likelihood of their relevance to the patient's phenotype.

WGS trio analysis revealed a 434 base pair homozygous deletion encompassing nine nucleotides of exon 2 and 425 base pairs of intron 2 of *HNMT*. The homozygous deletion was subsequently confirmed via polymerase chain reaction (PCR) and WGS analysis of each parent supported their heterozygous status. A similar deletion has not been reported within copy number variant databases or the literature nor was consanguinity declared or suspected based on patient records and WGS results. *HNMT* encodes a brain-specific histamine N-methyltransferase important in the degradation of histamine. Pathogenic variants in *HNMT* are associated with autosomal recessive intellectual developmental disorder 51 (OMIM: #605238). Pathogenic homozygous sequence variants have been reported in the literature in at least 3 families. However, copy number variants (CNVs) have not been reported to date, and we classify this as a variant of uncertain significance. Antihistaminergics and histamine diet restriction have ameliorated some clinical features in affected patients, suggesting a potential treatment option.

This case study provides evidence for the power of WGS to identify novel structural variants not detected by other technologies that may benefit patients in a diagnostic odyssey. We will also discuss the strengths and limitations of different technologies to detect such CNVs.

PB2350. The utility of whole exome sequencing in atypical cases of heterogeneous neurological disorders

Authors:

Z. Ali¹, J. Klar², M. Jameel³, a. fatima⁴, S. Baig⁵, N. Dahl⁶; ¹Ctr. for Biotechnology & Microbiol., Univ. of Swat, Pakistan, Mingora, Pakistan, ²IGP, Uppsala, Sverige, Sweden, ³Dept. of Biological and BioMed. Sci., Aga Khan Univ., Karachi 74000, Pakistan, Karachi, Pakistan, ⁴Aga Khan Univ., Karachi, Karachi, Pakistan, ⁵Pakistan Sci. Fndn., Constitution Avenue Islamabad, Pakistan, Islamabad, Pakistan, ⁶Uppsala Univ, Uppsala, Sweden

Abstract Body:

Autosomal recessive spastic ataxia is a neurological disorder characterized by cerebellar ataxia, spasticity and peripheral neuropathy. It is an inherited disease caused by homozygous mutations in different genes involved in development of cerebellum. In this study, we investigated two consanguineous families consisting of eight affected individuals manifesting peripheral neuropathy, spastic ataxia, intellectual disability (ID), aggressive behavior and epilepsy. Using whole exome sequencing, we identified two novel truncating mutations in *SACS* gene [c.2656C > T, p.(Gln886*) and c.4756_4760delAATCA, p.(Asn1586Tyrfs*3)], thus diagnosing it as autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS). Brain Magnetic Resonance Imaging (MRI) performed on probands from each family showed classical cerebellar and pontine changes, typically associated with ARSACS. Besides these, multiple supratentorial abnormalities were also observed, that are likely contributing factors to the cognitive symptoms. ID, behavioral abnormalities and epilepsy have been reported in few cases of ARSACS but are not a part of the classical triad of symptoms that includes cerebellar ataxia, spasticity and peripheral neuropathy. Our study shows that non-motor symptoms such as cognitive decline, ID and behavioral abnormalities may be important and even dominating clinical features in atypical cases with *SACS* mutations. This call for attention as ID is a disabling condition that further complicates the state, ability and care planning in this group of patients. Our combined findings further the knowledge about the phenotypic spectrum and genetic variability associated with the *SACS* gene that will contribute towards its improve diagnostics and this study also demonstrated the usefulness of WES as a diagnostic tool in atypical cases or in case of missing clinical information.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2351. Towards dried blood spot-based RNAseq in routine diagnosis of genetic disease

Authors:

C. Beetz, R. Al-Ali, M. Radefeldt, S. Lemke, P. Bauer; Centogene, Rostock, Germany

Abstract Body:

Introduction A high proportion of genetic diagnostic reports remains negative or indeterminate. Transcriptomic data have the potential to (partially) close this gap, but RNA analysis faces specific challenges in routine diagnostic setting. We set out to develop an RNAseq protocol that uses dried blood spots (DBSs), i.e. a sample type that is both easy and cheap to collect, ship and store. **Methods** Several protocols were tested to optimize filter card type, method of RNA extraction, depletion of unwanted RNA species, library preparation and bioinformatics pipeline. **Results** Our optimized protocol applies a proprietary filter card (CentoCard®). 100 ng total RNA are extracted from two blood spots (corresponding to 100 µl blood). Up to 14 days after sampling, RINs are between 3 and 6. Hemoglobin RNA depletion and polyA-tail capture were superior to alternative methods for mRNA enrichment. Sequencing generates 8-16 Million uniquely mapped RNA-seq reads. Gene body plots show acceptable underrepresentation of 5' ends of mRNAs. Gene expression patterns from DBS highly correlate with patterns obtained from fresh blood. Variants and splicing abnormalities were successfully detected across a wide range of genes. **Conclusions** Analyzing RNA from DBS has great potential for rare disease diagnostics. Combined with the primary DNA-based observations, higher diagnostic yield and less diagnostic uncertainty can be expected. Our protocol will facilitate routine implementation of RNAseq as a valuable add on to standard genetic diagnostics.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2352. Transposable element insertions in 1000 Swedish individuals

Authors:

J. Eisfeldt¹, K. Bilgrav¹, D. Nilsson¹, H. Thonberg¹, E. Tham¹, A. Ameer², A. Lindstrand³; ¹Karolinska Inst.t, Solna, Sweden, ²Uppsala Univ, Uppsala, Sweden, ³Karolinska Inst.t, Solna, Sweden

Abstract Body:

The majority of rare diseases are genetic, and regardless of advanced high-throughput genomics-based investigations, around 60 % of patients remain undiagnosed. A major factor limiting our ability to identify disease-causing alterations is a poor understanding of the morbid and normal human genome. A major genomic contributor of which function and distribution remain largely unstudied are the transposable elements (TEs), which constitute 50 % of our genome. In order to resolve this knowledge gap and increase the diagnostic yield of rare disease patients, we characterized TEs in 1000 Swedish individuals from the SweGen dataset using an in-house TE identification pipeline with a median of 1748 novel TEs detected. The pipeline was utilized to call novel TEs in 2504 individuals from the 1000 Genomes Project (1KGP) and a database with resulting TEs was created. Filtering the SweGen data using the TE-database effectively reduced the median to 18 (< 1 %) TEs remaining, proving that most insertions are common across populations. Next, we aligned rare and common TEs to genomic elements and found them to be significantly enriched in intronic regions ($p < 0.001$) and depleted in exonic regions ($p < 0.001$). Finally, we applied our TE identification pipeline on two clinical cases where disease causing TEs were suspected and could verify the presence of pathogenic TE insertions in both. Altogether we demonstrate the importance of TE detection and highlight possible clinical implications in rare disease diagnostics.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2353. Two new Tunisian cases of achondroplasia/hypochondroplasia : phenotype-genotype correlation.

Authors:

B. Abdelmoula, N. Bouayed Abdelmoula; Med. Univ. of Sfax, Sfax, Tunisia

Abstract Body:

Background: Achondroplasia and hypochondroplasia are among the most common skeletal dysplasia and short-limbed dwarfing conditions. The two autosomal dominant entities are similar, but the features of achondroplasia tend to be more severe. This study aimed to report two novel Tunisian cases of achondroplasia/hypochondroplasia for whom clinical, radiological and genetic assessment were conducted. **Material and methods:** The first patient was a female teenager with a severe short stature and a subtle body disproportion. The second patient was a female child with macrocephaly (+2 DS), external hydrocephalus and a failure to thrive (-2 SD). The two patients had specific facial dysmorphism of achondroplasia/hypochondroplasia. DNA was isolated from blood samples and genetic assessment of FGFR3 was conducted using 1/targeted sequencing for the first patient to confirm the presence of the 1620C>G mutation of FGFR3, common in hypochondroplasia, and 2/ PCR-RFLP for the second patient to confirm the presence of the typical 1138G>A mutation of FGFR3, common in achondroplasia. **Results:** Despite the absence of respectively Asn540Lys and Gly380Arg mutations in our two cases and based on clinical and radiological characteristics, the diagnosis of hypochondroplasia associated to severe dysplastic pulmonic valvular stenosis was suggested for the first patient, whereas the diagnosis of achondroplasia was suggested for the second patient. **Conclusion:** Most cases of achondroplasia/hypochondroplasia are due to a principal de novo mutation in the fibroblast growth factor receptor 3 (FGFR3 located at 4p16.3) which is the Gly380Arg mutation revealed in 98% of affected patients by achondroplasia. FGFR3 mutations c.1620C>A or c.1620C>G (p.Asn540Lys) appear to be frequent in children with hypochondroplasia with a more severe phenotype. Mutations of FGFR3, which is a negative regulator of linear bone growth by decreasing chondrocyte proliferation and differentiation in the growth plate, activate the receptor resulting in the gain-of-function with inadequate growth of the affected tissues. The most relevant features to the diagnosis are the shortening of the arms, macrocephaly, short fingers, trident configuration and hypermobility of the hips and knees as well as specific facial dysmorphism. When the diagnosis is uncertain after careful clinical and radiological assessment, molecular testing may be suggested. Nevertheless, targeted mutation analysis is not sufficient in our environment.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2354. Ultra-low DNA input with long-read sequencing identified complex chromosomal rearrangements involving *NIPBL* in a Cornelia de Lange syndrome patient

Authors:

N. Jiang¹, E. Spiegel¹, C. Lambert², P. Baybayan², A. Wenger², K. Anyane-Yeboah¹, R. Wapner¹; ¹Columbia Univ. Med. Ctr., New York, NY, ²Pacific BioSci.s, Menlo Park, CA

Abstract Body:

Background: Cornelia de Lange syndrome (CdLS) is a multisystem disorder characterized by distinctive facial features, growth restriction, upper limb malformations and mild to severe intellectual disability. Over the years, many genes have been identified to be associated with CdLS in an autosomal dominant or X-linked manner. Among them, *NIPBL* is the most commonly mutated CdLS gene. Approximately, disease causing variants can be detected in ~80% of the CdLS patients including mosaicism which leaves many CdLS cases genetically unexplained due to limitations of current diagnostic technologies. Here we describe a CdLS neonate who went through a long genetically unexplained medical mystery since the prenatal stage.

Study Description: The patient was first seen in the MFM clinic of our institute. Fetal ultrasound showed multiple abnormalities. Postnatally, He had clinical features that were compatible with CdLS, including synophrys, thin upper lip, micromelia, hirsutism. His presentation was severe and he passed away in two days. A variety of genetics testings have been done on this patient since the prenatal stage, including Prenatal FISH, karyotype, chromosomal microarray(trio) and WES(trio). However, the results were either negative or inconclusive. No pathogenetic variants or even VOUSes were identified in the known CdLS genes. Interestingly, multiple de novo deletions were seen on chromosome 5p with sizes ranging from 32kb to 2.05Mb, including a de novo 32 kb deletion in intron 1 of *NIPBL*. We hypothesized there were complex chromosomal rearrangements involving 5p which disrupted *NIPBL*.

With a very limited amount of fetal DNA left, we then performed whole genome HiFi sequencing using the PacBio ultra-low DNA input protocol. With only 30 ng of DNA input, we achieved excellent sequencing performance with 20.5x coverage and 9.9 kb average insert size. Multiple complex structural variants were identified involving chromosomal region 5p15.2p13.1. *NIPBL* was disrupted by multiple inversions and translocations, including an exon 1 inversion.

Conclusion: We hereby report a unique CdLS case with de novo complex chromosome 5p rearrangements that disrupted *NIPBL*. These disease-causing variants were not identified initially due to the limitations of the genetic sequencing options currently offered in the clinical lab. With the PacBio ultra-low DNA input long-read sequencing, we were able to identify clinically relevant structural variants with very limited amount of DNA. This case demonstrates the potential utility of long-read sequencing in routine genetic testing to increase diagnostic rate and shorten the diagnostic odyssey for patients and their families.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2355. Unexpected CNV anomalies using exome or genome-wide approach for complex phenotypes: report of a Regional Genetic Center experience

Authors:

V. Plaiasu, D. Ozunu, G. Motei, M. Ivan, L. Ghita, B. Pascu, G. Bar; INSMC Alessandrescu-Rusescu, Bucharest, Romania

Abstract Body:

Background Copy number variation (CNV) is a common source of genomic variation and an important genetic cause of disease. Copy number variation disorders arise from the dosage imbalance of one or more genes, resulting from deletions, duplications or other genomic rearrangements (translocations and inversions) that lead to the loss or gain of genetic material. Karyotype and microarray analyses have served as gold standards in molecular diagnostics for CNVs. The identification of CNVs in exome/genome data can improve diagnostic yield for a broad genetic disorder spectrum ranging from complex neurodegenerative, neuropsychiatric, sensory disorders, intellectual disability to congenital abnormalities. **Material and methods** The patients were recruited from the Regional Centre of Medical Genetics in the Paediatrics Clinics of INSMC Alessandrescu-Rusescu Bucharest. We studied 6 patients (5 girls and 1 boy, 1 year-17 years) who were seen in a 3-year period (July 2019 - September 2021) with diverse phenotypic alterations: neurodevelopmental disorders, metabolic disorders, craniofacial anomalies for which exome or genome sequencing was performed in a diagnostic setting due to the suspicion of monogenic condition. Three exome, respectively three genome sequencing data were analyzed for genomic findings. **Results** Different CNVs anomalies were identified involving chromosomes 1, 3, 10, 15 and X and they were validated by Chromosomal microarray analysis. 1 gain CNV and 5 loss CNVs were found, with CNVs ranging in size from 18,121 bp to 11,2 Mb, which resulted in 6 conclusive diagnoses based on a pathogenic CNV. CNVs were considered clinically relevant if they contained one or more disease genes for which the phenotype described in the literature corresponded with the patient's phenotype. One patient presented with double genetic pathology: a CNV anomaly combined with a monogenic disorder. The patients' CNV results have overlap with 3q27.3 microdeletion syndrome, 10q24.31q24.32 microduplication syndrome, large one copy loss on the long arm of chromosome 1 including 68 genes, encompassing the entire *LHX4* gene, 1q44 microdeletion syndrome combined with autosomal recessive Congenital disorder of glycosylation, type Im, heterozygous exon 1 and 2 deletion of the *CHD2* gene, a large intronic hemizygous 1-copy loss of chromosome X, affecting partially the *DMD* gene. **Conclusion** With the introduction of NGS (Next Generation Sequencing) technologies, it is now possible to detect both SNVs (Single nucleotide variants) and CNVs using an exome- or genome-wide approach with a single test and to increase in the diagnostic yield without additional testing of rare conditions.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2356. Unmasking of a chromothripsis event using the integrated approach of Chromosomal Microarray Analysis (CMA) and Optical Genome Mapping (OGM)

Authors:

S. Loddo¹, S. Di Tommaso¹, G. Astrea², S. Genovese¹, V. Alesi¹, D. Lopergolo², A. Morgia¹, R. Milone², A. Novelli¹; ¹Bambino Gesù Childrens' Hosp., Rome, Italy, ²Fondazione Stella Maris, Pisa, Italy

Abstract Body:

The phenomenon of chromothripsis is defined as a "chromosomal catastrophe", characterized by the shattering of one or several chromosomes up to hundreds of fragments, restored in random order and orientation, leading to complex cryptic rearrangement. We describe the case of a 3-year-old girl presenting with global developmental delay, axial hypotonia, dysmorphisms, hypertrichosis, short stature, renal anomalies and familial hyperCKemia with myopathic features. Clinical exome analysis revealed no pathogenetic variants in genes associated with the reported clinical condition. CMA (Chromosomal Microarray Analysis) was then performed, showing a 2p21 microduplication, of about 317 Kb, and two non-contiguous microdeletions at 7q36.1 and 7q36.3 regions, respectively of 1.9 Mb and 643 Kb in length. All the microrearrangements arose de novo. We used the Optical Genome Mapping (OGM), a new technology able to provide information on structural chromosomal rearrangements at high resolution, in order to verify the possible correlation between the microrearrangements detected by CMA. The analysis revealed a cryptic event of chromothripsis with six chromosomal breaks on the long arm of a chromosome 7, resulting in loss of 7q36.1 and 7q36.3 regions, corresponding to CNVs (Copy Number Variations) previously identified, and a random assembly of the rest of genomic fragments. The 2p21 microduplication seems to be occurred independently and plays a limited role. We hypothesize that the complex clinical features of our patient is the results not only of gene loss, but also of positional effects and/or disruptions of coding sequences related to the chromothripsis phenomenon. The integrated use of high resolution cytogenomic techniques has proven to be the key approach for a better diagnostic defining and for the understanding of the molecular mechanism at the base of disease.

PB2357. Unusual X-chromosome composition in mother and daughter with different karyotype constitutions

Authors:

M. Melaragno, A. Di Battista, M. Moysés-Oliveira; Univ.e Federal de São Paulo, São Paulo, Brazil

Abstract Body:

X-chromosome rearrangements are usually associated with distinct X inactivation patterns, which can influence in patient's phenotype. We studied two patients, mother and daughter, carriers of the same altered X-chromosome with a 10,6 Mb Xp deletion and a 32,4 Mb Xq duplication, but present as a supernumerary chromosome in the daughter. The mother presented intellectual disability, short stature, facial and body asymmetry, and hypothyroidism. She had five abortions and a daughter who showed normal stature, mild intellectual disability, and severe visual impairment, as well as an aggressive head cancer, which led to her death at the age 26 years. The mother showed a cytogenomic result as: 46,X,der(X)(qter→q25::p22.2→qter).arr Xp22.33p22.2(60,701_10,626,284)×1,Xq25q28(122,793,915_155,208,244)×3, and the daughter: 47,XX,der(X)(qter→q25::p22.2→qter)mat. HUMARA and EdU incorporation assay revealed an extremely preferential X inactivation pattern of the abnormal X-chromosome in the mother (100:1) and in the daughter (91:9), who probably had casual inactivation of both normal X-chromosomes. Their phenotypic differences are probably due to genic dosage imbalance in regions that escape X inactivation. In the mother, the partial X-chromosome monosomy resulted in some features of Turner syndrome, while the marked asymmetry (with also renal agenesis and ovarian absence at the right) could not be explained. These severe phenotypes were not transmitted to her daughter, who had 47 chromosomes including two normal X chromosomes and the abnormal X-chromosome. The daughter had a cytogenetically and phenotypically normal son, a finding that can be comparable with literature data that indicates fertility in XXX females. Financial support: FAPESP (2019-21644-0).

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2358*. Updated clinical practice guidelines for managing children and adults with 22q11.2 deletion syndrome

Authors:

A. Bassett^{1,2,3}, S. Óskarsdóttir⁴, T. Crowley⁵, J. C. Loo², E. Boot⁶, **D. McDonald-McGinn**⁵; ¹Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada, ²The Dalglish Family 22q Clinic, Univ. Hlth.Network, Toronto, ON, Canada, ³Dept. of Psychiatry, Univ. of Toronto, Toronto, ON, Canada, ⁴Queen Silvia Children's Hosp. and Dept. of Pediatrics, Sahlgrenska Academy at Univ. of Gothenburg, Gothenburg, Sweden, ⁵Children's Hosp. of Philadelphia, Philadelphia, PA, ⁶Advisium's Heeren Loo Zorggroep, Amersfoort, Netherlands

Abstract Body:

Background: Clinical practice guidelines for managing individuals with 22q11.2 deletion syndrome (22q11.2DS) were first published in 2011 and 2015 as part of an international collaborative effort. During the last decade knowledge has advanced with new research broadening our understanding of the many aspects of this multi-system condition over the lifespan. The aim of this investigation was to systematically review the literature and provide updated recommendations to facilitate optimal care while transcending nationalities, health care system differences, and subspecialty biases. **Methods:** The 22q11.2 Society recruited international 22q11.2DS experts to revise the clinical guidelines via a systematic literature review, abstracting relevant data and references, and preparing consensus recommendations, following the Preferred Reporting Items for Systematic reviews and Meta-Analysis protocol (PRISMA). In addition, leaders from eight 22q11.2DS patient advocacy organizations, based in seven countries on three continents and representing 7624 families, completed a REDCap survey, indicating top priorities for these guidelines including relevant subspecialty topics, best methods for knowledge transfer, and barriers to care. **Results:** 6018 publications were initially identified. After review, 2448 remained, 954 related to children/adolescents, 303 to adults, and 591 with uncertain/both pediatric and adult relevance. Recommendations were incorporated into pediatric and adult consensus documents. Given the evidence was limited for all studies (almost exclusively level III or IV), individual recommendations were not formally graded but provided as statements of good practice. Patient advocate survey results supported updated guidelines towards improving awareness, access, genetic testing, and genetic counseling, while suggesting knowledge transfer be shareable, portable, and available on social media. **Conclusions:** These guidelines present the best international consensus recommendations currently available during childhood and adolescence, with a major focus on changing issues across developmental stages. They include practical suggestions regarding evaluation, surveillance, and management of 22q11.2DS-associated physical, cognitive, behavioral and psychiatric co-morbidities, inclusive of genetic counseling and psychosocial issues. There is guidance regarding recommended investigations by age and at diagnosis, as well as suggested “do’s and don’ts”. Like the initial publications, these guidelines will continue to require updating as new information becomes available.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2359. Utilization of the Age-based Semi Quantitative Metric (ASQM) to evaluate gene-condition pairs for inclusion in Early Check's newborn sequencing panel.

Authors:

H. Cope¹, L. Milko², C. M. Powell², N. deJong², J. Hunter¹, A. K. Foreman², B. Powell², S. Shone³, E. Jalazo², J. Berg², H. Peay¹; ¹RTI Intl., Research Triangle Park, NC, ²Univ North Carolina at Chapel Hill, Chapel Hill, NC, ³North Carolina State Lab. of Publ. Hlth., Raleigh, NC

Abstract Body:

While genomic sequencing as a primary method of screening remains on the horizon for state-run newborn screening (NBS) programs, increasing numbers of research studies and commercial laboratories offer new parents supplementary screening via sequencing panels. However, methods used to select genes for these panels are not explicit, and the included genes vary widely. Here we describe our utilization of the previously published Age-based Semi Quantitative Metric (ASQM) to select gene-condition pairs for inclusion in a newborn sequencing panel for Early Check, a voluntary NBS study available to ~120,000 babies who receive NBS in North Carolina annually. The ASQM was previously used to score >800 gene-condition pairs enriched for pediatric onset on five criteria of clinical actionability on a scale of 0-3: **severity** and **likelihood** of the manifested condition, **efficacy** and **acceptability** of the intervention, and **knowledge** about the condition and intervention. A multidisciplinary Early Check Gene Panel Working Group (WG) used the scores (prioritizing scores ≥ 13) to identify an initial set of clinically diverse gene-condition pairs (n=26) to assess for inclusion in the panel. Age of action (initiation of the intervention) was set at ≤ 2 years to ensure identification of babies with conditions actionable neonatally or in infancy. The WG developed curated evidence summaries and a review process culminating in a group discussion and vote to include on/exclude from the panel. Of the 26 initial gene-condition pairs assessed, 23 were approved for inclusion. The WG identified additional important factors during the review process that impacted decisions for some conditions. For example, certain genes and conditions with variable ages of action but well-studied genotype-phenotype correlations (e.g., *RET*: Multiple endocrine neoplasia IIB), were included if specific early-action pathogenic variants (e.g., p.M918T) could be identified for return. Other genes and conditions were excluded because they accounted for an exceedingly small proportion of the associated phenotype (e.g., *ZAP70*: Immunodeficiency) or lacked adequate evidence to support genotyping in the absence of a clinical phenotype (e.g., *TTPA*: Ataxia with isolated vitamin E deficiency). The ASQM provides a method for ongoing evaluation of gene-condition pairs for inclusion in newborn sequencing panels that aligns with current NBS criteria. The Early Check process provides a reproducible methodology for selecting gene-condition pairs for NBS sequencing pilot studies that emulates a future integration into public health.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2360. Value of DNA testing in the diagnosis of Sickle Cell Anemia in Childhood in an environment with a high prevalence of other causes of anemia.

Authors:

G. Mbayabo Gloire¹, P. Lumbala Kabuyi¹, M. Ngole¹, A. Lumaka², K. Devriendt³, P. Lukusa Tshilobo¹, C. Van Geet⁴; ¹Univ. of Kinshasa/KU Leuven, Kinshasa, Congo, Democratic Republic of the, ²Univ. of Kinshasa/Univ. of Liège, Kinshasa, Congo, Democratic Republic of the, ³Univ Hosp Leuven, Leuven, Belgium, ⁴KU Leuven, Leuven, Belgium

Abstract Body:

Background: Sickle cell anemia (SCA) is the most common genetic disease worldwide caused by a single mutation in the gene *HBB*. DNA testing can help clarifying the diagnosis when Hb electrophoresis is inconclusive. We evaluated the usefulness and feasibility of DNA-based diagnosis of SCA in rural Central Africa. **Methods:** This is a cross-sectional study conducted from November 2016 to end October 2017 in the Hôpital Saint Luc de Kisantu, located 120 km from Kinshasa. This hospital offers the management of SCA patients, mainly identified using the Sickling test (Emmel test) combined with clinical features. We included patients aged 6 months to 18 years locally diagnosed as SCA and we collected clinical and hematological data. All patients were offered Hb electrophoresis and DNA testing at the Center for Human Genetics of the University of Kinshasa. **Results:** This study included 160 patients. Hemoglobin capillary electrophoresis suggested that 136 (85%) were homozygote SS, 13 (8.1%) were heterozygote (AS) and 11 (6.9%) were homozygote normal (AA). DNA testing confirmed these electrophoresis findings, with the exception of four patients, two AS in electrophoresis were found SS due to recent transfusion, and two SS in electrophoresis were found AS because they have compound heterozygous form S/ β^0 -thalassemia. The diagnosis of SCA was therefore wrongly ascertained with Emmel test in 15% of patients. **Conclusion:** This study reveals a high proportion of false positive SCA diagnoses in a rural environment in Central Africa, and underlines the importance of DNA testing in clarifying the diagnosis of SCA in the case of doubtful Hb electrophoresis.

Epigenetics Posters - Thursday

PB2361. A Bayesian interaction model to estimate cell-type-specific Methylation Quantitative Trait Loci (meQTLs) incorporating priors from flow-sorted sequencing data

Authors:

Y. Cheng¹, B. Cai¹, H. Li¹, A. Justice², K. Xu³, H. Zhao⁴; ¹Yale Sch. of Publ. Hlth., New Haven, CT, ²Yale Sch. of Med., New Haven, CT, ³Yale Sch. Med., New Haven, CT, ⁴Yale Univ. Sch. of Publ. Hlth., New Haven, CT

Abstract Body:

Methylation Quantitative Trait Loci (meQTLs) identification can shed lights on the complex interactions among genetic variants, DNA methylation (DNAm) patterns and complex human traits. The limited collection of large-scale, cell-type-specific (CTS) methylation profile hinders the extension of this framework from “bulk level” to “cell type level”. Although several methods have been developed to estimate cell-type-specific differentially methylated CpG sites with phenotypes, the field of cell-type-specific genetic effects on DNAm (CTS-meQTL) is less explored. In this presentation, we introduce a Bayesian interaction model to infer CTS meQTLs from bulk methylation data, and our model allows the incorporation of flow-sorted sequencing data of CTS methylome from a relatively small number of samples. By integrating bulk data and flow-sorted sequencing data, we show in simulations that our model improves the estimation of CTS genetic effects when compared to other methods that could provide sample-level CTS methylation estimates and then be applied to identify CTS meQTL as a comparison for our model. We applied our method to identify CTS-meQTL on cocaine use in a Veterans Aging Cohort Study Biomarker Cohort (N = 811). We were able to identify meQTLs on cocaine use related DNAm in granulocytes, lymphocytes, and monocytes. For example, the genetic effects for the CpG site cg03082779 (mapped to *ZMYND8*) were discovered in monocytes: nine meQTLs for this CpG were significant in monocytes ($p < 0.001$) while none of them were significant in granulocytes or lymphocytes. In contrast, for the CpG site cg00339441 (mapped to *RBM20*), we identified 17 meQTLs in lymphocytes while none of them were identified in the other two cell types. These findings highlight the importance of identifying genetic influences on methylation at cellular level. Our general framework will also facilitate combining CTS methylome for a small number of samples with the bulk data to enhance signal detections.

Epigenetics Posters - Wednesday

PB2363. A long short-term memory autoencoder approach for detecting CRISPR genomic edits.

Authors:

P. Hinson, M. Farris, P. Texter, T. Patterson III, E. Mace, K. Gemp, S. Russell; The Mitre Corp., McLean, VA

Abstract Body:

Clustered regularly interspaced short palindromic repeat (CRISPR) technology has revolutionized the way molecular genomic edits are implemented. As the accessibility of CRISPR genome-editing technology continues to expand in capability and application, there is an increased need to accurately identify all genomic modifications induced by CRISPR genomic edits, even those that may range beyond the modified nucleotides. Long short-term memory (LSTM) autoencoder machine learning techniques are proficient for anomaly detection within sequential data, like those observed within the methylation pattern of epigenome sequences. In this paper, we take an unsupervised learning approach using a LSTM autoencoder to examine anomalies within the sequential methylation patterns of CRISPR-edited mouse epigenomes, generated by whole genome bisulfite sequencing. Using 300 unedited mouse epigenomes from various tissues for training within a LSTM autoencoder, we developed a basis to reconstruct expected sequential biological noise across the mouse epigenome. The model was evaluated on 24 CRISPR-edited mouse epigenomes. The deep learning model includes an encoder that progressively decreases the number of LSTM units per layer and a decoder that progressively increases in units per layer until dimensionality of the layer matches the input dimensionality. These steps are performed using dropout within each LSTM layer to combat overfitting. To evaluate the effectiveness of our model in accurately predicting CRISPR edits, we developed an automated system that scans through all the sequences in a given genome and flags potential edits based on the reconstruction error for each of the sequences. Our findings demonstrate that CRISPR edit detection is possible by using CRISPR-edited epigenome samples for prediction and flagging CRISPR edits when reconstruction error surpasses an error threshold.

Epigenetics Posters - Thursday

PB2364. A methylation-based COVID-19 classification model to predict severe disease in vaccinated individuals

Abstract Body:

The development of vaccinations, antivirals, and other interventions, has precipitated a transition from the acute phase of the SARS-COV-2 pandemic to an endemic infection cycle. In this phase, mitigating the worst outcomes of an infection with SARS-COV-2, and managing burdens on hospital systems, is reliant on our ability to identify persons at high risk of developing severe COVID-19 disease and administering treatments efficiently. Epigenomic pattern alterations in response to SARS-COV-2 infection are evident in circulating white blood cells. Early in the pandemic, we designed a machine learning platform that leveraged methylation risk scores (MRS) derived from differentially methylated signatures in infected and uninfected individuals (Konigsberg et al 2021 *Comm. Med.*). This approach yielded highly predictive scores, measured as a classification-threshold-invariant (AUC), for both presence of SARS-CoV-2 infection (AUC=93.6%) and as a measure for COVID-19 disease severity (AUC=79.1%-84.4%). The goal of this work was to determine the prediction efficacy of a previously developed sparse regression based MRS model towards infection status and disease severity. The population in consideration included vaccinated individuals who visited the Emergency Department after March 2021. To accomplish this, we profiled peripheral blood samples from 304 additional patients (211 cases, 93 controls) on the customized Infinium MethylationEPIC array. These patients included a majority who had received at least one dose of the COVID-19 vaccine at the time of infection. Disease severity was assessed by hospitalization status, ICU admittance, administration of ventilator and death. This information was extracted from patient electronic health records. We assessed the efficacy of our previously developed sparse regression based MRS model in predicting disease severity in vaccinated individuals. This was achieved by comparing infection status and severity AUCs between the aforementioned cohort and an unvaccinated cohort from the original study. Our approach used a machine learning approach predicated on MRS to predict COVID-19 severity and demonstrated its utility in vaccinated and unvaccinated populations. Our study provides insights into how vaccination affects methylation status thereby offering protection from severe immune reactions due to deadly infections. In summary, our model previously designed and implemented on biospecimens from patients with SARS-CoV-2 infection prior to vaccination provides a powerful tool for clinicians to evaluate a patient's propensity to develop severe COVID-19 disease regardless of vaccination status.

Epigenetics Posters - Wednesday

PB2365. A simple workflow for methyl DNA analysis in FFPE-preserved Alzheimer and other neurodegenerative brain samples

Authors:

S. Jackson; Thermo Fisher Scientific, South San Francisco, CA

Abstract Body:

Neurodegenerative diseases, including Alzheimer and Parkinson diseases, affect millions of people and their families worldwide. Knowing the etiology, inheritance patterns and sensitivity factors are critical to understanding the pathology of these diseases. Changes in expression levels mediated by changes in DNA methylation patterns contribute to the pathologies. Several genes have been shown to be differentially methylated in these diseases. In this study, we demonstrate a workflow for analyzing methyl DNA at specific loci. Genomic DNA was extracted from FFPE-preserved samples and bisulfite converted. Primers specific for bisulfite-treated and unconverted sequences were used to amplify specific loci (ANK1 and HOX3). Resulting amplicons were cycle sequenced and analyzed on SeqStudio Flex instruments. This workflow provides researchers with a method for understanding changes in epigenetic patterns in neurodegenerative diseases.

Epigenetics Posters - Thursday

PB2366. A single cell chromatin accessibility and transcriptome atlas of the human heart improves the identification of risk variants and genes of Atrial Fibrillation

Authors:

A. Selewa¹, K. Luo¹, M. Wasney², L. Smith¹, H. Eckart², I. Moskowitz¹, A. Basu², X. He¹, S. Pott²; ¹Dept. of Human Genetics, Univ. of Chicago, Chicago, IL, ²Dept. of Med., Univ. of Chicago, Chicago, IL

Abstract Body:

Most genetic variants associated with complex traits from GWAS are located in noncoding regions with no clear functions, making it difficult to identify causal variants and understand their mechanisms. Single-cell genomics promises to close these gaps, by de-convoluting complex tissues into constituent cell types, and annotating functional elements in each cell type. In this work, we combined single cell RNA-seq and ATAC-seq to profile the human heart. We detected 8 major cell types and identified 349,000 open chromatin regions (OCRs), half of which are cell-type specific.

We used this dataset to study the genetics of Atrial Fibrillation (AF). AF is the most common cardiac arrhythmia and affects 33 million people world-wide. Among ~120 AF-associated loci, the causal variants have been identified and characterized only in a small number of loci. Using the single-cell data, we found that AF risk variants were >10-fold enriched in OCRs of cardiomyocytes (CMs) but not enriched in other cell types. Using a Bayesian fine-mapping procedure that leverages functional information, we identified 54 variants at posterior inclusion probability (PIP) > 0.5 (*i.e.* >50% probability of being causal), increasing the number of such variants by ~40% compared to fine-mapping without functional information. These SNPs show a high proportion of overlapping heart enhancers, and transcription factor (TF) targets. Several high confidence SNPs were experimentally validated. We developed a novel computational procedure, Mapgen, that combines fine-mapping results with information linking SNPs to genes, to identify causal genes. This procedure identified 45 high-confidence risk genes. Using AF-related gene pathways to assess the “plausibility” of prioritized genes, we found that Mapgen performs much better than existing methods for gene prioritization, including nearest genes, Activity-by-Contact (ABC) scores and expression QTLs. Our results support the importance of gene regulatory networks centered on TFs, including *TBX5*, *GATA4*, *NKX2-5*, and *PITX2*, in the AF genetics. Together, our study provides a comprehensive map of AF risk variants and genes, and demonstrates the power of combining single-cell genomics and advanced computational techniques to reveal the genetic basis of complex traits.

Epigenetics Posters - Wednesday

PB2367. A single-cell atlas of 3D genomic structure and DNA methylation in human subcutaneous adipose tissue.

Authors:

Z. Chen^{1,2}, K. Abuhanna³, M. Alvarez³, Y. Zhang³, O. Avram^{4,1,2}, K. H. Pietiläinen⁵, E. Halperin^{1,2,3,4}, C. Luo³, P. Pajukanta^{3,6}; ¹Dept. of Computer Sci., Univ. of California, Los Angeles, Los Angeles, CA, ²Dept. of Computational Med., Univ. of California, Los Angeles, Los Angeles, CA, ³Dept. of Human Genetics, David Geffen Sch. of Med. at UCLA, Los Angeles, CA, ⁴Dept. of Anesthesiology and Perioperative Med., David Geffen Sch. of Med. at UCLA, Los Angeles, CA, ⁵Obesity Res. Unit, Res. Program for Clinical and Molecular Metabolism, Faculty of Med., Univ. of Helsinki, Helsinki, Finland, ⁶Inst. for Precision Hlth., David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract Body:

Obesity is a serious, fast-growing global health problem, predisposing to multiple cardiometabolic disorders, such as type 2 diabetes and non-alcoholic fatty liver disease. In obesity, subcutaneous adipose tissue forms the key fat depot that has to expand to accommodate the extra fat. In some obese individuals, this task and other important adipose tissue functions are hampered by the low-grade inflammation induced by obesity, thus driving the obesity co-morbidities. Exploring how obesity impacts the cell-type composition of subcutaneous adipose tissue could shed light on how proinflammatory changes and biological mechanisms lead to obesity-related cardiometabolic disorders. Studying genomic cytosine methylation allows for further understanding of gene regulation at the nucleotide level, particularly for cell-type specificity. Chromatin conformation analysis, in turn, elucidates gene regulation at the chromosomal level by delving into the three-dimensional structure of the genome. Recent advancements in sequencing technologies like single-nucleus methyl-3C sequencing (sn-m3C-seq) permit us to simultaneously capture the methylation and chromatin conformation profiles within the same single cell. We employed sn-m3C-seq on more than 6,600 human nuclei isolated from subcutaneous adipose tissue biopsies from five obese female patients undergoing liposuction, with a BMI of >30. Utilizing both methylation and chromatin conformation data, sn-m3C-seq robustly discerns seven major cell types: adipocytes, endothelial cells, mast cells, myeloid cells, perivascular cells, stromal cells, and T cells. Moreover, cell type clustering demonstrates high consistency when performed independently under each modality. We further reconstruct cell-type-specific chromatin conformation maps and present the first-ever single-cell atlas of 3D genome structure and DNA methylation in human subcutaneous adipose tissue. These data comprise an extensive resource for exploring the decomposition of bulk adipose tissue methylation data as well as cell-type specific differential DNA methylation and chromatin conformation in obese individuals.

Epigenetics Posters - Thursday

PB2368. Activation of *Xist* by an evolutionarily conserved function of KDM5C demethylase

Authors:

M. Samanta¹, S. Gayen², C. Harris¹, E. Maclary³, Y. Murata Nakamura¹, R. Malcore⁴, R. Porter⁵, P. Garay¹, C. Vallianatos¹, P. Samollow⁶, S. Iwase⁷, S. Kalantry⁸; ¹Univ. of Michigan, Ann Arbor, MI, ²Indian Inst. of Sci., Bangalore, India, ³Univ. of Utah, Salt Lake city, UT, ⁴Univ. of Michigan Ann Arbor, Ann Arbor, MI, ⁵Univ MICHIGAN, Ann Arbor, MI, ⁶Texas A&M Univ., College Station, TX, ⁷The Univ. of Michigan, Ann Arbor, MI, ⁸Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract Body:

XX female and *XY* male therian mammals equalize X-linked gene expression through the mitotically-stable transcriptional inactivation of one of the two X chromosomes in female somatic cells. Here, we describe an essential function of the X-linked homolog of an ancestral X-Y gene pair, *Kdm5c-Kdm5d*, in the expression of *Xist* lncRNA, which is required for stable X-inactivation. Ablation of *Kdm5c* function in females results in a significant reduction in *Xist* RNA expression. *Kdm5c* encodes a demethylase that enhances *Xist* expression by converting histone H3K4me2/3 modifications into H3K4me1. Ectopic expression of mouse and human *KDM5C*, but not the Y-linked homolog *KDM5D*, induces *Xist* in male mouse embryonic stem cells (mESCs). Similarly, marsupial (opossum) *Kdm5c* but not *Kdm5d* also upregulates *Xist* in male mESCs, despite marsupials lacking *Xist*, suggesting that the KDM5C function that activates *Xist* in eutherians is strongly conserved and predates the divergence of eutherian and metatherian mammals. In support, prototherian (platypus) *Kdm5c* also induces *Xist* in male mESCs. Together, our data suggest that eutherian mammals co-opted the ancestral demethylase KDM5C during sex chromosome evolution to upregulate *Xist* for the female specific induction of X-inactivation.

Epigenetics Posters - Wednesday

PB2369. Additive effects of stress and alcohol exposure on accelerated epigenetic aging in Alcohol Use Disorder

Authors:

J. Jung¹, D. McCartney², J. Wagner¹, J. Yoo¹, A. Bell¹, L. Mavromatis¹, D. Rosoff¹, C. Hodgkinson³, H. Sun³, M. Schwandt³, N. Diazgranados³, A. Smith⁴, V. Michopoulos⁴, A. Powers⁴, J. Stevens⁴, B. Bradley⁴, N. Fani⁴, R. Walker², A. Campbell², D. Porteous², A. McIntosh², S. Horvath⁵, R. Marioni², K. Evans², D. Goldman³, F. Lohoff¹; ¹Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD, ²Univ. of Edinburgh, Edinburgh, United Kingdom, ³Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD, ⁴Emory Univ. Sch. of Med., Atlanta, GA, ⁵Univ California los Angeles, Los Angeles, CA

Abstract Body:

Background: Stress contributes to premature aging and susceptibility to alcohol use disorder (AUD) and AUD itself is a factor in premature aging; however, the interrelationships of stress, AUD and premature aging are poorly understood. We constructed a composite score of stress (CSS) from thirteen stress-related outcomes in a discovery cohort of 317 individuals with AUD and controls. We then developed a novel methylation score of stress (MS Stress) as a proxy of CSS comprising 211 CpGs selected by a penalized regression model. The effects of MS Stress on health outcomes and epigenetic aging were assessed in a sample of 615 AUD patients and controls using epigenetic clocks and DNAm telomere length (DNAmTL). Statistical analysis with an additive model using MS Stress and a methylation score for alcohol consumption (MS Alcohol) were conducted. Results were replicated in two independent cohorts (Generation Scotland GS n=7028 and the Grady Trauma Project GTP n=795). CSS and MS Stress were strongly associated with heavy alcohol consumption, trauma experience, epigenetic age acceleration (EAA) and shortened DNAmTL in AUD. Together, MS Stress and MS Alcohol additively showed strong stepwise increases in EAA. Replication analyses showed robust association between MS Stress and EAA in the GS and GTP cohort. A methylation-derived score tracking stress exposure is associated with various stress-related phenotypes and EAA. Stress and alcohol have additive effects on aging, offering new insights into the pathophysiology of premature aging in AUD, and potentially, other aspects of gene dysregulation in this disorder.

Epigenetics Posters - Thursday

PB2370*. Alcohol use-disorder associated DNA methylation differences in human nucleus accumbens and dorsolateral pre-frontal cortex

Authors:

J. White¹, C. Willis¹, S. Han², R. Tao², A. Deep-Soboslay², R. D. Mayfield³, B. T. Webb¹, E. O. Johnson¹, J. E. Kleinman², L. J. Bierut⁴, D. B. Hancock¹; ¹RTI Intl., Raleigh, NC, ²Lieber Inst. for Brain Dev., Baltimore, MD, ³The Univ. of Texas at Austin, Austin, TX, ⁴Washington Univ Sch Med, St Louis, MO

Abstract Body:

Alcohol use disorder (AUD), characterized by compulsive alcohol seeking despite adverse social, occupational, or health consequences, is a leading cause of preventable death worldwide. AUD has a strong genetic component: 50-60% heritability, with many loci identified in increasingly large genome-wide association studies. However, our understanding of the regulation of genes associated with AUD and their tissue specificity is limited. Previous studies have identified differential DNA methylation (DNAm), an epigenetic mechanism of gene regulation, associated with alcohol consumption and AUD in peripheral blood as well as postmortem brain tissue. However, recent work has suggested that there is little overlap in significant findings from different sample types, implying tissue specificity but also potentially due to different analytical strategies and small sample sizes, especially in studies of postmortem brain tissue. Here, we report a large epigenome-wide association study (EWAS) of AUD, focusing on two key tissues in the addiction cycle, nucleus accumbens (NAc) and dorsolateral prefrontal cortex (DLPFC). Illumina HumanMethylation EPIC array data from 122 decedents (61 cases with 2+ AUD symptoms, 61 controls with no AUD symptoms) were analyzed using robust linear regression, with adjustment for major depression diagnosis, age at death, sex, current smoking, DNAm-derived principal components, assay plate, and row position on plate. Results were corrected for inflation using the empirical null distribution estimation method implemented in *bacon*. At a false discovery rate (FDR) < 0.05, we identified 84 CpGs (annotated to 71 genes) significantly associated with AUD status for NAc and 55 CpGs (47 genes) for DLPFC. Three genes important to stress response and neuronal cell repair reached FDR significance in both NAc and DLPFC in our study: *PHF10* (novel), required for the renewal and proliferation of neural stem cells, *C11orf73* (novel), involved in protein transport following heat stress, and *RREB1* (previously implicated), a transcription factor implicated in axon death. Six CpGs (4 in NAc, 2 in DLPFC) were within 500 kb of results previously reported in EWAS of AUD in other postmortem brain tissues - ventral striatum, caudate nucleus, and BA9 and BA10 of the PFC. Additionally, 46 CpGs (27 in NAc, 19 in DLPFC) were annotated to genes previously implicated in EWAS of alcohol-related traits in blood. Taken together, our results highlight a subset of CpGs that may represent alcohol-related associations shared across blood and brain as well as a broader set of CpGs that may represent associations shared among and specific to brain regions important in addiction.

Epigenetics Posters - Wednesday

PB2371. Alterations of regulatory regions in T-cell Prolymphocytic Leukemia.

Authors:

H. Yan, S. Tian, H. Jin-Lee, H. Zhang, P. Hampel, E. Klee, W. Ding; Mayo Clinic, Rochester, MN

Abstract Body:

T cell prolymphocytic leukemia (T-PLL) is a rare disease showing a rapid clinical course with a median survival of <1 year. T-PLL patients respond poorly to conventional chemotherapy and demonstrate inevitable relapse after immunotherapy due to acquired resistance. Prevalence of structural variants, most notably *inv(14)(q11q32)*, *t(14;14)(q11;q32)* and *t(X;14)(q28;q11)*, has been identified. Recurrent somatic mutations were also identified in genes encoding chromatin regulators and in those associated with the JAK-STAT signaling pathway. Alterations of regulatory regions have been implicated in disease susceptibility and progression, in particular for distal regulatory elements such as enhancers. Given a lack of genome-wide epigenomics studies, the extent of epigenetic changes has not been well defined in T-PLL. We used histone H3 lysine 27 acetylation (H3K27ac) ChIP-seq to identify active enhancers and micrococcal nuclease digestion of linker DNA and sequencing (MNase-seq) to identify open chromatin regions in patients (n=6) and age-matched healthy individuals (n=3). Samples were collected with written consent and approval from the institutional review board at Mayo Clinic. Paired-end reads were mapped to the human reference sequence hg19 using BWA, and peaks were identified by MACS2 and filtered by blacklisted regions. Unsupervised clustering for both H3K27ac peaks and open chromatin regions revealed two distinct clusters separating T-PLL cases from normal, indicating a genome-wide change of regulatory regions in T-PLL. Specifically, we revealed a strong trend of losing H3K27ac-marked active enhancers in T-PLL, which was coupled with the down-regulation of nearby genes based on RNA-seq data. These genes are enriched in the immune system and adaptive immune response pathway. Similarly, we identified over 2,500 regions that lost open chromatin regions in T-PLL, but only 376 regions that gained open chromatin regions. A large portion of enhancers that lost H3K27ac in T-PLL became primed enhancers still carrying H3K4me1, while the gained active enhancers were often associated with an increase in chromatin accessibility. Together, our analyses provide further insights into the epigenetic alterations in T-PLL.

Epigenetics Posters - Thursday

PB2372*. Altered and allele-specific open chromatin landscape reveals epigenetic and genetic regulators of innate immunity in COVID-19

Authors:

(DZL), Na, Germany, ¹⁸Dept. of Gastroenterology, Hepatology and Endocrinology, Hannover Med. Sch., Hannover, Netherlands

Abstract Body:

While SARS-CoV-2 infection causes mild respiratory disease in the majority of individuals, a small group of patients develop severe COVID-19. Dysfunctional innate immune responses have been identified to contribute to differences in COVID-19 severity, but the key regulators are still unknown. Here, we present an integrative single-cell epigenetics, transcriptomics, and genetics analysis of peripheral blood mononuclear cells from hospitalized and convalescent COVID-19 patients. In classical monocytes, we identified 41.3% of significantly up-regulated genes in hospitalized COVID-19 patients potentially induced by differential chromatin accessibility. Sub-clustering and motif-enrichment analyses of monocytes reveal disease condition-specific regulation by transcription factors, such as C/EBPs and SPI1, and their targets, including a long-noncoding RNA *LUCATI*, which further regulates interferon responses and is associated with the need for oxygen supply of COVID-19 patients. The interaction between C/EBPs and *LUCATI* was validated through loss-of-function experiments. Finally, we investigated genetic risk variants that exhibit allele-specific open chromatin (ASoC) in promoters/enhancers of COVID-19 patients. Integrating our data with publicly available expression quantitative trait loci and chromosomal interactions indicates that ASoC SNP rs6800484-C is associated with lower expression of *CCR2*, which may contribute to higher viral loads in lungs and higher risk of COVID-19 hospitalization. Altogether, our study highlights the diverse genetic and epigenetic regulators that contribute to the innate immune responses of different COVID-19 patients.

Epigenetics Posters - Wednesday

PB2373. Analysis of methylation QTLs in breast cancer characterises the influence of germline variation on the abnormal cancer methylome

Authors:

R. Hannah, D. Sproul; Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract Body:

Introduction:

Population genetics has unravelled an important relationship between epigenetic modifications and transcriptional activity. One example is the observation that gene activity associates with DNA methylation patterns. Abnormal changes to the methylome are a pathological feature of many cellular disease and a hallmark of cancer. While significant changes in the DNA methylome of cancer are evident, the mechanisms underpinning these alterations are still unclear. Investigating the mechanisms and directionality of the interplay between DNA methylation and gene regulation may therefore reveal important insights into tumorigenesis. Previous studies have established the effects of genetic variation on the methylome of normal tissue. However, a similar characterisation of the genetic effects on the cancer methylome is missing from literature.

Methods:

Current models suggest that methylation changes may occur in an allele-dependent manner whereby genetic variation may associate with both local and global changes in the methylome. Methylation QTL (methQTL) analyses allow for the implication of genetic loci in regulating CpG methylation changes. Additionally, comparisons of functionally annotated methQTLs between tissues can help characterise their overall methylome identity. I compared methQTLs between normal and breast tissue samples to understand how local associations change during tumorigenesis. Focusing on methylation and genotype data from the cancer genome atlas (TCGA), I developed a robust pipeline for identifying methQTLs in cancer cells. I evaluated established processing steps for these datasets (including normalisation approaches, quality control filtering and addressing population structure bias in the genotype data) and consequently justified an optimal analysis model for the cohort.

Results:

I performed a methQTL analysis using germline genotype data and matched tumour methylation data in 333 subjects after robust data processing and filtering. A preliminary analysis using non-imputed genotype data confirms that germline variation does associate with changes in the breast cancer methylome.

Epigenetics Posters - Thursday

PB2374. *ASXL3* links chromatin biology to neurodevelopment disorders.

Authors:

E. Peirent¹, Y-C. Tsan², C. Ryan³, S. Bielas^{1,2,4,3}; ¹NeuroSci. Graduate Program, Univ. of Michigan Med. Sch., Ann Arbor, MI, ²Dept. of Human Genetics, Univ. of Michigan Med. Sch., Ann Arbor, MI, ³Cell and Molecular Biology Program, Univ. of Michigan Med. Sch., Ann Arbor, MI, ⁴Dept. of Pediatrics, Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract Body:

Human genetics studies of neurodevelopmental disorders highlight chromatin's importance in corticogenesis, with pathogenic variants enriched in networks linked to chromatin regulation. Dynamic regulation of histone modifications is especially critical for the transcriptional plasticity required during this cellular differentiation. One such modification is mono-ubiquitination of histone H2A (H2AUb1), a conserved, traditionally repressive histone mark that is reversed by the polycomb repressive deubiquitinase (PR-DUB) complex. We identified *de novo* dominant truncating variants in *ASXL3*, a key component of PR-DUB, as the genetic basis of both Bainbridge Ropers Syndrome (BRS) and autism spectrum disorder (ASD), characterized by failure to thrive, global developmental delay, feeding problems, hypotonia, profound speech deficits, and intellectual disability. We identified dysregulation of H2AUb1 as a key molecular pathology in primary cells derived from individuals with BRS. To investigate this *ASXL3*-dependent neuropathology in early corticogenesis, we generated 3D human cerebral organoids that histologically and molecularly recapitulate the context-dependent features of *in vivo* cortical development in a reproducible manner. In organoid models from CRISPR-edited and patient-derived iPSC lines, we observe *ASXL3*-dependent defects in the differentiation of pluripotent cells to the full spectrum of mature cortical neuron subtypes. We then utilized transcriptomic and epigenomic techniques to probe the role of *ASXL3*-dependent H2AUb1 deubiquitination in regulating transcriptional profiles critical to NPC fate decisions during corticogenesis. Together, our functional investigation of BRS- and ASD-associated genetic variants provides molecular insights towards uncovering the elusive role of H2AUb1 in neural development.

Epigenetics Posters - Wednesday

PB2375. Atypical Prader-Willi and Angelman syndrome deletion: Importance of parent of origin detection.

Authors:

N. Al-Sweel, B. Richardson, E. Palen, A. Baxter, M. Martin; Bionano Genomics, San Diego, CA

Abstract Body:

Prader-Willi (PWS) and Angelman syndrome (AS) are imprinting disorders caused by genetic defects of the 15q11.2q13 region that are molecularly distinguished based on whether the defect exists on the maternally- or paternally-derived chromosome. The majority of PWS and AS cases are caused by deletions of the paternal or maternal 15q11.2q13 region, respectively. Depending on a person's age and symptoms, clinical correlation can aid in the distinction of these two syndromes; however, determining the parent of origin is ultimately necessary to molecularly confirm the diagnosis and provide families and providers with the information needed for appropriate medical management. Traditionally, methylation analysis is the gold standard follow-up testing when a deletion of the PWS/AS region is identified by CNV analysis. However, methylation testing is not always informative, particularly in instances of atypical deletions of this region. Here we report an atypical 15q11.2 deletion of the PWS/AS critical region, identified on CMA, in a subject with global developmental delays, possible aspiration, overeating, hypotonia, and behavioral and sensory challenges. There is noted clinical overlap with both PWS and AS making clinical correlation challenging. The 791 kilobase deletion included *UBE3A*, but due to a gap in probe coverage, it is unclear if it extends to *SNURF-SNRPN*, which includes the imprinting center. To date, seven individuals with smaller atypical deletions of the PWS/AS region on the paternally-derived chromosome 15 have been reported with features of PWS. Because the imprinting center was undisturbed and methylation testing was normal, other methodologies to determine the parent of origin of these atypical deletions were necessary. Commercial testing options and interpretation software with the ability to identify and report on parent of origin for atypical deletions are not widely available due to lack of clinical validation for this purpose and insufficient informative genotyping markers within the region of interest. This case highlights the importance of parent of origin testing in cases of atypical AS/PWS deletions, and the utility and ease of use of the NxClinical software to accurately classify genetic conditions that exhibit a parent of origin effect, particularly in instances when traditional methylation analysis is uninformative.

Epigenetics Posters - Thursday

PB2376*. Cardiac development in mammalian models lacking the PR-DUB component ASXL3.

Authors:

S. Regan¹, B. McGrath¹, Y-C. Tsan¹, A. Srivastava², S. Bielas¹; ¹Univ. of Michigan, Ann Arbor, MI, ²Sanjay Gandhi PostGraduate Inst. of Med. Sci., Lucknow, India

Abstract Body:

ASXL3 (*Additional-sex combs like 3*) is the genetic basis of Bainbridge Ropers Syndrome (BRS). *ASXL3* is a component of the polycomb repressive deubiquitination (PR-DUB) complex, that deubiquitinates histone H2A mono-ubiquitination of (H2AUb1), highlighting a critical role for H2AUb1 in the pathogenic mechanisms of neurodevelopmental disorders. *De novo* dominant *ASXL3* truncating variants result in elevated H2AUb1 and altered transcriptional regulation. To understand epigenomic alterations and early development defects caused by truncating variants of *Asxl3*, we used CRISPR/Cas9-mediated genome editing to generate clinically relevant truncating variants in a novel mouse model of BRS. Constitutive loss of *Asxl3* results in highly penetrant developmental heart defects and perinatal lethality. *Asxl3*^{-/-} mice display severe right ventricle cardiac hypoplasia. An analysis of structural heart defects between the *Asxl1*, *Asxl2* and *Asxl3* null mouse models implicate nonredundant functions during heart development despite their interchangeable incorporation into the PR-DUB complex. This has implications for the three distinct developmental disorders associated with these genes. To understand the role of *Asxl3* in cardiac differentiation we have generated cardiac-fated tissue differentiated from *ASXL3*^{-/-} hESCs. Comparing the developmental mechanisms and single cell transcriptional changes revealed similar ECM pathology in heart phenotypes with species specific differential expression. These findings underscore the importance of *ASXL3* and family members in polycomb transcriptional repression during development.

Epigenetics Posters - Wednesday

PB2377. Catalysis of histone H3K27me3 by Polycomb-independent mechanisms.

Authors:

I. Mercado-Hernandez¹, K. Kasliwal², C. Harris¹, S. Kalantry¹; ¹Univ. of Michigan Med. Sch., Ann Arbor, MI, ²Weill Cornell Med., New York, NY

Abstract Body:

Histone marks are post translational modifications on histone tails that are associated with distinct transcriptional states. Histone H3 lysine 27 trimethylation (H3K27me3) is a facultative chromatin mark that often marks silenced genes. H3K27me3 is believed to be deposited solely by the Polycomb Repressive Complex 2 (PRC2). Insights into PRC2 and H3K27me3 functions have occurred through the study of X-chromosome inactivation. X-inactivation results in the silencing of genes on one of the two X-chromosomes in female cells to equalize X-linked gene expression between female and male mammals. The silencing of X-linked genes in X-inactivation occurs in significant part through chromatin modifications, including H3K27me3. PRC2 proteins and H3K27me3 are enriched on the inactive X-chromosome. We investigated PRC2 function in X-inactivation by ablating core PRC2 subunits in mouse extraembryonic endoderm (XEN) stem cells, which are a model of imprinted X-inactivation of the paternal X-chromosome. Unexpectedly, we found that loss of the PRC2 core proteins had a minimal impact on gene expression and X-inactivation. Upon examining H3K27me3 in XEN cells lacking PRC2 function, we found that H3K27me3 was not abrogated, thus controverting the existing models of H3K27me3 catalysis solely by PRC2. We therefore sought to identify non-PRC2 catalysts of H3K27me3.

Epigenetics Posters - Wednesday

PB2378. Characterization of nucleosome positioning and DNA methylation signatures using prostate cancer cells from diverse ethnic groups using NOME-EM-seq.

Authors:

L. Gonzalez-Smith, L. Yuri, E. Nelson-Moore, S. Rhie; Univ. of Southern California, Los Angeles, CA

Abstract Body:

Prostate cancer is the second most prevalent malignancy for men worldwide with over 1.4 million new cases and 400 thousand fatalities every year. However, this is not uniform amongst patients with different racial and ethnic backgrounds. For example, men of African ancestry have higher incidence of prostate cancer and more aggressive prostate cancer cases with more than double the mortality rate compared to men of European ancestry. Therefore, it is crucial to characterize tumor samples from different ethnic and racial backgrounds to better understand prostate cancer subgroups. Most cancer studies are centered around genetic variants, but more recent research has shown that epigenetic alterations, such as DNA methylation, can play a role in prostate carcinogenesis. Here, we have characterized normal prostate and prostate cancer cells from diverse ethnic groups using Nucleosome Occupancy Methylome Sequencing (NOME-seq), an epigenetic method that can profile endogenous methylation and nucleosome positioning simultaneously. NOME-seq traditionally utilizes bisulfite (NOME-bisulfite-seq) as its means of deaminating unmethylated cytosines converting them into uracils, allowing for differentiation from methylated cytosines upon downstream sequencing. Although successful, bisulfite is a harsh chemical that induces DNA damage and fragmentation which can decrease mappability in downstream bioinformatic analyses. Novel enzymatic alternatives (NOME-EM-seq) utilizes oxidizing enzyme TET2 and mRNA editing enzyme APOBEC2, as substitutes for bisulfite treatment. By performing NOME-bisulfite-seq and NOME-EM-seq methods in prostate cells and tissue samples from diverse ethnic groups, we characterized the epigenomes of prostate cells, identifying differentially nucleosome-positioned and methylated regions between normal prostate and prostate cancer cells and among ethnic groups. This study will help understand the underpinnings of prostate cancer specific epigenomic alterations and ethnicity-related differences.

Epigenetics Posters - Thursday

PB2379. Characterization Of Pten Expression Cis-Regulatory Elements Involved In Cowden Disease

Authors:

T. Matis^{1,2,3}, M. Lalanne^{2,3}, I. Lamrissi-Garcia^{2,3}, I. Moranvillier^{2,3}, E. Darbo^{2,3}, S. Dabernat^{2,3}, M. Longy^{1,3}, N. Sévenet^{1,2,3}; ¹Inst. Bergonié, Bordeaux, France, ²Université de Bordeaux, Bordeaux, France, ³BoRdeaux Inst. of Oncology, Bordeaux, France

Abstract Body:

PTEN Hamartoma Tumor Syndrome is a hereditary cancer predisposition syndrome characterized by the appearance of benign and/or malignant tumors affecting multiple organs and is associated with heterogeneous clinical traits, resulting from a germline pathogenic variant (GPV) in *PTEN*. *PTEN*'s GPVs, are also found in a wide phenotypic spectrum ranging from macrocephalus-autism syndrome to certain juvenile polyposis. The extension of the phenotypic spectrum was accompanied in the clinical laboratory by an increase in *PTEN* germline analysis indication. As a result, the identification of *PTEN*'s GPV led to defining a PTEN Hamartoma Tumor Syndrome (PHTS). In the last decade, the number of patients with a suspicious PHTS phenotype without any identified *PTEN*'s GPV variant has increased and is estimated at 20%, raising the question of missing heritability. The recent identification of *PTEN* structural modifications through Alu insertion in the coding region prompts us to continue exploring the allelic heterogeneity by hypothesizing that cis-regulatory region alterations may alter *PTEN* expression. *PTEN* expression is ubiquitous and controlled through a poorly defined promoter and unknown enhancers. Enhancers can target promoters by chromatin approximation in the 3D structure known to be organized in topologically associated domains (TAD). We propose that differences in *PTEN* genotype-phenotype can be explained by a loss of expression due to a TAD disruption or alterations of cis-regulatory noncoding regions. Using ENCODE data, we identified 4 putative enhancers located in 3' in a 1Mb-TAD. Our aim is to verify and confirm their role in *PTEN*'s TAD by Hi-C analysis as well as define their location by Tiled-C analysis to obtain an accurate definition of the *PTEN* cis-regulation region. and assess whether *PTEN*'s TAD may be altered using 8 cell lines, carrier of an increasing *PTEN* alteration state.

Epigenetics Posters - Thursday

PB2381. ChromGene: Gene-Based Modeling of Epigenomic Data

Authors:

A. Jaroszewicz, J. Ernst; Univ. of California Los Angeles, Los Angeles, CA

Abstract Body:

Various computational approaches have been developed to annotate epigenomes on a per-position basis by modeling combinatorial and spatial patterns within epigenomic data. However, such annotations are less suitable for gene-based analyses, in which a single annotation for each gene is desired. To address this, we developed ChromGene, which annotates genes based on the combinatorial and spatial patterns of multiple epigenomic marks across the gene body and flanking regions. Specifically, ChromGene models epigenomics maps using a mixture of hidden Markov models learned *de novo*, and is implemented on top of ChromHMM. Based on a ChromGene model with 12 mixture components, we generated annotations for the human protein-coding genes for over 100 cell and tissue types. We characterized the different mixture components based on their chromatin marks and relationship to external data. We found that gene expression levels varied substantially between some ChromGene annotations, but also that some ChromGene annotations with similar expression levels were associated with distinct sets of chromatin marks, showing that ChromGene captures biological information beyond gene expression. We identified specific ChromGene annotations enriched for genes with high probability of being loss of function intolerant, and found substantial variation among gene sets with similar expression distributions, further highlighting the additional information ChromGene captures relative to gene expression. We compared ChromGene to baselines that averaged epigenomic mark presence throughout the gene body or only considered annotations at transcription start sites. We found ChromGene annotations were more predictive of gene expression, and they yielded more significant enrichments for both cancer associated gene sets and Gene Ontology gene sets. Additionally, ChromGene annotations were less likely to be simply reflecting gene length than gene averaging annotations. We also identified specific ChromGene gene annotations that were relatively cell type specific, and others that were more constitutive across cell types. We expect that ChromGene and generated annotations will be a useful resource for gene-based epigenomic analyses.

Epigenetics Posters - Wednesday

PB2382. Clinical Epigenomic Testing in Canada: Discovery and Clinical Assessment of Episignatures

Authors:

H. McConkey¹, J. Kerkhof², M. Levy³, R. Relator³, K. Rooney³, A. Foroutan¹, S. Haghshenas¹, B. Sadikovic⁴; ¹Western Univ., London, ON, Canada, ²London Hlth.Sci. Ctr., London, ON, Canada, ³London Hlth.Sci. Ctr., London, ON, Canada, ⁴LHSC, London, ON, Canada

Abstract Body:

Introduction: Neurodevelopmental disorders (NDDs) often present with overlapping phenotypic characteristics, making a clinical diagnosis difficult. First-tier genetic testing includes microarray gene sequencing based on the phenotypic presentation. Approximately 75% of patients do not receive a diagnosis from this testing and must undergo reflex testing, which includes large gene panels, whole exome sequencing or whole genome sequencing. This testing can take months or years and is costly, and patients can be left with no variants detected or a variant of uncertain significance. DNA methylation is another mechanism that can impact gene expression. Expanding number of NDDs exhibit unique DNA methylation patterns in peripheral blood, called episignatures, which can be used as diagnostic biomarkers. EpiSign is a test that can determine if a patient's methylation pattern matches an episignature specific to a NDD. This study aims to assess the use of EpiSign in clinical setting, to expand the number of detectable episignatures, and assess the biological significance of genomic methylation changes in NDDs. **Methods:** EpiSign analysis is performed to assess genome wide DNA methylation using Illumina Infinium methylation arrays, then compares the detected profiles to known NDD episignatures. EpiSign-CAN is a Canadian national study designed to assess clinical utility and health system impact of EpiSign first-tier and reflex test setting. Second study objective is to expand the clinical utility of the EpiSign test through discovery of additional epigenetic signatures. **Results:** EpiSign includes more than 120 episignatures. Episignatures can be protein complex, gene, sub-gene, protein domain and even single nucleotide-level specificity. The EpiSign-CAN study is underway and enrolling patients in both the first-tier screening phase of their journey and in the reflex testing stage with 19% episignature positive results (June 2022). **Discussion:** The use of EpiSign in Canadian genetics clinics provides an additional strategy for physicians to assess patients with ambiguous clinical presentation or genetic findings. Additionally, it has the potential to impact healthcare resource allocation and provide a more cost-effective approach for the diagnosis of rare disease.

Epigenetics Posters - Thursday

PB2383. Conserved GATA4/5/6-mediated gene regulation in cardiac development and disease

Authors:

M. Wilson^{1,2}, M. Song^{1,2}, A. Prentice^{1,2}, X. Yuan^{3,1}, H. Hou¹, E. Erkut^{1,2}, C. Carlisle^{1,2}, S. Monis^{1,2}, E. Duncan¹, C. Somerville¹, R. Kim¹, R. Jobling⁴, I. Scott^{1,2}; ¹Hosp. for Sick Children, Toronto, ON, Canada, ²Univ. of Toronto, Toronto, ON, Canada, ³DFKZ, Heidelberg, Germany, ⁴The Hosp. for Sick Children, Toronto, ON, Canada

Abstract Body:

Early cardiac development is orchestrated by a core set of deeply conserved cardiac transcription factors (TFs) and the *cis*-regulatory elements (CREs) they bind. Mutations in these TFs, or the CREs that regulate them, can lead to congenital heart disease (CHD). However, we still have an incomplete knowledge of the CREs required for normal heart development. To identify cardiac CREs essential for heart development, we performed a comparative zebrafish-human epigenomic study focussing on the GATA4/5/6 family of TFs. GATA4/5/6 function at or near the top of the cardiac regulatory network hierarchy in animals and are among the earliest TFs expressed in the cardiac mesoderm. We first profiled the open chromatin landscape of *gata5*-expressing pre-cardiac cells in mid-gastrulation zebrafish embryos. Using a *Gata5/6* knockdown, we identified 1,470 differentially accessible regions (DARs) with reduced accessibility upon *Gata5/6* loss. Indicative of a direct role of *Gata5/6* in establishing chromatin accessibility, these closed DARs showed a strong enrichment for GATA motifs. We identified 47 mesendodermal-specific GATA-dependent DARs as accessible regions conserved between zebrafish and human, which we termed GATA-dependent accessible conserved non-coding elements (GaCNEs). 17 out of 18 GaCNEs tested so far displayed cardiac activity in transgenic zebrafish embryos. Supporting their functional conservation, three GaCNEs were identified as being GATA4 targets in human cardiomyocytes and accessible in cardiac progenitors. Zebrafish deletions of GaCNE1, which forms long range interactions with zebrafish *hand2* (130 kb) and human *HAND2* (460 kb), resulted in reduced *hand2* expression and laterality defects, including cardiac patterning defects. We found the remaining two GaCNEs contain hits for ultra-rare human variants in patients with unsolved congenital heart disease. One such region near *TBX20* (GaCNE20) interacts with the *TBX20* promoter in the human mesoderm. Both the zebrafish (zGaCNE20) and orthologous human (hGaCNE20) sequences can spatiotemporally recapitulate endogenous zebrafish *tbx20* expression. Initial work modelling the ultra-rare variants seen in hGaCNE20 in zebrafish enhancer reporter assays revealed that the mutant sequence drives ectopic skeletal muscle expression. Collectively, we identified zebrafish-human conserved GATA-dependent cardiac CREs, which likely contribute to vertebrate cardiac development. Given the proximity of many conserved accessible non-coding elements to dosage sensitive trans-factors, human genetic variation impacting these regions warrants further functional study.

Epigenetics Posters - Wednesday

PB2384*. Cord blood DNA methylation alterations potentially mediate associations between adverse pregnancy outcomes and childhood blood pressure

Authors:

J. Hu^{1,2}, J. Li^{1,2}, X. Hong³, G. Wang³, F. Hu^{1,2}, X. Wang³, L. Liang¹; ¹Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, ²Brigham and Women's Hosp., Boston, MA, ³Johns Hopkins Univ. Bloomberg Sch. of Publ. Hlth., Baltimore, MD

Abstract Body:

Background: High child blood pressure (BP) contributes to higher risk cardiovascular diseases in adulthood. Adverse pregnancy outcomes (APOs; e.g., gestational hypertension, pre-eclampsia, gestational diabetes, preterm birth, and low birth weight) have been associated with child BP. Cord blood DNA methylation (DNAm) alterations have been associated with APOs and child BP. However, it remains unknown whether cord blood DNAm mediates the associations between APOs and child BP.

Methods and results: This study included 855 mother-newborn pairs from the Boston Birth Cohort. Genome-wide DNAm was profiled on cord blood samples using Illumina MethylationEPIC BeadChip; 721,395 DNAm sites on autosomes and the X chromosome were eligible for analysis after quality control steps. Repeated measures of child systolic (SBP) and diastolic (DBP) BP from age 3 to 10 years (5,123 observations) were used. SBP and DBP percentiles were calculated based on the 2017 American Academy of Pediatrics Clinical Practice Guideline. **First**, using linear mixed-effects model, we observed 2,875 DNAm sites significantly associated with repeated measures of DBP percentiles (FDR<0.05) after adjusting for age at BP measurement, newborn sex, maternal characteristics (age at delivery, pre-pregnancy body mass index [BMI], self-reported race, education, and smoking) and cord blood cell compositions. No DNAm sites showed significant associations with SBP percentiles. **Second**, we used elastic net with 10-fold cross validation and identified DNAm signatures for BP percentiles for each age from 3 to 10 years. The identified DNAm signatures were predictive of SBP and DBP percentiles at age 3 and 4 years ($p \leq 0.01$). **Third**, we observed significant sex ($p < 1.2 \times 10^{-6}$) and race (maternal self-reported Black vs. others; $p < 0.04$) differences in DNAm signatures for SBP and DBP percentiles at age 3 and 4 years; the DNAm signatures were associated with pre-pregnancy BMI ($\beta = 0.05$; $p = 0.03$), severe pre-eclampsia ($\beta = 1.32$; $p = 0.02$), gestational diabetes ($\beta = 2.24$; $p = 0.04$), smoking during pregnancy ($\beta = -1.32$; $p = 0.03$), and gestational age at delivery ($\beta = -0.19$; $p = 0.03$). **Finally**, in mediation analysis, DNAm signatures mediated 14-26% of associations of severe pre-eclampsia, gestational diabetes, smoking during pregnancy, and gestational age at delivery with child BP percentiles at age 3 and 4 years, with marginal significance ($p = 0.06-0.08$).

Conclusions: Cord blood DNAm signatures were associated with APOs and child BP, and might mediate associations between APOs and child BP at younger ages. These findings indicate that DNAm changes may underline the link between APOs and offspring future cardiovascular risk.

Epigenetics Posters - Thursday

PB2385. Could the difference in DNA methylation status explain phenotypic variability in patients with 5p- syndrome?

Authors:

V. Almeida¹, S. Chehimi², G. Carvalho¹, Y. Gasparini³, A. Nascimento⁴, L. Liro¹, B. Wolff⁴, L. Kulikowski⁵; ¹Faculdade de Med. da Univ.e de São Paulo, São Paulo, Brazil, ²Faculdade de Med. da USP, Sao Paulo, Brazil, ³Univ. of São Paulo, São Paulo, Brazil, ⁴Faculdade de Med. na Univ.e de São Paulo, São Paulo, Brazil, ⁵Univ.e de Sao Paulo, São Paulo, Brazil

Abstract Body:

Cri Du Chat Syndrome or 5p- Syndrome (OMIM #123450) is characterized by a genomic loss in the short arm of chromosome 5 and by variable clinical manifestations, that include high-pitched cry in newborns. The phenotypic variability in this syndrome may not be limited only to variations in gene structure - such as deletions, duplications, inversions, insertions and translocations - as DNA methylation mechanisms, which occurs mainly in the “CpG Islands”, are also possible. Therefore, we studied the DNA methylation of the remaining allele of region of breakpoint at 5p- in fifteen patients. DNA samples from fifteen patients with 5p- delimited by genomic array HumanCyto850K BeadChip were evaluated using the Infinium MethylationEPIC BeadChip platform. The bioinformatics analysis was performed in R programming language. We noticed a significant difference in methylation status in the remaining allele at the breakpoint of region of 5p- in the patients. We infer that this difference in methylation status may explain the phenotypic differences in patients with this syndrome.

Epigenetics Posters - Wednesday

PB2386. Critical epigenomics association between methylation and clinical phenotype

Authors:

L. Kulikowski¹, G. Carvalho¹, L. Vieira², Y. Gasparini³, V. Almeida², A. Nascimento^{4,1}, C. Kim⁵; ¹Univ.e de Sao Paulo, São Paulo, Brazil, ²Faculdade de Med. da Univ.e de São Paulo, São Paulo, Brazil, ³Univ. of São Paulo, São Paulo, Brazil, ^{4,5}Inst. da Criança, Sao Paulo, Brazil

Abstract Body:

Introduction: Copy number variations (CNVs) are DNA fragments deleted or duplicated in relation to a reference genome. Some genome variants, classified as variants with uncertain significance (VUS), do not present a safe conclusion with clinical phenotypes, which makes the diagnostic conclusion difficult. We know that hypermethylation of gene promoter regions often leads to transcriptional silencing, in addition to DNA methylation changes in gene and/or intergenic regions can play a critical role in genomic regulation and stability. With epigenomic investigation, we can gain a more comprehensive understanding of the modulation in gene expression associated with genomic imbalance in different diseases and in different genomic variations. **Materials and Methods:** In order to better understand the impact of methylation status associated with genomic imbalances, in clinical phenotypes, our study evaluated, using the Infinium MethylationEPIC BeadChip platform, 10 DNA samples from patients with intellectual disability and dysmorphic features with CNVs classified as VUS without a definitive clinical diagnosis, in addition to six control samples from participants without clinical conditions. **Results:** We were able to identify significant differences when comparisons of methylation status were performed individually. The ontological analyzes of methylation results suggest a phenotypic impact consistent with the clinical presentation of the patients, indicating a possible association between the phenotype and the DNA methylation status. **Conclusion:** Genomic methylation, associated with genomic structural imbalances, can play a critical role in clinical features and can be used as an important marker for patients with uncertain clinical diagnosis.

Epigenetics Posters - Thursday

PB2387. Cross-species and tissue imputation of species-level DNA methylation samples.

Authors:

E. Maciejewski¹, S. Horvath^{1,2}, J. Ernst¹; ¹Univ. of California, Los Angeles, Los Angeles, CA, ²Altos Labs, San Diego, CA

Abstract Body:

DNA methylation is an epigenetic marker that is widely profiled in humans, but for many other mammals there is more limited data available. The ability to accurately profile DNA methylation across mammalian species at loci highly conserved at the sequence level was recently vastly enhanced by the development of the mammalian methylation array. However, biological samples from certain tissues in some species, including human, can be difficult to obtain. This motivates the development of methods to accurately impute DNA methylation samples representing species and tissue type combinations that were not experimentally profiled, but other tissues were profiled in the species of interest and the tissue of interest was profiled in other species. However, existing methods for DNA methylation imputation do not take advantage of said cross-species DNA methylation information. To address this limitation, we designed a method to leverage cross-species DNA methylation to predict mean DNA methylation levels for combinations of tissues and species for which such data was not previously available. The method uses a neural network, specifically a Conditional Variational Autoencoder (CVAE) with optimal hyperparameters selected via grid search, to generate a prediction of DNA methylation values for unobserved combinations of species and tissue types in its input compendium. We simulate different training scenarios by applying this method to various subsets of 13,245 samples generated by the Mammalian Methylation consortium representing 746 species-tissue combinations from 59 tissues. We show that the method when applied in cross-validation correlates well with held-out ground truth values and outperforms multiple baselines. We demonstrate that the method yields high-quality imputed samples even with limited other tissue types in a target species available. We also show that the predictions effectively preserve species and tissue relationships among samples. After performing cross-validation analyses, we use all available data to impute mean methylation samples for species-tissue combinations that have not previously been experimentally profiled. We expect the method and imputed data resource we have developed will be useful for DNA methylation analyses of species and tissue-level characteristics across mammalian species.

Epigenetics Posters - Wednesday

PB2388*. Cross-tissue patterns of DNA hypomethylation reveal genetically distinct histories of cell development

Authors:

T. Scott¹, T. Hansen², E. McArthur¹, E. Dorans¹, E. Hodges^{1,2}; ¹Vanderbilt Genetics Inst., Vanderbilt Univ., Nashville, TN, ²Dept. of Biochemistry, Vanderbilt Univ., Nashville, TN

Abstract Body:

DNA methylation (DNAm) is essential for balanced multi-lineage cellular differentiation, but exactly how DNAm drives cellular phenotypes is unclear. While >80% of CpG sites are stably methylated, tens of thousands of discrete CpG loci form hypomethylated regions (HMRs). Because they lack DNAm, HMRs are considered transcriptionally permissive, but not all HMRs participate in genome regulation. Contrary to long-held views about the role of DNAm in controlling promoter function, most promoter HMRs are invariable across cell-types regardless of transcriptional status. In contrast, a subset of HMRs is cell-type specific and enriched for tissue specific enhancers. Recently, we showed that, while enhancer HMRs correlate with chromatin accessibility and other indicators of permissive chromatin, their temporal dynamics are distinct from chromatin—HMRs can persist long after accessibility is lost. These studies suggest that establishment of HMRs is an important step in enforcing cell identity, and that patterns of HMR establishment are more complex than previously appreciated.

To understand their functional significance, we systematically dissected HMR patterns across diverse cell types and developmental timepoints, including human embryonic stem cells, fetal spine and heart, adult hematopoietic lineage, liver, and adrenal tissues. Unsupervised clustering of 102,390 distinct HMRs revealed that levels of HMR “sharedness” across cell-types reflects a developmental hierarchy supported by enrichment of stage-specific transcription factors and gene ontologies. Using a pseudo-time course of embryonic to adult hematopoietic development, we further show that a majority of HMRs observed in differentiated cells (~70-75%) are established at early developmental stages and accumulate as development progresses. HMRs that arise during differentiation frequently (~35%) establish near existing HMRs (≤ 6 kb away), leading to the formation of HMR clusters associated with stronger enhancer activity. Using SNP-based partitioned heritability from GWAS summary statistics of diverse traits and clinical lab values, we discovered that genetic contribution to trait heritability is enriched within HMRs. Moreover, heritability of cell-relevant traits increases with both increasing developmental specificity and HMR clustering, supporting the role for distinct HMR subsets in regulating normal cell function. Altogether, our findings reveal that HMRs can predict cellular phenotype by providing genetically distinct historical records of a cell’s journey through development, and this attribute distinguishes DNAm from other epigenomic features.

Epigenetics Posters - Thursday

PB2389. Defining the gene regulatory roles of non-coding variants in the pathogenesis of autism.

Authors:

E. Sosa, J. Grealley; Albert Einstein Coll. of Med., Bronx, NY

Abstract Body:

Autism spectrum disorder (ASD) is a neurodevelopmental disorder of variable severity characterized by restricted interests/behaviors and difficulties with social interactions. Advanced genomic sequencing approaches applied to large autism cohorts have successfully identified pathogenic variants in genes, partially explaining the genetic underpinnings of the phenotype. However, diagnostic sequencing using these insights only yields a diagnosis in a limited proportion of cases ($\approx 17\%$), leaving most families without answers. While it is increasingly clear that variants in the non-coding majority of the human genome are mediating human diseases, we currently lack the tools to predict pathogenicity of variants outside coding sequences. We hypothesize that non-coding variants fulfill pathogenic roles in genetically unresolved cases of autism by disrupting the transcriptional regulatory landscape of neuronal cells, resulting in disturbed synaptic function and excitatory-inhibitory balance.

Our goal in this project is to understand how de novo variants (DNVs) in non-coding DNA cause autism. We have generated preliminary data from whole genome sequencing (WGS) data that show an enrichment of DNVs in cis-regulatory sequences from brain cell types. Using genomic editing in induced pluripotent stem cells (iPSCs) followed by in vitro differentiation to GABAergic neurons, we will test high-priority candidate pathogenic DNVs for molecular genomic and cellular phenotypes, not only compared with unedited cells, but also cell lines engineered with known pathogenic coding sequence variants.

We have generated preliminary data combining WGS from $\approx 11,000$ individuals from the MSSNG cohort (Autism Speaks) with ATAC-seq data from 54 cell types showing the locations of cis-regulatory loci. We show that DNVs in children with autism are significantly enriched at the cis-regulatory open chromatin regions (OCRs) in both glial cells and certain neuronal types, and that these OCRs with DNVs are located near genes implicated in autism. Through permutation analyses we have determined that the burden of DNVs in the cis-regulatory loci of brain cells is significantly enriched. This finding was reconfirmed in the Simons Simplex Collection (SSC) cohort (1,902 individuals), and validated using the TOPMed cohort, a negative control group not selected for neurodevelopmental disorders. Finally, we will introduce prioritized DNVs into iPSCs to understand their contributions to neuronal morphology. This approach will provide a powerful tool for identifying and modelling the effects of non-coding variants, enhancing our ability to diagnose and understand autism.

Epigenetics Posters - Wednesday

PB2390*. Defining the genetic background of immunoglobulin G galactosylation in humans

Authors:

(DZD), Neuherberg, Germany, ⁸Helmholtz Zentrum Munchen, Neuherberg, Germany, ⁹King's Coll. London, London, United Kingdom, ¹⁰Faculty of Med. and Med. Ctr., Univ. of Freiburg, Freiburg, Germany, ¹¹Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, ¹²Inst. of Genetics and Cancer, Univ. of Edinburgh, Edinburgh, United Kingdom, ¹³Usher Inst., Univ. of Edinburgh, Edinburgh, United Kingdom, ¹⁴Faculty of Pharmacy and Biochemistry, Univ. of Zagreb, Zagreb, Croatia

Abstract Body:

Glycosylation is the key posttranslational modification of IgG that affects its stability and function. However, genetic mechanisms behind this essential structural modification are not well known. Previous genome-wide association studies (GWAS) cumulatively identified 29 genomic regions that associate with IgG glycosylation, but only a few of these associations were functionally validated. One of the key functional aspects of IgG glycome composition is galactosylation, the presence of galactose units in the glycan structure. In this study, we performed GWAS of IgG galactosylation phenotypes (agalactosylation, monogalactosylation and digalactosylation) in seven cohorts of European descent with a total of 13,705 individuals. We identified 16 genome-wide significant genomic loci at $p \leq 2.5 \times 10^{-8}$ and replicated twelve ($p \leq 0.05/16$ loci = 0.0031) in 7,775 individuals. Gene prioritization efforts including pleiotropy with gene expression in whole blood, gene-based association testing and functional annotation of associated SNPs, resulted in a total of 37 credible genes with a putative role in IgG galactosylation. We then used recently developed transient expression system HEK293FS for IgG production to up- and downregulate expression of seven new candidate genes, including *KIF3C*, *NFKB1*, *MANBA*, *SLC38A10*, *TNFRSF13B*, *EEF1A1* and *HIVEP2*, followed by release of glycans from secreted IgG and quantification using ultra-performance liquid chromatography. The effect on IgG galactosylation was observed upon upregulation of three genes: *EEF1A1*, *MANBA*, and *TNFRSF13B*. These findings further indicate that IgG galactosylation is indeed regulated by a complex network of genes that were previously not known to be involved in IgG glycosylation. However, the mechanism behind their involvement in the IgG galactosylation pathway remains to be elucidated.

Epigenetics Posters - Thursday

PB2391. Differential newborn DNA methylation among individuals with complex congenital heart defects and pediatric lymphoma.

Authors:

M. Richard¹, W. Yang², P. Sok¹, M. Li³, S. Carmichael⁴, J. von Behren⁵, P. Reynolds⁵, P. Fisher², T. Collins², C. Hobbs⁶, P. Lupo¹, G. Shaw⁷; ¹Baylor Coll. of Med., Houston, TX, ²Stanford Univ., Palo Alto, CA, ³Indiana Univ. at Bloomington, Bloomington, IN, ⁴Stanford Univ. Sch. of Med., Stanford, CA, ⁵Univ. of California San Francisco, San Francisco, CA, ⁶Rady Children's Inst. for Genomic Med., San Diego, CA, ⁷Stanford Univ., P, CA

Abstract Body:

Background: Children with birth defects are at increased risk for pediatric cancer. Data from the California Birth Defects Monitoring Program and the California Cancer Registry indicated individuals with complex congenital heart defects (CHDs) were at 8-fold greater risk for pediatric lymphoma. We sought to characterize molecular changes related to complex CHD and subsequent pediatric lymphoma development (“CHD-lymphoma”) through newborn DNA methylation patterns. **Methods:** From > 3 million live births (1988-2004) in the linkage cohort, we obtained newborn dried bloodspots from eight children with CHD-lymphoma through the California Newborn Screening Program. We performed case-control epigenome-wide association analyses (EWAS) to identify differential methylation (CpGs) using two comparison groups: 1) 45 boys without birth defects or cancer, and 2) 46 individuals with complex CHD. Analyses of the Illumina EPIC array were adjusted for technical variation and CpGs at $P < 6.9 \times 10^{-8}$ were considered statistically significant. **Results:** After correction for multiple testing, individuals with CHD-lymphoma had differential newborn methylation at 177 CpG sites compared to unaffected individuals and two CpG sites compared to individuals with complex CHD. *PPF1A1* cg25574765 was hypomethylated in CHD-lymphoma cases (mean beta=0.04) relative to both unaffected individuals (mean beta=0.93, $P=1.5 \times 10^{-12}$) and individuals with complex CHD (mean beta=0.95, $P=3.8 \times 10^{-8}$). *PPF1A1* encodes a ubiquitously expressed liprin protein that is conserved in evolution and resides in one of the most commonly amplified regions in many cancers (11q13). Further, cg25574765 is a proposed differentially methylated marker of pre-eclampsia, a maternal risk factor for CHDs that has not been fully evaluated for lymphoma risk in offspring. Additionally, *EXD3* cg13408086 was hypomethylated in CHD-lymphoma cases (mean beta=0.04) relative to unaffected individuals (mean beta=0.95, $P=1.0 \times 10^{-17}$) and individuals with complex CHD (mean beta=0.95, $P=3.8 \times 10^{-7}$). *EXD3* encodes an exonuclease protein associated with atrial septal defects. Annotation of significant CpG sites in the EWAS Catalog revealed methylation patterns previously associated with prenatal smoking, autoimmune traits, pollution, and markers of maternal health present in newborn DNA. **Conclusions:** Using multiple approaches, we identified associations between molecular changes present in the genome at birth and risk of pediatric lymphoma among those with CHD. Our findings also highlight novel environmental and perinatal exposures that may underlie methylation changes in CHD predisposing to lymphoma.

Epigenetics Posters - Wednesday

PB2392. Differentially methylated probes and regions associated with the Healthy Eating Index.

Authors:

K. Yuan, R. M. Lucia, W-L. Huang, D. Forman, D. Goodman, A. Ziogas, H. L. Park, T. M. Norden-Krichmar; Univ. of California, Irvine, Irvine, CA

Abstract Body:

Background: Diet quality has been linked with various health outcomes but may be difficult to measure in epidemiologic studies. DNA methylation markers from blood samples have been utilized to reveal associations with a variety of environmental exposures. However, the association between DNA methylation markers and measures of diet quality remains unclear. This epigenome-wide association study (EWAS) was conducted to identify Differentially Methylated Probes (DMPs) and Differentially Methylated Regions (DMRs) associated with diet quality scores according to the Healthy Eating Index (HEI). **Methods:** 199 participants from the Markers for Environmental Exposure (MEE) Study, comprised of postmenopausal women residing in Southern California, were included in the study. HEI scores were calculated from each participant's responses to two diet quality survey instruments: the Automated Self-Administered 24-hour Dietary Assessment Tool (ASA24) and the Diet History Questionnaire II (DHQII). Peripheral blood DNA methylation was measured using the Illumina Infinium MethylationEPIC Chip. The DMPs and DMRs associated with the HEI scores were identified using linear models with a false discovery rate p-value of 0.05, using a resampling method to improve the stability of results. **Results:** HEI scores calculated using the ASA24 versus DHQII were moderately correlated (Pearson correlation 0.557). We identified 6375 and 4257 significant DMPs associated with the ASA24 and DHQII HEI scores, respectively, 486 of which were associated with both scores. Sixteen DMRs were associated with the ASA24 HEI scores, and 17 with the DHQII HEI scores; none were associated with both scores. Among the top DMRs associated with ASA24 HEI scores was the gene *EBF3*, which is found in pathways related to differentiation of white and brown adipocytes. The top DMRs associated with DHQII HEI scores were the genes *FOXP2* (a transcription factor), and *PREX1* (a gene which has been associated with gastric cancer). **Conclusions:** Our results suggest that dietary intake is a complex exposure, potentially affecting many methylation sites in the epigenome. We also found that there was little overlap between results that used different dietary recall instruments to calculate the HEI scores, reflecting differences in the information collected by the two approaches. These preliminary results suggest that DNA methylation could be used as a biomarker for measuring diet quality, but further research is needed to identify markers that are robust to different methodological approaches.

Epigenetics Posters - Thursday

PB2393. Digitally untangling the 3D genome

Authors:

G. Fudenberg; Univ. of Southern California, Los Angeles, CA

Abstract Body:

Maps of 3D genome folding reveal that mammalian interphase genomes are segmented into a series of self-associating regions. Genetic variants disrupting this folding have been associated with disease phenotypes. Experimental work points to two major factors underlying this mode of interphase genome folding: cohesin, a Structural Maintenance of Chromosomes (SMC) complex that actively compacts chromosomes, and CTCF, an 11 zinc finger protein that binds specific DNA sequence motifs and delineates domain boundaries. Still, despite this knowledge, it remains challenging to predict how a given DNA variant may affect genome folding. Depending on the locus, folding can either be sensitive to single nucleotide changes, or resilient even to large-scale structural variants. The finite throughput for experimental perturbations and large potential consequences of disrupted folding call for computational solutions to both quickly and accurately predict the impacts of DNA variants on genome folding. Convolutional neural networks (CNNs) are powerful computational methods for modeling genomic data. Starting from DNA sequences as inputs, CNNs now enable state-of-the-art predictions for transcription factor binding, DNA accessibility and transcription. Moreover, rather than requiring exhaustive engineering of all predictive features by hand, CNNs can instead learn the relevant features from the data. New analysis methods make DNA sequence features learned by these models increasingly interpretable. Here I present the latest sequence-to-folding models of 3D genome organization. I will illustrate the strength of these approaches by drawing applications that include: (i) rapid DNA sequence mutagenesis, (ii) predicting the impacts of disease and engineered genetic variants, (iii) predicting genome folding across species. Finally, I will discuss an emerging computational toolkit for analyzing large sparse genome folding datasets that were crucial to the development of sequence-to-folding models for the 3D genome.

Epigenetics Posters - Wednesday

PB2394. Disparities in epigenetic modifications in *NRF1* and *FTO* genes in children.

Authors:

P. Patel, V. Selvaraju, X. Wang, R. Jeganathan, G. Thangiah; Auburn Univ., Auburn, AL

Abstract Body:

Despite vigorous efforts by health experts, childhood obesity has affected the health of millions of children worldwide. Obesity prevalence rates differ significantly by race and ethnicity, with African Americans being 50% more likely to be obese than non-Hispanic whites. Identifying factors influencing different populations is critical to successfully reducing obesity-related health disparities. A remarkable breakthrough has been seen in the field of epigenetics in the past few years. Epigenetic alterations, including DNA methylation, histone modification, and mRNA modifications are increasingly being implicated in the development of obesity. The expressions of various obesity-related genes are affected due to such epigenetic modifications. Here we used real-time quantitative PCR-based multiplex MethyLight technology to assess the DNA methylation percentage of the genes *NRF1* and *FTO* from the saliva of children aged 6-10 years. *ALU* was used as a reference gene, and the Percent Methylation Rate (PMR) was calculated for each sample. Results showed that European American children had a significant increase in PMR of *NRF1* and *FTO* in overweight/obese participants compared to normal weight. In contrast, there was no significant increase in overweight/obese children's PMR of *NRF1* and *FTO* than the normal weight in African American children. After adjusting for maternal education and annual family income by regression analysis, the PMR of *NRF1* and *FTO* was substantially linked with BMI z-score in European Americans, but not in African American children. The results also indicate that in the African American population, not only the obesity status but also other factors such as different health disparities could be playing a role in causing increased DNA methylation as we did not see a significant association between obesity markers and DNA methylation of *NRF1* and *FTO* gene in them. These findings contribute to a race-specific link between *NRF1* and *FTO* gene methylation and childhood obesity.

Epigenetics Posters - Thursday

PB2395. Dissecting mechanisms underlying expression divergence of human duplicated genes

Authors:

M. Dennis¹, C. Shew¹, G. Kaya²; ¹Univ. of California, Davis, Davis, CA, ²Univ. of California, Davis, Davis, CA

Abstract Body:

A growing body of evidence links genes within human-specific segmental duplications (HSDs) to traits and diseases unique to our species. Despite being nearly identical by sequence (>98.5%), HSD genes display paralog-specific expression patterns across human cell lines and primary tissues, suggesting that they have functionally diverged. We identified candidate *cis*-regulatory elements (cCREs) within HSDs using ChIP-seq data from human lymphoblastoid cell lines (LCLs) and adult/fetal cortex and showed that paralogous enhancers can be differentially active *in vitro*. We hypothesize that changes to the expression of recently duplicated and rearranged genes can be modeled with a more complete picture of their regulatory environment. To assay duplicated cCRE activity in high throughput, we performed a massively parallel reporter assay (MPRA) to quantify *cis*-regulatory activity of 5,701 HSD sequences in human LCLs and SH-SY5Y neuroblastoma cells to identify differentially active sequences. From 5,064 pairwise comparisons of human cCREs against chimpanzee orthologs in LCLs, we identified 371 differentially active sequences, of which 218 (59%) belonged to human derived paralogs and 211 (57%) showed higher human activity. Of the five top-scoring sequences, three reside within genes with known roles in human neurodevelopment: *ARHGAP11A*, *HYDIN*, *SRGAP2*. Additionally, 304 of 2,952 human derived sequences were differentially active with respect to the ancestral human locus. Preliminary analysis of Hi-C in human and chimpanzee LCLs, using a modified approach that quantifies multimapping Hi-C data across duplicated regions, identified human-specific contacts associated with the insertion of *DUSP22B* on chromosome 16, as well as paralog-specific chromatin loops at the *NCF1* promoters. Both genes mediate autoimmune response. Together, these assays will identify differences in the connectivity and activity of a comprehensive set of regulatory elements associated with HSDs and other structural variants in humans. This work represents the first comprehensive analysis of *cis* regulatory mechanisms contributing to divergent duplicated gene expression. Results will also offer potential insights into neurological and immunological traits unique to our species.

Epigenetics Posters - Wednesday

PB2396*. Dissecting the molecular machinery and sequence of histone to protamine transition during spermiogenesis.

Authors:

M. Rabbani, L. Moritz, S. Hammoud; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Spermiogenesis is the process by which post meiotic haploid germ cells undergo global chromatin remodeling to transition from a histone-based chromatin packaging to an alternative packaging system, driven primarily by sperm-specific nuclear proteins called protamines. Successful completion of this step is critical to producing mature sperm and maintaining male fertility. Despite being one of the most remarkable chromatin remodeling events known to occur during cellular differentiation, little is known about the chromatin remodeling events or the molecular machinery involved in this process. To explore this question, we tagged the endogenous protamine 1 and 2 loci with V5-tag and performed immunoprecipitation followed by mass spectrometry (IP-MS) to identify interactors. The ISWI chromatin remodeling family members, notably, SNF2H and BAZ1A, were among the most highly enriched candidates of protamine 1 interactors. The ISWI complex is a canonical nucleosome remodeling complex, that uses ATP hydrolysis to regulate nucleosome positioning and DNA accessibility. The identification of the ISWI complex was unexpected since it was presumed that histone removal and protamine deposition are temporally uncoupled events. Specifically, it was thought that histones are first replaced by transition proteins and subsequently by protamines. Given our MS data, we carefully followed the dynamics of these proteins during spermiogenesis and found that indeed protamine 1 deposition precedes transition protein and protamine 2 incorporations. These findings suggest that histone to protamine exchange may not occur as previously outlined, but rather protamine 1 may directly replace histones, and the reliance on classic histone machinery is therefore plausible. To confirm the plausibility of these interactions, we co-stained the testis cross sections with anti-V5 and SNF2H and show that the two proteins colocalize in vivo. In vitro reciprocal IPs with SNF2H confirm its specific interaction with protamine 1 but not transition proteins. Consistent with these molecular findings, germ cell knockouts of the ISWI complex display defects in histone to protamine exchange. Based on our observations, we propose a model where the ISWI complex may directly interact with protamine1 and facilitate the removal of histones and allow the deposition of protamine 1.

Epigenetics Posters - Thursday

PB2397. Distinct signatures in malignant PEComa and leiomyosarcoma identified by integrative RNA-seq and H3K27ac ChIP-seq analysis

Authors:

K. Giannikou^{1,2,3}, A-A. Azim², E. Adib², I-M. Schaefer⁴, N. Kesten³, L. Taing³, Z. Zhu², J. L. Hornick⁴, M. S. Hirsch⁴, H. W. Long³, A. J. Wagner⁵, M. L. Hemming⁵, D. J. Kwiatkowski²; ¹Div. of Hematology and Oncology, Cancer and Blood Disease Inst., Children's Hosp. Los Angeles, Los Angeles, CA, ²Cancer Genetics Lab., Div. of Pulmonary and Critical Care Med., Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, ³Ctr. for Functional Cancer Epigenetics, Dana-Farber Cancer Inst., Harvard Med. Sch., Boston, MA, ⁴Dept. of Pathology, Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, ⁵Ctr. for Sarcoma and Bone Oncology, Dept. of Med. Oncology, Dana-Farber Cancer Inst., Boston, MA

Abstract Body:

Background: Malignant perivascular epithelioid cell tumor (PEComa) and leiomyosarcoma (LMS) are two sarcoma tumor subtypes with overlapping morphologic and immunophenotypic features which can make their diagnostic distinction challenging. **Aim:** To characterize the transcriptional and epigenetic landscape of PEComa and LMS to identify distinguishing features. **Methods:** We performed whole transcriptome RNA-sequencing on 19 PEComas and compared their gene expression profile to 259 sarcomas from The Cancer Genome Atlas (TCGA) including 104 LMS. ChIP-sequencing for H3K27ac, a histone modification associated with activation of nearby genes/open chromatin, was conducted on 9 malignant PEComas and 12 LMS and were compared with publicly available data from 5 other sarcoma subtypes (GIST; chordoma; osteosarcoma; undifferentiated pleomorphic sarcoma; rhabdomyosarcoma). **Results:** Genome-wide epigenetic and transcriptional analyses revealed overlapping patterns between PEComa and LMS, which were distinct from other sarcomas. However, we also identified a set of highly expressed and epigenetically distinct transcripts which may represent diagnostic biomarkers: e.g., *DAPL1*, *MLANA*, *SULT1C2*, *GPR143*, and *CHI3L1* for PEComa; and *MYOCD*, *WDFC2*, *DES*, *MYH11*, and *CNN1* for LMS; each of which showed >17x fold higher expression for each tumor entity by DESeq2 (FDR<0.0001). Gene Set Enrichment Analyses (GSEA) demonstrated enrichment in the KEGG Lysosome pathway for PEComa (FDR=0.11), whereas myogenesis and smooth muscle contraction pathways were enriched in LMS (FDR=0.09). Integrative transcriptomic and epigenetic analyses revealed a unique set of master core transcription factors for each tumor type including among others MYOCD for LMS; MITF for PEComa, which require further functional investigation. Twelve selected genes including new as well as known and standard diagnostic markers (e.g., *DAPL1*, *MLANA*, *GPR143*, *PNL2*, *CHI3L1*, *DES*, *MYH11*, *ER*, *CD68*, *PU.1*, *pS6* and *CNN1*) were validated by immunohistochemistry (IHC) in multiple sections from PEComa and LMS (n=26 tumors/marker). The combination of three melanocytic markers (HMB45, *MLANA*, *PNL2*) and *pS6* can distinguish LMS from PEComas (p<0.0001). IHC for *CD68* and *PU.1* macrophage markers did not show any difference regarding the degree of immune infiltration in PEComa vs. LMS. **Conclusions:** PEComa and LMS present distinct expression and epigenetic features, however there are cases which overlap each tumor type. Given the success of mTOR inhibitors in the treatment of *TSC1/TSC2* mutant PEComa, genetic analysis of LMS for *TSC1/TSC2* mutations should be considered for all LMS patients to facilitate diagnosis.

Epigenetics Posters - Wednesday

PB2398. Divergent age-related methylation patterns in long and short-lived mammals

Authors:

A. Haghani; Altos Labs, San Diego, CA

Abstract Body:

Age-related changes to cytosine methylation have been extensively characterized across the mammalian family. Some cytosines that are conserved across mammals exhibit age-related methylation changes that are so consistent that they were used successfully to develop cross-species age predictors. In a similar vein, the methylation state of some conserved cytosines correlates extremely well with species lifespan. Surprisingly, little to no commonality is found between these two sets of cytosines even though the relationship between aging and lifespan is, by most measures, linked. We ventured to address this conundrum by first identifying age-related cytosines whose methylation change in opposite directions between short and long-lived species. We hypothesized that age-related CpGs that are also associated with species lifespan would tap into biological processes that simultaneously impact aging and lifespan. To this end, we analyzed age-related cytosine methylation patterns in 82 mammalian species. For each CpG, we correlated the intra-species age correlation with maximum lifespan across mammalian species. We refer to this correlation of correlations as “*Lifespan Uber Correlation (LUC)*”. This approach is unique in incorporating age and species lifespan in a single analysis. We identified 629 CpGs with opposing methylation aging patterns in long and short-lived species. Many of these are found to be near *BCL11B*, *NPTN*, and *HOXC4* loci. Methylation and transcription analyses of *BCL11B* knockout mice indicate that this gene partially regulates the methylation state of LUC CpGs. We developed DNAm age estimators (epigenetic clocks) based on LUC CpGs. These LUC clocks exhibited expected behavior in benchmark aging interventions such as caloric restriction, growth hormone receptor knockout and high-fat diet. Furthermore, we found that *BCL11B* knockout mice increased the epigenetic age of their striatum. Overall, we present a bioinformatics approach that identified CpGs and their associated genes implicated in both aging and lifespan. These cytosines lend themselves to developing highly accurate epigenetic clocks that are sensitive to perturbations that impact both age and lifespan.

Epigenetics Posters - Thursday

PB2399. DNA methylation changes among Ethiopian women diagnosed for cervical cancer.

Authors:

B. Kumbi Jufara¹, Y. Gebrehiot², D. Seifu³, D. Beyene², A. Lorincz⁴; ¹Ethiopian Police Univ., Addis Ababa, Ethiopia, ²Addis Ababa Univ., Addis Ababa, Ethiopia, ³Univ. of Global Hlth.Equity, Kigali, Rwanda, ⁴Queen Mary Univ. of London, London, United Kingdom

Abstract Body:

Infection by high risk human papillomavirus (hrHPV) is the major risk factor for cervical cancer with almost all cases being infected. HPV infection is a very common sexually transmitted infection that majority of sexually active women acquire. Most of the infected women however clear the infection spontaneously in short time while it persists and causes cervical cancer in only small portion of the infected women. Various factors are known to determine the outcome of the infection but with scarce information on the mechanisms. DNA methylation changes in both human genes and HPV genes are among the biological events associated with cervical cancer progression. This study was aimed at determining prevalence of hrHPV, socio-demographic risk factors for cervical cancer and epigenetic changes associated with cervical cancer and evaluate their potential as diagnostic markers. The study was conducted as an observational case-control study. The human *EPB41L3* gene promoter region and HPV L1 and L2 regions were PCR amplified from bisulphite converted DNA. The PCR amplicons were then pyrosequenced and proportion of converted cytosine is measured and means of the targeted CpG sites methylation were recorded. The DNA methylation assays were evaluated and compared for their performance using Receiver Operating Characteristics (ROC) curve analysis. HPV16 was the most prevalent virus constituting 84% of all hrHPV positive cases and 33.3% of hrHPV positive controls. HPV45, HPV18 and HPV31 were detected in 17.7%, 5.2% and 3.8% respectively of the hrHPV positive cases. Level of methylation in both human and hrHPV DNA was found to be higher in higher grade lesions than in low grade lesions (CIN1) and normal cervical cells. Methylation assays, both *EPB41L3* promoter methylation and S5 score discriminated normal and CIN1 from CIN3 or worse lesions with sensitivity and specificity of greater than 95%. In conclusion, higher parity and earlier age at first sexual intercourse are among the factors that put women at higher risk of cervical cancer in addition to hrHPV infection. HPV16 is the most prevalent (69.8%) hrHPV type followed by HPV45 (14.6%) in Ethiopian women with cervical lesions. Methylation levels of the human *EPB41L3* promoter region and HPV L1 and L2 regions are potential biomarker to improve precision of diagnosing the cancer and targeting for therapy. *EPB41L3* methylation alone discriminated normal and CIN1 cells from CIN3 or worse lesions with 95% sensitivity and 96% specificity while S5 detected with 96% sensitivity and 95% specificity.

Epigenetics Posters - Wednesday

PB2400. DNA methylation changes associate with measured glomerular filtration rate in an American Indian cohort with type 2 diabetes.

Authors:

S. Day¹, R. Hanson¹, K. Susztak², R. Nelson¹, C. Bogardus¹, L. Baier¹; ¹NIDDK, Phoenix, AZ, ²Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Diabetes is a leading cause of progressive kidney disease characterized by a decline in the glomerular filtration rate (GFR), but the molecular mechanisms underlying this decline are not completely understood. DNA methylation is an epigenetic mechanism that can regulate gene expression. The goal of this project was to identify DNA methylation changes associated with declining GFR in Southwest American Indians (SWAI). In 108 SWAI with type 2 diabetes (T2D), blood for DNA methylation and urine for GFR analyses were collected at 3 exams that were spaced 5 years apart (10 years total). Methylation was measured using the Infinium HumanMethylation450 array and GFR was directly measured by the urinary clearance of iothalamate. Normalization and analysis of variance (ANOVA) was performed using Partek Genomics Suite. To maximize the power of this limited sample size, association analysis was assessed between methylation and concomitantly measured GFR using all time points. One of our top methylation probes associated with GFR was cg19693031, in the 3'untranslated region of Thioredoxin Interacting Protein (*TXNIP*). This probe was also strongly associated with hyperglycemia as measured by HbA1c ($r = -0.55$; $P=1 \times 10^{-17}$), and the effect on GFR was explained by adjustment for HbA1c, a major risk factor for kidney disease progression. A functional effect of the methylation site captured by cg19693031 on *TXNIP* expression has been previously established, as well as its association with HbA1c and risk of T2D in other ethnic groups. The present results show that this methylation finding is also observed in SWAI. In analysis of association with GFR adjusted for HbA1c, no single probe achieved epigenome-wide significance (3.0×10^{-8}). Therefore, we conducted a pathway analysis using DAVID on a set of 1,540 genes (2,263 probes) that contained methylation sites associated with GFR at nominal significance ($P \leq 0.01$). This analysis identified endocytosis to be the most enriched pathway; loss of endocytosis function is associated with chronic kidney disease. The top methylation probe associated with GFR was cg12590521 in Calcium/Calmodulin Dependent Protein Kinase Kinase 2 (*CAMKK2*; $r = 0.32$; $P=3 \times 10^{-6}$). This site has not been previously implicated in diabetic kidney disease, but falls within a predicted enhancer region. Our plans for this ongoing project include functional assessment of this DNA methylation site (cg12590521) in *CAMKK2*.

Epigenetics Posters - Thursday

PB2401. DNA methylation epi-signature and biological age in attention deficit hyperactivity disorder patients

Authors:

G. Carvalho¹, T. Costa², A. Nascimento¹, B. Wolff¹, J. Damasceno¹, L. Vieira¹, V. Almeida¹, Y. Gasparini², C. Mello³, M. Muszkat³, L. Kulikowski¹; ¹Faculdade de Med. da Univ.e de São Paulo, São Paulo, Brazil, ²Univ.e de Sao Paulo, Sao Paulo, Brazil, ³Departamento de Psicobiologia da Univ.e Federal de São Paulo, São Paulo, Brazil

Abstract Body:

Attention Deficit/Hyperactivity Disorder (ADHD) is a common behavioral syndrome that begins in childhood and affects 3.4 % of children worldwide. Due to its etiological complexity, there are no consistent biomarkers for ADHD, however the high heritability that the disorder presents indicates a influence of genetic/epigenetic factors. The main epigenetic mechanisms is DNA methylation, a process with an important role in gene expression. Methylation status can be used as a biomarker for clinical conditions, such as cancer and neuropsychiatric diseases with specific epi-signatures, and it is used as a marker of biological senescence by several studies to determine biological age (DNAmAge). Thus, our study sought to identify epi-signatures biomarkers in 29 children clinically diagnosed with ADHD. Our results suggest that the biological response in patients with ADHD is not sufficient to determine an epi-signature. However, the results highlight the interaction of energy metabolism and oxidative stress pathways in ADHD patients detected by differential methylation patterns. We were able to identify a marginal association between the DNAmAge and ADHD. Thus, we present new methylation biomarkers in ADHD patients and propose that further multiethnic studies with larger cohorts should be done to demonstrate a definitive association between ADHD and these methylation biomarkers.

Epigenetics Posters - Wednesday

PB2402. DNA Methylation Episignature of Valproate Embryopathy.

Authors:

S. Haghshenas¹, J. Reilly¹, M. A. Levy¹, **R. Relator**¹, H. McConkey¹, J. Kerkhof¹, P. Edery², G. Lesca², C. Coubes³, M. Willems³, M. Barat-Houari⁴, Q. Sabbagh³, D. Genevieve^{3,5}, A. Putoux², B. Sadikovic^{1,6}; ¹London Hlth.Sci. Ctr., London, ON, Canada, ²Hospices Civils de Lyon, Service de Génétique, Groupement Hosp.ier Est, Bron, France and Université Claude Bernard Lyon 1, Lyon, France, ³Ctr. for Rare Disease Malformative Syndromes, Genetic Clinic Unit, CHU Montpellier, Montpellier, France, ⁴Laboratoire de Génétique des Maladies Rares et Autoinflammatoires, CHU Montpellier, Montpellier, France, ⁵Montpellier Univ., Inserm U1183, Montpellier, France, ⁶Western Univ., London, ON, Canada

Abstract Body:

Valproate is an effective antiepileptic drug and a mood-stabilizer with generally mild side effects. However, it is also recognized as a teratogen, since its consumption during pregnancy has been associated with increased susceptibility of the offspring to congenital anomalies and neurodevelopmental defects, referred to as valproate embryopathy or fetal valproate syndrome (FVS). Diagnosis of FVS can be difficult as there are currently no reliable molecular biomarkers for FVS. Peripheral blood DNA methylation patterns, known as episignatures have been established as stable and accurate diagnostic biomarkers for an increasing number of genetic neurodevelopmental disorders. However, it is currently not known if similar episignatures exist in patients affected by neurodevelopmental disorders that are caused by non-genetic factors, and in particular teratogenic exposures. By assessing a cohort of patients affected by FVS we demonstrate the existence of a highly accurate, sensitive and specific episignature for FVS. We developed a binary classification mode enabling an accurate molecular diagnosis of patients with FVS. We also describe the genome-wide changes in DNA methylation in FVS and compare the changes relative to above 120 other genetic neurodevelopmental syndromes with known DNA methylation episignatures. This expands the rapidly growing list of disorders with a known diagnostic episignatures and demonstrates diagnostic utility of EpiSign analysis beyond genetic syndromes.

Epigenetics Posters - Thursday

PB2403. DNA methylation in twins discordant for van der Woude syndrome

Authors:

A. Petrin¹, X. J. Xie¹, E. Zeng¹, D. Moretti-Ferreira², M. Marazita³, J. Murray⁴, L. Moreno¹; ¹Univ. of Iowa Coll. of Dentistry and Dental Clinics, Iowa City, IA, ²São Paulo State Univ. - UNESP, Botucatu, Brazil, ³Univ Pittsburgh, Ctr. for Craniofacial and Dental Genetics, Pittsburgh, PA, ⁴Univ. of Iowa Carver Coll. of Med., Iowa City, IA

Abstract Body:

Van der Woude Syndrome (VWS) is an autosomal dominant disorder responsible for 2% of all syndromic orofacial clefts (OFCs). Mutations in *IRF6* and *GRHL3* account for 70% and 5% of VWS cases, respectively. VWS presents with lip pits and/or cleft lip, cleft lip/palate, or cleft palate, with markedly variable expression. The phenotypic variation observed in monozygotic twins suggests epigenetic influence on the phenotype. We report the genome-wide DNA methylation (DNAm) profiling of one pair of monozygotic twins discordant for VWS. The affected twin has a missense mutation in *IRF6* that is absent in the unaffected co-twin. Our goal is to explore epigenetic contributions to this phenotypic discordance such as DNAm differences, which can alter the expression of additional craniofacial genes, especially genes of the *IRF6* pathway. Genome-wide DNAm profiles were generated using Illumina's Infinium Methylation EPIC BeadChip. We used ChAMP/RnBeads R packages to obtain beta values, which were used for calculation of the absolute DNAm difference. Moreover, we used the beta values of the 13 unaffected individuals as additional control. Cell type composition was estimated with EpiDISH followed by a logistic regression to correct for cell type heterogeneity. Finally, we performed gene ontology (GO) and enrichment analysis using GREAT. We found 19,196 differentially methylated positions (DMPs). 78 genes that contained DMPs when the Affected > Unaffected (affected more methylated) also contained binding sites for *IRF6*. GO analysis showed 170 genes enriched for the DMPs when Affected > Unaffected, with *TP63* ($p = 7.82E^{-12}$) among the top hits. Unaffected > Affected showed 91 genes enriched, with *TNF* ($p = 8.69E^{-09}$) and *PAX7* ($p = 2.82E^{-03}$) among the top hits. Several relevant human phenotypes associated with clefting had their causal genes enriched in the dataset including epidermal, ectodermal, and epithelial disorders, and craniofacial anomalies like craniofacial dysostosis and broad philtrum. Expression of *IRF6* requires normal function of *TP63*. Our data shows higher DNAm levels in *TP63* and many *IRF6* targets in the affected twin in addition to the causal *IRF6* mutation. The change in DNAm can add to the disruption of the biological regulatory loop that controls epithelial proliferation and differentiation, therefore contributing to phenotypic variability, often seen among VWS cases. This exploratory approach paves the way to further studies on epigenetic contributions to the phenotypic variability. Epigenetic changes can act as modifiers to causal mutations, contributing to phenotypic variability and penetrance of craniofacial Mendelian disorders like VWS.

Epigenetics Posters - Wednesday

PB2404. DNA methylation profile in multiple system atrophy and progressive supranuclear palsy

Authors:

P. Reho¹, S. Solaiman¹, T. G. Beach², G. E. Serrano², K. L. Newell³, R. Chia¹, H. Houlden⁴, J. C. Troncoso⁵, O. Pletnikova⁶, H. P. Easwaran⁷, S. W. Scholz¹; ¹NIH, Bethesda, MD, ²Banner Sun Hlth.Res. Inst., Sun City, AZ, ³Indiana Univ. Sch. of Med., Indianapolis, IN, ⁴Univ. Coll. London, London, United Kingdom, ⁵Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ⁶Jacobs Sch. of Med. and BioMed. Sci., Buffalo, NY, ⁷The Johns Hopkins Sch. of Med., The Sidney Kimmel Comprehensive Cancer Center, Baltimore, MD

Abstract Body:

Multiple system atrophy (MSA) and progressive supranuclear palsy (PSP) belong to a heterogeneous group of neurodegenerative disorders called atypical parkinsonism syndromes. Despite the discoveries of genetic risk factors, the causes and epigenetic changes underlying these understudied conditions are poorly understood. We performed an epigenome-wide association study on cerebellar DNA samples from 65 MSA and 95 PSP patients, and 193 neurologically healthy controls. The mean age of each group of subjects was 68.8 years, 73.3 years, and 72.8 years respectively. All samples were genotyped using the Illumina Infinium MethylationEPIC and Infinium Neuro Consortium (v1-1) arrays. After stringent quality control checks according to the gold-standard of the field, we performed a DNA methylation profiling focusing on, genome-wide significance, enrichment pathways analysis, differentially methylated regions analysis, and known risk genes for MSA and PSP (*GBA*, *SNCA*, *COQ2* and *MAPT*). We detected 175 differentially methylated probes (adjusted P value < 0.05) in MSA, of which 152 (87 %) were hypermethylated and 23 (13 %) were hypomethylated in cases compared to controls. Among PSP patients, we identified 108 differentially methylated probes, of which 49 (45 %) were hypermethylated and 59 (55 %) were hypomethylated. Of note, MSA and PSP patients shared five differentially methylated probes in *EXOSC4*, *RIMBP2*, *FIBCD1* and *C10orf129* genes. We found no evidence for differential methylation signatures at known risk genes. Here we will describe differentially methylated regions and disease-associated pathways. Our preliminary data highlight an important epigenetic modulation in MSA and PSP that could potentially lead to the identification of new molecular targets for therapeutic development.

Epigenetics Posters - Thursday

PB2405. DNA methylation signatures in Arab and Middle Eastern families with neurodevelopmental disorders provide insight to disease etiology.

Authors:

A. Nour^{1,2}, R. Mathew¹, I. Diboun¹, M. Hashmi¹, M. Ghorbani¹, N. Yousri³, K. Fakhro^{4,5,2}, N. Hajj², Y. Mokrab^{1,5}; ¹Sidra Med., Doha, Qatar, ²Hamad Bin Khalifa Univ., Doha, Qatar, ³Weill Cornell Med. - Qatar, Doha, Qatar, ⁴Sidra Med., Doha, Qatar, Qatar, ⁵Weill Cornell Med.-Qatar, Doha, Qatar

Abstract Body:

Epigenetic signatures (EpiSigns) have been identified in more than 60 neurodevelopmental disorders (NDDs) and helped reclassify variants of uncertain significance, aiding in the diagnosis of many idiopathic disorders. Most EpiSigns were studied in European and American subjects, while little is known about them in Arab and Middle Eastern ancestries. Here, we used the Epic Illumina array (850,000 CpG) to explore DNA methylation levels amongst 10 families, recruited in Qatar, with disease patients with NDDs (mostly intellectual disability and epilepsy). Each family consisted of unaffected parents and a sibling and an undiagnosed proband. Next, we investigated whether published NDD-associated epigenetic signatures explain our emerging data. For this, we trained an Orthogonal Partial Least Squares classifier on epigenetic data from 89 children with intellectual disability and 18 controls from a previously published study (PMID: 26003415). The classifier detected one significant component explaining 60% variation in the phenotype due to risk of NDD and was able to discriminate one of our probands from its control parents. CpGs assigned very important (VIP) scores by the classifier corresponded to three sites: (1) *chr7:117171038* from the *Cystic Fibrosis Transmembrane Conductance Regulator* gene (*CFTR*) involved in the regulation of neuronal excitability, (2) *chr3:93780377* in the 5' untranslated region (5'UTR) of *Dihydrofolate Reductase* gene (*DHFRL1*), an enzyme that produces tetrahydrofolate which regulates DNA methylation and (3) *chr17:73056681* within *Potassium Channel Tetramerization Domain Containing 2* gene (*KCTD2*) which has a well-established neuromodulatory function (all chromosomal positions based on GrCh37). This study sheds light on the epigenetics of an understudied population and leads to valuable results that can help hasten the clinical diagnostic journey for NDD patients.

Epigenetics Posters - Wednesday

PB2406. Dysregulation of serum and exosomal miR-7-1-5p and miR-223-3p in Parkinson's disease

Authors:

L. Citterio¹, R. Mancuso¹, S. Agostini², M. Meloni¹, M. Clerici^{1,3}; ¹IRCCS Don Carlo Gnocchi Fndn., Milan, Italy, ²IRCCS Don Gnocchi Fndn., Milano, Italy, ³Univ. of Milan, Milan, Italy

Abstract Body:

The etiology of Parkinson's disease (PD) is poorly understood mainly because of the interaction between genetic and environmental factors that appears to play a fundamental role. In this context, it is essential to investigate the presence of possible biomarkers potentially useful both for prognostic and diagnostic purposes and to understand the mechanisms that regulate the etiology of PD. Over the past decade, several studies reported dysregulated microRNAs (miRNAs) expression in neurodegenerative disorders, included PD. Using ddPCR, we investigated the potential differences of expression of miR-7-1-5p, miR-499, miR-223-3p and miR-223-5p, miRNAs involved in α -Synuclein pathway and inflammation, extracted from serum of 94 subjects (45 PD patients and 49 age- and sex-matched HC). Furthermore, we evaluated the expression of these four miRNAs also from serum-isolated exosomes, extracellular vesicles able to carry small molecules, including miRNAs, from a body district to another even passing through the blood brain barrier. Serum miR-7-1-5p expression resulted to be significantly increased in PD (35.54 copies/ng; 5.82 - 89.61 copies/ng) compared to HC (0.00 copies/ng; 0.00 - 30.97 copies/ng; $p=0.0007$). Notably, it also showed a positive correlation with α -Synuclein in the PD group ($p=0.05$), while its expression in exosomes showed no statistically relevant differences. miR-223-3p showed as well a statistically increased expression in the serum of PD subjects (7843.02 copies/ng; 3761.14 - 26972.84 copies/ng) compared to HC (2593.12 copies/ng; 502.96 - 10989.89 copies/ng; $p=0.0006$) and, remarkably, it resulted to be more expressed also in exosomes from PD (4715.67 copies/ng; 2832.13 - 16175.03 copies/ng) compared to exosomes from HC (1698.53 copies/ng; 463.20 - 5547.85 copies/ng; $p=0.0002$). Furthermore, we also found that this miRNA positively correlates with the age of the enrolled population ($p=0.04$) and, in the PD group, with the equivalent daily dose of levodopa (LEDD, mg/mL), the precursor of dopamine neurotransmitters and to date one of the most effective treatments for this disorder, both in serum ($p=0.0008$) and in exosomes ($p=0.006$). On the other hand, miR-499-3p and miR-223-5p showed no statistical differences between the two groups and resulted to be undetectable in exosomes. Our results suggest that both miR-7-1-5p and miR-223-3p are able to distinguish between patients and healthy subjects and in particular, due to the correlation with α -Synuclein, that serum miR-7-1-5p has the potential to be a useful and no-invasive biomarker in Parkinson's disease.

Epigenetics Posters - Thursday

PB2407. Early Embryos Employ a Unique Mechanism of CENP-A Equalization during the First Cell Cycle

Authors:

C. Tower¹, G. Manske¹, K. Jorgensen¹, S. Chakraborty¹, B. Ma², M. Abo-Elenin³, S. Schon¹, B. Black⁴, K. Schindler³, X. Chen⁵, S. S. Hammoud¹; ¹Univ. of Michigan, Ann Arbor, MI, ²Johns Hopkins Univ., Baltimore, MD, ³Rutgers Univ., Piscataway, NJ, ⁴Univ. of Pennsylvania, Philadelphia, PA, ⁵Johns Hopkins, Baltimore, MD

Abstract Body:

CENP-A is a centromere-specific histone H3 variant that is responsible for defining centromeric chromatin in most eukaryotic species. Previous investigations studying CENP-A inheritance in somatic cells have shown that existing CENP-A nucleosomes direct the deposition of new CENP-A nucleosomes during late telophase of mitosis. This mechanism results in quantitative maintenance of CENP-A levels and preserves the genomic location of centromeres across mitotic divisions. In addition to somatic inheritance, CENP-A nucleosomes are also known to be inherited intergenerationally. Work from our lab and others has established that CENP-A nucleosomes are inherited from both the maternal and paternal germline into the totipotent embryo. Additionally, our lab has recently uncovered that the paternal genome contributes lower levels of CENP-A to the early embryo, which poses a problem for faithful chromosome segregation during the first cell division. This suggests that early embryos might employ specific mechanisms during the first cell cycle to equalize CENP-A between homologous chromosomes. To investigate the mechanisms regulating CENP-A dynamics in early embryos, our lab tagged the endogenous Cenpa locus in mice and performed various in vitro fertilization experiments to monitor the distribution of CENP-A across different pronuclear stages in the zygote in response to various treatments. From these experiments, we observed that, unlike in somatic cells, deposition of CENP-A into the paternal pronucleus is linked to the start of S phase (PN3), which occurs after the protamine to histone exchange. Moreover, we found that a large portion of these newly deposited CENP-A nucleosomes are originally derived from maternally inherited, chromatin-bound CENP-A. Although this redistribution of CENP-A nucleosomes was linked to the start of S phase, it is not dependent on DNA replication. Additional experiments also demonstrated that zygotic transcription and translation were not necessary for the redistribution of maternal CENP-A into the paternal pronucleus to occur. Lastly, dissemination of maternal CENP-A to the paternal pronucleus does not appear to be predominantly regulated by CDK1 or PLK1, which were previously identified as mitotic CENP-A licensing factors in somatic cells. Future studies in our lab will focus on identifying the key factors regulating CENP-A dynamics in early embryos.

Epigenetics Posters - Wednesday

PB2408*. Epigenetic Age Acceleration is Suggestively Associated with Stroke Precursor Phenotypes

Authors:

N. Dueker¹, H. Zhao², C. Dong³, D. Cabral⁴, R. L. Sacco⁴, S. Blanton³, L. Wang⁴, T. Rundek³; ¹Univ. of Miami Miller Sch. of Med., Miami, FL, ²Yale Univ. Sch. of Publ. Hlth., New Haven, CT, ³Univ Miami, Miami, FL, ⁴Univ. of Miami, Miami, FL

Abstract Body:

Epigenetic clocks have been developed using DNA methylation levels at select CpG sites to predict chronological age (Hannum and Horvath clocks) and mortality (GrimAge and PhenoAge clocks). Epigenetic age acceleration (AgeAccel), which occurs when a person's epigenetic age is older than their chronological age (CA), has been associated with adverse health outcomes including cardiovascular diseases and obesity. Studies investigating the association between epigenetic aging and stroke precursor phenotypes, however, are limited. We previously assembled a collection of 61 extended families (n=799 people) from the Dominican Republic on whom stroke precursor phenotypes and CpG methylation data are available. We utilized this data to determine if epigenetic AgeAccel was associated with total carotid intima-media thickness (cIMT), carotid bifurcation thickness (BIF) and left ventricular mass (LVM). CpG methylation in blood was assayed using the Illumina Infinium Human MethylationEPIC BeadChip. Using these data, we estimated participants' epigenetic age using four epigenetic clocks; Horvath, Hannum, GrimAge and PhenoAge. AgeAccel measures for each of these epigenetic clocks were estimated by regressing resulting epigenetic ages onto CA. We then performed linear mixed model analyses regressing each AgeAccel measure onto LVM, cIMT and BIF. Adjustment was made for CA, sex, ancestry principal components and cell composition proportions as fixed effects and family was included as a random effect. Mean CA in our sample was 46.3 years and mean AgeAccel was -0.33 years for Horvath, 0.05 years for Hannum, 1.45 years for GrimAge and 7.38 years for PhenoAge epigenetic clocks. We found that Horvath AgeAccel is associated with increased BIF (beta=0.02, p=0.01). We also observed the following suggestive associations (0.05 < p < 0.1): 1). Horvath AgeAccel and increased cIMT and LVM, 2). Hannum AgeAccel and increased LVM, and 3). PhenoAgeAccel and increased BIF. GrimAgeAccel was not associated with any precursor phenotype (p > 0.1). A previous study in adults (mean CA = 57y) found epigenetic AgeAccel estimated using the Horvath and Hannum epigenetic clocks to be significantly associated with increased cIMT. Taken together, these results suggest that epigenetic AgeAccel, as measured by the Horvath epigenetic clock, is associated with stroke precursor phenotypes in older individuals. Additional analyses investigating the effects of CA and sex on the association between epigenetic AgeAccel and stroke precursor phenotypes are in progress.

Epigenetics Posters - Wednesday

PB2409. Epigenetic profiling of isolated blood cells reveals highly cell-type specific smoking signatures and links to disease risk

Authors:

X. Wang, M. Campbell, H-Y. Cho, S. Martos, D. Bell; Natl. Inst. of Environmental Hlth.Sci., Research Triangle Park, NC

Abstract Body:

Tobacco smoking leads to many human health problems and diseases. We hypothesize alteration of DNA methylation may underpin some of the pathogenesis of smoking-associated complex diseases. However, knowledge of how smoking-driven epigenetic effects in specific blood cell-types may link with disease risk is unknown. In this study, we isolated DNA from 6 major leukocyte subtypes (including CD14⁺ monocytes, CD15⁺ granulocytes, CD19⁺ B-cells, CD4⁺ T cells, CD8⁺ T cells, CD56⁺ natural killer cells) and whole blood from healthy adult smokers (n=64) and nonsmokers (n=71), and generated DNA methylation profiles with Illumina 450k and EPIC arrays. We identified 238 cell-type specific, smoking-associated CpGs (or smoking-CpGs) at genome-wide ($p < 1.2E-7$) from 6 major leukocytes. The numbers of smoking-CpGs varied from only 5 CpGs in CD8⁺ T cells to 111 CpGs in CD19⁺ B-cells, although B-cells and CD8⁺ T cells are both less than 10% of total leukocytes in normal whole blood samples. We found unique smoking effects in each cell-type, some of which were not apparent in whole blood because the whole blood effect is a sum of the collective change in individual cell-types. Using cell-type deconvolution analysis we observed that naïve B-cell proportions were reduced among smokers. We observed distinctive cell-type specific enrichment of canonical pathways, in particular, canonical pathways related to immune response and transcriptional regulation via transcription, were highly enriched among B-cell smoking-CpGs. Compared with published EWAS results, the cell-type specific smoking-CpGs were overrepresented among 8 EWAS CpG sets, most significantly, the “lung function” EWAS CpG set, which overlaps 35 smoking-CpGs (normalized enrichment score = 3.48; $p = 8.8E-88$). Integrating with large-scale public mQTLs and GWAS datasets, we found that 52 smoking-CpGs had mQTL SNPs that were either GWAS SNPs or in complete LD with GWAS SNPs, which associated with 4 categories of human phenotypes including lung function, disease risk, blood traits, and other traits. Tracing the cell type origin of these smoking-CpGs, we found lung function traits mainly linked to myeloid cells; but disease risk and blood traits were linked to both B-cell and myeloid cells. Examining functional connections between smoking-CpGs and gene expression, we found 8 smoking-CpGs associated in cis with mRNA levels at $p < 1.0E-5$, and 44 smoking-CpGs had 341 mQTL SNPs that were also cis-eQTL SNPs (10 kb to TSS). This comprehensive analysis of smoking-associated DNA methylation changes in human blood cell-types provides a path to better understanding of potential mechanisms in smoking-associated diseases.

Epigenetics Posters - Thursday

PB2410. Epigenetic regulation of Wnt signaling pathway associated with age-related mobility loss.

Authors:

E. Quillen, B. Frye, J. Negrey, T. Register, C. Shively; Wake Forest Sch. of Med., Winston Salem, NC

Abstract Body:

Non-human primate models (NHPs), including vervets (*C. pygerythrus*), show age-related decline in musculoskeletal mass and physical function similar to what is seen in humans with a decline starting around age 20 (60 human-equivalent years) and a broad distribution of gait speed within each age group. To identify epigenetic variants associated with lean muscle mass or gait speed in a cohort of 30 female vervets aged 8-28 years (~25-90 years in humans), we investigated methylation levels at 107,490 genome-wide loci in vastus lateralis biopsies collected during routine health checks. We performed differential methylation analysis using the R package *minfi* and fit generalized linear mixed models to account for underlying genetic relatedness. Two methylation loci are associated with variation in DXA-derived muscle mass after age adjustment at a false discovery rate (FDR) < 0.05. One - *LOC103231767* - is known to be differentially expressed in white blood cells with age based on RNAseq data from the vervets, but its role is unknown. Decreased muscle mass was also associated with increased methylation of *CD82*, which would be expected to decrease gene expression. In mice, knock-out of *CD82* results in loss of muscle mass and - critical for older adults - decreased activity of satellite cells necessary for myofiber repair. This may be due to the role of *CD82* in regulating autophagy in response to intracellular stressors via the Wnt signaling pathway. Additionally, we identified 15 methylation loci associated with gait speed, a reliable indicator of overall physical function in vervets as in humans. Many of these genes are implicated in the disordered aging of both bone and muscle, reflecting the known pleiotropy at some of these genes highlights the overlap of these physically integrated tissues. For example, *SOX2* and *WNT2* are both well-known regulators of Wnt signaling in osteoblasts, but the Wnt signaling pathway is also essential for the self-renewal of muscle. *LBX2* is a highly conserved gene regulating myofibril formation via the Wnt pathway. Master regulator of Wnt and other signaling pathways, *HOXC10* has also been linked to bone, muscle, and ligament formation and regeneration. We note that these associations in the HOX gene family overlap several of our previous findings in cartilage and bone methylation changes associated with bone shape and osteoarthritis in baboons. Additional genes with methylation changes in muscle associated with gait speed have only previously been associated with bone mass or fracture risk including *HAND122*, *CALCR23*, *IRX224*. In total, these findings point to the involvement of the Wnt signalling pathway in age-related decline in mobility.

Epigenetics Posters - Wednesday

PB2411. Epigenetic signatures of asthma in nasal epithelium from African ancestry populations from the CAAPA consortium

Authors:

M. Boorgula¹, M. Campbell¹, B. Szczesny², K. Kammers², I. Ruczinski², S. Chavan¹, C. Arehart¹, C. Cox¹, R. K. Johnson¹, I. R. Konigsberg¹, E. Thompson³, A. Morin³, C. G. McKennan⁴, C. Figueiredo⁵, C. Taub²; ¹Univ. of Colorado, Aurora, CO, ²Johns Hopkins Sch. of Med., Baltimore, MD, ³Univ. of Chicago, Chicago, IL, ⁴Univ. of Pittsburg, Pittsburg, PA, ⁵Univ. of Bahia, Salvador, Brazil, ⁶Natl. Human Genome Ctr., Howard Univ. Coll. of Med., Washington DC, DC, ⁷The Univ. of the West Indies, Queen Elizabeth Hosp., Bridgetown, St Michael, Barbados, ⁸Univ. of Chicago Med., Chicago, IL, ⁹Children's Hosp., Aurora, CO, ¹⁰Icahn Sch. of Med. at Mt Sinai, New York, NY

Abstract Body:

Asthma is a complex disease with striking disparities across racial and ethnic groups. A main goal of the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA) is to understand the etiology of asthma through epigenetic mechanisms in the nasal epithelium focusing on populations with asthma health disparities. We measured DNA methylation in nasal epithelial cells from subjects collected across four CAAPA sites (Baltimore, Chicago, Denver, and Washington DC) using the Illumina EPIC array. Sample and probe level QC was performed using the minfi Bioconductor package. Cases were defined as asthmatics with asthma severity index indicating active asthma (N=149) and controls were non-asthmatics (N=182). We ran a differential methylation analysis adjusting for age, sex, plate, site, 2 ancestry principal components estimated from MEGA chip genotypes and 12 latent factors estimated using the CorrConf R package to correct for unwanted variation. CpGs with a q-value <0.05 were considered differentially methylated (DMCs). We also performed a stratified analysis in 195 adults (age ≥ 18, 83 cases and 112 controls) and 136 pediatric subjects (66 cases and 70 controls) to identify epigenetic signature differences between adult and pediatric asthmatics. CpGs were mapped to the nearest gene as well as target genes identified using an external promoter-capture dataset. We found 192 DMCs in the full sample set. Genes near the top DMCs (q<0.001) included *ZBTB16*, *CCL26*, *FKBP5*, *ATP6V0d2* and *CDHR3*, which are primarily associated with T cell development, chemokine binding, and responsiveness to glucocorticoid receptors, respectively, and are known susceptibility loci for asthma. *CDHR3* is an epithelial cell receptor for RV-C and is associated with asthma exacerbations/hospitalizations in the first 5 years of life. The DMC mapping to the *ZBTB16* gene was also among the 182 DMCs in pediatric subjects (q=0.03). Genes near other DMCs in pediatric subjects include *RAB37*, *SOX5* and *ACOT7*, all involved in immune related pathways and previously associated with asthma. The DMC near *ZBTB16* is in the promoter of *C11orf71*, and using CAAPA-generated RNA-Seq data from the same individuals, we observed a negative association in a multivariate linear regression relating methylation levels at this DMC to gene expression levels of *C11orf71* in all samples (p=0.0012), indicating potential regulation of this asthma-associated gene by methylation. A full integrative analysis of methylation and gene expression data is ongoing. The epigenetic associations we identify may reveal underlying mechanisms of asthma, including some contributing specifically to pediatric disease.

Epigenetics Posters - Thursday

PB2412*. Epigenome-wide association meta-analysis of DNA methylation with lifetime cannabis use

Authors:

F. Fang¹, B. Quach¹, K. G. Lawence², J. van Dongen³, J. A. Marks¹, S. Lundgren⁴, M. Lin⁵, V. V. Odintsova³, R. Costeira⁶, Z. Xu², L. Zhou¹, M. Mandal¹, J. Vink⁷, L. J. Bierut⁸, M. Ollikainen⁴, J. Taylor², J. Bell⁶, J. Kaprio⁴, D. Boomsma³, K. Xu⁹, D. P. Sandler², D. Hancock¹, E. Johnson¹⁰; ¹RTI Intl., Research Triangle Park, NC, ²NIH/NIEHS, Research Triangle Park, NC, ³VU Univ. Amsterdam, Amsterdam, Netherlands, ⁴Univ Helsinki, Helsinki, Finland, ⁵Yale Univ., Tenafly, NJ, ⁶King's Coll. London, London, United Kingdom, ⁷VU Univ, Amsterdam, Netherlands, ⁸Washington Univ Sch Med, St Louis, MO, ⁹Yale Sch. Med., New Haven, CT, ¹⁰RTI Intl., Duluth, MN

Abstract Body:

Cannabis is a commonly used drug. Understanding its links to adverse health outcomes would be enhanced by the availability of a reliable biomarker of cannabis exposure. DNA methylation can serve as a reliable biomarker of substance exposures, as previously shown for cigarette smoking. We conducted an epigenome-wide association study (EWAS) of peripheral blood-based CpG methylation and lifetime cannabis use (ever vs. never) in a meta-analysis of 7 European and the United States cohorts, including 9,436 participants (7,795 European- and 1,641 African-ancestry). Our EWAS meta-analysis revealed four CpG sites significantly associated with lifetime cannabis use at a false discovery rate of 0.05 ($p < 5.85e-7$): cg22572071 near gene *ADGRF1*, cg15280358 in *ADAM12*, cg00813162 in *ACTN1*, and cg01101459 near *LINC01132*. None of the four cannabis use-associated CpGs has been reported at genome-wide significance in EWAS for any substance exposure, including cigarette smoking, which is an important comorbid factor for cannabis use. Although our EWAS model accounted for cigarette smoking as a covariate, we further investigated the associations between CpG methylation and lifetime cannabis use in the subset of participants who never smoked cigarettes (N=3,861). All four top CpGs from the overall analysis remained associated with cannabis use in never smokers ($p < 0.05$). Additionally, the EWAS meta-analysis for cannabis use in never smokers identified another epigenome-wide significant CpG, cg14237301 annotated to *APOBR*, which was implicated in a prior genome-wide association study of lifetime cannabis use ($p = 7.56e-9$).

To examine whether a peripheral blood-based biomarker is indicative of lifetime cannabis use, we trained a multi-CpG classifier with penalized regression models (LASSO) on DNA methylation data from our single largest cohort, the Sister Study (N=2,073). We compared predictive models trained from the significant CpG sets obtained in EWAS using models with and without cigarette smoking as a covariate, with different p-value cutoffs. Based on the area under the receiver operating characteristic (AUROC) metric, predictors trained on the CpGs sets from the EWAS model without cigarette smoking as a covariate performed better. The best predictor, consisting of 64 CpGs, produced an AUROC=0.67 ($p = 9.57e-10$) in an independent dataset from the Sister Study (N=517). Thus, our preliminary results in the Sister Study demonstrated that the methylation signature can be used to predict lifetime cannabis use with reasonable accuracy.

Epigenetics Posters - Wednesday

PB2413. Epigenome-wide association of DNA methylation markers for dilated cardiomyopathy in left ventricular heart tissues.

Authors:

K. Tan¹, W. Tan², E. Wong³, M. Morley⁴, G. K. Singhera⁵, P. J. Hanson⁵, T. Cappola⁴, K. Margulies⁴, R. Foo⁶, M. Loh¹, F. Tai¹; ¹Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore, ²Stanford Cardiovascular Inst., Stanford Univ., Palo Alto, CA, ³Genome Inst. of Singapore, Agency for Sci., Technology and Res., Singapore, Singapore, ⁴Penn Cardiovascular Inst., Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, ⁵Ctr. for Heart Lung Innovation, Univ. of British Columbia, Vancouver, BC, Canada, ⁶Yong Loo Lin Sch. of Med., Natl. Univ. of Singapore (NUS), Singapore, Singapore

Abstract Body:

Dilated cardiomyopathy (DCM) is the most common form of cardiomyopathy worldwide. It is characterized by a thinning and weakening of the left ventricular heart walls, resulting in contractile dysfunction. An estimated one-third of DCM cases are inherited, suggesting a strong genetic contribution. A further half of DCM cases remain unexplained by known causes, genetic or non-genetic, and receive the idiopathic classification. With most DCM patients eventually succumbing to sudden cardiac death (SCD), developing methods for early diagnosis is an urgent task.

Epigenetic mechanisms have been suggested to underlie the marked variability in the onset and severity of idiopathic DCM. Nevertheless, the biological relevance of significant hits surfaced by genome-wide association studies (GWAS) and epigenome-wide association studies (EWAS) of heart failure has been hindered by insufficient power and heterogeneity of etiology. Additionally, cross-study replicability of findings has been limited owing to differences in the array technologies employed and resultant variations in CpG sites coverage.

The current study is by far the largest EWAS for DCM as a single etiology of heart failure. This investigation aims to expand the current set of DNA methylation loci with statistically-significant disease associations, utilising the Illumina Infinium Methylation EPIC array which covers >850,000 methylation sites on left-ventricular heart tissues from DCM cases (n=172) and non-heart failure controls (n=174). Concurrent transcriptomic profiling of a subset of samples was conducted via RNA sequencing (RNAseq).

Pilot analysis of the methylation data surfaced 28 independent methylation signals ($P < 1 \times 10^{-5}$) independent of adjustments for confounders, including weight, height, heart mass, diabetes, and hypertension status. Among the 754 genes within 500kb of the 28 sentinel methylation loci, 302 were found to be expressed in our RNAseq dataset. Of the 302 expressed genes, a subset of 90 contained significant expression quantitative trait loci (eQTLs; $P < 1.7 \times 10^{-4}$). The significant eQTLs include an established marker for heart failure with plausible involvement in cardiac remodeling, suggesting an influence of dysmethylation on pathological gene expression in idiopathic dilated cardiomyopathy. With ongoing validation analyses on independent heart tissue samples and generation of causal inferences via applying statistical methods such as Mendelian Randomisation, the findings of this study could facilitate the identification of biomarkers with robust associations with DCM, toward an improved mechanistic understanding of disease and risk stratification.

Epigenetics Posters - Thursday

PB2414*. Epigenome-wide association study in multi-ethnic Asian populations identifies novel markers for incident type 2 diabetes

Authors:

M. Loh^{1,2,3}, D. Tay¹, L. Lakshmanan¹, H. Ng¹, F. Tai¹, R. M. van Dam⁴, X. Sim⁴, J. C. Chambers^{1,2}; ¹Lee Kong Chian Sch. of Med., Singapore, Singapore, ²Imperial Coll. London, London, United Kingdom, ³Natl. Skin Ctr., Singapore, Singapore, ⁴Saw Swee Hock Sch. of Publ. Hlth., Singapore, Singapore

Abstract Body:

Introduction Type 2 diabetes (T2D) is a major public health problem that currently affects 425 million people worldwide. The burden of diabetes is especially high in Asia, with both East and South Asians at increased risk for T2D. This increased risk of T2D in Asians is not accounted for by traditional risk factors such as obesity, diet and physical inactivity. Recent studies have suggested that epigenetic factors, in particular DNA methylation, may be associated with T2D development. However, these studies have been carried out predominantly amongst people of European ancestry, consistent with genetics and other omics data worldwide. In this study, we aim to identify variations in DNA methylation associated with incident T2D among a large multi-ethnic Asian population comprising of 6,168 East Asians, Malays and South Asians from United Kingdom and Singapore.

Methods We performed an epigenome-wide association study using peripheral blood samples from East Asians, Malays and South Asians with incident T2D with age, gender and ethnicity-matched controls from UK and Singapore. DNA methylation was measured on the Illumina 450K and EPIC array, using baseline samples collected before onset of T2D. Epigenome-wide significance was set at $P < 8.62E-8$, a threshold determined via permutation testing. To further evaluate the association between the identified T2D methylation sites with gene expression both in *cis* and in *trans* in our South-East Asian population, we additionally performed RNAseq in approximately 1,200 samples.

Results We identified 420 CpG sites across 314 independent loci to be significantly associated with incident T2D, with relative risk per 1% increase in methylation ranging from 0.87 to 1.18 (P-values: $8.51E-08$ to $9.08E-46$). Among the 314 sentinel markers, only 15 (5%) has been previously reported to be associated with T2D. Our top five hits were cg06500161 in *ABCG1*, cg11024682 in *SREBF1*, cg19693031 in *TXNIP*, cg19758958 in *AHNAK*, and cg19750657 in *UFMI*. Replication testing in independent cohorts is currently underway. Initial functional annotation and expression quantitative trait loci (eQTL) analysis suggest that the identified methylation are likely to be play functionally important roles.

Conclusion Epigenome-wide association studies performed in non-European populations may identify novel methylation markers and provide new insights into the pathways underlying T2D, as well as open up new strategies for risk stratification and prevention of T2D in Asian and other populations.

Epigenetics Posters - Wednesday

PB2415. Epigenome-wide association study reveals CpG sites associated with thyroid function and regulatory effects on *KLF9*

Authors:

A. Teumer^{1,2,3}, A. Weihs¹, L. Chaker⁴, T. C. Martin^{5,6}, J. T. Bell⁶, M. Medici⁴, ThyroidOmics Consortium; ¹Univ. Med. Greifswald, Greifswald, Germany, ²DZHK (German Ctr. for Cardiovascular Res.), Partner Site Greifswald, Greifswald, Germany, ³Med. Univ. of Bialystok, Bialystok, Poland, ⁴Erasmus Med. Ctr., Rotterdam, Netherlands, ⁵Icahn Sch. of Med. at Mount Sinai, New York, NY, ⁶King's Coll. London, London, United Kingdom

Abstract Body:

Thyroid hormones play a key role in cellular growth, development and metabolism, and are known regulators of gene expression through both genomic and non-genomic processes including DNA methylation. The aim of this study was to examine associations between thyroid hormones and DNA methylation.

We carried out an epigenome-wide association study of leucocyte DNA methylation sites from blood in up to 7,073 participants from 8 cohorts of both European and African ancestry individuals from the ThyroidOmics Consortium. Significant associations from the discovery stage were replicated in independent samples. The validated findings were correlated with gene expression levels and genetic variants. Causal influence of thyroid hormones on the DNA methylation levels was assessed by Mendelian randomization.

Epigenome-wide significant associations (p -value $< 1.1E-7$) of 3 CpGs for free T4, 5 for free T3, and 2 for TSH were discovered and replicated in independent cohorts (combined p -values = $1.5e-9$ to $4.3e-28$). The associations included CpG sites annotated to *KLF9* (cg00049440) and *DOTIL* (cg04173586) that overlap with all three traits, with consistent effect directions. Significant associations were also found for CpGs in *FKBP5* for free T4, and at *CSNK1D/LINCO1970* and *LRRC8D* for free T3. Differences in circulating TSH levels have a causal effect on DNA methylation of *KLF9*. DNA methylation of cg00049440 in *KLF9* was inversely correlated with *KLF9* gene expression in blood. The CpG at *CSNK1D/LINCO1970* overlapped with THRA binding peaks in liver cells. The total additive heritability of the methylation levels of the six significant CpG sites is between 25% and 57%. Significant methylation QTLs were identified for CpGs at *KLF9*, *FKBP5*, *LRRC8D* and *CSNK1D/LINCO1970*. We report novel associations between TSH, thyroid hormones and blood-based DNA methylation. This study advances our understanding of thyroid hormone action, and serves as a proof-of-concept that similar integrations of EWAS and other OMICS techniques can provide a valuable tool for unravelling thyroid hormone signaling next to classical *in-vitro* and animal studies.

Epigenetics Posters - Wednesday

PB2416. Epstein-Barr Nuclear Antigen 2 (EBNA2) types 1 and 2 have shared and distinct host DNA binding partners.

Authors:

K. Viel¹, S. Parameswaran², O. Donmez², C. Forney², L. Kottyan², M. Weirauch²; ¹Univ. of Cincinnati, Cincinnati, OH, ²Cincinnati Children S Hosp. Med. Ctr., Cincinnati, OH

Abstract Body:

Epstein-Barr Virus (EBV) is a human gammaherpesvirus that infects 90-95% of the human population and is a risk factor for several autoimmune diseases including Multiple Sclerosis. Furthermore, EBV infection increases one's risk for certain cancers such as Burkitt's lymphoma and nasopharyngeal carcinoma. There are two distinct genetic variations of EBV: EBV1 and EBV2, which differ substantially within Epstein Barr Nuclear Antigen 2 (EBNA2), a transactivator protein that mimics activated Notch. EBNA2 lacks a DNA binding domain, and instead regulates genes through interactions with human transcription factors such as RBPJ, EBF1, and PU.1. Type 1 and type 2 EBNA2 proteins share only 55% amino acid identity between the B95.8 (EBV1) and AG876 (EBV2) virus strains. The difference in genomic binding patterns between EBNA2 type 1 and type 2 is currently unknown. We hypothesized that EBNA2 type 2 has a different genomic binding pattern than EBNA2 type 1 and regulates different genes. To test this hypothesis, we performed ChIP-seq in B cell lines transformed with EBV2 (Jiyoye and AG876) and EBV1 (MutuIII and GM12878) to examine how EBNA2 genomic binding regions vary between EBV1 and EBV2. Through differential peak analysis, we found that ~2629 peaks are shared between EBV1 and EBV2, ~3704 peaks are unique to EBV2, and ~6727 peaks are unique to EBV1. We then computationally identified transcription factor DNA binding motifs that are enriched within these genomic regions. PU.1 motifs are similarly enriched in EBNA2 type 1 and type 2 peaks. Predicted EBF1 motifs are found at a higher frequency in EBNA2 type 1 than EBNA2 type 2, while AP-1 and RBPJ is found at higher percentages in EBNA2 type 2 peaks than EBNA2 type 1 peaks. These findings suggest that type 1 and type 2 EBNA2 have both shared and differential binding partners. As predicted by motif analysis, when we performed anti-PU.1, anti-EBF1, anti-AP-1, and anti-RPBJ ChIP-seq, we found that RBPJ and AP-1 (JUNB) colocalized with EBNA2 type 2 at more genomic regions than EBNA2 type 1. Moreover, in agreement with our predictions, EBF1 colocalized with EBNA2 type 1 at more genomic regions than EBNA2 type 2. Future studies will identify shared and unique disease risk loci that are enriched at EBNA2 from EBV type 1 and type 2.

Epigenetics Posters - Thursday

PB2417*. Expanded studies of a methylation-based COVID-19 classification model to predict severity of disease and its ability to differentiate from other respiratory viruses.

Authors:

B. Peterson¹, W. Zhou², G. F. Harrison³, M. P. Boorgula⁴, M. Campbell⁴, S. Chavan⁴, B. Barnes⁵, R. PORECHA⁵, R. A. Mathias⁶, I. V. Yang⁴, C. Gignoux⁴, A. Taye⁵, A. Monte⁴, K. C. Barnes⁷; ¹Tempus Labs, Inc., Boulder, CO, ²Tempus Labs, Inc., Redwood City, CA, ³Tempus Labs, Inc., Chicago, IL, ⁴Univ. of Colorado, Aurora, CO, ⁵Illumina, San Diego, CA, ⁶Johns Hopkins Univ., Baltimore, MD, ⁷Univ. of Colorado, Anschutz Sch. of Medicin, Aurora, CO

Abstract Body:

SARS-CoV-2 infection triggers many molecular changes including epigenome patterns, in humans. Previously, we demonstrated that DNA methylation signatures differentiate patients with SARS-CoV-2 infection from uninfected individuals. Methylation Risk Scores (MRS) derived from the differential methylation signatures yielded highly predictive scores to determine the presence of SARS-CoV-2 infection (AUC=93.6%) and measure COVID-19 disease severity (AUC=79.1%-84.4%; Konigsberg et al 2021 *Comm. Med.*). In the original study, we observed a positive trend towards specificity of the COVID-19 disease signatures in comparison with other viral upper respiratory infections. However, the study was underpowered to determine the utility of the model to create disease classifiers specific to non-SARS-CoV-2 infections. To expand on this work, we profiled peripheral blood samples from 304 additional patients on the customized Infinium MethylationEPIC array. These patients were either uninfected, infected with SARS-CoV-2, or SARS-CoV-2 negative but infected with other respiratory viruses. Measurements for disease severity, progression (hospitalization, ICU admittance, ventilator use), and vaccination and booster status were extracted from electronic health record data. An epigenome-wide association analysis in this expanded cohort validated genes and pathways that were previously found to be significantly associated with SARS-CoV-2 infection. The previously reported sparse regression based MRS, when tested in this expanded cohort, yielded higher AUCs for case-vs-control status, hospitalization, ICU admission, and progression to death. Additionally, we observed higher predictive scores for other respiratory viruses. In summary, the COVID-19-specific epigenetic signature (in peripheral blood) driven by expression/activation of key immune-related pathways was related to infection status, disease severity, and clinical deterioration. This study provides useful insights for diagnosis and prognosis in patients with COVID-19.

Epigenetics Posters - Wednesday

PB2418. Exploring novel regulatory elements in X-chromosome inactivation.

Authors:

D. Beseiso¹, M. Cloutier¹, M. Hinten², S. Kalantry¹; ¹Univ. of Michigan Med. Sch., Ann Arbor, MI, ²Mayo Clinic, Rochester, MN

Abstract Body:

X-chromosome inactivation equalizes X-linked gene expression between the mammalian sexes by silencing genes on one of the two X chromosomes in females. A long non-coding RNA known as the *X-inactive-specific transcript* (*Xist*) is expressed exclusively from the future inactive X chromosome where it facilitates the deposition of repressive histone marks to initiate gene silencing. Replicated copies of the inactive X chromosome remain silenced through subsequent rounds of cell division making X-inactivation a paradigm of epigenetic transcriptional regulation. Our lab recently found that loss of the *Xist* gene results in a defected X-inactivation in mouse trophoblast stem cells. Unexpectedly, in a separate series of experiments, we found that loss of *Xist* RNA expression, while leaving the underlying DNA sequence intact, results in a significantly milder derepression of silenced genes. These findings may suggest that the *Xist* DNA silences X-linked genes through other mechanisms in addition to the expression of *Xist* RNA. The goal of my work is to explore alternate mechanisms by which silencing of genes on the inactive X chromosome is maintained. The results may shed light on novel regulatory elements of X-inactivation as well as reveal previously uncharacterized mechanisms of gene silencing at the DNA and chromatin levels.

Epigenetics Posters - Thursday

PB2419. Extracellular vesicles microRNAs in traumatic brain injury patients with and without intracranial abnormality

Authors:

R. Vorn¹, C. Lai², C. Turtzo³, C. Devoto⁴, N. Peterkin³, L. Latour³, J. Gill¹; ¹Johns Hopkins Univ., Baltimore, MD, ²Ctr. for NeuroSci. and Regenerative Med., Uniformed Services Univ. of Hlth.Sci., Bethesda, MD, ³Natl. Inst. of Neurological Disorders and Stroke, NIH, Bethesda, MD, ⁴Henry M. Jackson Fndn. for the Advancement of Military Med., Bethesda, MD

Abstract Body:

Mild traumatic brain injury (mTBI) is a major public health burden; however, objective diagnosis remains challenging. Extracellular vesicle (EVs) derived from biofluids is a promising source of biomarkers specific to neurological disorders, including TBI. However, EV-associated microRNAs (miRNAs) have not been adequately studied in acute mTBI patients. Therefore, the objective of this study was to investigate the EV-associated miRNAs from plasma of mTBI patients with and without evidence of intracranial findings. This analysis was a part of the Traumatic Head Injury Neuroimaging Classification (THINC) study and included 27 healthy controls (HCs) and 190 mTBI patients with a mean age of 46 years. Patients presented to the emergency department, received standard of care computed tomography (CT), and received research magnetic resonance imaging (MRI) and peripheral blood draw within 48 hours of injury. For subgroup analysis, TBI patients were classified based on imaging findings, specific to TBI, as CT-MRI- (n= 53), CT-MRI+ (n = 60), and CT+MRI+ (n = 53). EVs-miRNAs profiling was measured using the nCounter miRNA expression panel (human 798 targets) developed by NanoString Technology. We identified 67 significantly deregulated (32 upregulated and 35 downregulated) miRNAs in mTBI patients compared to HCs with the cutoff 0.05 False Discovery Rates and \pm 1.5-fold change. In subgroup analysis, we found 42 miRNAs significantly dysregulated (17 upregulated and 25 downregulated) in mTBI patients with MRI-CT-, 83 miRNAs significantly dysregulated (36 upregulated and 47 downregulated) in mTBI patients with MRI+CT-, and 54 miRNAs significantly dysregulated (26 upregulated and 28 downregulated) in mTBI patients with MRI+CT+ relative to HCs. We observed that 27 miRNAs were overlapping among subgroups and overall TBI patients. Top 10 deregulated miRNAs are miR-1283, miR-496, miR-601, miR-32-5p, miR-376c-3p, miR-6724-5p, miR-1268a, miR-124-3p, miR-296-3p, and miR-579-5p. Our study provided insight into the molecular changes after mTBI and has potential application as diagnostic biomarkers for mTBI.

Epigenetics Posters - Wednesday

PB2420. Finding the Right Match: the Role of ZCWPW1 in Mammalian Meiosis

Authors:

W. Xie, D. Bazzano, S. Hammoud; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Meiosis is an essential process of sexually reproducing organisms to maintain the copy number of chromosomes and generate genetic diversity across generations, characterized by a single round of DNA replication followed by two ensuing divisions. While the second division separates sister chromatids, resembling mitosis, the first division is reductive with the segregation of homologous (maternal and paternal) chromosomes. Faithful segregation of homologs requires a series of coordinated steps: chromosome pairing, synapsis, and homologous recombination (HR) during meiotic prophase I. These events are initiated by the generation of double-strand-breaks (DSBs) at sites specified by PRDM9, a methyltransferase that tri-methylates lysine 4 and 36 of histone 3 (H3K4me3 and H3K36me3). However, it remains poorly understood how H3K4me3/H3K36me3 modifications facilitate pairing and recombination.

Recently, ZCWPW1 is identified as a dual H3K4me3 and H3K36me3 “reader”. The *Zcwpw1* mutants display defects in synapsis, and crossover formation, leading to male sterility consequently. To investigate the function of ZCWPW1 in meiosis, we performed ZCWPW1 immunoprecipitation followed by mass spectrometry and found that ZCWPW1 interacts with a diverse set of proteins including those that function in chromosome movement, chromosome axis assembly, and DNA repair. Specifically, components of the linker of nucleoskeleton and cytoskeleton (LINC) complex and interacting proteins are identified. SUN2, a component of the LINC complex, mislocalizes in the absence of ZCWPW1. While the telomere movement is not abolished, the dynamics is potentially slowed down. Using immunofluorescence combined with fluorescent in situ hybridization (FISH), we found that homolog pairing of chromosome 1 and 19 are impaired in ZCWPW1 knockout mice, with frequent heterologous synapsis and asynapsis.

Given these results, we hypothesize that ZCWPW1 facilitates homolog pairing by interacting with the LINC complex to promote telomere-led chromosome movement and bringing euchromatin into proximity. These studies will help illustrate how a histone methylation writer/reader system contributes to the germline integrity, faithful genomic transmission, and speciation. Additionally, identifying a euchromatic pairing mechanism will shed light on how cells ensure the homolog pairing on a large scale in conjunction with telomere-driven movement and local homology search.

Epigenetics Posters - Thursday

PB2421. First trimester human placenta DNA methylation correlates to maternal estradiol levels

Authors:

T. Gonzalez¹, B. Lee¹, T. Sun¹, K. D. Taylor², J. I. Rotter², Y-D. I. Chen², J. Williams III¹, S. S. Rich³, C. R. Farber³, M. O. Goodarzi¹, J. Cui¹, M. D. Pisarska¹; ¹Cedars-Sinai Med. Ctr., Los Angeles, CA, ²Lundquist Inst., Harbor-UCLA Med Ctr, Torrance, CA, ³Univ. of Virginia, Charlottesville, VA

Abstract Body:

Background: The placenta is critical for normal fetal development and may impact health outcomes later. Gamete manipulation during in vitro fertilization (IVF) has previously been implicated to alter DNA methylation in the placenta. However, recent studies demonstrate minimal differences, but suggest underlying infertility and/or other treatments may be contributory. We found elevated 17-beta-estradiol and progesterone levels in the late first trimester of subjects pregnant through fertility treatments, compared to those conceived spontaneously. To determine if elevated hormonal states drive some of the methylation differences, we investigated if maternal hormones correlate to human placenta DNA methylation in first trimester, regardless of infertility status. **Methods:** Pregnant subjects were recruited into the SMAART cohort. Late first trimester placenta was collected from leftover sample after prenatal diagnostic testing, chorionic villus sampling. Maternal plasma was collected in the same visit and ELISA assays were previously performed to measure maternal levels of 17-beta-estradiol and progesterone (PMID: 30445606). Here, DNA methylation of first trimester placenta was measured using the Illumina Infinium MethylationEPIC Array. Probes were excluded if identified as masked (unreliable), if not on autosome chromosomes, or if located at single nucleotide polymorphism sites, leaving 741,145 CpG sites for analysis. We used data from N=88 subjects (37 spontaneous conceptions, 25 non-IVF fertility treatments, and 26 IVF fertility treatments) and a generalized linear model to find correlations between placenta DNA methylation and maternal hormones. Covariates of fetal sex and maternal age were considered. **Results:** In the generalized linear model without covariates, DNA methylation correlated positively with 17-beta-estradiol in maternal plasma at 5 CpG sites with genome wide significance at $P < 9E-8$. Significant sites were cg20868379 (*LRRC20* gene), cg13873263 (no gene context), cg06929324 (*VRTN* gene), cg08140055 (*EPHB1* and *KY* genes), and cg22611570 (*SLC2A9* gene). There were no CpG methylation sites that correlated with progesterone levels. Fetal sex did not correlate to either estradiol ($P=0.889$) or progesterone ($P=0.0667$) and was not used as a covariate. Maternal age also did not correlate to estradiol ($P=0.452$) or progesterone ($P=0.234$). **Conclusion:** Maternal 17-beta-estradiol levels, but not progesterone levels, correlate to CpG site methylation in first trimester human placenta. Clinically, embryo transfers into a physiologic hormonal environment may minimize these outcomes.

Epigenetics Posters - Wednesday

PB2422. Functional Analysis of CHD2 and CHD8 *De Novo* Mutations and Related Molecular Events Involved in Neurodevelopmental Disorders

Authors:

T. Muhammad¹, S. F. Pastore¹, T. T. Madanagopal², A. Mikhailov², J. B. Vincent¹; ¹Univ. of Toronto, Toronto, ON, Canada, ²Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract Body:

Background: Neurodevelopmental disorders (NDDs) such as ID and ASD are associated with impaired intellectual and adaptive functioning, deficits in social communication accompanied by the presence of limited interests and repetitive behaviors. A number of genes that have been identified to regulate chromatin remodeling-an active and key epigenetic mechanism of altering the structure and function of chromatin- have been implicated in both disorders. Chromodomain helicase DNA-binding (CHD) proteins are important factors for remodeling chromatin and for gene regulation. CHD2 and CHD8 pathogenic variants have been extensively reported for ID and ASD. **Objectives:** The initial goals of this study are to evaluate the effects of *CHD2* and *CHD8* pathogenic missense mutations on DNA/chromatin binding dynamics, on protein stability and gene expression, and to assess the effects of mutations in these genes on neuronal morphology and differentiation. **Methods:** We performed a review of the literature to identify de novo missense mutations, and checked for prediction of pathogenicity using SIFT, PROVEAN, Mutation taster, and Polyphen. Next, we cloned *CHD2* and *CHD8* into vectors for transfection into cell lines. We examined methyltransferases via immunoblotting followed by RT-qPCR and ChIP experiments to evaluate important genes involved in development. We have generated in silico data for the effects of SNVs on the CHD2/CHD8 protein surface energy, stability, flexibility and binding dynamics using docking and MD simulations analysis. **Results:** Preliminary findings revealed that these mutations affect the expression of active histone H3.3, key methyltransferases such as RbBP5, Set8, Set7/9, ESET etc., that are required for numerous development-related gene expressions and regulation. Preliminary ChIP data suggests that these mutations affect the binding dynamics of the CHD2 and CHD8 proteins. **Conclusion:** These pathogenic mutations affect the expression of active histone H3.3, dysregulate various methyltransferases, and affect binding dynamics of CHD2 and CHD8 proteins. We are now utilizing the CRISPR/Cas9 system to knockout CHD2 and CHD8, and introduce point mutations, in HEK293T, P19 embryonic cells and iPSCs to get isogenic cell lines for detailed mechanistic studies.

Epigenetics Posters - Thursday

PB2423*. Gene regulatory network synchronizes genetic and epigenetic signals, prioritizes GWAS SNPs, and identifies repurposable drug candidates for multiple sclerosis

Authors:

A. Manuel, Y. Dai, Z. Zhao; The Univ. of Texas Hlth.Sci. Ctr., Houston, TX

Abstract Body:

Background: Multiple sclerosis (MS) is an autoimmune disease that leads to demyelination and neurological disability. Although the exact cause of MS is undetermined, both genetic and environmental risk factors have been established. Genome-wide association studies (GWAS) have identified 233 single nucleotide polymorphisms (SNPs) associated with MS with genome-wide significance. Epigenetic studies have pinpointed differentially methylated CpG sites in the genomes of individuals with MS. However, the interplay between genetic factors and epigenetic regulation remains elusive. **Methods:** We applied systems biology approaches to harmonize the effects of genome-wide genetic and epigenetic signals in MS. We extended the dense module search of GWAS (dmGWAS) network model to integrate SNP-level association signals from the largest MS GWAS of 14,802 MS cases and 26,703 controls, DNA methylation profiles from 140 MS cases and 139 controls, and the human interactome. We obtained differentially methylated genes by aggregating additive effects of differentially methylated CpG sites within respective promoter regions. Literature-curated transcription factor (TF) interactions were used to reconstruct a gene regulatory network (GRN). Colocalization of the MS GWAS and methylation quantitative trait loci (mQTL) was performed to assess the genes of GRN. Cell-type specificity of the GRN was also investigated by the Web-based Cell-type Specific Enrichment Analysis of Genes (WebCSEA). Lastly, we performed drug target enrichment analysis using the Therapeutic Target Database (TTD). **Results:** The MS-associated GRN was comprised of 25 genes and several TF interactions. We highlight genome-wide significant SNPs with GWAS-mQTL colocalization pairs: rs6032663, rs6065926, and rs2024568 of *CD40* locus, rs9913597 of *STAT3* locus, and rs887864 and rs741175 of *CIITA* locus. Interestingly, *CD40* and *STAT3* had aligned mQTL and eQTL signals, indicating these SNPs may be affecting epigenetic mechanisms and gene expression. WebCSEA analysis showed that the GRN was enriched (p-value = 0.0016) in T follicular helper (Tfh) cells. The GRN was also enriched (p-value = 3.89×10^{-4}) with three successful drug targets and eight clinical trial drug targets, which revealed repurposable candidates for MS treatment: vorinostat (*HDAC1* inhibitor), napabucasin (*STAT3* inhibitor), and others. **Conclusion:** We prioritize a GRN (25 genes) with genetic and epigenetic signals, Tfh cell-specificity, and drug target genes. We pinpoint GWAS SNPs that may alter DNA methylation and gene expression patterns in MS. We propose repurposable candidates for MS, which warrant further investigation.

Epigenetics Posters - Wednesday

PB2424*. Genetic variation in correlated regulatory region of immunity

Authors:

D. Avalos^{1,2}, G. Rey², D. M. Ribeiro¹, A. Ramisch², E. T. Dermitzakis², O. Delaneau¹; ¹Univ. of Lausanne, Lausanne, Switzerland, ²Univ. of Geneva, Geneva, Switzerland

Abstract Body:

Studying the interplay between genetic variation, epigenetic changes and regulation of gene expression in immune cells is important to understand the modification of cellular states in various conditions, including immune diseases. Here, we built cis maps of regulatory regions with coordinated activity - Cis Regulatory Domains (CRDs) - in neutrophils, monocytes and T cells. For this, we leveraged (i) whole-genome sequencing (WGS), (ii) chromatin immunoprecipitation sequencing (ChIP-seq), (iii) DNA methylation (450k arrays), and (iv) transcriptional profiles (RNA-seq) from the BLUEPRINT consortium, for up to 200 individuals. Our study uncovers 9287, 7666 and 5480 histone CRDs (hCRDs) and 6053, 6112, 5701 methyl CRDs (mCRDs) in monocytes, neutrophils and T-cells, respectively. We discovered 15294 hCRD-gene and 6185 mCRD-gene associations (5% FDR). Only 33% of hCRD-gene associations and 37% of mCRD-gene associations were shared between cell-types, revealing the dynamic nature of regulatory interactions and how similarly located regulatory regions modulate the activity of different genes on different cell types. We mapped Quantitative Trait Loci associated with CRD activity (CRD-QTLs) and found that 89% and 70% of these hCRDs and mCRDs are under genetic control highlighting the importance of genetic variation to study the coordination of cellular regulatory programs. We found CRD-QTLs to be enriched in cell-type-specific transcription factor binding sites, such as SPI1, STAT3, RFX1, SOX4, ATF3 for neutrophils and monocytes and TCF4 and BCL11A for T-cells, in line with the Human Protein Atlas. We integrated PChi-C data, which showed that most significant associations discovered within gene-CRD associations and co-expressed genes associated with the same CRD, involving large genomic distances, tend to happen between genomic regions in close spatial proximity. Finally, we mapped trans regulatory associations between CRDs, which enabled the discovery of 207 trans-eQTLs across cell types. Overlapping our hits with trans eQTLs from eQTLGen Consortium meta-analysis in whole blood revealed 81 trans-eQTLs shared between the two studies. Overall, we show that mapping functional regulatory units using population genomics data allows discovering important mechanisms in the regulation of gene expression in immune cells and gain a greater understanding of cell-type specific regulatory mechanisms of immunity.

Epigenetics Posters - Thursday

PB2425. Genome-wide DNA methylation profiling in subcortical regions reveals epigenetic signatures associated with PTSD and MDD

Authors:

H. Li¹, J. Wang², D. Cruz³, J. Modliszewski⁴, D. Corcoran⁵, Traumatic Stress Brain Research Group, J. Krystal^{6,7}, R. Duman⁸, H. Zhao^{1,2}, D. Williamson³, M. J. Girgenti^{6,7}; ¹Dept. of Biostatistics, Yale Sch. of Publ. Hlth., New Haven, CT, ²Program of Computational Biology and Bioinformatics, Yale Univ., New Haven, CT, ³Dept. of Psychiatry and Behavioral Sci., Duke Univ. Med. Ctr., Durham, NC, ⁴Duke Univ., Durham, NC, ⁵Duke Univ, Durham, NC, ⁶Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT, ⁷Natl. Ctr. for PTSD, U.S. Dept. of VA, New Haven, CT, ⁸Yale Univ., New Haven, CT

Abstract Body:

Methylation of DNA (DNAm) is a critical regulator of genome architecture, gene expression, and cell function. These processes are important for mammalian development, genomic imprinting, aging and response to external stimuli such as stress. Post-traumatic stress disorder is a debilitating psychiatric disorder with an approximately 7% prevalence in the general population and occurs in the aftermath of a traumatic event, making PTSD one of the best psychiatric disorders to be understood from an epigenetic standpoint. We generated DNAm data from 6 postmortem brain regions (subiculum, dentate gyrus, CA subfields, basolateral amygdala, medial amygdala and central amygdala nuclei) from 171 individual donors using the Illumina Methyl-seq system. This resource provides genomic coverage across (1,065,750 probes representing 22,544 genes, a large sample size (117 cases versus 54 controls), across two unique diagnostic cohorts (PTSD and MDD) in regions not typically analyzed in large genomic cohorts (amygdala and hippocampus) in an effort to comprehensively measure DNA methylation changes across the stressed brain. We find differential DNAm signatures across all regions including many non-overlapping, sex-specific differences. Gene set enrichment identified pathways including glucocorticoid signaling, inflammation and GABAergic signaling as mechanisms differentially enriched in PTSD and MDD. DNAm signals aggregate near PTSD risk variants for genes such as *ELFN1*, *CRHI*, and *MAD1L1*. Taken together, we present a unique and powerful resource for exploring DNA methylation changes in human postmortem subcortical regions important for stress disorder pathology.

Epigenetics Posters - Wednesday

PB2426*. Genome-wide dysregulation of R-loops in Ataxia Telangiectasia neurological pathogenesis.

Authors:

K. Westover, Y. Hou, Y. Li, B. Yao; Emory Univ., Atlanta, GA

Abstract Body:

Ataxia Telangiectasia (AT), a multisystemic neurodegenerative disease characterized by decreasing motor coordination, mental development, immune defects, and telangiectasia of the eyes, affects up to 1 in 40,000 to 100,000 people worldwide. A recessive early childhood onset disorder, AT is caused by mutations within the ataxia telangiectasia mutated (ATM) threonine/serine kinase which plays crucial roles within the DNA damage response (DDR). However, the precise molecular mechanisms underlying AT pathogenesis and how ATM loss-of-function leads to deficient DDR remain elusive. R-loops, three stranded RNA-DNA structures composed of an DNA-RNA hybrid and a non-template DNA strand, have emerged as key components of double strand break (DSB)-induced DDR. Mounting evidence has documented critical roles of R-loops in both causing and responding to DSBs. As DSBs and the failure of their repair play major roles in the pathology of AT, R-loop dysregulation is likely to contribute to AT pathogenesis. One recently identified kinase substrate of ATM is methyltransferase like 3 (METTL3) protein, a N6-methyladenosine (m6A) methyltransferase. m6A on the RNA strand of R-loops is present inside nuclei and affects R-loop formation during DSB repair. The relationship between ATM-METTL3 phosphorylation in response to DNA damage and regulation of R-loop formation through m6A deposition, which could play crucial roles in AT pathogenesis, has yet to be defined. Our preliminary data has demonstrated a global trend of R-loops decreasing in AT patient-derived neurons compared to healthy controls. ~20% of these downregulated loci were rescued in an isogenic line where the ATM mutation had been corrected. We hypothesize that in AT, the lack of METTL3 phosphorylation by ATM could globally dysregulate R-loop formation and underlie AT progression. We have successfully inserted wild-type, phospho-mimetic, and phospho-deficient METTL3 into plasmids for future experiments to determine the role of ATM-phosphorylated METTL3 on R-loop formation. We are currently generating iPSC-derived motor neurons from age-matched healthy controls, AT patients, and their isogenic lines with the pathogenic mutations corrected by genome editing systematically identify critical R-loop loci that are associated with AT and mechanistically explore the role of ATM truncations in AT progression through METTL3-dependent R-loop regulation.

Epigenetics Posters - Thursday

PB2427*. Genome-wide evaluation of the effect short tandem repeat variation on local DNA methylation

Authors:

A. Martin Trujillo, P. Garg, N. Patel, B. Jadhav, A. J. Sharp; Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Short tandem repeats (STRs) represent a class of repetitive sequences that are widely distributed throughout the human genome and contribute significantly to genetic diversity, including disease-causing variation. While the functional consequences of STRs on gene expression have been extensively assessed, their impact on epigenetics has been poorly studied. Here, we hypothesized that STRs can act as methylation quantitative trait loci (mQTL), i.e. STRs that are able to regulate DNA methylation profiles (mSTRs). To test this hypothesis, we performed association analysis between STR length and DNA methylation variation using genotypes from 131,635 polymorphic STRs derived from Whole Genome Sequencing (WGS) and the Illumina Infinium MethylationEPIC Bead Chip, respectively. After accounting for biological and technical covariates as well as multiple testing, we identified 11,870 STRs that were associated with DNA methylation levels of 11,774 unique CpGs in a discovery cohort of 245 individuals. Importantly, we validated ~90% of the detected STR:CpGs associations in a second independent cohort of 484 individuals, underscoring the robustness of the detected signals and our method. mSTRs were enriched for regulatory elements such as promoters (OR=2.57) and enhancers (OR=2.52), supporting their potential role in regulating genome function. Subsequent fine-mapping analysis indicated that 585 of these mSTRs represent the main genetic driver responsible for DNA methylation variation. Furthermore, using STR genotypes obtained from 1000 Genomes Project samples, we observed an enrichment for population divergent alleles at fine-mapped mSTRs, suggesting that they might have been subject to selection as a result of environmental pressures. Finally, by integrating GWAS-signals in our analysis, we identified dozens of fine-mapped mSTRs linked to a wide variety of human traits that range from blood-related traits to neurodegenerative diseases, providing evidence to support that variation at these STRs could underlie a fraction of human traits. Overall, our findings expand the catalog of functional variants in the genome and show that a fraction of STRs act as regulators of genome function by modulating DNA methylation levels in cis, which ultimately can represent the molecular mechanism underlying phenotypic variation and disease.

Epigenetics Posters - Wednesday

PB2428*. Genome-wide mapping implicates 5-hydroxymethylcytosines in diabetes and Alzheimer's disease

Authors:

Z. Zhang¹, A. Beadell², A. W. Capuano³, D. Bennett³, C. He², W. Zhang¹, Z. Arvanitakis³; ¹Northwestern Univ., Chicago, IL, ²Univ. of Chicago, Chicago, IL, ³Rush Univ. Med. Ctr., Chicago, IL

Abstract Body:

Background: Diabetes mellitus (DM) is a recognized risk factor for dementia including due to Alzheimer's disease (AD). Because DM is a potentially modifiable risk factor, a greater understanding of the mechanisms linking DM to the clinical expression of AD may provide insights into the much needed dementia therapeutics or intervention approaches. Epigenetic analysis offers a powerful approach, and previous studies including our team's exploration in circulating cell-free DNA (cfDNA) suggested that the under-investigated 5-hydroxymethylcytosines (5hmC) is now emerging as a promising measure to investigate in DM-related conditions. Methods: We used samples and data from the Rush Memory and Aging Project. Using the 5hmC-Seal technique, a highly sensitive chemical labeling technique developed by our team, we performed genome-wide profiling of 5hmC in cfDNA samples (n=74) from antemortem blood samples and brain tissue (n=75) genomic DNA (gDNA) from postmortem prefrontal cortex tissue from 80 deceased individuals across four groups: AD (neuropathologically defined), DM (clinically defined Type 2 DM), DM with AD (AD+DM), and non-AD/non-DM controls. Differential analysis and machine learning approaches were used to investigate 5hmC signatures associated with different conditions and summarize epigenetic scores to evaluate diagnostic potential for AD in cfDNA. Pathway enrichment analysis was performed on differential 5hmC signatures to explore biological mechanisms underlying DM-associated AD. Results: We identified distinct 5hmC signatures and biological pathways, such as Wnt signaling and inflammatory mediator regulation of TRP channels, as well as amino sugar and nucleotide sugar metabolism, that are associated with AD or AD+DM compared to non-AD/non-DM controls or DM alone. We further demonstrated the potential diagnostic value of 5hmC profiling in circulating cfDNA. Specifically, a 4-gene model showed capacity for distinguishing AD+DM from DM (AUC [area under the curve]= 82.7%; 95% CI [confidence interval], 67.6-97.9%), while an 11-gene model distinguished AD from non-AD/non-DM controls (AUC = 90.0%; 95% CI, 80.4-99.6%). Conclusions: Genome-wide 5hmC profiling uncovered epigenetic features and biological pathways related to nucleotide sugar metabolism that link DM to DM-associated AD. Our findings also demonstrated the potential of utilizing 5hmC in circulating cfDNA as diagnostic biomarkers or disease monitoring tools, with the ultimate goal of preventing or ameliorating DM-associated AD dementia and improving clinical outcomes. This study was supported partially by RF1AG074549 from the NIH.

Epigenetics Posters - Wednesday

PB2430. Genome-wide neonatal epigenetic changes associated with maternal exposure to the COVID-19 pandemic

Authors:

K. Kocher^{1,2,3}, S. Bhattacharya^{4,5}, N. Andescavage^{6,5}, C. Lopez^{6,5}, M. Almalvez^{1,5}, D. Henderson^{6,5}, E. Vilain^{1,5,3}, C. Limperopoulos⁶, E. Delot^{1,3}; ¹Children's Natl. Res. and Innovation Campus, Washington, DC, ²Children's Natl. Hosp., Washington DC, DC, ³The George Washington Univ., Washington, DC, ⁴Children's Natl. Res. and Innovation Campus, Washington DC, DC, ⁵Children's Natl. Hosp., Washington, DC, ⁶Children's Natl. Hosp., Washington, DC

Abstract Body:

With the sudden outbreak of COVID-19 in early 2020 came a prolonged period of quarantine and shutdown of society leading to widespread psychological distress for many. During gestation, stressors to the fetus, including maternal psychological distress, can fundamentally alter the neonatal epigenome and may be associated with long-term impaired neurological or developmental outcomes. In this study we aimed to determine whether there are unique epigenetic signatures in newborns associated with the stress of the COVID-19 pandemic. We investigated DNA methylation differences in newborns who experienced otherwise healthy pregnancies that occurred during the COVID-19 pandemic (Project RESCUE). Widespread differential methylation was found between newborns born and *in utero* during the pandemic (delivered after June 2020) and a cohort of age- and sex-matched healthy controls, delivered before the start of the pandemic (before December 2019). In contrast, there were no apparent epigenetic differences associated with maternal COVID-19 infection during pregnancy. Differential methylation was observed among genomic sites that underpin important neurological pathways and have been previously reported in the literature to be differentially methylated as a result of prenatal stress, such as *NR3C1*. Our study reveals that the onset and continuation of the COVID-19 pandemic has fundamentally altered the epigenomes of newborns born during this time, even in otherwise healthy pregnancies, which should be taken into account in any current and future DNA methylation study. It will also be critical to document longitudinal neurodevelopmental outcomes of these cohorts to understand if these altered epigenetic signatures predict resilience or susceptibility to the stressors.

Epigenetics Posters - Thursday

PB2431. Genome-wide screening of epigenetic variations in the EpiSign Knowledge Database

Authors:

R. Relator¹, M. Levy¹, J. Kerkhof¹, H. McConkey^{1,2}, B. Sadikovic^{1,2}; ¹London Hlth.Sci. Ctr., London, ON, Canada, ²Western Univ., London, ON, Canada

Abstract Body:

The EpiSign Knowledge Database (EKD) contains more than 10,000 genome-wide peripheral blood DNA methylation profiles including individuals with genetic neurodevelopmental disorders and unaffected controls (general population samples) with varying age and racial background. An expanding number of genetic disorders included in these cohorts have been shown to be associated with distinct epigenetic profiles, with over 120 such episignatures currently identified. While episignatures represent effective diagnostic biomarkers, they don't include assessment of individual, genomic locus-specific epigenetic changes in individual patients. To date, many studies have shown that epigenetic variation, also referred to as epivariants or epimutations, are associated with various human diseases. However, there is limited information on their prevalence in patients with known and suspected genetic neurodevelopmental syndromes. In this study we have catalogued the epivariants in the EKD by performing a robust outlier analysis. From Illumina Infinium EPIC arrays, hypo/hypermethylated regions are defined with at least three contiguous probes within 1000bp. For each sample with a known episignature disorder, we investigate all predefined regions and compare methylation levels with a fixed set of reference controls. We aggregate regions identified meeting the criteria of epivariations, followed by visual inspection. The identification of epivariants, which are usually hypo- or hypermethylation events located in gene promoter regions, can provide better understanding of disease etiology and aid in the development of regional biomarkers for prediction models in clinical diagnostics.

Epigenetics Posters - Wednesday

PB2432. Global identification of cortical circRNAs and circRNA clusters associated with Alzheimer's disease

Authors:

F. Wang¹, Y. Li¹, P. Martinez-Feduchi¹, J. Kuehner¹, Y. Feng², B. Yao¹; ¹Dept. of Human Genetics, Emory Univ. Sch. of Med., Atlanta, GA, ²Dept. of Pharmacology and Chemical Biology, Emory Univ. Sch. of Med., Atlanta, GA

Abstract Body:

Circular RNAs (circRNAs) have recently emerged as novel class of regulatory RNAs with spatial and temporal expression control during development and aging. Several key cis-regulatory elements and trans-factors were identified to contribute to the production of circRNA, including Alu repetitive elements in flanking introns and RNA-binding proteins (RBPs), respectively. Many circRNAs are evolutionary conserved from invertebrate to mammals, suggesting their essential biological functions. A great number of circRNAs are highly enriched in the brain and have been shown to play important roles in brain development, maturity, and functions. Recently data shed light on their global dysregulation and potential roles in neurodegenerative disorders, such as Alzheimer's disease (AD). However, how circRNAs participate in AD-related pathophysiology remains poorly elucidated. Our recent study established a robust platform to identify circRNA landscape in human neurons and oligodendrocytes. Using this platform, we identify and quantify circRNA landscape from early development to aging process in 5xFAD mice cortex. We identified a group of differentially expressed circRNAs in AD mouse cortex and found many of these AD-related circRNAs changed of their expression in human AD postmortem brains. Many circRNA-forming loci produce multiple circRNAs by different combinations of exon sequences. These "clustered" circRNAs may play additive effects in regulating miRNA or RBP activities through their common sequences. In addition to individual circRNAs that were significantly altered in AD, we identified 440 circRNAs clusters that were significantly differentially expressed in AD mouse brain. These circRNA clusters contained many statistically insignificant low expressing circRNAs that could additively contribute to AD pathogenesis. In summary, our study provides novel mechanistic link between circRNAs, circRNA clusters and AD pathogenesis during aging progression.

Epigenetics Posters - Thursday

PB2433*. High dimensional co-expression network analysis unravels transcriptomic drivers of diverse biological systems

Authors:

S. Morabito, V. Swarup; Univ. of California Irvine, Irvine, CA

Abstract Body:

The parameters that dictate the onset, progression, and genetic basis of human disease are encoded in biological networks. To date, many single-cell transcriptomic analyses remain at the level of individual genes rather than biological networks, partially due to a lack of sufficient tools for gene network analysis in high dimensional data. Here, we describe hdWGCNA, an analytical framework for co-expression network analysis in high dimensional transcriptomics data such as single cell RNA-seq and spatial transcriptomics. We optimized the bioinformatics protocol for co-expression network analysis for high dimensional transcriptomic data, and we maximize the usability of this pipeline via an open source R package that is directly compatible with Seurat formatted data objects. We show that hdWGCNA yields cell-type-specific co-expression modules in the human cortex, and we demonstrate that these networks are reproducible across independent datasets. We applied hdWGCNA to inhibitory neurons from published single-cell RNA-seq data of the prefrontal cortex from autism spectrum disorder (ASD) patients, identifying gene modules that contribute to neuronal dysfunction, as well as gene modules containing key ASD GWAS hits. We performed a consensus co-expression network analysis of microglia in Alzheimer's Disease (AD) using three independent single-nucleus RNA-seq datasets, revealing distinct networks that are critical in the transition from homeostatic to disease-activated cells. Additionally, gene modules identified in single cell data can be projected into relevant spatial datasets to discover their spatial expression patterns, and hdWGCNA is also capable of constructing co-expression networks in spatial transcriptomics datasets themselves. Furthermore, hdWGCNA offers a statistical framework for comparing networks across different biological systems and data modalities. Together, we demonstrate that hdWGCNA is a powerful tool for uncovering the transcriptomic drivers of diverse biological systems.

Epigenetics Posters - Wednesday

PB2434. High-dimension to high-dimension screening for detecting genome-wide epigenetic regulators of gene expression.

Authors:

H. Ke¹, Z. Ren², J. Qi³, S. Chen³, G. C. Tseng², Z. Ye³, T. Ma¹; ¹Univ. of Maryland, Coll. Park, College Park, MD, ²Univ. of Pittsburgh, Pittsburgh, PA, ³Univ. of Maryland, Baltimore, Baltimore, MD

Abstract Body:

The advancement of high-throughput technology characterizes a wide range of epigenetic modifications across the genome involved in disease pathogenesis via regulating gene expression. The high-dimensionality of both epigenetic and gene expression data make it challenging to identify the important epigenetic regulators of genes. Conducting univariate test for each epigenetic-gene pair is subject to serious multiple comparison burden, and direct application of regularization methods to select epigenetic-gene pairs is computationally infeasible. Applying fast screening to reduce dimension first before regularization is more efficient and stable than applying regularization methods alone. Here we propose a novel screening method based on robust partial correlation to detect epigenetic regulators of gene expression over the whole genome, a problem that includes both high-dimensional predictors and high-dimensional responses. Compared to existing screening methods, our method is conceptually innovative that it reduces the dimension of both predictor and response, and screens at both node (epigenetic features or genes) and edge (epigenetic-gene pairs) levels. We develop data-driven procedures to determine the conditional sets and the optimal screening threshold, and implement a fast iterative algorithm. Simulations and applications to long non-coding RNA and microRNA regulation in Kidney cancer and DNA methylation regulation in Glioblastoma Multiforme illustrate the validity and advantage of our method.

Epigenetics Posters - Thursday

PB2435. High-resolution analysis identifies ancestry-specific chromatin 3D interactions

Authors:

W. Xu^{1,2}, L. Wang^{3,4}, X. Liu¹, O. Oron³, F. Rajabli^{3,4}, L. Lu¹, D. Dykxhoorn^{3,4}, A. Griswold^{3,4}, M. Pericak-Vance^{3,4}, J. Young^{3,4}, F. Jin^{1,5}, J. Vance^{3,4}; ¹Dept. of Genetics and Genome Sci., Sch. of Med., Case Western Reserve Univ., Cleveland, OH, ²The BioMed. Sci. Training Program (BSTP), Sch. of Med., Case Western Reserve Univ., Cleveland, OH, ³John P. Hussman Inst. for Human Genomics, Univ. of Miami Miller Sch. of Med., Miami, FL, ⁴John T. Macdonald Fndn. Dept. of Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL, ⁵Dept. of Computer and Data Sci., Dept. of Population and Quantitative Hlth.Sci., Case Comprehensive Cancer Ctr., Case Western Reserve Univ., Cleveland, OH

Abstract Body:

Introduction: Alzheimer's disease (AD) has ancestry-specific risk. We and others have shown that the local ancestry (LA) block surrounding *ApoE* confers differential genetic risk for *ApoE* ε4 carriers in Non-Hispanic Whites (NHW) and African American (AA). However, the mechanism underlying the ancestry-specific AD risk remains unclear. 3D genome architecture plays an important role in transcriptional regulation via long-range chromatin looping. Genome-wide Hi-C analyses have revealed highly dynamic genome architecture during development and disease progression. The variation of 3D genome architecture on different ancestry background has not been characterized, especially at the level of chromatin loops, which are most likely representing enhancer-promoter interactions. Mapping chromatin loop is a major challenge in the 3D genome research. Due to the complex bias structure and severe data sparsity, it is generally believed that multibillion-read sequencing depth is required for kilobase (kb)-resolution loop calling. **We recently developed *DeepLoop* which allows robust mapping of chromatin loops with <10-fold Hi-C reads.** **Methods:** Chromatin Hi-C libraries were constructed with 4-cutter enzyme on astrocytes derived from induced pluripotent stem cells (iPSCs) from four individuals with different ancestry composition. *DeepLoop* was used to call chromatin loops at 5kb-resolution. LA at each locus across the genome was calculated using RFMix with SNP-array data. A reference panel with diverse populations from 1000 Genomes was used for European (EU), African (AF) and Amerindian (AI) ancestries. **Results:** On average, ~500 million pair-end reads were obtained for each library. Among the four samples, the proportion of AF ancestry (AF%), EU ancestry (EU%), and AI ancestry (AI%) ranges from 0.3% to 14.9%, 72.5% to 99.7%, and 0% to 13.6%, respectively. In 5 out of 6 pair-wise comparisons, we detected a significant enrichment of sample-specific chromatin loops in regions with different LA ($P < 0.05$, Fisher's exact test; two-side). Some genes residing in these ancestry-enriched chromatin loops are relevant to brain functions, e.g. *SLC1A5*. **Conclusion:** These early results revealed that genome architecture can be variable between different ancestry backgrounds, suggesting that LA is a major source for differential chromatin loops between individuals. Future efforts will explore if and how such differences may contribute to ancestry-specific AD risk.

Epigenetics Posters - Wednesday

PB2436. Human epi- and transcriptomic trajectories in the postprandial state.

Authors:

R. Costeira¹, L. D. Ruiz², L. Sinke³, C. Christiansen¹, Y. Raza¹, M. Tomlinson¹, B. Heijmans³, E. Slagboom³, K. Small¹, M. Waldenberger⁴, S. Berry¹, J. M. Ordovas⁵, J. T. Bell¹; ¹King's Coll. London, London, United Kingdom, ²IMDEA Food Inst., Madrid, Spain, ³Leiden Univ. Med. Ctr., Leiden, Netherlands, ⁴Helmholtz Zentrum München, Munich, Germany, ⁵Tufts Univ., Boston, MA

Abstract Body:

Background and objectives: The postprandial state, i.e., the period following a meal, is characterized by a highly individualized response to food that remains little explored at the molecular level. DNA methylation (DNAm) is a key regulator of gene function and has the potential to explain some of the inter-individual variation observed postprandially through changes in the activation and expression of genes. Within the JPI-DIMENSION consortium, we aimed to characterise the changing epi- and transcriptomic postprandial landscapes and elucidate the metabolic flexibility of humans in response to food.

Methods: To do this, whole blood EPIC DNAm profiles were obtained for altogether 270 participants of the ZOE PREDICT 1 (n = 120 individuals) and CORDIOPREV (n = 150 individuals) studies at three and two timepoints, respectively. Time-matched whole blood transcriptomes were further obtained for 50 participants of ZOE PREDICT 1 using Illumina RNA sequencing technologies. Epi- and transcriptome-wide association analyses were carried at >756,000 CpG-sites and >23,000 genes. First, glycemic (t_{30m}) and lipemic (t_{4h}) methylation and gene expression level changes were compared to fasting (t₀) in ZOE PREDICT 1. Second, peak lipemia DNAm level changes were meta-analysed between the ZOE PREDICT 1 and CORDIOPREV studies. Linear mixed effects models were used, and results are adjusted for age, sex, BMI, smoking, blood cell type proportions, technical and cohort-specific variables (FDR = 10%).

Results: Overall, 19 differentially methylated positions (DMPs) showed postprandial trajectory changes in ZOE PREDICT 1. The peak signal was in the *CAMTA1* gene, with decreased methylation at 30m after test meal (cg23021268; $b=0.311\pm0.050$, $p=2.40E-08$). ZOE PREDICT 1 and CORDIOPREV meta-analysis identified 125 DMPs across 94 genes that changed postprandially at 4h, including in the cholesterol efflux gene *ABCG1* (cg27518648: $b=0.078\pm0.016$, $p=1.11E-06$). Pathway analysis identified enrichment in the PKA pathway, as well as in pathways of cardiac and metabolic signaling. Preliminary transcriptomic results identified gene expression changes in ZOE PREDICT 1 over the 3 timepoints analysed. Ongoing analyses focus on exploring the gene expression data in the context of linking specific expression changes to the DNAm trajectories observed.

Conclusions: In summary, we observe significant changes in DNAm and gene expression at target genomic regions postprandially. Signals were observed in metabolically relevant genes that help elucidating the link between the individual response to food and the development of cardiovascular disease.

Epigenetics Posters - Thursday

PB2437. Human gene regulatory evolution is driven by divergence in both *cis* and *trans*.

Authors:

T. Hansen¹, S. Fong², J. Capra², E. Hodges¹; ¹Vanderbilt Univ., Nashville, TN, ²Univ. of California San Francisco, San Francisco, CA

Abstract Body:

Phenotypic differences between closely related species are frequently driven by variation in gene expression patterns. At the transcriptional level, regulatory differences that drive differential gene expression can occur in *cis*-, that is mutations that affect DNA regulatory element sequence, or in *trans*-, mutations that affect the cellular environment (e.g., transcription factor expression levels). However, to date studies investigating differential gene regulatory function typically have not been able to distinguish the effects of *cis*- and *trans*-regulation. Since a *trans*-effect can offset a *cis*-effect and visa-versa, it is critical to analyze the two effects independently to understand the mode of gene regulatory evolution. To address this challenge, we applied ATAC-STARR-seq to investigate divergent enhancer activity, chromatin accessibility, and transcription factor (TF) binding between human and rhesus macaque lymphoblastoid cell lines (LCLs). The modular design of the ATAC-STARR-seq assay allows us to decouple each species' genome sequence from its cellular environment and test the activity of all accessible human and macaque sequences in both human and macaque cellular environments. This enables global identification of species-specific regulatory regions driven exclusively by either *cis*- or *trans*-regulatory differences.

We discovered that *cis* and *trans* effects on gene regulatory activity occur at similar frequencies among 29,531 shared accessible regions. This strongly contrasts with the current presumption based on small-scale studies that the majority of gene regulatory divergence occurs in *cis*. Furthermore, we find that *cis* and *trans* effects most often affect the same regulatory element, suggesting they cooperate to drive most of the divergent gene regulation between human and macaque LCLs. Leveraging TF footprinting, we observe that ~57% of human specific *trans* effects are explained by differential expression of key TFs, including IRF family members and NF- κ B, which alters their availability in the respective cellular environments. By contrast, *cis* effects are enriched for regions with accelerated substitution rates characteristic of positive selection, indicating DNA sequence divergence at those loci is functionally important for driving human evolution.

Altogether, our high-resolution genome-wide study reveals that evolutionary divergence in the *trans*-regulatory environment drives a substantial degree of the gene regulatory differences between human and macaque LCLs, and these observations highlight an underappreciated role for *trans*-regulatory divergence in human evolution.

Epigenetics Posters - Wednesday

PB2438. Identification of diagnostic DNA methylation epesignatures associated with large structural chromosomal variations in patients with neurodevelopmental disorders.

Authors:

K. Rooney¹, R. Relator¹, M. Levy¹, H. McConkey¹, J. Kerkhof², M. Alders³, P. Henneman⁴, G. Cappuccio⁵, N. Brunetti-Pierra⁵, M. Niceta⁶, M. Tartaglia⁶, P. Prontera⁷, G. Merla⁸, A. Brusco⁹, G. B. Ferrero⁹, M. Tedder¹⁰, B. DuPont¹⁰, B. Sadikovic¹; ¹London Hlth.Sci. Ctr., London, ON, Canada, ²London Hlth.Sci. Ctr., London, ON, Canada, ³Amsterdam UMC, Amsterdam, Netherlands, ⁴Univ. of Amsterdam, Academic Med. Ctr., Amsterdam, Netherlands, ⁵Federico II Univ., Naples, Italy, ⁶Bambino Gesù Children's Hosp., Rome, Italy, ⁷Univ. and Hosp. of Perugia, Perugia, Italy, ⁸Univ. of Naples Federico II, Naples, Italy, ⁹Univ. of Torino, Torino, Italy, ¹⁰Greenwood Genetic Ctr., Greenwood, SC

Abstract Body:

Background: An expanding number of neurodevelopmental disorders (NDDs), associated with genetic alterations, have demonstrated distinct changes in the DNA methylation profile. These epigenetic changes, called epesignatures, are highly consistent and specific amongst individuals affected by the same underlying genetic aberration. This study assesses DNA methylation profiles in cohorts of individuals with more than 20 common recurrent copy number variants (CNVs) associated with genomic disorders. **Methods:** Genome-wide DNA methylation analysis was performed on peripheral blood samples from cohorts of patients with known CNV disorders using the Illumina 850K BeadChip array. Each cohort was assessed for methylation changes against a subset of age and sex matched controls. Methylation levels for each CpG probe were measured and 100-500 differentially methylated probes were used to define the disorder epesignature. The robustness and sensitivity of the selected probes were tested using clustering and cross validation methods. A support vector machine learning model was constructed to confirm the specificity for the epesignature to classify each disorder. **Results:** Patients with CNVs, associated with specific genomic disorders, exhibit distinct clinical epesignatures that can be differentiated from each other and from other NDDs with established epesignatures. These epesignatures are highly sensitive and specific biomarkers that can be used as a clinical diagnostic screening test. Assessment of breakpoints provides evidence of epigenetic regulatory genes and regions in some of the CNV disorders. **Conclusion:** We mapped epesignatures in CNV disorders that provide a specific, differentiating biomarker for these conditions. These epesignatures have the potential to improve the diagnostic yield of clinical testing in patients with NDDs, and future work to assess molecular insights into disease pathology through differentially methylated regions is underway.

Epigenetics Posters - Thursday

PB2439. Identifying functional interactors of conserved meiotic histone reader ZCWPW1

Authors:

D. Bazzano¹, W. Xie¹, C. Zuckerman¹, J. Nandakumar¹, F. Cole², S. Hammoud¹; ¹Univ. of Michigan, Ann Arbor, MI, ²MD Anderson Cancer Ctr., Univ. of Texas, Houston, TX

Abstract Body:

Spermatogenesis is a highly regulated process necessary for the generation of haploid gametes that transmit genetic and epigenetic information from one generation to the next. Mature spermatid differentiation relies on a specialized form of cell division called meiosis, where homologous chromosomes from a diploid genome pair together, recombine genetic information through induced DNA double-strand breaks (DSBs) and separate into genetically distinct haploid daughter cells. Homologous recombination is tightly controlled, since defects in the DSB repair process result in de novo mutations, large structural variations and aneuploidies. The sites of homologous recombination in mammals, called crossovers, are determined by PRDM9, a zinc-finger H3K4/K36 methyltransferase. Although PRDM9 is recruited to thousands of sites in the human and mouse genome, only 200-300 sites recruit downstream DSB repair factors and ~20 of these sites are resolved as crossovers. Currently, the mechanism that link sites of H3K4/K36 trimethylation with recombination is largely unknown. Preliminary data from our lab and others has shown that a H3K4/K36 reader expressed in meiotic prophase, known as ZCWPW1, has defects in homologous chromosome pairing and recombination. Despite these characterizations, the mechanism of homolog engagement and DSB repair promoted by ZCWPW1 remains unsolved. Here, we propose that ZCWPW1 can mediate pairing by reducing the homologue search grid in the nucleus and bridging homologous chromosomes together prior to DSB formation through self-interaction. Another non-mutually exclusive possibility is that ZCWPW1 interacts with structural components or DSB repair factors to promote crossover formation and stabilize interhomolog contacts. To test these ideas, we developed genetic and biochemical approaches to determine whether ZCWPW1 can interact with itself and/or other proteins involved in meiotic DSB repair. These approaches include co-immunoprecipitation experiments in HEK293T cells, yeast two-hybrid assay and purification of recombinant protein to perform IP pull down experiments and SEC-MALS. Together, these experiments will provide new insight into the role of ZCWPW1 during crossover formation and provide further clarity into the mechanisms of homolog pairing and engagement in meiosis. The knowledge gained from this project will further characterize the conserved epigenetic mechanisms underlying heredity, chromosome segregation and genomic fidelity in the germline.

Epigenetics Posters - Wednesday

PB2440. Immune cell-type level epigenome-wide association analysis on chronic HIV infection highlights hallmark genes for HIV pathogenesis and cancer

Authors:

X. Zhang¹, Y. Hu², A. Justice³, C. Yan², B. Aouizerat⁴, K. Xu⁵; ¹Yale Univ., New Haven, CT, ²NCI, Rockville, MD, ³Yale Sch. of Medicine, New Haven, CT, ⁴, New York Univ., New York, NY, ⁵Yale Sch. Med., New Haven, CT

Abstract Body:

Background: Previous epigenome-wide association studies (EWAS) have identified CpG sites associated with chronic HIV infection from the heterogeneous blood cells or from CD4+ T cells, which offer the limited knowledge of cell type-specific methylation aberrant in other immune cells for HIV infection. **Methods:** Applying a deconvolution method that is validated by capture methylation sequencing, we conducted a cell-type based EWAS and identified DNA methylation aberrant for chronic HIV infection among five immune cell types in blood: CD4+, CD8+, B, Natural Killer (NK), and Monocytes in a cohort: Veteran Aging Cohort Study (VACS) (N=718). The VACS cohort included HIV-negative and HIV-positive participants who were on antiviral therapy. **Results:** A cell-type level EWAS revealed the distinct patterns of HIV-associated methylation CpG sites with 67.9% of CpG sites unique to individual cell type (False discovery rate, FDR <0.05). We identified 2,212 CpG sites in CD4+ T cells and 21 CpG sites in monocytes for HIV infection. One of the top significant CpG, cg16411857, on *NLRC5* showed a large effect size in CD4+, B, and monocytes. Significant CpG sites were located on the genes that are involved in immunity and HIV pathogenesis (e.g. *RUNX3* in CD4+, *STAT3* in B, *IL7* in NK, *LCK* in monocyte). More importantly, HIV-associated CpG sites were overrepresented on hallmark genes involved in cancer pathology (q<0.05) (e.g. *BCL* family, *STAT3*, *PRDM16*, *ESR1*, *DNMT3A*). HIV-associated CpG sites are enriched on the pathways involved in HIV pathogenesis and carcinogenesis such as Kras-signaling and apoptotic pathways. **Conclusions:** Our findings provide new insights on cell type specific epigenetic modifications in the HIV infected host genome that support a notion of pathogen-induced epigenetic cancerization and further elucidate mechanisms of HIV and its comorbid with cancer.

Epigenetics Posters - Thursday

PB2441*. Investigating aberrant DNA methylation in pediatric epilepsies

Authors:

C. LaFlamme¹, E. Almanza Fuerte¹, S. Russ-Hall², A. Schneider², University of Washington Center for Mendelian Genomics, D. Miller³, M. Galey³, Z. Wang¹, B. Sadikovic⁴, L. Sadleir⁵, S. Berkovic², I. Scheffer², H. Mefford¹; ¹St. Jude Children's Res. Hosp., Memphis, TN, ²Univ. of Melbourne, Melbourne, Australia, ³Univ. of Washington, Seattle, WA, ⁴LHSC, London, ON, Canada, ⁵Univ. of Otago, Dunedin, New Zealand

Abstract Body:

Developmental and epileptic encephalopathies (DEEs) are a group of disorders characterized by drug-resistant seizures and developmental slowing or regression with epileptiform activity on EEG. Advances in sequencing technology have enabled Mendelian genetic diagnosis in ~50% of patients with the potential for developing targeted therapies. Those without known pathogenic DNA variants are deemed “unsolved.” DNA methylation is an important epigenetic modification implicated in various neurodevelopmental disorders, such as Fragile X syndrome. Rare differentially methylated regions (DMRs) affect gene expression and can be influenced by DNA sequence variations, such as GC-rich repeat expansions impossible to detect by standard sequencing modalities, but have not been studied in DEEs. Additionally, as a part of EpiSign analysis, distinct genome-wide “episignatures” have been derived for ~120 monogenic neurodevelopmental disorders, including >20 genetic epilepsy syndromes and DEEs. Episignatures indicate the presence of a pathogenic variant in a specific gene. Thus, a patient with unsolved DEE could display an episignature informing the gene to examine for missed or misinterpreted coding and noncoding variants. The diagnostic utility of episignature analysis for unsolved DEE is not known. We hypothesize that DNA methylation analysis can be used to uncover novel causes of DEE by (i) investigating rare DMRs as an alternative disease mechanism and (ii) using recently established methylation episignatures of monogenic disorders to inform the identification of previously hidden, novel pathogenic variants. We generated Illumina EPIC methylation array data for >400 patients with unsolved DEEs, identified rare DMRs using a robust outlier approach, and performed episignature analysis. We have validated 15 DMRs to date using targeted bisulfite sequencing and nanopore long-read sequencing. We then identified potential underlying DNA defects of DMRs and candidate pathogenic variants associated with episignatures using a combination of short and long-read sequencing. We find that patients with unsolved DEEs harbor rare outlier DMRs and episignatures that inform potentially disease causative DNA variants. To investigate the effects of DMRs and candidate pathogenic variants on gene expression, we will perform RNA-seq of patient-derived or genetically engineered cell lines. Our findings will provide insights into novel epigenetic mechanisms underlying DEEs, facilitate molecular diagnoses of patients with unsolved DEE, and potentially lead to improved diagnostics and the discovery of novel therapeutic targets for these devastating disorders.

Epigenetics Posters - Wednesday

PB2442. Investigation of the effects of alcohol exposure on the chromatin binding and localization of cohesin and CTCF.

Authors:

C. Cummings, M. Rowley; Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract Body:

Alcohol exposure is associated with a wide array of medical problems, including both acquired and congenital phenotypes. Examples of these phenotypes include increased incidence of multiple cancer subtypes and diagnoses under the fetal alcohol spectrum disorders umbrella. While much work has attempted to elucidate the downstream molecular mechanisms induced by ethanol exposure, there are large gaps in our understanding. One promising question is how ethanol exposure affects epigenetics, including the impact of ethanol on DNA methylation, histone modifications, and chromatin organization. The three-dimensional structure of chromatin is formed by multiple co-occurring levels of genome organization and is impacted by architectural proteins and chromatin modifications. Patients with genetic defects in the architectural proteins CTCF or cohesin present with overlapping syndromes characterized primarily by a neurodevelopmental disorder with growth defects and to a lesser degree multiple congenital anomalies. In cell culture models of ethanol exposure, we performed ChIP-Seq experiments and found alterations to the chromatin binding of cohesin. This indicates alteration of insulator proteins and may suggest changes to the regional chromatin organization and effects on local gene regulation. In summary, ethanol treatment alters the localization of the architectural protein cohesin on chromatin. This likely influences nearby chromatin organization and may correspond to the observed downstream transcription changes known to be induced by ethanol treatment. We are currently evaluating the dose sensitivity and persistence of these observed effects, and their molecular mediators. Together, this data reveals a previously unknown mechanistic-functional explanation of ethanol exposure phenotypes, indicating that the phenotypes may be due in part to disrupted chromatin organization. Intriguingly, this work may provide a link between the well-described cohesinopathy phenotypes and fetal alcohol spectrum disorders, explaining their phenotypic similarities.

Epigenetics Posters - Thursday

PB2443. Investigation of Tissue Level of Molecular Pathways Effective in Vascular Calcification at Chronic Renal Insufficiency Patients

Authors:

E. Arslan, P. Ata; Marmara Üniversitesi, Istanbul, Turkey

Abstract Body:

Objective: Chronic renal insufficiency (CRI) is a public problem affecting more than two million people. Vascular calcification (VC), emerging from pathological mineral deposition at medial and intimal parts of the vessels, affects morbidity and mortality. Although it is an end result of normal aging process, VC emerges from pathological processes effective in CRI. **Material and Methods:** Herein we investigated hsa-miR-30a-5p and hsa-miR-223-3p with RNA PCR kit at waste vascular tissue taken from 37 patients during renal transplantation operation. For expression levels of target miRNA analysis qRT-PCR technique was used in Biorad Real time PCR platform. **Results:** There were 8 females and 29 male patients with an average age of 36 +/- 14 years of age. For normalization of expression levels hsa-miR-145-5p was used as internal control which is expressed at vascular tissue at physiological condition. **Conclusion:** Hsa-miR-223-3p is an important miRNA at inhibition of (*IL-6*)/*STAT3* signaling pathway that is effective in induction of vascular calcification. Hsa-miR-30a-5p targeting *RUNX2* signalling effects osteoblastic differentiation. We have detected that both Hsa-miR-223-3p and Hsa-miR-30a-5p expressions were increased in vascular tissue. **Keywords:** Chronic renal insufficiency, vascular calcification, epigenetic control of gene expression.

Epigenetics Posters - Wednesday

PB2444. KDM6A/B inhibition rescues an osteoblast phenotype and altered gene expression in a novel mouse model of Weaver Syndrome with skeletal overgrowth.

Authors:

J. Fahrner¹, W-Y. Lin¹, L. Boukas², C. W. Gao³, P. Kushwaha¹, B. Spiegelberg¹, H. T. Bjornsson⁴, R. C. Riddle¹, K. D. Hansen⁵; ¹Johns Hopkins Sch. of Med., Baltimore, MD, ²Johns Hopkins Univ., Baltimore, MD, ³Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ⁴Univ. of Iceland, Reykjavik, Iceland, ⁵Johns Hopkins Univ, Baltimore, MD

Abstract Body:

Mendelian disorders of the epigenetic machinery (MDEMs) result from germ-line mutations in genes encoding chromatin modifying machinery. They are characterized by intellectual disability and abnormal growth, which may manifest as growth retardation or overgrowth. Weaver syndrome (WS) is a classic overgrowth MDEM and exhibits striking tall stature, mild to moderate intellectual disability, and characteristic facial features. WS results from heterozygous, typically *de novo* variants in *EZH2*, which encodes a histone methyltransferase writer that methylates lysine 27 on histone H3 (H3K27me) as part of the Polycomb repressive complex 2 (PRC2). Most pathogenic variants in *EZH2* are hypomorphic missense changes. Others' work revealed that homozygous ablation of *Ezh2* in mice led to embryonic lethality, whereas heterozygotes had no apparent phenotype. Conditional models have not fully recapitulated the WS phenotype; however, a recent constitutional knock-in mouse model exhibited mild overgrowth. We used CRISPR gene editing and homology-directed repair to generate a mouse model of WS with the most common causative variant, R684C. WS mice (*Ezh2*^{R684C/+}) exhibit overgrowth, reminiscent of the human phenotype. Specifically, high-resolution micro-CT of long bones reveals skeletal overgrowth, and *in vivo* labeling reveals increased osteoblast activity in *Ezh2*^{R684C/+} compared to *Ezh2*^{+/+}. Staining of osteoblasts after isolation of precursors from mouse bone marrow and differentiation *in vitro* confirms increased bone matrix deposition in *Ezh2*^{R684C/+} compared to *Ezh2*^{+/+}. Genome-wide transcriptome profiling of *Ezh2*^{R684C/+} and *Ezh2*^{+/+} osteoblasts with RNA-seq reveals differential expression of known PRC2 targets. Most notably, we show extensive overexpression of genes involved in bone morphogenetic protein (BMP) signaling, which is important in osteogenesis. *Ezh2*^{R684C/R684C} mouse embryonic fibroblasts show global loss of H3K27me3, confirming the variant as hypomorphic. Notably, counteracting the deficient EZH2 writer of H3K27me3 by inhibiting the opposing eraser using a KDM6A/B inhibitor rescued the osteoblast phenotype and partially corrected expression of select BMP pathway genes. Our findings establish a role for altered BMP signaling and H3K27me3 in WS overgrowth and, importantly, point to KDM6A/B inhibition as a potential targeted treatment for WS. Ongoing ChIP-seq studies will further define the precise role of H3K27me3, and planned preclinical therapeutic trials with this epigenetic drug may pave the way for the first treatment for individuals with WS, as well as for related MDEMs and more common forms of overgrowth.

Epigenetics Posters - Thursday

PB2445. Learning a generalized regulatory model from paired chromatin accessibility and transcriptome

Authors:

L. Xiong^{1,2}, M. Kellis^{1,2}, ¹Computer Sci. and Artificial Intelligence Lab., Massachusetts Inst. of Technology, Cambridge, MA, ²Broad Inst. of MIT and Harvard, Cambridge, MA

Abstract Body:

The fundamental mechanisms that diversify the cells into various cell types and generate cell-type specific gene expression from the same DNA sequences remains unclear. Recent multi-modal single-cell sequencing technologies jointly profiling chromatin accessibility and transcriptome in the same cell enable us to investigate the regulatory mechanisms that link the chromatin change and gene expression in single cell resolution. However, the searching space of the regulatory relationships from millions of chromatin accessible regions and tens of thousands of genes is huge and complex. Hard to distinguish the missing signals in scATAC-seq data between biological ones or technical issues makes the question even more challenging due to the sparse nature of scATAC-seq data. Variations from cell to cell and batch effects existing in both scATAC-seq and scRNA-seq are also troublesome confounding factors. Currently, researchers are calculating gene activity score based-on distance using single-cell ATAC-seq data to predict the gene transcriptome level. However, there is no standard gene regulatory model that adopts all of the genes and situations vary a lot from gene to gene. Here, we developed a deep learning method to by building a generalized regulatory model that decodes the cis-regulatory code of gene expression and allows to accurately predict expression of tens of thousands of genes for each cell using epigenetic information. First, we trained our model on million-sized multi-omics ADRD datasets and a million-sized public scATAC-seq human atlas dataset to obtain a generalized model among multiple cell types across various tissues. Second, we identified cell subpopulations, gene modules and chromatin accessible elements modules and identified their connections on the module level by clustering and visualized the learned representations for cell, gene and chromatin accessible regions in the UMAP embeddings. Third, we tried to interpret the cis-regulatory code of each gene by identify the most contributing regulatory elements in the gene neighborhood, and constructed a regulatory network based-on these regulatory elements and their target genes. Fourth, we expected to predict the outcome of the in silico perturbation based-on the regulatory network and validate them with perturbation experiments.

Epigenetics Posters - Wednesday

PB2446. Learning the cis and trans sequence features of gene regulatory divergence between human and rhesus macaque

Authors:

S. Fong¹, T. Hansen¹, J. Capra², E. Hodges³; ¹Vanderbilt Univ., Nashville, TN, ²Univ. of California San Francisco, San Francisco, CA, ³Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract Body:

Motivation: The evolution of non-coding gene regulatory elements is a major driver of species divergence, yet the mechanisms underlying this evolution genome-wide are poorly understood. Recently, we systematically categorized gene regulatory activity divergence between closely related species due to *cis* changes—mutations that directly affect the regulatory potential of an individual element and the expression of its target gene—or in *trans*—changes that alter the cellular environment (e.g., transcription factor abundance) and expression of multiple genes. We found that divergent elements commonly require both species-specific *cis*- and *trans*-variation for activity in human and rhesus macaque lymphoblastoid cell models. However, the underlying sequence determinants that produce species-specific *cis*- and *trans*-activity are unknown.

Results: Here, we investigate sequence features that distinguish human-specific *cis*- from *trans*- gene regulatory activity generated by massively parallel ATAC-STARR-seq reporter assays. First, we develop two supervised machine learning classifiers to separately model the sequence features underlying *cis* or *trans* gene regulatory activity divergence between humans and rhesus macaques, and validate model predictions with differential transcription factor footprinting analyses. Then, we apply these evolutionary classifiers to investigate elements with both phenotypic *cis*- and *trans*- divergent features and dissect the contributions of *cis*-like or *trans*-like sequence features to divergent activity.

Conclusions: Our work rigorously models the sequence features and associated mechanisms underlying gene regulatory divergence between human and macaque genome-wide. Highlighting the sensitivity of these sequences to both genetic and cellular environment changes, we provide valuable insights into the molecular mechanisms that have produced species-specific gene regulatory activity and have contributed to the divergence of humans and rhesus macaques.

Epigenetics Posters - Thursday

PB2447. Linking genetic variants associated with gluteofemoral fat storage to determine their role in adipogenesis

Authors:

J. Belanich¹, C. Tomaselli², A. Hecq³, M. G. Urena¹, B. Emanuelli¹, T. O. Kilpeläinen¹; ¹Univ. of Copenhagen, København, Denmark, ²Pompeu Fabra Univ., Barcelona, Spain, ³Univ. of Mons, Mons, Belgium

Abstract Body:

While obesity as a whole is linked to an increased risk of type 2 diabetes, this blurs and disregards individual body fat distribution, which plays a role in individual risk and health outcomes. By examining the physical location of adipose tissue, gluteofemoral fat has been found to be protective, preventing fat deposition in critical areas such as visceral, intra-hepatic, and intra-pancreatic fat depots. Additionally, there have been several studies that have indicated an inverted linkage; those individuals who express decreased levels of gluteofemoral fat show increased insulin resistance. With this, we aim to identify and experimentally follow up on SNPs in order to explain the mechanistic actions behind the protective gluteofemoral fat. The overall goal is to further understand and parse the mechanisms underlying lower gluteofemoral fat and higher risk of cardiometabolic disease, independent of BMI. We took forward all genome-wide significant SNPs associated with WHR or WHR adjusted for BMI in the largest GWAS published to date, and identified SNPs that are associated with lower BMI but higher WHR. We prioritized candidate causal genes in the corresponding genetic regions, and assessed the genes' roles in differentiation and maturation of mouse and human preadipocytes by microscopy and quantitative methods. Altogether 252 independent loci showed an association with lower BMI but higher WHR. We prioritized six candidate causal genes for initial perturbation studies using siRNA. The studies showed an inhibition of adipogenesis for four of the six tested genes: ADAMTS9, ABHD15, EMILIN2 and COL18A1. Following this, small interfering RNA (siRNAs) were used in mouse and human pre-adipocyte cultures to knockdown the expression of the discovered target genes. The cultures were differentiated into white adipocytes, and were examined at various stages of differentiation in order to better examine the genes' roles in growth, lipid deposition, and how they affect the expression of other genes. In further experiments, we are determining the effects on lipid metabolism and insulin signaling through downregulation and dCas9 overexpression, and will examine the resulting expression profile data. Through this, we hope to explain the paradoxical findings on genetic variants associated with a leaner body weight yet an unfavorable body fat distribution and cardiometabolic risk profile, and begin to identify new targets for drug development and treatments.

Epigenetics Posters - Wednesday

PB2448*. Loss of DNMT3A or TET2 activity in stimulated macrophages alters transcription factor binding and enhances inflammatory gene expression.

Authors:

K. B. Rodrigues, J. Gopakumar, M. Maurer, Z. Weng, T. Eulalio, S. Mitchell, D. Nachun, D. Estrada, T. Mazumder, L. Ma, S. Montgomery, S. Jaiswal; Stanford Univ., Stanford, CA

Abstract Body:

A source of increased age-associated inflammation is Clonal Hematopoiesis of Indeterminate Potential (CHIP). CHIP occurs when a somatic mutation arises in a bone marrow stem cell and promotes clonal expansion of that stem cell and its progeny. Furthermore, the function of macrophages derived from these bone marrow stem cells is thought to be affected by CHIP mutations, possibly explaining the increased risk of cardiovascular diseases in people with CHIP. Strangely, the mutations that cause CHIP most frequently occur in genes with opposite function: loss-of-function mutations in *DNMT3A* and *TET2*. These enzymes methylate and demethylate DNA, respectively. To evaluate how DNMT3A and TET2 contribute to inflammatory responses in the context of CHIP, we exposed bone marrow derived macrophages from *Dnmt3a* KO, *Tet2* KO, and wild type (WT) control mice to a low dose of the inflammatory stimuli lipopolysaccharide (LPS). We then measured gene responses with RNA-seq across 12 time points from 0 to 24 hours, paired with ATAC-seq and whole genome methyl-seq for multiple time points. A key subset of inflammatory genes (including *Il1b*, *Il6*, and *Il23a*) were expressed around twice that of WT in both KOs by 2 hours of stimulation, despite the opposing activity of the enzymes on DNA methylation. Further, DNA methylation changed in WT upon stimulation in cis-regulatory regions of many of these inflammatory genes. Additionally, KO of *Dnmt3a* or *Tet2* affected DNA methylation both before and during stimulation. DNA footprinting and motif enrichment analysis from ATAC-seq similarly showed that the binding of transcription factors before and during stimulation was affected by loss of either enzyme. This supports a mechanism whereby the activity of DNMT3a and TET2 alters DNA methylation, modifying binding of nearby transcription factors. Our integrative multi-omic analysis demonstrates how DNMT3A and TET2 modulate DNA methylation to limit inflammatory gene expression in healthy macrophages. Targeting these sites of inflammation-associated DNA methylation defects is a suggested therapeutic avenue for blocking the pathogenic role of CHIP for many inflammatory diseases of aging.

Epigenetics Posters - Thursday

PB2449*. Mapping chromatin accessibility QTL in 138 liver tissue samples identifies coordinated regulation, links regulatory elements to genes, and predicts mechanisms at GWAS loci.

Authors:

K. Currin¹, H. J. Perrin¹, A. S. Etheridge^{1,2}, S. Vadlamudi¹, A. A. Alkhawaja¹, K. A. Broadaway¹, J. D. Rosen¹, A. S. Chaudhry³, P. J. Gallins⁴, Y. Zhou⁴, F. Wright⁴, E. G. Schuetz³, F. Innocenti⁵, K. L. Mohlke¹; ¹Dept. of Genetics, Univ. of North Carolina, Chapel Hill, NC, ²Eshelman Sch. of Pharmacy and Ctr. for Pharmacogenomics and Individualized Therapy, Univ. of North Carolina, Chapel Hill, NC, ³Dept. of Pharmaceutical Sci., St. Jude Children's Res. Hosp., Memphis, TN, ⁴Bioinformatics Res. Ctr., North Carolina State Univ., Raleigh, NC, ⁵AbbVie Inc., South San Francisco, CA

Abstract Body:

Chromatin accessibility maps have been used to identify regulatory elements and plausible molecular mechanisms at GWAS loci. However, chromatin accessibility maps for many tissues are based on one or a few individuals, which limits identification of regulatory elements that vary across individuals due to genetic and environmental factors. To address this limitation, we profiled chromatin accessibility using ATAC-seq in frozen liver tissue from 138 individuals. We identified 358,304 consensus accessible chromatin regions (peaks) present in at least 5% of individuals. To identify genetic effects on chromatin accessibility, we mapped chromatin accessibility QTL (caQTL) with FastQTL using variants within 100 kb of peak centers and identified 27,289 peaks with a caQTL (caPeaks, FDR<5%). Using colocalization (linkage disequilibrium (LD) $r^2 \geq 0.8$) between caQTL and existing liver eQTL (1,181 individuals), we linked 3,182 caPeaks to 2,032 genes. We also identified dozens of GWAS-caQTL colocalizations, including 122 for total cholesterol, 112 for body mass index, 27 for coronary artery disease, and 45 for type 2 diabetes. We observed widespread coordinated genetic regulation of caPeaks, with 7,988 caPeaks sharing a genetic signal (LD $r^2 \geq 0.9$) with at least one other caPeak. Most of the 2,941 coordinated caPeak sets (69%) consist of 2 peaks, and 238 (8%) of sets contain 5 or more peaks. 607 coordinated caPeak sets contained both promoter and distal peaks, which can be used to link peaks to target genes. A large set of 23 coordinated caPeaks near *SORT1* is associated with rs12740374, previously identified as an eQTL for *SORT1*, *CELSR2*, and *PSRC1*, and a well-characterized GWAS variant for cardiovascular traits. This set of 23 peaks includes a peak at both the *SORT1* and *MYBPHL* promoters, providing evidence for coordinate regulation of multiple peaks and genes at this locus. At another locus, a caQTL signal is colocalized with a GWAS signal for total cholesterol and an eQTL for *MICAL2*. This caQTL signal contains 3 coordinated peaks, including a peak at the *MICAL2* promoter, providing multiple lines of evidence supporting *MICAL2* as the target gene and implicating 3 peaks in its regulation. We and others have previously shown that caQTL often disrupt transcription factor (TF) motifs, suggesting that many caQTL may result from altered TF binding. Our results demonstrate that mapping chromatin accessibility in increased sample sizes identifies widespread genetic effects on chromatin accessibility and that these data can be combined with eQTL and GWAS to predict variants that alter chromatin accessibility leading to effects on gene expression and disease-relevant traits.

Epigenetics Posters - Wednesday

PB2450. Methylation-based machine learning classification of osteoarthritis in the Multicenter Osteoarthritis Study.

Authors:

P. Okoro¹, I. K. Haugen², J. A. Lynch³, M. Nevitt³, C. E. Lewis⁴, J. Torner⁵, D. T. Felson⁶, M. S. Yau^{1,7}; ¹Hebrew SeniorLife - Harvard Med. Sch., Roslindale, MA, ²Ctr. for treatment of Rheumatic and Musculoskeletal Diseases (REMEDY), Diakonhjemmet Hosp., Oslo, Norway, ³Dept. of Epidemiology and Biostatistics, Univ. of California San Francisco, San Francisco, CA, ⁴Dept. of Epidemiology, Univ. of Alabama, Birmingham, AL, ⁵Dept. of Epidemiology, Univ. of Iowa, Iowa City, IA, ⁶Section of Rheumatology, Dept. of Med., Boston Univ. Sch. of Med., Boston, MA, ⁷Div. of Gerontology, Dept. of Med., Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract Body:

Purpose: Osteoarthritis (OA) is the most common form of arthritis and a leading cause of physical disability in older individuals. Currently, there are no biomarkers available to assess OA disease status. This may be attributed to the highly heterogeneous nature of OA and possible underlying OA endotypes. Epigenetic mechanisms like DNA methylation may play an important role in OA pathophysiology. For example, expression of *GDF5*, a well-known OA gene, is modulated by demethylation of the 5' untranslated region. There may be other loci under epigenetic regulation that could provide mechanistic insights into OA. Thus, we aim to build methylation-based joint-specific and multi-joint OA case classifiers using machine learning.

Methods: We analyzed data from a subset of participants in the Multicenter Osteoarthritis Study (MOST) who had bilateral hand and knee x-rays and methylation array data available (n=671). Hand OA was defined as the presence of 1) three or more hand joints with Kellgren-Lawrence (KL) grade ≥ 2 where at least two are part of the same DIP, PIP, or CMC1 joint group, 2) KL grade ≥ 2 in at least one DIP, and 3) bilateral involvement in ≥ 1 of the DIP, PIP, or CMC1 joint groups. Knee OA was defined as KL grade ≥ 2 in one or both knees. Multi-joint OA was defined as the presence of both hand and knee OA. About 23% had hand OA, 25% had knee OA, and 8% had multi-joint OA. DNA methylation was measured on peripheral whole blood with the Illumina Infinium MethylationEPIC 850K array. We removed poor quality probes and conducted quantile normalization. We also removed probes overlapping SNPs, cross-reactive probes, and probes on sex chromosomes, resulting in 774,460 CpG probes. The CpG methylation beta-values were log₂ transformed to M-values for modeling. We developed Elastic net-penalized classification models on the final datasets. Following 80%-training, 20%-testing data split, we carried out 10-fold cross validation on the training data; optimized models were applied on the test data. Model performance was evaluated using receiver operator characteristic area under the curve (AUC-ROC).

Results: The methylation profiles classified OA with AUC-ROC \pm SD as follows: Hand (Train-set=0.57 \pm 0.09; Test-set=0.61), Knee (Train-set=0.52 \pm 0.15; Test-set=0.46), Multi-joint (Train-set=0.64 \pm 0.19; Test-set=0.63).

Conclusion: Our models performed better with multi-joint OA, underscoring its possible systemic etiology, which may be better captured with blood DNA methylation biomarkers. While models performed better with multi-joint joint OA, AUCs were generally low. We plan to further improve and validate these models in other independent cohorts.

Epigenetics Posters - Thursday

PB2451*. MIMOSA: A method for improved methylome imputation increases power to identify CpG site-phenotype associations

Authors:

H. Melton¹, C. Wu¹, Z. Zhang¹, L. Wu²; ¹Florida State Univ., Tallahassee, FL, ²Univ. of Hawaii Cancer Ctr., Honolulu, HI

Abstract Body:

Inter-individual variation in DNA methylation (DNAm) has been linked to many complex traits through conventional epidemiological studies. However, its role in disease mechanisms is not yet well-characterized, primarily due to several common biases encountered in observational studies, including selection bias, unmeasured confounding factors, and reverse causation. One strategy to decrease such limitations is employing methylome-wide association studies (MWAS), one type of instrumental variable regression that involves two steps. First, MWAS builds DNA methylation prediction models for each CpG site using a reference panel with individual-level genetic and DNA methylation data. Second, MWAS tests the association between predicted DNA methylation levels and traits of interest. While appealing, current MWAS methods rely on an individual-level reference panel to build DNAm prediction models, thus limiting statistical power due to the limited sample size of these reference panels. To fill this gap, we introduce the Method to Impute Methylome Obliging Summary-level mQTLs and Annotation information (MIMOSA), a novel MWAS approach that unifies summary-level DNAm reference panels and functional annotation information with trait-specific genome-wide association study (GWAS) results to pinpoint CpG sites that are likely causally associated with the trait of interest. Briefly, we build DNAm imputation models in blood for each CpG site using summary-level mQTL data ($n=27,750$ individuals) from the Genetics of DNA Methylation Consortium (GoDMC). Likely due to sample size limitations in individual-level mQTL data, only imputation models with $R^2 > 0.01$ are typically included in MWAS. In contrast, MIMOSA further includes imputation models with $0.005 < R^2 < 0.01$, corresponding to CpG sites with lower heritability. To build more accurate DNAm imputation models, we further include functional annotations from the Functional Annotation of Variants - Online Resource (FAVOR) as prior information to prioritize genetic variants that are more likely to play a role in DNAm.

Through both simulation studies and analysis of GWAS summary statistics for complex traits, we demonstrate that MIMOSA successfully and substantially increases the accuracy of DNAm imputation in blood and identifies markedly more CpG sites-trait associations than existing methods. To conclude, we present case studies for Alzheimer's Disease and Prostate Cancer and identify 111 and 444 significantly associated CpG sites, respectively.

Epigenetics Posters - Wednesday

PB2452. Multiscale phase separation by explosive percolation with the single chromatin loop resolution

Authors:

D. Plewczynski¹, K. Sengupta¹, A. Agarwal¹, M. Denkiewicz¹, A. Mollah¹, T. Szczepinska¹, R. DSouza², Y. Ruan³; ¹Univ. of Warsaw, Warsaw, mazovia, Poland, ²Dept. of Computer Sci., Univ. of California, Davis, CA, ³The Jackson Lab. for Genomic Med., Farmington, CT

Abstract Body:

We propose models of dynamical human genome folding into hierarchical components in human lymphoblastoid and stem cell lines. Our models are based on explosive percolation theory. The chromosomes are modeled as graphs where CTCF chromatin loops are represented as edges. The folding trajectory is simulated by gradually introducing loops to the graph following various edge addition strategies that are based on topological network properties, chromatin loop frequencies, compartmentalization, or chromatin epigenomic features. Finally, we propose the genome folding model as a biophysical pseudo-time process of chromatin loops formation guided by a single scalar order parameter, which value is calculated by Linear Discriminant Analysis from chromatin features to classify the compartments efficiently. The chromatin phase separation, where fiber is condensing in three-dimensional space into topological domains and compartments, is observed when the critical number of contacts is reached. Overall, our in silico model integrates the high-throughput 3D genome interaction experimental data with the novel theoretical concept of phase separation, which allows us to model event-based time dynamics of chromatin loop formation and folding trajectories. Epigenetics Posters - Thursday

PB2453*. NANOME: A Nextflow pipeline for haplotype-aware allele-specific consensus DNA methylation detection by nanopore long-read sequencing

Authors:

Y. Liu¹, Z. Pan^{1,2}, C. Chatzipantsiou³, T. Slocum¹, L. Karuturi¹, S. Li^{1,2,4}; ¹The Jackson Lab. for Genomic Med., Farmington, CT, ²Uconn Hlth., Farmington, CT, ³Lifebit Biotech Ltd., London, United Kingdom, ⁴Univ. of Connecticut, Storrs, CT

Abstract Body:

Nanopore long-read sequencing expanded the capacity of long-range, single-base, and single-molecule DNA-methylation (DNAm) detection and haplotype-aware allele-specific epigenetic phasing. Previously, we benchmarked and ranked the robustness of seven computational tools for DNAm detection using nanopore sequencing. Overall, the top performers were Megalodon, Nanopolish, DeepSignal, and Guppy. The methylation detection at regions with discordant non-singleton DNAm patterns, intergenic regions, low CG density regions, and repetitive regions exhibited lower performance. The state-of-the-art algorithms for allele-specific methylation detection using nanopore sequencing, e.g., NanomethPhase and PRINCESS, only incorporate on single methylation calling tool - Nanopolish. Thus, it is desirable to further enhance the performance of the DNA methylation calling for long-range epigenetic phasing. Furthermore, long-read sequencing analysis for the mammalian genome requires much more computing resources than next-generation sequencing. Thus, scalability and reproducibility are desirable for nanopore sequencing data analysis. Currently, no pipeline integrates and automates nanopore sequencing DNA methylation detection using cloud computing. Therefore, we developed NANOME, the first Nextflow-based container environment (Docker and Singularity) for consensus DNA methylation detection. We designed a consensus DNA methylation predictive model using XGBoost, a gradient boosting meta-learning algorithm which integrate the output of the top three performers from our benchmarking results. The consensus model improves the F1-score accuracy of DNA methylation detection by 3-5% at single-molecule resolution and enhances the mean square error (MSE) by 9%-13% at single-base resolution. The consensus model also detects more CpGs (1-7%) than other tools. Combing the variants calling by Clair3 and long-read phasing by WhatsHap, NANOME detects the haplotype-aware allele-specific DNA methylation of known imprinting control regions using two normal human B-lymphocyte cell lines (NA12878 and NA19240). Moreover, the pipeline supports tera-base scale data analysis with a single command. NANOME is an open-source, reproducible, and end-to-end pipeline for whole-genome DNAm detection, and is compatible with multiple HPC clusters and cloud OS platforms. A web-based interface is available using Lifebit CloudOS for cloud-based analysis, monitoring processes, and visualizing results from a single command line. NANOME is a complete step forward for DNA methylation detection and long-range epigenetic phasing.

Epigenetics Posters - Wednesday

PB2454. Nascent RNA reveals new links between genetic variation and disease at multiple levels of regulation

Authors:

C. Buen Abad Najjar, B. J. Fair, Y. Zeng, G. Mossian, S. Lozano, J. Staley, Y. I. Li; Univ. of Chicago, Chicago, IL

Abstract Body:

RNA sequencing is the most popular approach to study the effects of genetic variants on gene expression and splicing. Many expression QTLs (eQTLs) have been traced back to changes in chromatin accessibility or promoter activity. However, many regulatory steps between chromatin activation and the final mRNA molecule, as well as a myriad of non-coding RNAs, are not captured by standard sequencing of mature mRNA. Here we use RNA sequencing of nascent RNA (chRNA-seq) on 86 LCL Yoruba cell lines to explore the effect of genetic variation on these previously “invisible” regulatory steps. As expected, we find that chRNA-seq recovers the majority of the eQTLs and splicing QTLs (sQTLs) that are captured by standard RNA-seq (73% and 79%, respectively). In addition, we identified a large set of molQTLs that have not yet been studied. In total, 430 splicing and intron retention QTLs were associated with mature mRNA eQTLs; of these, 126 were exclusively discovered in chRNA-seq. Many of these chRNA-seq specific QTLs are linked to steady-state eQTLs. Some of these effects occur through nonsense-mediated decay, while others are associated with effects in chromatin marks. We also discover hundreds of novel links between genetic variation, expression of non-coding RNAs, including previously unannotated transcripts, and that of protein-coding genes. Using colocalization of molQTLs and GWAS data, we find that many new variants are linked to disease susceptibility. In conclusion, profiling nascent RNA reveals a large class of previously unknown links between genetic variation and disease at multiple levels of regulation.

Epigenetics Posters - Thursday

PB2455. Network analysis across cellular reprogramming states.

Authors:

C. Thangavelu¹, T. M. Norden-Krichmar²; ¹Univ. of California Irvine, Irvine, CA, ²Univ of California Irvine, Irvine, CA

Abstract Body:

Background: Cellular reprogramming is a process in which somatic cells, such as fibroblasts, are converted into pluripotent stem cells (iPSCs). In this study, we integrated time course chromatin accessibility and gene expression data to create time-resolved regulatory networks as cells undergo reprogramming in order to further investigate the regulatory patterns involved. **Methods:** RNA and ATAC-sequencing data that was generated as mouse fibroblasts transitioned to iPSCs was obtained from the publicly available GEO database, GSE101905. Biological replicates were merged and differentially accessible peaks were identified (bedtools2 v2.29.2). For each timepoint, motifs that were the most highly enriched in accessible peaks were identified (HOMER v4.11.1) Pre-processed RNA-seq files were consolidated (TxImport v1.18.0). ATAC-seq SRA files were aligned to the mouse mm10 genome using bowtie2 v2.3.2. ATAC-seq files were sorted and indexed (samtools v1.10) and mitochondrial DNA alignments were excluded (removeChrom Harvard ATAC-seq module). PCR duplicates were then removed (Picard v2.24.1) and mouseENCODE blacklisted genomic regions (Boyle Lab Blacklist.v2) were filtered out (bedtools2 v2.29.2). For each sample, ATAC-seq BAM files were integrated with TPM gene expression files (PECA2 v3.0.1) to generate network files (Cytoscape v3.9.1). **Results:** Timepoint comparison showed key network changes across fibroblast, intermediate, and pluripotent states, including the silencing of the somatic transcription program and the activation of the pluripotency gene regulatory network. These changes were consistent with motif enrichment findings across the different timepoints. **Conclusions:** Integrating transcriptomic and epigenomic data revealed distinct network changes as fibroblasts reprogrammed to a pluripotent state. This integrative analysis expands upon studies that use single data types to construct networks by leveraging multi-omics to gain novel insights into the mechanism of reprogramming.

PB2456. Nucleosome spike-in controls identify best-in-class antibodies and enable reliable next-generation epigenomic mapping approaches

Authors:

N. Husby, L. M. Lewis, K. E. Maier, E. Weinzapfel, I. K. Popova, B. J. Venters, K. Novitzky, D. N. Maryanski, K. L. Rodriguez, M. R. Marunde, C. P. Lin, A. Gladney, R. Watson, Z. B. Gillespie, A. Adeleke, S. Gopinath, H. Willis, L. Sun, M. Cheek, M. J. Meiners, J. R. Bone, M. Cowles, Z-W. Sun, M-C. Keogh; EpiCypher Inc, Durham, NC

Abstract Body:

Mapping the genomic localization of transcriptional signaling proteins and epigenetic modifications is critical to understand chromatin function in basic biology and disease. However, applications in clinical research and other high impact projects have been limited by available technologies, such as ChIP-seq. Despite its widespread use, ChIP-seq suffers from multiple drawbacks, including high cell inputs, low reliability/accuracy, and high costs. The accuracy of antibodies to chromatin targets, particularly histone post-translational modifications (PTMs), is also a major concern. To enable improved ChIP-seq studies, we developed panels of DNA-barcoded recombinant nucleosome spike-in controls, which represent the physiological targets of chromatin mapping assays. We first validated these tools in ChIP-seq by characterizing >400 commercially available histone PTM antibodies, revealing alarming rates of cross-reactivity and poor enrichment (>70%; data available at www.ChromatinAntibodies.com). These problems with ChIP-seq emphasize the broad need for alternative epigenomic mapping methodologies as well as the development of compatible spike-in control standards. The recent development of new immunotethering assays, such as Cleavage Under Targets and Release Using Nuclease (CUT&RUN), deliver high signal-to-noise mapping data using a fraction of the required cells, sequencing depth, and costs compared to ChIP-seq. We show that CUT&RUN enables reliable genomic profiling for a variety of targets, including histone post-translational modifications (PTMs), transcription factors, and traditionally intractable ChIP targets, such as chromatin remodelers. We have also recently begun developing nucleosome spike-in controls for CUT&RUN assays and are using them to identify best-in-class histone PTM antibodies and optimize workflows. This antibody validation effort, coupled with routine use of the spike-in controls for continuous assay monitoring, improves assay rigor and reproducibility to ultimately advance CUT&RUN into the next frontier of genomic mapping research.

Epigenetics Posters - Wednesday

PB2457*. Peripheral immune roles in bipolar disorder: genomic, epigenomic, and phenotypic integration

Authors:

L. Hou¹, Y. Li², Y. Park³, X. Xiong⁴, M. Frye⁵, J. Biernacka⁵, T. Ordog⁵, M. Kellis⁶; ¹MIT & Broad Inst., Cambridge, MA, ²McGill Univ., Montreal, QC, Canada, ³Univ. of British Columbia, Vancouver, BC, Canada, ⁴MIT, Brookline, MA, ⁵Mayo Clinic, Rochester, MN, ⁶MIT, Cambridge, MA

Abstract Body:

Aims: Immune dysfunction is implicated in bipolar disorder (BD) but remains poorly studied. Here, we systematically chart the epigenomic landscape of immune alterations in BD in 188 whole-genome-sequenced and deeply phenotyped individuals, to characterize the genetic variants, epigenetic alterations, and gene-regulatory circuits underlying immune contributors to BD. Methods: We profile and integrate 940 histone mark profiles targeting active (H3K27ac), repressed (H3K27me3), enhancer (H3K4me1), promoter (H3K4me3), and transcribed (H3K36me3) signatures from blood samples (buffy coat) of 94 BD patients and 94 healthy controls, with whole-genome sequencing and medical records. We annotate 450k cis-regulatory elements (CREs), study their variation across individuals, and cluster BD-informative features into 23 latent factors, used to group individuals into medical-record-informed patient subtypes. We also integrate BD-associated genetic variants, BD-differential CRE activity, chromatin interactions, and expression quantitative trait loci, to recognize BD-associated gene-regulatory circuits. Results: We find 33k CREs in 2257 genes showing significant differences between BD and controls, enriched in inflammation-related processes. Our epigenomics-based clustering reveals 5 patient subgroups correlated with different medical terms: addiction-related, inflammation/infection-enriched, polyethylene-glycol-3350-enriched (constipation) and glucose intolerance-enriched, hypertension-enriched and a final group with no associated medical term. Our gene-regulatory analysis reveals two main biological immune drivers of BD: inflammatory/autophagy-related circuits specific to blood immune cells, and cellular-structural-related circuits shared between blood immune cells and brain neural cells. Conclusion: Our study demonstrates the power of genome-epigenome-phenotype integration, and the important roles that immune cells play in complex mental disorders, with implications for biomarker discovery, disease or treatment progression monitoring, and for potential interventions targeting causal peripheral immune contributors to BD.

Epigenetics Posters - Thursday

PB2458. Rare inherited Copy Number Variants as genetic modifiers of Developmental Disorders.

Authors:

M. Atzori¹, L. Hannes^{1,2}, E. Pelgrims¹, A. Swillen^{1,2}, A. Sifrim^{1,3}, J. Breckpot^{1,2}, C. Attanasio¹; ¹KU Leuven, Leuven, Belgium, ²Univ. Hosp. Leuven, Leuven, Belgium, ³KU Leuven Inst. for Single Cell Omics (LISCO), Leuven, Belgium

Abstract Body:

Neurodevelopmental disorders (NDDs) are a group of cognitive and/or behavioural conditions that have onset in childhood. They are often characterized by variable phenotype expressivity, incomplete penetrance, and pleiotropy of clinical features. Rare inherited Copy-Number Variants (CNVs), which are usually discarded as putatively pathogenic in the diagnostic set up, could play a pivotal role in the sensitization of the genome and modulation of NDD phenotypic traits. To test this hypothesis, we have designed a family-based study combining transcriptomics and chromatin conformation analyses in carriers and non-carriers. Specifically, we have recruited 6 family trios, for 6 unique rare CNVs that range from 118kb to 1Mb in size and map preferentially to gene-poor regions of the genome ($n \leq 10$). In all families the CNV was transmitted to the affected child by a seemingly healthy parent. EBV-transformed lymphoblastoid cell lines were established for each individual and used for gene expression (RNA-seq) and chromatin structure analysis (Capture Hi-C). To complement these data, whole-genome sequencing (WGS) and deep familial phenotyping are also being performed to identify additional putative NDD causative genetic variants and correlate CNV familial segregation with NDD phenotypes. Our multi-layered analyses are still ongoing, however for our family 2 (F2) the results show that the rare inherited CNV is not associated to other *de novo*, recessive, X-linked or paternally inherited variant or SNV, indels and additional CNVs. Deep phenotyping analysis, instead, indicates that the segregation of the 450kb deletion CNV on chromosome 4 correlates with a progressive aggravation of cognitive and behavioral abilities, with mild symptoms in the carrier parent and severe one in the affected child. At the level of gene expression analyses, our data show differential gene expression for genes within ($n = 1$) and in the flanking regions ($n = 2$) of the CNV. This points toward a role for genes not yet associated to NDDs, such as *ZNF330*, which is disrupted by the deletion, and *SETD7*, which is upstream of the CNV. Finally, Capture Hi-C data seem to reveal a unique chromatin interaction profile in the F2 index patient compared to the parents and additional non-carrier controls. Interestingly, the F2 index patient shows a depletion of interactions at the promoter of *ZNF330* compared to the non-carrier controls which could explain the decreased of expression observed in RNA-seq data. These preliminary results are still subjected to further study. Overall, however, our data on F2 seems to point toward a contributory effect of rare inherited CNVs to DD's phenotypic variability.

Epigenetics Posters - Wednesday

PB2459. Reduced-Representation Methylation Sequencing (RRMS): Oxford Nanopore's alternative to RRBS enables accurate and easy to use methylation calling in CpG islands, shores, shelves, and promotor regions using a MinION flowcell.

Authors:

P. Rescheneder¹, R. Esteban¹, I-A. Vasilescu¹, S. Juul², D. Stoddart¹; ¹Oxford Nanopore Technologies, Oxford, United Kingdom, ²Oxford Nanopore Technologies, New York, NY

Abstract Body:

Nanopore sequencing enables direct detection of methylated cytosines (e.g., at CpG sites). CpG sites frequently occur in clusters called CpG islands (CGI) and >60% of human genes have their promoters embedded within CGIs. Changes in methylation patterns within promoters is associated with changes in gene expression. Reduced representation bisulphite sequencing (RRBS) is a method for methylation analysis without the need to sequence the whole genome but is expensive and time consuming. Furthermore, the complex library preparation method does not specifically target any promoter region. Oxford Nanopore's Adaptive sampling (AS) enables targeting regions of interest (e.g., CGIs) by rejecting off-target reads during sequencing with no requirement for upfront sample manipulation. Here we introduce Reduced-Representation Methylation Sequencing (RRMS). We use AS to target 310 Mb of the human genome that are enriched for CpGs including ~28,000 CpG islands, ~50,600 shores and ~42,700 shelves as well as ~21,600 promotor regions. We performed RRMS on five replicates of a metastatic melanoma cell line and its normal pair and a triple negative breast cancer cell-line pair and compared results to RRBS. RRMS resulted in high confidence methylation calls for 7.3 - 8.5 million CpGs per sample. RRBS in comparison yielded 1.7 - 2.5 high confidence calls per sample. Methylation frequencies called by RRMS and RRBS are highly similar for CpGs covered by both technologies ($R > 0.967$). We show that coverage across target regions is extremely uniform and reproducible with RRMS. As a result, we were able to detect in total 62 mega bases of differentially methylated regions (DMRs) between tumour and normal pairs of which a high proportion overlaps with cancer genes. In comparison RRBS yielded 20 mega bases of DMRs. When investigating the DMRs further we identified the de-novo methyltransferase *DNMT3A* promoter to be methylated in both tumours but not in their normal counter parts. These methyltransferases are essential for establishing and maintaining normal levels of methylation, and so their dysregulation can contribute to cancer development. Finally, we demonstrate that the short rejected reads can be used to call copy-number variation across the whole genome. Furthermore, target regions can easily be extended to specific genes of interest to enable SNP and SV calling if required. Combined with its ease of use and ability to scale to a high number of samples, these characteristics make RRMS perfectly suited to investigate methylation differences in large cohorts as well as provide deeper insight into the mechanisms behind diseases like cancer or monitoring tumour progression.

Epigenetics Posters - Thursday

PB2460. RFX transcription factors regulate genes involved with primary cilium in glioma

Authors:

S. Chua^{1,2}, I. Inoue^{2,1}; ¹The Graduate Univ. for Advanced Studies, Hayama, Japan, ²Natl. Institute of Genetics, Mishima, Japan

Abstract Body:

The brain and spinal tumors derived from the neuron-supporting glial cells called glioma is classified as astrocytoma, oligodendroglioma, and the highest-grade glioblastoma. Glioblastoma cell lines and patient tumors have abnormal primary cilium or completely lack it. The primary cilium is crucial for glioma proliferation and drug sensitivity as it houses the sensors for extracellular signals and regulates signaling pathways. We hypothesize a gene is causing the defect to the primary cilium and identifying this gene may have the potential to restore ciliary function. To investigate, we used publicly available ATAC-sequencing, RNA-sequencing, and clinical data of glioma. We found a ciliary transcription factor Regulatory factor X (RFX) Xbox motif enriched in the active chromatin regions of patients. We also found that *RFX1*, *RFX2*, and *RFX3* are differentially expressed in patients compared to normal brain samples. The abundance of the Xbox motif indicates that the irregularity of *RFX1-3* expression may affect numerous regulated genes, which our gene ontology analysis showed are important for ciliogenesis. Furthermore, we show that *RFX1* and *RFX3* expression are prognostic markers for low-grade glioma and glioblastoma patients, respectively, and can be used to determine high- and low-risk groups. This study provides target genes for manipulating primary cilium formation or length and opens the potential of ciliotherapy as a therapeutic strategy in glioma.

Epigenetics Posters - Wednesday

PB2461*. Role of TET1-mediated epigenetic modulation in Alzheimer's disease

Authors:

M. Armstrong¹, Y. Jin², T. S. Wingo², A. P. Wingo^{2,3}, P. Jin²; ¹Emory University, Atlanta, GA, ²Emory Univ. Sch. of Med., Atlanta, GA, ³Atlanta VA Med. Ctr., Decatur, GA

Abstract Body:

Alzheimer's disease (AD) is a neurodegenerative disease with development and progression influenced by a complex interplay between environmental, epigenetic, and genetic components. DNA methylation (5mC) and hydroxymethylation (5hmC) are DNA modifications that function as tissue-specific and temporal regulators of gene expression. These epigenetic modifications are dynamically regulated by TET family enzymes in response to environmental conditions and provide a link between environmental factors and gene expression. Prior epigenetic studies have identified 5mC and 5hmC changes associated with AD and more recently, rare AD-associated variants have been identified in *TET2* through deep sequencing. We performed *TET1* targeted sequencing on 349 early-onset AD (EOAD) and 940 control samples from the National Alzheimer's Coordinating Center and National Centralized Repository of Alzheimer's Disease and Related Dementias (NACC/NCRAD) cohort. Through gene-wise burden analysis, we identified significant enrichment of rare *TET1* variants associated with AD ($p=0.04$). Using the RUSH Religious Orders Study and Rush Memory and Aging Project (ROSMAP) cohort, we observed a significant increase in expression of *TET2* ($p = 0.0009$), *TREM2* ($p<0.0001$), and a near significant increase in expression of *TET1* ($p=0.0523$) in the AD group. We further profiled 5hmC using a subset of AD and control samples. Analysis of 5hmC identified DhMRs in key genes responsible for regulating the methylome *TET3*, *DNMT3L*, *DNMT3A*, and *MECP2*. To further test the role of Tet1 in AD pathogenesis, we utilized the 5xFAD mouse model with Tet1 KO allele to examine how the loss of Tet1 influences AD pathogenesis. We observed significant changes in behavior, neuropathology, 5hmC, and RNA expression associated with the loss of Tet1. Loss of Tet1 significantly increased amyloid plaque burden in the 5xFAD mouse ($p = 0.0197$) and increased mobility in the Forced-swim assay ($p = 0.0369$). At the molecular level, we observed significant DhMRs enriched in pathways responsible for neuronal projection organization, dendritic spine development and organization, and myelin assembly. RNA-Seq analysis revealed a significant increase in the expression of AD-associated genes such as *Mpeg1*, *Ctsd*, and *Trem2*. Taken together, our results suggest that the TET enzymes responsible for regulating the methylome, in particular TET1, could contribute to the pathogenicity of AD: where the loss of TET function increases AD-associated pathology.

Epigenetics Posters - Thursday

PB2462. Scoring individual cells in snATACseq dataset based on GWAS fine-mapping identifies disease-relevant cell-types in neurodegenerative diseases

Authors:

A. Mohamed¹, B. van de Geijn², J. Blischak³, M. McCarthy³, B. Friedman³, T. Bhangale³; ¹Hoffman La Roche Ltd, Calgary, AB, Canada, ²Genentech, Foster City, CA, ³Genentech, South San Francisco, CA

Abstract Body:

Since most common variants causal to complex traits likely act through their impact on non-coding regulatory elements, approaches for integrating GWAS results with scATAC-seq data offer great potential to provide insights into the underlying cell-types and mechanisms. One technique for such integration, recently described by Yu et al (bioRxiv 2022, SCAVENGE), is to calculate a trait relevance score (TRS) for individual cell based on the overlap of its open chromatin with putative causal variants identified using fine-mapping (FM) of GWAS loci, followed by correlating the scores with cell-types/sub-populations, cell-state, and trajectory. We extend this approach to include signals outside of established GWAS loci using genome-wide FM, substantially boosting the attributable proportion of trait heritability and allowing us to apply TRS to neurodegenerative disease traits (NT).

We fine-mapped summary statistics from the largest GWAS for four NTs: Alzheimer's disease (AD), Parkinson's disease (PD), amyotrophic lateral sclerosis (ALS), and multiple sclerosis (MS). For comparison, we fine-mapped four non-neurological traits (non-NT): RBC distribution width, hypertension, blood glucose, and height. FM was performed in 3Mb tiled windows across the genome to obtain posterior inclusion probabilities (PIP) for all common variants. We obtained snATAC- and snRNA-seq data for 191,890 nuclei from postmortem brains of 12 AD and 11 healthy brains from the work by Morabito et al (Nat Genet 2022) and used the ArchR framework for data processing, analysis and integration. We then used SCAVENGE to obtain TRS based on PIPs and snATAC for each combination of nucleus and trait. snRNA-seq data was used to predict neurons and various glia nuclei based on previously known markers.

We find significantly high TRS ($\Delta \text{TRS} > 1$ and $p \text{ value} < 1E-7$) relative to non-NT traits for: 1. microglia (MG) in MS and AD; 2. Astrocytes (ASC) in AD; 3. Excitatory (EXC) neurons in AD; 4. Oligodendrocytes (ODC) in AD. ASC showed significantly depleted scores for ALS and MS. Similar patterns were observed in analyses stratified by AD cases and controls. Cases had a higher value of TRS compared to controls for subclusters of activated 1. MG TRS across all NT but not in non-NT, 2. ASC and OPC TRS for AD, and 3. ODC for ALS.

The role of microglia in AD and MS has been well described in the past, but our approach was able to capture additional cell-populations which could point to distinct pathways and mechanisms. In summary, our technique systematically integrates genome-wide causal variant information from GWAS with snATAC-data and can offer novel insights into the causal mechanisms.

Epigenetics Posters - Wednesday

PB2463*. Serum miR-451a is up-regulated in sarcopenic patients compared to healthy controls

Authors:

S. Agostini¹, R. Mancuso¹, L. Citterio¹, F. Trecate¹, M. Clerici^{1,2}; ¹IRCCS Don Gnocchi Fndn., Milano, Italy, ²Univ. of Milano, Milan, Italy

Abstract Body:

Sarcopenia is a geriatric syndrome characterized by loss of muscle strength and mass, associated with declining physical function. miRNAs are short molecules of RNA able to modulate gene expression; they can be found in serum and often are useful biomarkers of several diseases. The aim of the present work is to verify if the circulatory miR-451a is differentially expressed in sarcopenic patients compared to age- and sex- matched controls (HC). miR-451a expression was evaluated in serum of 45 severe sarcopenic patients (SPPB<3) 50 mild sarcopenic patients (3≤SPPB≤9) and of 136 HC by droplet digital PCR (ddPCR), an innovative technique that can measure miRNA expression as absolute values and not relative to a reference gene as traditional qPCR. We found that the expression of circulatory miR-451a was significantly higher ($p<0.05$) in serum of severe sarcopenic patients (5.45×10^3 ; 2.85×10^3 - 1.26×10^4 c/ng) and mild sarcopenic patient (6.59×10^4 ; 1.12×10^4 - 2.5×10^5 c/ng) compared of HC (2.31×10^4 ; 1.94×10^3 - 2.01×10^5 c/ng). The severe sarcopenic patients underwent a rehabilitation program of 30-days, and, interestingly, the rehabilitation caused a significantly increase of circulatory miR-451a expression (1.22×10^4 ; 5.15×10^3 - 3.00×10^4 c/ng; $p=0.01$), and, when the difference of the expression before and after rehabilitative treatment (delta) was calculated for miRNAs in relationship with SPPB, a significant negative correlation was found between the delta of miR-451a expression and the delta of SPPB ($p<0.05$). In conclusion our results suggest that the measurement of serum miR-451a can discriminate between HC sarcopenia, both for mild or severe symptoms, and can be a useful biomarker for the rehabilitative outcome for the disease.

Epigenetics Posters - Thursday

PB2464. Simultaneous sequencing of genetics and epigenetics provides opportunities for new biological insights.

Authors:

C. Lumby¹, S. Balasubramanian², P. Burns¹, T. Charlesworth¹, P. Creed¹, J. Füllgrabe¹, W. Gosal¹, J. D. Holbrook¹, D. Morley¹, S. Yu¹; ¹Cambridge Epigenetix, Cambridge, United Kingdom, ²Univ. of Cambridge, Cambridge, United Kingdom

Abstract Body:

There is more to DNA than the genetic alphabet A, C, G and T. Epigenetics is of growing scientific interest and plays a causal role in cell fate, ageing, response to environment and disease development. The ability to accurately determine both genetic and epigenetic letters, and their interaction with each other, is important for deriving new biological insights.

In humans, chemical modification of cytosines represents the most common form of epigenetic letters. Of these, 5-methylcytosine and 5-hydroxymethylcytosine are the most frequent and exhibit distinct biological functions. Current approaches for determining modified cytosines apply next-generation sequencing in combination with a pre-sequencing protocol that differentially converts genetic bases dependent on epigenetic status. However, the ability to discriminate epigenetic state comes at a cost of incomplete genetic determination; inherently, it is impossible to determine full genetics and epigenetics from a system limited to only four states of information. Partial genetic sequencing results in suboptimal read mapping and variant discovery.

An alternative approach is to perform multiple analyses on aliquots from the same sample. However, multiple analyses are not only expensive in terms of sample volume, time and reagent costs, but also yield suboptimal information due to the inherent inaccuracy of data integration and the loss of phasing between genetic and epigenetic letters.

We present a technology, 5-Letter seq, that addresses these challenges by expanding the number of information states in next-generation sequencing from four to sixteen. This is accomplished by utilising pairs of bases (some of which have been differentially converted) to code for each of sixteen states. The expansion of the information content to sixteen states allows direct, digital and phased discrimination of genetic and epigenetic letters on the same read. Sixteen state encoding also enables suppression of sequencing derived artefacts resulting in very high accuracy for both genetics and epigenetics. The generation of phased high-quality variant call data and epigenetic information enables 5L-seq to examine unique biological phenomena. One functionally important example is allele specific methylation, in which differential methylation levels are observed across alleles at a heterozygous variant site. Additionally, our method facilitates the exploration of methylation at CpG sites absent from the reference genome by using variant call data to define sample specific CpGs. Overall, 5L-seq delivers a more comprehensive and accurate genetic and epigenetic assessment than was previously possible.

Epigenetics Posters - Wednesday

PB2465*. Single-cell sequencing links reduced glucose metabolism to cocaine addiction-like behavior in rats

Authors:

J. Zhou¹, G. McVicker², F. Telese¹; ¹Univ. of California San Diego, San Diego, CA, ²Salk Inst. for Biological Studies, La Jolla, CA

Abstract Body:

The United States faces an epidemic of substance use disorders with an alarming increase in overdose deaths involving stimulants, such as cocaine. However, we still have limited knowledge of the cell type-specific mechanisms underlying cocaine addiction. Prior studies examining the effects of cocaine on transcriptional changes in rodent brains primarily analyzed bulk tissues, hindering our understanding of how distinct cell types respond to cocaine. Here we applied single-nucleus RNA-seq (snRNA-seq) and ATAC-seq (snATAC-seq) to the amygdala of heterogeneous stock (HS) rats trained to self-administer cocaine under extended access conditions and subjected to 5 weeks of abstinence. Rats were classified as having a low or high addiction index based on several behavioral measures of addiction severity. We identified major neuronal and glial cell types in the amygdala and based on this annotation analyzed differences in the transcriptomic and epigenomic data coming between the high addiction index rats versus the low addiction index rats. Pathway enrichment analysis of cell type-specific DEGs revealed that several signaling pathways were perturbed by cocaine use in a cell type-specific manner, including changes in glucose metabolism in neuronal cell types. We experimentally perturbed a step in the glycolysis pathway and successfully rescued key cellular and behavioral measures associated with addiction-related phenotypes. This may be due to changes in levels of methylglyoxal, a partial agonist for the GABA-A receptor, indicating that disruption of GABA transmission is associated with differences in cocaine addiction. To better understand the mechanisms driving this phenomenon, we examined the cell type-specific differentially accessible genomic regions between nuclei from high and low addiction index rats. Indeed, we found that these regions were enriched for TSS and promoter regions compared to background and that DEGs were enriched for having differentially accessible promoter regions in the same cell. We identified enriched transcription factor motifs in the cell type-specific differentially accessible OCRs and performed a co-accessibility analysis to link differential OCRs to DEGs. Overall, we identified a number of candidate regulatory mechanisms driving perturbation of glucose metabolism in neuronal cells. Our work has unveiled a new cell-type-specific pathway associated with cocaine addiction and the mechanisms driving its perturbation to advance understanding of the molecular basis of the neuroadaptations induced by long-term use of cocaine.

Epigenetics Posters - Thursday

PB2466. Single-molecule architecture and heterogeneity of human telomeric DNA and chromatin

Authors:

A. Stergachis, D. Dubocanin, A. Seden Cortes, J. Ranchalis, T. Real, B. Mallory; Univ. of Washington, Seattle, WA

Abstract Body:

Telomeres are essential for linear genomes, yet their repetitive DNA content and somatic variability has hindered attempts to delineate their genetic and chromatin architectures. We performed single-molecule chromatin fiber sequencing (Fiber-seq) on human cells with a fully resolved genome, enabling nucleotide-precise maps of the genetic and chromatin structure of all telomeres. Telomere fibers are predominantly comprised of three distinct chromatin domains that co-occupy individual DNA molecules - multi-kilobase telomeric caps, highly accessible telomeric-subtelomeric boundary elements, and subtelomeric heterochromatin. Extended G-rich telomere variant repeats (TVRs) punctuate nearly all telomeres, and telomere caps imprecisely bridge these degenerate repeats. Telomeres demonstrate pervasive somatic alterations in length, sequence, and chromatin composition, with TVRs and adjacent CTCF-bound promoters impacting their stability and composition. Our results detail the structure and function of human telomeres.

Epigenetics Posters - Wednesday

PB2467. SnapHiC-G: identifying long-range enhancer-promoter interactions from single cell Hi-C data via a global background model

Authors:

W. Liu¹, W. Zhong², P. Giusti-Rodriguez³, M. Hu⁴, Y. Li¹; ¹Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ²Merck & Co., Inc., Rahway, NJ, ³Univ. of Florida Coll. of Med., Gainesville, FL, ⁴Cleveland Clinic, Cleveland, OH

Abstract Body:

Harnessing the power of single cell genomics technologies, single-cell Hi-C and its derived co-assays such as sc-methyl-Hi-C and sn-m3c-seq, provide powerful tools to measure spatial proximity between cis-regulatory elements in individual cells. In our recently developed SnapHiC method, we combined both global and local background models to identify chromatin loops from scHi-C data. As a result, most SnapHiC-identified chromatin loops are CTCF-anchored interactions, while the sensitivity to identify cell-type-specific long-range enhancer-promoter interactions is limited. To fill in this gap, we propose SnapHiC-G, a new computational approach based solely on the global background model to identify long-range enhancer-promoter interactions from scHi-C data. We applied SnapHiC-G to analyze scHi-C datasets generated from mouse embryonic stem cells (mESCs) and human brain cortical cells, and showed that SnapHiC-G outperformed SnapHiC and other existing methods designed for bulk Hi-C data (FitHiC2, FastHiC, HiC-ACT, HiC-DC+), demonstrating higher sensitivity in identifying long-range enhancer-promoter interactions. Moreover, SnapHiC-G-identified enhancer-promoter interactions were significantly enriched with brain eQTL-gene pairs, using scHi-C data from human brain cortical cells and brain eQTL data from the CommonMind Consortium. Finally, we showed that SnapHiC-G can identify putative target genes of GWAS variants, and genetic heritability for neuropsychiatric diseases was enriched for SNPs within SnapHiC-G identified interactions in a cell type-specific manner. SnapHiC-G is a powerful tool for characterizing cell-type-specific enhancer-promoter interactions in single cells from complex tissue samples, and fostering the interpretation of noncoding GWAS variants. The SnapHiC-G software is freely available at <https://github.com/wjzhong/SnapHiC-G>.

Epigenetics Posters - Thursday

PB2468. SpliceVI: a visualization tool for predicting protein consequences based on SpliceAI data.

Authors:

Y. Cho, J. Kim, H. Lee, G. Seo; 3billion, Seoul, Korea, Republic of

Abstract Body:

SpliceAI, an *in silico* tool that calculates how likely a given variant may alter splicing, outputs Δ scores and relative positions from the variant in question for each Δ type [acceptor loss (AL), acceptor gain (AG), donor loss (DL) and donor gain (DG)] within a preset distance. Variants with high Δ score are likely to be interpreted as potential null, just like essential splice site variants are commonly interpreted as. However, the actual protein consequence (PC) may as well be an inframe change and therefore, even though SpliceAI output is a likelihood, predicting the PC accordingly is important. Currently, the user has to manually figure out the possible PC based on SpliceAI output. Here, we developed a user-friendly visualizer, SpliceVI, that displays the genomic positions of the Δ type relative to the given variant and outputs predicted PC. SpliceVI uses 'raw' SpliceAI scores with max distance of 1Kb as default. The MANE transcript is used for predicting the PC. The following rules are applied if the Δ scores are >0 for a pair of Δ type: 1) AL/AG or DL/DG: the region in between is spliced out if AG or DG is upstream of AL or DL in the flanking intron or exon, respectively, and retained if AG or DG is downstream of AL or DL in the flanking exon or intron, respectively, 2) AL/DL: the exon in between is skipped if AL and DL flank the same exon and AL is upstream of DL, and the intron in between is retained if AL and DL flank the same intron and AL is downstream of DL, 3) AG/DG: pseudoexon is created if AG and DG are more than a base apart, reside within an intron and AG is upstream of DG, and the region in between is spliced out if DG and AG are more than a base apart, reside within an exon and DG is upstream of AG. Then, the frame of the transcript and if/where a new stop-codon gets created are determined. For other scenarios such as 1) only one of the 4 Δ type has a Δ score, 2) DL/AL does not occur at a canonical splice site 3) the Δ type pair spans more than 1 exon or intron, the SpliceVI will only give a message that a manual inspection is required. For validation, we compared the PC prediction by SpliceVI to that by manual inspection, using 100 variants with Δ score >0.6 . All 100 were concordant, and it took 113 and 0.5 seconds on average by manual inspection and SpliceVI, respectively. SpliceVI is a reliable and convenient tool that not only provides visualization of where a cryptic splice site (CSS) may occur but also predicts what the PC could be based on SpliceAI data and therefore, utilization of SpliceVI will reduce human burden and error in interpreting a potential CSS variant. Lastly, even though SpliceVI currently only takes SpliceAI results as input, it could be flexible for data from other tools.

Epigenetics Posters - Wednesday

PB2469. Stability of genetic regulation of gene expression over time.

Authors:

Y. Raza¹, J. S. El-Sayed Moustafa¹, A. Ramisch², D. Wang¹, G. Leday³, Y. Jiao⁴, G. Nicholson⁴, M. Stevens⁵, M. Abdalla⁴, C. Menni¹, C. Holmes⁴, T. Spector¹, M. McCarthy⁴, S. Richardson³, E. Dermitzakis², K. Small¹; ¹King's Coll. London, London, United Kingdom, ²Univ. of Geneva, Geneva, Switzerland, ³Med. Res. Council Biostatistics Unit, Cambridge, United Kingdom, ⁴Univ. of Oxford, Oxford, United Kingdom, ⁵Univ. of Geneva, Geneva, Switzerland

Abstract Body:

Ageing is associated with a decline in function and an increased risk of disease. Unravelling the molecular changes that occur over time can help us understand the process of ageing. Whilst cross-sectional studies have identified strong links between ageing and changes in gene expression, few studies have explored the changes that occur within an individual over time. Given the heterogeneity of ageing, exploring individual trajectories allows us to better understand disease risk factors and the progression of ageing.

To investigate variation of gene expression we instigated the MultiMuTHER study of the TwinsUK cohort; a longitudinal dataset measured across three time points between 2009-2017, comprised of 335 individuals (mean age 60 years) with gene expression (whole blood RNASeq of 16,292 genes) and metabolomics (Metabolon profile 1,197 metabolites). The study also captured short-term technical and biological variation. We found a systemic effect of time on the transcriptome, with 40% of genes showing a linear association with time.

We aimed to understand whether the genetic regulation of gene expression is stable or changes over time using allele specific expression (ASE) to consider allelic imbalance within an individual. Following haplotype phasing of RNASeq reads using phASER (phasing and Allele Specific Expression from RNA-seq), to generate data across heterozygous SNPs and subsequently aggregated across haplotypes, ASEP (Allele-Specific Expression in a Population) was utilised to test for ASE in individuals and to compare differences in ASE across time.

Following multiple testing correction (FDR 5%) we observed a median of 9% of genes which display ASE, with 1045, 1021, and 1053 genes exhibiting ASE at timepoints 1, 2 and 3, respectively. 552 of these genes were common across all three timepoints, indicating ~ 500 unique genes with ASE at each timepoints. We further observed 694 genes common between timepoints 1 and 2, 671 common genes between timepoints 2 and 3, and 676 common genes between timepoints 1 and 3. We tested for differential ASE between timepoints to understand the stability of ASE over time. We found differential ASE in 18 genes between timepoints 1 and 3, with 27 genes in differential ASE between timepoints 1 and 2 and 20 genes between timepoints 2 and timepoints 3. This indicates genetic regulation of most genes remain stable over time, with a small number displaying changes over time. We observed genes which exhibit changes in ASE but did not show a change in gene expression levels indicating complex regulation. Further work will utilise methods to incorporate environment and phenotypic measures to consider gene-environment interactions.

Epigenetics Posters - Thursday

PB2470*. Subsetting systemic lupus erythematosus patients based on clustering of DNA methylation at the time of disease flare

Authors:

M. Horton¹, J. Nititham¹, K. Taylor², L. Trupin², P. Katz², C. Ye³, J. Yazdany², M. Dall'Era⁴, L. F. Barcellos⁵, L. A. Criswell⁶, C. Lanata¹; ¹NIH/NHGRI, Bethesda, MD, ²Univ. of California, San Francisco, San Francisco, CA, ³Univ. of California, San Francisco, San Francisco, CA, ⁴Univ. of California, San Francisco, San Francisco, CA, ⁵Univ. of California, Berkeley, Berkeley, CA, ⁶NIH/NIAMS, Bethesda, MD

Abstract Body:

Current treatments for systemic lupus erythematosus (SLE) do not adequately prevent disease progression. This lack of efficacy, in part, relates to the molecular heterogeneity of SLE. The objective of this study was to use DNA methylation from flaring SLE patients to identify distinct biological subtypes of SLE associated with disease activity. Fifty-three SLE flaring patients were studied. A flare was defined by the treating rheumatologist and characterized with the SLE Disease Activity Index (SLEDAI) score. Blood samples and clinical data were collected at the time of flare and three months later. Genome-wide methylation profiles were generated using Illumina's Infinium Human MethylationEPIC BeadChip. After CpG quality control, differentially methylated positions (DMPs) associated with SLEDAI score were identified using *limma*. Models accounted for the paired design and adjusted for confounders such as blood cell proportions, batch effects, age, sex, medications and genetic PCs. Consensus hierarchical clustering was performed on the 5,000 most significant DMPs to identify patient subgroups. Clinical features and DMPs unique to each subgroup were identified using t-tests, chi-square, and *limma*. Gene ontology enrichment analysis was performed on the set of DMPs unique to each subtype. Participants were predominantly female (85.5%) and of diverse racial and ethnic backgrounds. Three clusters of patients were identified using DNA methylation data. Mean SLEDAI was lowest for Cluster 1 (7.5 (sd=7.2)) and increased for each subsequent group (11.0 (sd=7.2) and 14.7 (sd=3.9) for Cluster 2 and Cluster 3, respectively). The most significant gene ontology pathways for Cluster 1 included phosphorylation processes and regulation of defense response by viruses. For Cluster 2, notable DMPs were found in *EBF1* (B-cell transcription factor), *C12orf66* (regulator of mTOR signaling, the target of rapamycin), and *SWTI* (riboendonuclease expressed in basophils). Top pathways included import into the nucleus and adrenergic receptor signaling. For Cluster 3, notable DMPs include *KMT2C* (methyltransferase expressed in neutrophils), *RFXP3* (receptor of relaxin, associated with monocyte recruitment and differentiation), and *ITSN2* (regulator of clathrin-coated vesicles and induction of T cell antigen receptor endocytosis). Pathways for Cluster 3 included synaptic transmission and several neuronal membrane pathways. Three biologically distinct subgroups of flaring SLE patients were identified using DNA methylation data. This subtyping might be used to better inform treatment decisions and targeted therapies based on relevant underlying biological pathways.

Epigenetics Posters - Wednesday

PB2471. TDP-43 depletion results in aberrant gene expression and TE activation via dysregulation of R-loop homeostasis.

Authors:

Y. Hou, Y. Li, P. Jin, B. Yao; Dept. of Human Genetics, Emory Univ. Sch. of Med., Atlanta, GA

Abstract Body:

TAR DNA-binding protein 43 (TDP-43; also known as TARDBP) is a DNA and RNA-binding protein involved in many aspects of RNA metabolism. TDP-43 pathological aggregation is a hallmark of many neurodegenerative disorders. However, the detailed mechanistic role underlying TDP-43 pathology in neurons remains largely elusive. R-loop, a three-stranded DNA:RNA hybrid structure formed when a single-stranded RNA invades the DNA double strand and hybridizes with a complementary DNA strand, has been revealed to be required for several cellular processes, such as regulation of gene expression and DNA damage repair. Recent studies have established a direct link between TDP-43 dysfunction and aberrant regulation of R-loops. To investigate the long-term impact of TDP-43 loss-of-function in neurons, we first established TDP-43 stable knockdown (TDP-43 KD) neuronal cells by infecting TDP-43 shRNA containing lentivirus into SH-SY5Y neuroblastoma cells. Genome-wide dysregulated R-loops were identified in the absence of TDP-43 by DNA-RNA immunoprecipitation (DRIP) sequencing. Given 5-hydroxymethylcytosine (5hmC) is an important epigenetic mark that regulates gene expression, and it has been shown to positively correlate with R-loops on genomic loci, we correlated abnormal R-loops/5hmC co-occurring peaks with aberrant gene expression and found a strong positive correlation between dysregulation of gene expression and imbalanced R-loops and 5hmC, suggesting an important role of TDP-43 in modulating gene expression via R-loop and 5hmC alteration. We also found TDP-43 loss induced transposable elements activation, which has been demonstrated as a phenotype observed in many neurodegenerative disorders and may have deleterious effects by disturbing the transcriptional landscape and causing cellular dysfunctions. Together, TDP-43 depletion modulates gene expression and TE activation via R-loop regulation, which may contribute to neurodegeneration.

Epigenetics Posters - Thursday

PB2472. The association of cigarette smoking with DNA methylation and gene expression in human tissues

Authors:

L. I. Tamayo¹, L. Tong¹, F. Jasmine¹, K. G. Muhammad¹, K. Demanelis², M. Oliva³, L. Chen¹, B. L. Pierce¹; ¹Univ. of Chicago, Chicago, IL, ²Univ. of Pittsburgh, Pittsburgh, PA, ³AbbVie, Mettawa, IL

Abstract Body:

Background: Cigarette smoking has detrimental effects on many aspects of human health. Associations between smoking and features of the human epigenome have been described previously, including associations with DNA methylation (DNAm). Most prior studies assessed DNAm in leukocytes, and those studies identified numerous smoking-associated regions (e.g., *AHRR*). In this study, we identify smoking-associated DNAm features in non-blood tissue types, tissues that are typically inaccessible in human studies and therefore understudied. **Methods:** We generated DNAm data using the Illumina EPIC array for 929 Genotype-Tissue Expression (GTEx) tissue samples representing 9 tissue types (lung, colon, ovary, prostate, whole blood, breast, testis, kidney, and muscle). For each tissue type, the association of smoking status (ever/never) with DNAm (and existing gene expression data) was estimated using linear models, adjusting for age, sex, BMI, race/ethnicity, ischemic time, and surrogate variables (FDR of 0.05). We conducted gene set enrichment analysis using missMethyl (gometh) and hallmark gene sets from MSigDB (FDR of 0.05). **Results:** We identified 6350 smoking-associated CpGs in lung (n=212) and 2735 in colon (n=210), the majority of which (6219) had not been reported previously. For all 7 other tissue types (sample sizes 46-153), no clear associations were observed (based on FDR); however, CpGs showing the smallest P-values in lung, colon, ovary, and kidney showed clear enrichment for CpGs reported in past studies of smoking and DNAm in leukocytes. For ~1500 loci, smoking was associated with both DNAm and local gene expression (in lung). For smoking-associated loci detected in both lung and colon (e.g., *AHRR*, *CYP1B1*), we observed general consistency across tissues in terms of the location of smoking-associated CpG clusters (and the direction of association), but differences in patterns of association for CpGs within clusters. Seventeen hallmark gene sets were enriched for genes that annotated to smoking-associated CpGs (in lung), with the top 10 sets including a xenobiotic metabolism gene set and 9 cancer-related gene sets (e.g., apoptosis, p53). At least 4 smoking-associated regions in lung were impacted by lung methylation-QTLs that co-localize with GWAS signals for lung function (FEV1/FVC) in UK Biobank. This suggests that smoking-related epigenetic alterations may mediate the effects of smoking on lung health. **Conclusion:** A multi-tissue approach for studying the effects of smoking on DNAm has identified novel smoking-associated regions in disease-relevant tissues, inducing effects that are both tissue-specific and shared across tissues.

Epigenetics Posters - Wednesday

PB2473. The interplay of epigenetic, genetic, and traditional risk factors on blood pressure: Findings from the Health and Retirement Study.

Authors:

X. Zhang, F. Ammous, L. Lin, S. Ratliff, W. Zhao, S. Kardia, J. Smith; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Elevated blood pressure (BP) is a major public health burden and a leading cause of morbidity and mortality. BP is complex phenotype often resulting from an interplay between genetics and the environment. Little is known about how the epigenome, a cellular mechanism that regulates gene expression and is modifiable by the environment, interacts with traditional or genetic risk factors to influence BP. In this study, we leveraged 13 previously reported DNA methylation sites (CpGs) that have been significantly associated with BP and evaluated their association with systolic and diastolic BP, individually and aggregated into methylation risk scores (MRS) in 3,070 participants (437 African Americans (AA), 2,021 European Americans (EA), and 612 of other ancestries) aged ≥ 50 years from the Health and Retirement Study (HRS). We also evaluated interactions between the MRS, and genetic risk score (GRS), age, sex, and education on BP. We performed both full sample (trans-ancestral) and ancestry-specific analysis (for EA and AA). Using linear regression models adjusted for age, sex, education, parental education, type 2 diabetes, smoking, alcohol use, exercise, and genetic PCs we detected significant associations with either systolic or diastolic BP ($P < 0.05$) in 10 of the 13 CpGs in the full sample analysis. MRS_{SBP} was a significant predictor of SBP in the full sample ($P = 2.6 \times 10^{-5}$) and EA ($P = 0.001$) with adjusted effect estimates of 1.7 (full sample) and 1.6 (EA) mmHg increase in SBP for each 1 standard deviation (SD) increase in the risk score. MRS_{DBP} was also associated with DBP in the full sample ($P = 1.8 \times 10^{-6}$) and in ancestry-specific analysis (EA, $P = 7.2 \times 10^{-5}$; AA, $P = 0.033$), with adjusted effect estimates ranging between 1.1 (full sample and EA) and 1.4 (AA) mmHg increase in DBP for each 1 SD increase in MRS_{DBP} . After further adjustment for GRS, both MRS_{SBP} and MRS_{DBP} remained significant predictors of BP in EA. In the full sample and EA, the effects of MRS_{SBP} and MRS_{DBP} on BP decreased as age increased (all $P_{interaction} < 0.05$). For the full sample, this was equivalent to an effect estimate of 2.9 vs. 0.95 mmHg increase for each 1 SD increase in MRS_{SBP} and 1.9 vs. 0.65 mmHg increase for each 1 SD increase in MRS_{DBP} at the 25th and 75th percentile of age, respectively. In AA, MRS_{SBP} was associated with higher SBP in females but not in males ($P_{interaction} = 0.01$). We noted no significant interactions between the MRS and education nor the GRS. In summary, we show that MRS_{SBP} and MRS_{DBP} were significant predictors of BP after accounting for genetic and traditional risk factors, with evidence of interactions with age and sex and variation by genetic ancestry.

Epigenetics Posters - Thursday

PB2474. The role of genetic and epigenetic mechanisms in the definition of the circular RNA landscape in multiple sclerosis.

Authors:

E. Paraboschi^{1,2}, F. Airi², G. Liberatore³, G. Soldà^{1,2}, E. Nobile-Orazio^{3,4}, R. Asselta^{1,2}; ¹Humanitas Univ., Milan, Italy, ²IRCCS Humanitas Res. Hosp., Milan, Italy, ³Neuromuscular and Neuroimmunology Service, IRCCS Humanitas Res. Hosp., Milan, Italy, ⁴Univ. of Milan, Milan, Italy

Abstract Body:

Alternative splicing (AS) is a post-transcriptional mechanism that increases the information content of the transcriptome through the expression of different mRNAs from single genes. AS directly competes with the backsplicing (BS) process, a mechanism that leads to a non-canonical splicing of genes to generate non-coding, circular RNAs (circRNAs). AS and BS processes are intertwined, since their functions are based on the same spliceosomal machinery, and they are tuned by the same trans-acting factors. A dysregulation of AS/BS has been implicated in human disorders, including multiple sclerosis (MS), a chronic autoimmune neuroinflammatory and neurodegenerative disease in which autoreactive T lymphocytes attack antigens of the central nervous system.

The aim of this project is to unravel the mechanisms involved in the dysregulation of AS/BS processes in MS by integrating different omics data.

We decided to specifically evaluate the BS profile in CD4⁺/CD8⁺ T lymphocytes, considering their essential role in the disease pathogenesis, and recruited 20 MS patients and 20 controls. A first analysis conducted on CD4⁺ T lymphocytes showed 176 differentially expressed circRNAs (P<0.05).

Interestingly, they derive from genes implicated in chromatin organization, neuroinflammation, and regulation of gene expression by epigenetic mechanisms, thus highlighting the importance of epigenetic features in circRNAs determination. Then, given the differential expression of circRNAs in MS patients, and the existence of a genotype-dependent regulation, we explored a possible role of the genetic background on circRNAs modulation, focusing on known MS-associated genetic variants. We evidenced the existence of significant QTLs, thus suggesting possible correlations between the genetic background and circRNA expression profiles.

In conclusion, we described the circRNA expression profile of specific T lymphocyte classes in MS patients, suggesting that MS-associated variants may tune the expression levels of circRNAs acting as circ-QTLs. The analysis of the BS landscape in CD8⁺ T lymphocytes, as well as the correlation with the methylation profile is currently being performed. All omics data will be integrated in a unified framework to infer regulatory relationships, and to gain a detailed insight on the cellular states characterizing the disease. This approach will unmask the biological processes that are driving the development of the disease phenotype and that would not be observable if the single omics were analyzed separately.

Acknowledgments. This work is supported by Fondazione Regionale per la Ricerca Biomedica (FRRB), Early Career Award.

Epigenetics Posters - Wednesday

PB2475. Tobacco smoke-derived metabolites in plasma are associated with cardiometabolic traits, are genetically regulated, and may modulate adipose tissue DNA-methylation in African Americans.

Authors:

S. Das, M. Comeau, C. Langefeld; Wake Forest Univ. Sch. of Med., Winston-Salem, NC

Abstract Body:

Genetic factors influence susceptibility to cardiometabolic diseases. However, lifestyle factors including smoking, are important environmental risk factors for these diseases. Interestingly smoking-cessation leads to weight gain. Genetic factors influence smoking behavior and addiction, and metabolic pathways may determine the systemic effects of smoking by influencing the level of tobacco smoke-derived metabolites. As compared to self-reported smoking, plasma levels of tobacco-derived metabolites provide empirical and accurate evaluation of chronic smoking or exposure to tobacco smoke. Untargeted LC-MS profiling (Metabolon) of fasting plasma in 253 non-diabetic African Americans from AAGMEx cohort quantified 1124 metabolites, including 124 xenobiotics, and allowed us to evaluate the role of environmental exposures, including smoking in determining gluco-cardio-metabolic traits. Three tobacco metabolites: cotinine, hydroxycotinine, and 2-hydroxyfluorene sulfate were associated with obesity and insulin sensitivity. In linear regression analyses adjusted for age, sex, and admixture, hydroxycotinine level was inversely and directly associated with BMI ($\beta = - 5.09$, $p = 7.88 \times 10^{-7}$), and insulin sensitivity ($\beta = 3.53$, $p = 5.14 \times 10^{-4}$), respectively. Genome-wide association analysis identified significant quantitative trait loci for these metabolites. SNP rs2835863_G in intron of *KCNJ6* ($P = 2.05 \times 10^{-7}$), and rs7609906_A in intron of *FAM19A4* ($P = 1.5 \times 10^{-7}$) was most significantly associated with hydroxycotinine and cotinine, respectively. Previous studies suggest that *KCNJ6* variants associate with susceptibility to nicotine dependence/failure of smoking cessation, and *FAM19A4* is involved in addiction behavior. Altered DNA-methylation is an epigenetic change that reflects exposure to lifestyle factors including cigarette smoking. We identified association ($p < 0.0001$) between plasma hydroxycotinine level with DNAm levels of 75 CpG sites in adipose tissue. These CpG sites were annotated to 48 genes, including 5 sites in *AHRR* gene reported previously in multiple EWAS's for smoking. Thus plasma levels of tobacco smoking-derived metabolites are under genetic regulation, and these metabolites are involved in smoking-induced altered DNAm in adipose tissue of African Americans.

Epigenetics Posters - Thursday

PB2476. Transcriptome and chromatin accessibility dynamics across 25 brain regions identify novel susceptibility gene sets for neuropsychiatric disorders

Authors:

P. Dong¹, J. Bendl², J. Fullard³, G. Hoffman³, P. Roussos³; ¹Icahn school of Medicine at Mount Sinai, New York, NY, ²Icahn Sch. of Med. at Mount Sinai, New York City, NY, ³Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Transcriptome and epigenome dynamics across brain regions and cell types are strongly associated with neuropsychiatric disease. We profiled chromatin accessibility and gene expression in two cell types (neurons and non-neurons) across 25 distinct brain regions. We found extensive molecular features and regulome alterations across brain regions. Leveraging a system biology approach, we identified brain region-specific chromatin co-accessibility and gene-coexpression modules that are robustly associated with neuropsychiatric disease. The genes associated with a promoter module are enriched for regulatory, instead of synaptic, function but are strongly overrepresented for common variants associated with different neuropsychiatric disorders, including Autism spectrum disease, bipolar disorder, and schizophrenia, as well as rare variants and fine-mapped gene sets. After conditioning using schizophrenia-associated cell types, the association with schizophrenia common variants is still highly significant. Similarly, the module still overrepresents common variants following the removal of all known schizophrenia-associated pathways. Our analysis highlights the function of non-synaptic genes and the polygenic basis of neuropsychiatric disorders.

Epigenetics Posters - Wednesday

PB2477. Transfer learning of a methylation based COVID19 severity model for DNA viral infection by eczema herpeticum.

Authors:

W. Zhou¹, M. P. Boorgula², M. Campbell², S. Chavan², G. Harrison¹, B. R. Peterson¹, N. Rafaels², B. Barnes³, R. PORECHA³, R. Mathias⁴, A. Taye³, K. Barnes^{1,2}; ¹Tempus Labs, Chicago, IL, ²Univ. of Colorado, Denver, CO, ³Illumina, Inc., La Jolla, CA, ⁴Johns Hopkins Univ., Baltimore, MD

Abstract Body:

Methylation risk score (MRS) is an algorithmic aggregation of methylation states that are increasingly used to infer clinical phenotypes. An advantage of MRS is that it captures multi-factorial predispositions as methylation states are influenced by both genetic and environmental factors. Whether MRS can be universally applied across closely relevant phenotypes remains unexplored. Additionally, factors to be taken into account for reaching a satisfactory model generalization are undetermined. DNA and RNA viruses have evolved to utilize epigenetic modifications including DNA methylation as a means to maximize viral gene expression and to escape host immunity during infection. Previously, we customized Illumina's MethylationEPIC array to enhance immune response detection. We profiled peripheral blood samples from patients infected with SARS-CoV-2 (a RNA virus) thereby developing a COVID-19 MRS model to predict disease severity. In the current study, we aimed to assess the utility of COVID-19 MRS model in DNA viral infections. The clinical outcome of focus was atopic dermatitis (AD)-associated eczema herpeticum (ADEH), a severe complication in AD caused by disseminated herpes simplex virus (HSV, a double-stranded DNA virus). We profiled peripheral blood DNA samples with the customized MethylationEPIC array from 258 ADEH+ and 100 ADEH- patients with disease severity measures. We further compared data to the COVID-19 positive cases and negative controls from recently reported study (Konigsberg et al 2021, Comm. Med.). Firstly, we demonstrated the COVID-19 MRS model accuracy on ADEH severity prediction. We then stratified model performance based on cohort characteristics to understand contributing factors that influence model transferability and generalizability. Next, we trained a separate MRS model for specificity to ADEH cases alone. Both models were compared to quantify specificity of methylation patterns induced by different viral types. In summary, our study reveals the occurrence of both common and differential methylation states in infectious diseases caused by different viral classes. In addition, our study provides evidence to delineate host DNA modifications utilized by unique viruses to cause infections in humans. Overall, this work serves as a case study to evaluate the validity and utility of MRS in its implementation towards infectious disease healthcare.

Epigenetics Posters - Thursday

PB2478. Transposable elements are associated with the variable response to influenza infection

Authors:

X. Chen¹, A. Pacis², K. Aracena³, S. Gona³, T. Kwan⁴, C. Groza⁵, Y-L. Lin³, R. H. M. Sindeaux⁶, V. Yotova⁶, A. Pramatarova⁴, M-M. Simon⁴, T. Pastinen^{7,8}, L. Barreiro^{3,9,10}, G. Bourque^{1,2,4,8}; ¹Inst. for the Advanced Study of Human Biology (WPI-ASHBi), Kyoto Univ., Kyoto, Japan, ²Canadian Ctr. for Computational Genomics, McGill Univ., Montreal, QC, Canada, ³Dept. of Human Genetics, Univ. of Chicago, Chicago, IL, ⁴McGill Genome Ctr., Montreal, QC, Canada, ⁵Quantitative Life Sci., McGill Univ., Montreal, QC, Canada, ⁶Ctr. de Recherche, CHU Sainte-Justine, Université de Montréal, Montreal, QC, Canada, ⁷Genomic Med. Ctr., Children's Mercy Hosp. and Res. Inst., Kansas City, MO, ⁸Dept. of Human Genetics, McGill Univ., Montreal, QC, Canada, ⁹Section of Genetic Med., Dept. of Med., Univ. of Chicago, Chicago, IL, ¹⁰Committee on Immunology, Univ. of Chicago, Chicago, IL

Abstract Body:

Influenza A virus infections are frequent every year and result in a range of disease severity between individuals. The variability in the human response is a combination of viral- and host-factors but many of the underlying mechanisms remain largely elusive. Given that transposable elements (TEs) have been shown to contribute to the activation of innate immunity, we wanted to explore their potential role in this variability. We profiled the transcriptional program before and after influenza infection using RNA-seq in monocyte-derived macrophages from 39 human individuals and observed significant inter-individual variability in viral load post-infection (from 3.8% to 57.8% of RNA reads). Using the same cells, we profiled the epigenetic landscape using ATAC-seq and ChIP-seq and identified a set of TEs with either enhanced (37 families) or reduced (39 families) accessibility in response to infection. Notably, of the enhanced families, 15 showed high variability in chromatin accessibility changes between individuals. We showed that enhanced and reduced TE families were enriched for various histone modifications (H3K27ac, H3K4me1, H3K4me3 or H3K27me3) and in proximity to genes that are regulated in the response to infection. Motif analysis revealed an association with known immune regulators in families stably enriched across individuals and, in contrast, an enrichment of putatively novel host factors in highly variable families, including ZNF460 and other KRAB-ZNFs. Finally, we observed an association between TE transcripts levels before infection and viral load post infection. Using this information combined with the new host factors identified, we built a predictive model for viral load post infection suggesting that TEs, and host factors regulating TEs, contribute to the variable response to infection.

Epigenetics Posters - Wednesday

PB2479. Trinity of chromatin architects - The coordination of CTCF, RNAPOL2 and Cohesin in shaping the genomic landscape

Authors:

A. Agarwal¹, D. Plewczynski^{1,2}, M. Chilinski²; ¹Ctr. Of New Technologies, Univ. Of Warsaw, Warsaw, Poland, ²Warsaw Univ. of Technology, Warsaw, Poland

Abstract Body:

Genome-wide architectural landscapes of chromatin in the nucleus can be identified by the advanced high-throughput sequencing-based 3C-type methods such as Hi-C, ChIA-PET, and HiChIP. The spatial organisation of chromatin in the nucleus is stabilised by structural proteins, such as the CCCTC-binding factor (CTCF), RNAPOL2 and cohesin complex. These proteins play an essential role in establishing long-range chromatin interactions (chromatin loops), facilitating topologically associating domain formation and allowing for the coordination of genes with their corresponding regulatory elements. Here, we discuss the exact role of CTCF, RNAPOL2 and cohesin in shaping chromatin multiscale three-dimensional architecture, in particular how static architecture defined by CTCF is re-shaped by the dynamical activity of cohesin (LEM: loop extrusion model), and re-organized during transcriptional activity by RNAPOL2. We analyse in detail CTCF, cohesin and RNAPOL2 binding sites that account for the topological regulation of chromatin loops, the dynamics of loop extrusion, and phase separation condensates related to the transcriptional factories.

Epigenetics Posters - Thursday

PB2480. Uncovering Novel Functions of Histone Demethylase KDM5 Through a Genome-wide Approach

Authors:

M. Yheskel¹, J. Cadiz¹, S. Sidoli¹, J. Secombe²; ¹Albert Einstein Coll. of Med., Bronx, NY, ²Albert Einstein Coll. of Med., New York, NY

Abstract Body:

Mutations throughout human histone lysine demethylase KDM5C are associated with intellectual disability (ID). KDM5C's main canonical function is the removal of H3K4me3, a histone mark associated with transcriptional activation. Recent studies have shown that KDM5 has both demethylase-dependent and independent functions in neurons. Nevertheless, little is known about the molecular consequences of ID-associated mutations in KDM5. Thus, we have modeled patient KDM5C ID-associated mutations in *Drosophila melanogaster* to understand how they affect KDM5 binding, demethylase activity, transcriptional regulation, and protein binding. Here, we assay genome-wide KDM5 binding and local changes to H3K4me3, and how these mutations affect transcription of mRNA. Furthermore, we use the novel technique of proximity labeling to reveal that KDM5 associates with insulator proteins that help partition the genome in 3D-space to ensure proper regulation of genes. Key among these insulator proteins is CTCF, the sole insulator found in mammals which has been shown to result in ID when mutated. KDM5 extensively co-localizes with insulator proteins and topologically associated domain (TAD) boundaries. Interestingly, TAD boundaries are found near housekeeping genes such as ribosomal protein genes (RPGs); a class of gene that is transcriptionally downregulated ID-mutant strains. Together, these analyses reveal that ID-associated KDM5 mutations may impart their deleterious effects through dysregulation of genome organization in a conserved manner.

Epigenetics Posters - Wednesday

PB2481. Using allele-specific expression to assess intra- and inter- individual heterogeneity in X-chromosome inactivation within human tissues

Authors:

H. Markus¹, B. Jiang², L. Carrel³, D. Liu²; ¹Penn State Coll. of Med., Hershey, PA, ²Pennsylvania State Univ. Coll. of Med., Hershey, PA, ³Penn State Univ Col Med, Hershey, PA

Abstract Body:

Functional genomics and disease association studies of X-linked genes remains understudied due to the unique biology of X chromosome. In humans, males carry one copy of the X-chromosome while females carry two. X-chromosome inactivation (XCI) epigenetically silences one copy of the X in females to maintain balanced gene dosage with males. Yet up to 10% of genes escape XCI and are transcribed from both Xs. Another 30% of genes variably escape XCI in a subset of tissues or individuals. Understanding how XCI states vary between individuals and tissues will help elucidate the contribution of X-linked genes to human diseases and pinpoint causal tissue types. We recently developed a statistical method XCIR to identify XCI escape genes from RNA-seq data. XCIR estimates sample skewing (i.e., the fraction of cells where a particular X chromosome is inactivated) by examining allele-specific expression (ASE) from a gene set known to be silenced by XCI. XCI states are then inferred for each X gene and concluded to escape XCI if the gene ASE is statistically significantly more balanced than sample skewing. Using XCIR we assessed XCI states in samples from Genotype Tissue Expression (GTEx) Project (v8p release). We limit our analysis to samples with XCI skewing > 70:30, which provides XCIR sufficient power to infer XCI states per gene within a sample. In total we assess XCI states for 542 X-linked genes in 1,775 transcriptomes from 274 female donors across 44 tissues and infer XCI states for all genes with transcribed well-expressed SNPs. Across all tissues/samples, 78% of our inferred XCI states agreed with previous male-female differential gene expression results across genes and tissue types. In addition, we provide XCI states for 2,686 gene and tissue pairs not previously described among which 1,421 are from female-specific tissues. We also annotate 39 X-linked genes not previously described. Among these genes, ARSD-AS1 escaped XCI and PNMA6F, RAP2C-AS1, PLXNB3-AS1, DIAPH2-AS1 and LINC00106 variably escaped in more than 1 tissue. Lastly, using a method similar to the analysis of variance, we examine how the XCI states vary between tissue types in the same individual, and between different individuals of the same tissue type. Using paired t-test, we found XCI states exhibit much higher variability between different individuals across tissue types (p -value $< 2.2 \times 10^{-16}$), pointing to possible influence of genetic variation. Overall, we provide updated and accurate XCI states of genes based on ASE across human tissues. We believe these results will increase our understanding of the extent of intra- and inter- individual variability of XCI and help us study its effect on sex-biased diseases.

Epigenetics Posters - Thursday

PB2482*. Using iPSC-derived microglia and oligodendrocytes to study ancestry-specific gene expression in the context of Alzheimer's Disease (AD).

Authors:

S. Moura¹, A. Ramirez¹, J. Shepherd¹, S. Simon¹, M. Muniz¹, P. Whitehead¹, L. Adams¹, T. Starks², P. Mena¹, M. Illanes-Manrique³, S. Tejada¹, A. Griswold¹, J. Young¹, G. Byrd⁴, M. Cornejo-Olivas⁵, B. Feliciano-Astacio⁶, M. Pericak-Vance¹, J. Vance¹, D. Dykxhoorn¹; ¹Univ. of Miami, Miami, FL, ²Wake Forest Sch. of Med., Winston-Salem, NC, ³Neurogenetics Res. Ctr., Inst. Natl. de Ciencias Neurologicas, Lima, Peru, ⁴NC A&T State Univ, Greensboro, NC, ⁵Inst. Natl. de Ciencias Neurologicas, Lima, Peru, ⁶Univ. Central del Caribe, Bayamón, Puerto Rico

Abstract Body:

Genome-Wide Association Studies (GWAS) studies in AD have been performed mainly in Non-Hispanic Whites (NHW). However, GWAS studies in admixed populations such as (African and NHW ancestries) and Hispanics (African, NHW, and Amerindian ancestries) are now underway. We have shown that different ancestry groups carry distinct genomic architectures that could lead to differing genetic susceptibility to AD. Thus, to study the functional mechanisms of GWAS studies in these admixed populations, we are identifying the impact of ancestry-specific genetic variants on the regulome and transcriptome across different cell types of the central nervous system. As part of this study, we analyzed the regulatory maps of iPSC-derived microglia (iMG) and oligodendrocytes (iOLs) derived from individuals with high global African (AF), Amerindian (AI), or NHW ancestry. iPSCs lines were derived from AD patients and non-cognitively impaired (NCI) controls which have >90% genomic content from different ancestral populations - Non-Hispanic Whites, African, and Amerindian. These iPSC lines were validated for pluripotency and chromosomal stability and were differentiated into MG and OLs. These differentiated cell populations were validated via immunocytochemistry (ICC) and qRT-PCR for the expression of cell type-specific markers. Bulk ATAC-seq, Hi-C, and RNA-seq were performed to study the regulatory architecture of the genomes from these cells in both case and control lines and their associated impact on gene expression. We optimized the differentiation of iMG and iOLs and validated it using ICC and qRT-PCR for lineage-specific markers. We analyzed and compared the regulatory maps in AF and AI ancestries by aligning chromatin accessibility (ATAC-seq) and promoter-enhancer interaction (Hi-C) data in iMG and iOLs. Moreover, we investigated the downstream effects the regulatory architecture might have on transcription (RNA-seq) specific for these cell types and ancestral backgrounds. This is one of the first studies to provide ancestry-specific regulatory data on the ancestral backgrounds that contribute to a large part of the US population. Our data provide new insights into ancestry-specific risk factors and candidate genes in AD pathophysiology, specifically, we report novel data on chromatin accessibility and transcriptomics data in AF and AI iPSC-derived microglia and oligodendrocytes, with the latter not having been a main research focus in AD pathology.

Epigenetics Posters - Wednesday

PB2483. Using machine learning to predict 3D genome organization across thousands of diverse individuals reveals conservation and population differentiation.

Authors:

E. Gilbertson¹, E. McArthur², C. Brand¹, D. Rinker², J. Capra¹; ¹Univ. of California San Francisco, San Francisco, CA, ²Vanderbilt Univ., Nashville, TN

Abstract Body:

A central goal of human population genetics is to quantify all aspects of genotypic and phenotypic variation across diverse populations, including human variation in genome folding. Quantifying human genetic and phenotypic variation in diverse populations is necessary to enable equitable science and medicine. DNA sequence variants that influence genome folding can have massive regulatory impacts on disease by altering chromatin interactions. However, current methods for interpreting the effect of non-coding variants do not consider this mechanism because we do not understand how 3D folding relates to function and how genetic variants affect this critical function. Understanding the breadth of chromatin contact diversity across human populations is critical for interpreting 3D genome variants, yet it is prohibitively costly to experimentally determine chromatin-interactions at a population-scale. Here, we use machine learning to predict 3D chromatin organization from genome sequence and map the diversity of 3D folding across thousands of modern humans. To explore the variation of human 3D folding patterns, we derive a metric for quantifying population-level 3D genome differentiation motivated by the sequence-based F_{ST} . Applying the 3D F_{ST} genome-wide, we identify regions with significant differentiation in contact maps between human populations that may contribute to phenotypic differences between populations. We find that 3D folding similarity genome-wide follows patterns of sequence divergence and that pressure to maintain 3D folding patterns has broadly constrained chromatin-interacting sequence evolution. However, we also identify loci with significant variation in 3D genome organization that associates with observable expression differences and phenotypic diversity. In summary, we infer 3D genome folding maps across diverse human populations and quantify the variational and functional implications of diverse folding patterns. We anticipate that these maps of 3D folding diversity will provide a reference for future work on the interpretation of 3D genome folding variation across human populations.

Epigenetics Posters - Thursday

PB2484. Validation and Methylome analysis of the CRISPR-edited DUX4 locus in immortalized myoblast cell lines modeling FSHD using long-read sequencing.

Authors:

J. Sakr, X. Kong, N. Nguyen, K. Yokomori, A. Mortazavi; Univ. of California, Irvine, Irvine, CA

Abstract Body:

Facioscapulohumeral muscular dystrophy (FSHD) is one of the three most common forms of muscular dystrophy in adults. The major form of FSHD (FSHD1) is associated with contraction of D4Z4 macrosatellite repeats on chromosome 4q35 with loss of DNA methylation in haplotypes with a distal “permissive” specific SNP on the last D4Z4 repeat that creates a polyadenylation site for the transcription factor DUX4, which is then misexpressed in muscle. The chromosome 10q subtelomere contains an almost identical repeat array but contractions on this locus are non-pathogenic. These highly homologous repeats on both chromosomes make modeling the disease and characterizing the mechanisms especially challenging with short-read sequencing. We assessed the contraction status of the D4Z4 repeat of several FSHD model cell lines using the Oxford Nanopore cas9 kit to selectively sequence the genome region associated with the disease. By using long reads, we are able to capture complete contracted D4Z4 repeat region and the distal permissive allele in a single read. Furthermore, by directly sequencing the genome, we are able to study the epigenetic signatures of the disease. We are further analyzing the methylation status in the contracted repeats to assess the extent of methylation loss and its correlation with Dux4 and Dux4-target expression in order to select the most representative immortalized cell models of FSHD1.

Epigenetics Posters - Wednesday

PB2485. Variable *cis*-regulatory landscapes associate with gene function and expression patterns

Authors:

M. Benton¹, J. Capra², D. M. Ruderfer³; ¹Baylor Univ., Waco, TX, ²Univ. of California San Francisco, San Francisco, CA, ³Vanderbit Univ. Med. Ctr., Nashville, TN

Abstract Body:

Motivation: *Cis*-regulatory elements (CREs) regulate gene expression by binding transcription factors and controlling transcription across diverse cell types. Multiple CREs can cooperate to regulate the expression of a single gene, and individual CREs can have multiple gene targets. However, despite evidence that the groups of CREs associated with genes—the CRE landscapes—are ubiquitous, we do not understand how CRE landscape variability across genes relates to the strength and tissue-specificity of expression for those gene targets. Furthermore, genetic variation in CREs has been implicated in the etiology of complex disease, yet, current strategies do not consider the impact of CRE variation in the context of the CRE landscape. **Results:** Here, we quantify the CRE landscape composition across ten human tissues and relate landscape attributes to the expression of genes in the landscapes. We integrate three-dimensional chromatin conformation data with functional and evolutionary characterization of human CREs to assess CRE landscape attributes such as the number of active CREs, DNA sequence conservation, and the tissue-specificity of the component CREs. For example, we find that expressed genes have larger CRE landscapes than non-expressed genes in the same tissue and that genes with an increased proportion of tissue-specific elements are more likely expressed in specific tissues. We also find that CRE landscapes with genes under constraint on their expression (e.g., loss-of-function intolerant and housekeeping genes) have more evolutionarily conserved sequences than expressed genes overall. We hypothesized that genes with large CRE landscapes would be more robust to changes in expression due to the potential for CRE redundancy within the landscape. However, we do not observe a strong relationship between the size of the CRE landscape and expression variability across individuals. Nonetheless, we do observe a relative depletion for overlap with eQTL in larger CRE landscapes. **Conclusions:** Overall, this work highlights how differences in gene function, expression, and evolutionary constraint are reflected in the features of their CRE landscapes. Thus, considering the CRE landscape of a gene is an essential component to understanding gene expression dynamics across biological contexts. In the future, quantifying the effects of CRE alteration in the context of these CRE landscapes will facilitate interpretations of the effects of gene regulatory perturbations to disease risk.

Epigenetics Posters - Thursday

PB2486. Variation in DNA methylation is associated with cognitive function in post-surgery breast cancer patients prior to adjuvant therapy.

Authors:

S. Liu¹, D. Liu², C. M. Bender³, K. I. Erickson⁴, S. M. Sereika³, Y. P. Conley^{3,1}, J. R. Shaffer^{1,5}, D. E. Weeks^{1,6}; ¹Dept. of Human Genetics, Sch. of Publ. Hlth., Univ. of Pittsburgh, Pittsburgh, PA, ²Dept. of Genetics and Genomic Sci., Icahn Sch. of Med. at Mount Sinai, New York, NY, ³Sch. of Nursing, Univ. of Pittsburgh, Pittsburgh, PA, ⁴Dept. of Psychology, Kenneth P. Dietrich Sch. of Arts and Sci., Univ. of Pittsburgh, Pittsburgh, PA, ⁵Dept. of Oral and Craniofacial Sci., Sch. of Dental Med., Univ. of Pittsburgh, Pittsburgh, PA, ⁶Dept. of Biostatistics, Sch. of Publ. Hlth., Univ. of Pittsburgh, Pittsburgh, PA

Abstract Body:

Background: Compared to age-matched controls, up to 33% of women with breast cancer have poorer cognitive function before they begin adjuvant therapy. However, the underlying biological basis remains unclear. The purpose of this study was to explore the role of DNA methylation (DNAm) on four objective (*i.e.*, concentration, attention, mental flexibility, and executive function) and one subjective (*i.e.*, total scores from the Patient Assessment of Own Functioning Inventory) cognitive function phenotypes in postmenopausal women diagnosed with early-stage hormone-receptor positive breast cancer after breast-conserving surgery and prior to initiating aromatase inhibitor (AI) therapy.

Methods: Genome-wide DNAm data were generated from blood samples in 63 individuals using Infinium MethylationEPIC Beadchips. 700,772 CpGs and 62 samples passed quality control checks and were then used for analysis. An epigenome-wide association study (EWAS) that evaluated CpG-specific associations was conducted for each cognitive domain phenotype adjusting for age, verbal IQ score, and global patterns of DNAm. The dmrff R package was then applied to identify differentially methylated regions (DMR) using EWAS summary statistics.

Results: The samples were primarily in stage 0 and I of breast cancer with a mean age of 64 and a mean verbal IQ score of 112. No CpGs met the genome-wide significance threshold of 9×10^{-8} in EWAS of the four objective cognitive domains, but several significant DMRs with Bonferroni-adjusted p-value less than 0.05 were identified, a few of which were known to be associated with cancer or tumorigenesis. Two DMRs were identified for concentration in/near *RGS12* and *HMG3*. Three DMRs in/near *USP10*, *TRAPPC5*, and *PIK3IP1* were identified for attention. Two DMRs were found in/near *TRAV2* and *MUCL1* for mental flexibility. For subjective cognitive function, higher mean DNAm levels of cg13769506 in the promoter region of the tumor suppressor gene *BNIP3L* were significantly associated with better cognitive function with p-value of 2.8×10^{-9} ; in addition, five DMRs were significant after Bonferroni-adjustment which mapped to or near the genes *UVRAG-DT*, *MAGOH*, *MSRB1*, *ACCN3*, and *CIQL2*.

Conclusions: Our results suggest that epigenetic changes in breast cancer patients may be associated with cognitive function even before receiving endocrine therapy. This study lays the foundation for future research to assess association between DNAm levels and cognitive function in a later time point in context of AI therapy and/or an exercise intervention which may provide insights on the interplay of DNAm, treatment, and exercise on cognitive function in women with breast cancer.

Epigenetics Posters - Wednesday

PB2487. *Variation in miRNAs may contribute to orient future therapeutic strategies in hidradenitis suppurativa; An epigenome-widescreening approach*

Authors:

V. Aaren¹, U. Radhakrishna², D. Jhala³, N. Saiyed², G. Damiani⁴; ¹Andhra Univ., Visakhapatnam, India, ²Oakland Univ. William Beaumont School of Med., Royal Oak, MI, ³Sch. of Sci., Gujarat Univ., Ahmedabad, India, ⁴Istituto Ortopedico Galeazzi, Milan, Italy

Abstract Body:

Background: Hidradenitis suppurativa (HS) is a chronic inflammatory disease, influenced by non-genetic factors that modulate the expression of miRNAs. Currently, no miRNA data are available for HS. Thus, we aimed to identify miRNA gene methylation profiles associated with HS susceptibility. **Objectives:** Identify miRNA gene methylation profiles associated with HS susceptibility. This study examined the whole genome-wide methylation patterns of DNAs from 24 healthy controls and 24 patients with HS using Illumina Infinium MethylationEPIC BeadChip array analysis. The differentially methylated miRNAs were analyzed using Ingenuity Pathway Analysis (IPA) to explore the inversely correlated pathways regulated by miRNAs. **Results:** In the study, 54 and 6 CpGs in HS patients were respectively significantly hypomethylated and hypermethylated compared to controls. Some of these CpGs were found to be critical for skin function, such as mir-29, miR-200, mir-205, mir-548, and mir-132. The miR-200c gene was identified as a vital determinant in regulating skin repair after injury and may contribute to age-associated alterations in wound repair. miR-132 was significantly upregulated during the inflammation phase of wound repair, enhancing the activity of *STAT3* and *ERK* pathways that promote keratinocyte proliferation. **Conclusions:** Many of the microRNA genes that were epigenetically altered are known to be involved in wound healing, inflammation, keratinocyte proliferation, and modulation of wound tissues. This is the first study to analyze methylation profiles of miRNA genes in the HS population. This report highlights the unique role that miRNAs could play in the both diagnosis and treatment of HS.

Epigenetics Posters - Thursday

PB2488. Vitamin c contributes to epigenetic regulation of genes related to diabetic retinopathy in retinal endothelial cells.

Authors:

D. Sant¹, J. Reynolds¹, E. Turner¹, T. Alger¹, N. Islam¹, V. Manukyan¹, A. Sheppert¹, G. Wang²; ¹Noorda Coll. of Osteopathic Med., Provo, UT, ²Univ Miami, Miami, FL

Abstract Body:

Diabetic retinopathy is a complication of diabetes that leads to irreversible vision loss and remains the leading cause of blindness in working-age adults. It is primarily a complication of microvascular endothelial cells in the retina and the breakdown of the inner blood-retinal barrier. Vitamin c passes through the blood-retinal barrier through GLUT1 transporters, which also transport glucose. Glucose acts as a competitive inhibitor to vitamin c, and hyperglycemia leads to a local vitamin c deficiency in the eyes of diabetics. Vitamin c acts as a cofactor for the TET enzymes, and a local deficiency leads to impaired DNA methylation-demethylation dynamics.

Primary, human retinal endothelial cells were cultured in 15.7 mM glucose (283 mg/dL) either in the presence or absence of vitamin c (50 µM) for five days. Immunofluorescent staining showed a robust increase in global hydroxymethylcytosine levels, consistent with previous reports in other cell types. Whole transcriptome sequencing (RNA-seq) was performed, and differential expression was determined using a combination of DESeq2 and edgeR. RNA-seq revealed that 437 genes were found to have upregulated transcription and 308 genes were found to have downregulated transcription.

Pathway analysis highlighted changes in genes related to leukocyte adhesion, tethering and rolling. Inflammation is an early characteristic of diabetic retinopathy that precedes measurable changes in vasculature or vision. In particular, vitamin c treatment caused a reduction in transcription of *SELP*, the gene that codes for P-selectin. GWAS studies have found that mutations in *SELP* are associated with diabetic retinopathy and plasma levels have found an association of P-selectin levels in the plasma and severity of diabetic retinopathy. Vitamin c-induced reduction in *SELP* was confirmed by qPCR in a second batch of cells. Glutathione, an antioxidant stronger than vitamin c, failed to reduce *SELP* transcription, indicating that the reduction is likely due to the epigenetic effects of vitamin c treatment. These data suggest that local vitamin c deficiencies in the eyes of diabetics affect transcription of genes related to leukocyte adhesion and may contribute to the progression of diabetic retinopathy.

Epigenetics Posters - Wednesday

PB2489. Whole genome bisulfite sequencing identifies methylation markers in cord blood linked to maternal hyperglycaemia and childhood metabolic abnormalities

Authors:

Y. Li¹, K. K. Wong², C. H. Tam^{2,3}, C. K. Lim^{2,3}, C. C. Wang⁴, X. L. Yang⁵, A. El-Osta⁶, W. L. Lowe⁷, W. H. Tam⁴, K. Y. Yip^{1,8,9}, R. C. Ma^{2,3,9}; ¹Dept. of Computer Sci. and Engineering, The Chinese Univ. of Hong Kong, Hong Kong, China, ²Dept. of Med. and Therapeutics, The Chinese Univ. of Hong Kong, Hong Kong, China, ³Li Ka Shing Inst. of Hlth.Sci., The Chinese Univ. of Hong Kong, Hong Kong, China, ⁴Dept. of Obstetrics and Gynaecology, The Chinese Univ. of Hong Kong, Hong Kong, China, ⁵Dept. of Epidemiology and Biostatistics, Tianjin Med. Univ., Tianjin, China, ⁶Dept. of Diabetes, Central Clinical Sch., Monash Univ., Melbourne, Australia, ⁷Ctr. for Diabetes and Metabolism, Northwestern Univ., Chicago, IL, ⁸Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA, ⁹Hong Kong Inst. of Diabetes and Obesity, The Chinese Univ. of Hong Kong, Hong Kong, China

Abstract Body:

Hyperglycaemia affects around 1 in 6 pregnancies globally. Offspring of women with hyperglycaemia in pregnancy have an increased risk of diabetes and obesity in later life and epigenetic mechanisms have been implicated. We performed epigenomic profiling in cord blood to identify methylation changes associated with maternal glycaemic status and later risk of metabolic disease in the offspring. We included 84 mother-offspring pairs (including 27 GDM mothers) from the Hyperglycaemia and Adverse Pregnancy Outcome (HAPO) study Hong Kong field centre. All mothers underwent oral glucose tolerance tests (OGTTs) between 24-32 weeks of gestation. Cord blood was collected at the time of birth. Cord blood DNA was subjected to whole-genome bisulfite sequencing using Illumina HiSeq platform at 150PE. After the removal of low-quality bases and adapter sequences, alignment and methylation calling were performed using gemBS. Cell type compositions were estimated using methylCC with cord blood reference. We used linear regression models to assess the association between cord blood DNA methylation and clinical traits of the pregnant mothers and the offspring at follow-up at age 7. Maternal age at pregnancy, maternal pre-pregnancy BMI, offspring sex, gestational age, the estimated cell type proportions and batch information were added as confounders in the regression models. We identified 13 CpG sites (each with $p < 10^{-5}$, adjusted $p < 0.2$) associated with maternal 2-hour glucose levels during OGTT, located within or close to genes including *GBP3*, *AASS*, *LINC01339*, *GPR137B*, *ERO1B*, *SLC12A2*, *FGF1*, *ZNF516* and *PLCB4*. The gene *FGF1* has been shown to regulate glucose levels while the role of other genes in metabolic programming has not been previously demonstrated. We also found 4 significant CpG sites (each with $p < 10^{-8}$, adjusted $p < 0.05$) whose methylation levels in cord blood were associated with follow-up variables in the offspring at age 7, including insulinogenic index and beta-cell function. The most significant CpG site ($p = 2.06 \times 10^{-13}$, adjusted $p = 3.79 \times 10^{-7}$) associated with insulinogenic index is located within the gene *SFII*. We performed functional enrichment analysis of the top genes associated with antenatal maternal glucose, follow-up insulinogenic index and beta-cell function respectively and pathways related to neural development were identified in all the analyses. In summary, our results suggest that cord blood methylation is not only associated with maternal glucose during pregnancy, but also with metabolic traits in the offspring during follow-up.

Epigenetics Posters - Thursday

PB2490. Whole-methylomics reveals differentially methylated genes in blood associated with Late-onset Alzheimer's disease.

Authors:

C. Breen, K. J. Hogan, A. Madrid, L. A. Papale, L. R. Clark, S. Johnson, S. Asthana, S. Keles, R. Alisch; Univ Wisconsin - Madison, Madison, WI

Abstract Body:

Alzheimer's disease (AD) is the most common neurodegenerative disease in adults. Late-onset sporadic AD (LOAD) is characterized by signs and symptoms of dementia that present after the age of 65. While the full etiologies of LOAD remain unknown, recent evidence suggests that environmental influences increase risk of disease in part through interactions with the epigenome. Epigenome-wide association studies (EWAS) of brain tissue report differential DNA methylation in known and newly recognized LOAD genes, thereby underscoring the utility of EWAS in disclosing novel genes and pathways associated with LOAD pathogenesis. As an alternative to the study of donor brain tissues, investigation of DNA methylation in accessible peripheral tissues offers the opportunity to improve LOAD diagnosis and prognosis. Using a comprehensive whole-methylome sequencing approach and existing banked biofluids with phenotypic data from the Wisconsin Alzheimer's Disease Research Center's (WADRC), we profiled more than 25 million CpGs from male and female LOAD and non-LOAD participants (N = 71) and found ~80,000 differentially methylated loci (DMLs; FDR < 0.05), of which 49% are hypermethylated. Filtering these DMLs to those residing in gene bodies or their corresponding promoter regions (2kb upstream of transcription start site), we identify ~2,600 genes with differentially methylated regions (DMRs) of five or more DMLs, all hypomethylated or hypermethylated associated with dementia, including DMRs in KIF25/KIF25-AS1, MBP, PIEZ02, and DOK6 genes, which have been reported by others to directly participate in LOAD methylation, expression, and pathogenesis. Among the top ten significant gene ontology terms associating with DMR-associated genes are several with known roles in LOAD pathology: axogenesis, regulation of GTPase activity, and regulation of neuron projection development. Together, these data provide evidence that DNA methylation levels in blood can be used to develop novel biomarkers useful in clinical settings and suggest a complex relationship between DNA methylation levels in brain and blood.

Epigenetics Posters - Wednesday

PB2491*. Widespread age-associated changes in the chromatin architecture of skeletal muscle cell type populations.

Authors:

K. Moo¹, R. Albanus², A. Varshney¹, P. Orchard¹, N. Manickam¹, M. Laakso³, J. Tuomilehto⁴, T. A. Lakka³, K. L. Mohlke⁵, M. Boehnke¹, L. Scott¹, H. A. Koistinen⁴, F. S. Collins⁶, S. C. J. Parker¹; ¹Univ. of Michigan, Ann Arbor, MI, ²Washington Univ., St. Louis, MO, ³Univ. of East Finland, Kuopio, Finland, ⁴Univ. of Helsinki, Helsinki, Finland, ⁵Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ⁶NIH, Bethesda, MD

Abstract Body:

Aging progressively alters the regulatory landscape of the epigenome and is associated with increased risk for multiple diseases including cancer, Alzheimer's, and type 2 diabetes. Genome-wide association studies have identified hundreds of genetic signals associated with these aging-related diseases, and the majority of these signals occur in noncoding regions of the genome. Together, these findings suggest that aging-related epigenomic changes are one component of disease risk. Here we analyze skeletal muscle biopsies from 284 Finnish study participants ranging from age 20 to 79 (mean 60) using single nucleus ATAC-seq to identify patterns in chromatin architecture that are associated with age. To find aging-related open chromatin regions in an unbiased way without assuming a linear relationship we used Autoregressive Integrated Moving Average (ARIMA) models. Of the 13 skeletal muscle cell types we identified, we selected the most abundant six (Type 1, 2a, and 2x muscle fiber, endothelial, mesenchymal stem cells, and smooth muscle) for analysis. We identified 983,155 consensus chromatin accessibility peaks across the 13 cell types and focused our analyses on the 149,751 to 289,430 peaks within each of the six selected cell types. Using a generalized linear model, we adjusted the sample-specific peak accessibility for body mass index and technical covariates such as batch. Then, we used the ARIMA modeling framework and found that between 6.2% and 15.5% of tested peaks had an age-associated pattern. The age-associated peaks were assigned to three broad categories (increasing, decreasing, and dynamic) using unsupervised clustering. Breakpoint analysis of these three categories showed that the chromatin landscape is changing at its greatest magnitude around 60, a result that was similar across the cell types. We are currently performing pathway enrichments to determine the underlying molecular and biological processes associated with these changes. These results highlight age-associated epigenomic differences in six skeletal muscle cell types, giving us insight into cellular dynamics across human lifespan.

Molecular Effects of Genetic Variation Posters - Thursday

PB2492. A Catalogue of Transcriptomes and Associated Genetic Effects on 2,000 Qataris Uncovering the Functional Impact of Middle Eastern Genetic Variation and Identifying Novel Pathways Underlying Human Traits and Diseases

Authors:

Y. Mokrab¹, H. Naeem¹, I. Diboun¹, M. Ghorbani¹, R. Razali¹, M. Hashmi¹, R. Mathew¹, V. Mattei¹, N. James¹, L. Mathew¹, L. Silcock¹, K. Wang¹, M. Kalikiri¹, F. Vempalli¹, M. Tamanni¹, A. Khouly¹, S. Poolat¹, T. Zaid¹, A. Akil¹, S. Lorenz¹, R. Al Ali¹, Q. Consortium², K. Fakhro¹, S. Tomei¹, D. Chaussabel¹, S. Montgomery³; ¹Sidra Med., Doha, Qatar, ²Weill Cornell Med.-Qatar, Dept. of Genetic Med., Doha, Qatar, ³Stanford Univ., Stanford, CA

Abstract Body:

Mapping genetic variation to transcriptome activity at a population level is a robust approach to linking regulatory mechanisms to traits and diseases, allowing both association and causality to be inferred. Here, we present a large study of predominantly healthy individuals from the Qatar Genome Project (QGP), combining whole genome sequencing (WGS) (30x coverage; n=6,216) and whole blood RNA-Seq (20-100 M reads; n=2,127) data to build a comprehensive catalogue of genetic variants regulating various transcription traits. Data were processed using cutting-edge bioinformatics pipelines and comparative analysis revealed significant transcriptome variation among the major genetic subgroups of Arab populations characterized recently (Razali et al. Nature Comms. 2021). Most of this variation was mapped to immune related pathways implying ancestral differences in disease risk and susceptibility to infection between the genetic subgroups. We further investigated the effects of SNPs, Indels, and Structure Variants (SVs) on gene expression, splicing (isoform-level and intron-level), and allelic expression (variant-level and gene-level) in cis, identifying genetic regulatory associations for 13,195 genes at FDR 0.05. These included novel hits for 3.8m gene expression quantitative trait loci (eQTLs), 3m alternate isoform expression quantitative trait loci (isoQTLs), 1.3m splicing quantitative trait loci (sQTLs), and (1.1m variant-level and 3.5m gene-level) allele-specific expression QTL (aseQTLs). We co-localized the QTL signals with a published GWAS on 6,218 subjects from the same QGP cohort, featuring 45 clinically relevant traits. With this analysis, we identified 845 SNPs in 832 genes to be causal for both genetic expression and disease pathology in a set of target genes previously associated with a range of Anthropometric, Electrolytes, Enzymes, Coagulation, Blood Cells, Lipids, other biochemical-related trait loci. The generated data constitutes the largest whole blood multi-QTL resource available to date based on non-imputed data and samples, uniformly-generated and processed in a single center. By revealing novel loci unique to Arab and Middle Eastern populations, this contributes to generating a valuable reference dataset to further characterize under-studied populations with important relevance worldwide. Our QTL and GWAS colocalization analysis revealed underlying molecular mechanisms to allelic heterogeneity and pleiotropic effect on complex traits.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2493. A gain-of-function recurrent missense variant leads to a GABAergic/glutamatergic imbalance in a forebrain organoid model of PACS1 syndrome

Authors:

L. Rylaarsdam, A. Guemez-Gamboa; Northwestern Univ., Chicago, IL

Abstract Body:

PACS1 syndrome is a neurodevelopmental disorder characterized by intellectual disability and craniofacial abnormalities resulting from a *de novo* p.R203W variant in phosphofurin acidic cluster sorting protein 1 (PACS1). PACS1 is known to play roles in both the endosomal pathway and nucleus, but little is known about how this variant affects the developing nervous system and patients have few therapeutic options. Here, we used stem cell-derived forebrain organoids to show that PACS1^(+/R203W) cells share convergent molecular features of autism spectrum disorder (ASD) through a gain-of-function mechanism. These features include an aberrant propensity towards GABAergic differentiation, increased inhibitory synaptic density, and impaired expression of an ASD-specific gene network enriched at synapses. This work is the first to investigate the impact of the p.R203W variant on the developing brain and suggests a therapy that either clears p.R203W PACS1 or targets convergent pathological mechanisms of ASD could be beneficial for patients.

Molecular Effects of Genetic Variation Posters - Thursday

PB2494. A genome-first approach characterizing the frequency and phenotype of potentially pathogenic germline *DGCR8* variants in two large, unselected cohorts

Authors:

J. Kim¹, J. Haley², D. Smelser², DiscovEHR Collaboration, B. Rivera³, W. Foulkes⁴, D. Carey², D. Stewart⁵; ¹Natl. Cancer Inst., Rockville, MD, ²Geisinger Hlth.System, Danville, PA, ³Bellvitge BioMed. Res. Inst., Barcelona, Spain, ⁴McGill Univ. Hlth.Ctr., Montreal, QC, Canada, ⁵Natl. Cancer Inst., ROCKVILLE, MD

Abstract Body:

DGCR8 forms a microprocessor complex with *DROSHA*, where it is required for processing pri-microRNAs. Recent work identified two unrelated families with a germline *DGCR8* missense variant, p.Glu518Lys, segregating with schwannoma/thyroid neoplasia or hyperplasia. We used a genome-first approach to characterize prevalence and phenotype in individuals with germline *DGCR8* variants. We used the Geisinger DiscovEHR study (175K exomes) and UK Biobank (200K exomes). We analyzed predicted loss-of-function (pLOF) variants; missense and splice site variants were classified as “damaging” if 3 of 4 missense predictors (metaSVM, CADD, REVEL, bayesdel) or 2 of 3 splice-site predictors (dbscSNV, spliceAI, spidex) exceeded set thresholds. We queried neoplasms, thyroid phenotypes and procedure codes using a self-reported questionnaire, EHR, and/or cancer and death registries. Controls were selected from the full cohort who do not carry a *DGCR8* pLOF or “damaging” missense variant. We identified 29 individuals (1:6,050) and 16 individuals (1:12,540) with a pLOF variant and 16 individuals (1:12,540) and 17 individuals (1:10,321) with missense variants in the DiscovEHR and UKBiobank, respectively. In both cohorts, we did not see any enrichment of neoplasms with pLOF variants. However, in DiscovEHR, we identified one woman with a papillary thyroid cancer at 27 and an ovarian cystic teratoma at 17 (a tumor reported in the original *DGCR8* pedigree). In the UK Biobank there was a male never-smoker with tonsil cancer at 34. Next, we evaluated thyroid phenotypes in pLOF carriers. We did not find anyone with thyroid phenotypes in UK Biobank; in the DiscovEHR cohort, only hyperthyroidism was found to be significant (p=0.04) vs controls. In both cohorts there was no difference in age at diagnosis for malignancy, but age was significantly younger for thyroid phenotypes in DiscovEHR (40.3 in pLOF vs. 52.4 in non-carriers, p=0.01). Individuals with a missense variant did not show any enrichment or earlier age at diagnosis for malignancy or thyroid phenotypes. However, one female in the UK Biobank with a “damaging” missense variant (p.Pro346Ala) had a cranial nerve neurilemmoma (schwannoma) diagnosed at 40; she had no germline variant in *NF2*. *DGCR8* Glu518Lys was not observed in either cohort. In DiscovEHR, we observed an earlier age of diagnosis for some thyroid phenotypes; lack of thyroid diagnoses in the UK Biobank may reflect differences in medical culture between the US and UK. Our study suggests that germline *DGCR8* variants are not associated with increased risk of cancer, however, the detection of a schwannoma, teratoma and papillary thyroid cancer diagnoses merit follow-up.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2495*. A Homozygous IER3IP1 Mutation Causes Secretory Protein Trafficking Defects in Neural Progenitor Cells

Authors:

L. Ahn¹, K. Chase², A. Peden³, K. Zhang², A. Schaffer¹; ¹Case Western Reserve Univ., Cleveland, OH, ²Mayo Clinic, Dept. of NeuroSci., Jacksonville, FL, ³The Univ. of Sheffield, Sheffield, United Kingdom

Abstract Body:

Microcephaly with simplified gyration, generalized epilepsy, and permanent neonatal diabetes syndrome (MEDS) is a severe autosomal recessive disorder characterized by the aforementioned clinical features. It is caused by deleterious bi-allelic variants in the *immediate early response-3 interacting protein-1* (*IER3IP1*) gene. The role of IER3IP1 in the pathogenesis of MEDS remains elusive. Yos1p, a yeast homolog, has been reported to be involved in the anterograde transport of cargos from the endoplasmic reticulum (ER) to the Golgi via COPII vesicles. Also, recent proteomic data collected from HeLa cells, as well as a genetic knockout screen performed in cerebral organoids, suggest that IER3IP1 may perform a conserved function in protein trafficking. Based on prior research and the clinical presentations of MEDS patients, we hypothesize that human IER3IP1 regulates secretory protein trafficking during neurogenesis. To test this hypothesis, we generated isogenic neural progenitor cells (NPCs) and induced pluripotent stem cells (iPSCs) lines reprogrammed from MEDS patient fibroblasts for phenotypic analysis. To investigate whether IER3IP1^{L78P/L78P} causes structural changes in organelles critical in protein trafficking, we performed immunocytochemistry for Calnexin, a marker for ER structures, as well as electron microscopy imaging of organelles. We saw IER3IP1^{L78P/L78P} NPCs had reduced expression of Calnexin, swollen ER morphology with abundant multilamellar bodies, and an increased number of vacuolized mitochondria upon electron microscopy imaging, compared to IER3IP1 wildtype NPCs. Structural abnormalities in organelles in IER3IP1^{L78P/L78P} NPCs suggested functional defects in protein secretion. Thus, we sought to quantify and compare protein secretion capacity directly in IER3IP1^{L78P/L78P} and control NPCs. We generated a GFP trafficking reporter that utilizes an inducible FKBP aggregation domain. The reporter enables us to measure the rate of GFP-fused protein trafficking in real-time and small molecule-dependent manner. Using this reporter, we found the patient variant caused a defect in protein trafficking and secretion. These phenotypes were ameliorated after correcting the IER3IP1 variant through CRISPR/Cas9 gene-editing of the patient-derived cells, indicating these cellular phenotypes were caused by the IER3IP1^{L78P/L78P} variant. In summary, we demonstrate that IER3IP1^{L78P/L78P} is deleterious and likely leads to MEDS by disrupting ER structure and secretory protein trafficking.

Molecular Effects of Genetic Variation Posters - Thursday

PB2496. A humanized yeast model to identify disease-associated, dominant-negative effects on protein function

Authors:

A. Antonellis¹, R. Meyer-Schuman², S. Marte¹, T. Smith¹, S. Feely³, M. Kennerson⁴, G. Nicholson⁵, M. Shy⁶, K. Koutmou¹; ¹Univ. of Michigan, Ann Arbor, MI, ²Baylor Coll. of Med., Houston, TX, ³Univ Iowa, Iowa City, IA, ⁴ANZAC Res. Inst., Concord, Australia, ⁵Concord Hosp, Concord, Australia, ⁶Univ. of Iowa, Iowa City, IA

Abstract Body:

Aminoacyl-tRNA synthetases (ARSs) are ubiquitously expressed, essential enzymes that translate the genetic code by charging tRNA molecules with cognate amino acids. Heterozygosity for missense variants or small in-frame deletions in five ARS genes causes dominant axonal peripheral neuropathy, a disorder characterized by impaired motor and sensory function in the distal extremities. The majority of neuropathy-associated ARS variants reduce enzyme activity, but do not significantly decrease protein levels. Interestingly, all five implicated ARS genes encode enzymes that function as homodimers. These observations raise the possibility of a dominant-negative effect, where non-functional mutant ARS subunits dimerize with wild-type ARS subunits and reduce overall ARS activity below 50%, which may breach a threshold required for peripheral nerve axons and activate the integrated stress response, as recently shown *in vivo* for neuropathy-associated glycyl-tRNA synthetase (*GARS1*) variants. To test for dominant-negative properties of neuropathy-associated ARS alleles, we developed a humanized yeast assay to co-express pathogenic human alanyl-tRNA synthetase (*AARS1*) mutations with wild-type human *AARS1*. Here, we will present our unpublished data on a series of pathogenic, neuropathy-associated *AARS1* missense variants and show that: (1) pathogenic variants cause a loss-of-function effect; (2) pathogenic variants do not ablate protein-protein interactions with wild-type *AARS1*; (3) pathogenic variants directly impair the function of wild-type *AARS1*; and (4) reducing dimerization between mutant and wild-type *AARS1* rescues the impaired function of wild-type *AARS1*. In sum, these data demonstrate that neuropathy-associated *AARS1* variants exert a dominant-negative effect, which supports a common, loss-of-function mechanism for ARS-mediated dominant peripheral neuropathy.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2497. A lupus-associated variant in IRF7 amplifies IFN- α production.

Authors:

S. Virolainen^{1,2}, K. Dunn¹, C. Forney¹, O. Donmez¹, S. Parameswaran¹, M. Weirauch¹, L. Kottyan¹; ¹Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH, ²Univ. of Cincinnati Coll. of Med., Cincinnati, OH

Abstract Body:

Systemic Lupus Erythematosus (SLE) is an autoimmune disease characterized by widespread inflammation and organ destruction that disproportionately affects individuals with two X chromosomes and those of African American ancestry. SLE has high heritability, with genetics contributing to nearly half of disease risk. More than 90 genetic risk loci are implicated in the etiology of SLE, with additive effects of these loci likely contributing to SLE risk through dysregulation of immune cells. Genetic variants within loci encoding multiple Interferon regulatory factors (IRFs) are associated with SLE. IRF proteins are key regulators of the expression of and response to type I interferons (IFNs). While IFNs are critical for antiviral immune responses, dysregulation of IFNs is a major contributor to autoimmunity. A majority of SLE patients exhibit elevated levels of circulating IFN, a feature that correlates with disease activity. The genetic mechanisms contributing to chronically elevated IFN in SLE patients are poorly understood, but have been generally correlated with the SLE risk genotype at the *IRF7*, *IRF5*, and *STAT1* SLE risk loci. In this study, we examine the downstream consequences of an SLE-associated missense variant in IRF7 on IFN secretion.

We focus on rs1131665 (p -value $< 5 \times 10^{-8}$, OR =1.24 in Europeans and OR =1.17 in African Americans). rs1131665 results in an arginine (R, non-risk) to glutamine (Q, risk) amino acid change in the autoinhibitory domain of IRF7. We generated human cell lines expressing both the risk and non-risk IRF7 proteins and assessed differential IFN production at both the mRNA and protein levels before and in response to toll-like receptor-7 (TLR-7) stimulation. Strikingly, genotype-dependence was evident prior to TLR-7 induction, with cells expressing the risk allele showing higher baseline IRF7 activity at the mRNA and protein levels as assessed by RNA-seq and ELISA, respectively. Following TLR-7 stimulation, bulk RNA-seq analysis revealed ~20 differentially expressed genes between cells expressing the risk and non-risk constructs. A majority of these genes are involved in the IFN pathway and were upregulated in cells expressing the risk construct. IFN- α ELISA on cell supernatant showed similar heightened (~2 fold) IFN- α secretion at the protein level in cells expressing the IRF7 risk variant compared to those expressing the non-risk variant.

We conclude that the SLE-associated variant within IRF7 results in heightened IRF7 activity as measured by IFN output at the mRNA and protein levels. This genotype dependent activity can be independent of TLR-7 stimulation but is also observed with TLR-7 stimulation.

Molecular Effects of Genetic Variation Posters - Thursday

PB2498. A Novel De novo Likely Pathogenic Variant of *WFS1* gene in a Pakistani Child

Authors:

M. Hanif¹, S. A. Ahmed², M. N. Ibrahim¹, S. J. Raza¹; ¹NICH, KARACHI, Pakistan, ²Kaiser Permanente, Oakland, CA

Abstract Body:

Abstract Background: Wolfram Syndrome is a rare autosomal recessive genetic disorder caused by mutations in *WFS1* gene, located on chromosome 4p16.1. This gene encodes for wolframin membrane-embedded protein of endoplasmic reticulum. Pathogenic genetic alterations in *WFS1* gene usually result in endoplasmic reticulum (ER)-stress leading to neurodegeneration pancreatic β -cell dysfunction and apoptosis. Wolfram syndrome is associated with juvenile onset diabetes mellitus, optic atrophy, sensorineural deafness, and diabetes insipidus. This syndrome is also known as DIDMOAD (Diabetes Insipidus, Diabetes Mellitus, Optic Atrophy, and Deafness). Though Wolfram syndrome is generally considered an autosomal recessive disorder, heterozygous pathogenic variants have been noted to cause Wolfram like syndrome (congenital progressive hearing impairment, diabetes mellitus, and optic atrophy). **Objective:** The aim of this study is to highlight a novel de-novo likely pathogenic variant of *WFS1* in a Pakistani child liable to cause Wolfram like syndrome. **Case Discussion:** We report a novel de novo likely pathogenic variant in a Pakistani child in *WFS1* gene who presented with clinical features consistent with wolfram like syndrome (MedGen UID: 481988). This seven-year-old boy initially presented to our endocrine clinic for management of uncontrolled type 1 diabetes mellitus despite of being on glargine and aspart insulin his HbA1c was high (14%) though other investigations were normal. A physical exam noted a short stature (-4.55 SDS for age 7 years), otherwise, he appeared normal. Past history was significant for sensorineural deafness in his first year of life. He also had bilateral cataract surgery at the age of five years. Family history is only significant for type 2 diabetes on his paternal side. Based on these clinical findings diabetes with extra-pancreatic features was suspected and genetic testing was ordered for a multi-gene panel which included the *WFS1* gene. The original report noted c.2586G>T (p.Lys862Asn) as a variant of uncertain significance but subsequent parental testing led to the reclassification of the variant as a likely pathogenic variant. **Conclusion:** Based on this new diagnosis an eye exam was requested that showed bilateral moderate optic atrophy which further supported this diagnosis our report highlights the rare possibility of a heterozygous variant causing Wolfram like syndrome and identifies a novel likely pathogenic variant in this gene which is supported by clinical features consistent with Wolfram like syndrome.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2499. A rare genetic variant in the cleavage site of *prepro-orexin* is associated with idiopathic hypersomnia

Authors:

T. Miyagawa¹, S. Tanaka², M. Shimada³, N. Sakai⁴, S. Nishino⁴, K. Mishima⁵, K. Tokunaga³, M. Honda¹; ¹Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan, ²Kansai Med. Univ., Osaka, Japan, ³Natl. Ctr. for Global Hlth.and Med., Tokyo, Japan, ⁴Stanford Univ., Stanford, CA, ⁵Akita Univ. Graduate Sch. of Med., Akita, Japan

Abstract Body:

Idiopathic hypersomnia (IH) is a rare, heterogeneous sleep disorder characterized by excessive daytime sleepiness. The exact prevalence of IH remains unknown due to the absence of epidemiological studies. A high proportion of IH patients (26.9-39.1%) reported a family member with excessive daytime sleepiness. In contrast to narcolepsy type 1, which is a well-defined type of central disorders of hypersomnolence, the etiology of IH is poorly understood. No susceptibility loci associated with IH have been clearly identified, despite the tendency for familial aggregation of IH. We performed a variation screening of *prepro-orexin/hypocretin* and *orexin receptors* genes, and an association study for IH in a Japanese population, with replication (598 IH patients and 9826 controls). We identified a rare missense variant (g.42184347T>C; p.Lys68Arg; rs537376938) in the cleavage site of *prepro-orexin* that was associated with IH (minor allele frequency of 1.67% in cases versus 0.32% in controls, $P = 2.7 \times 10^{-8}$, odds ratio = 5.36). All patients with this mutation were heterozygous carriers. Subjective sleepiness as evaluated with the Epworth Sleepiness Scale scores in unmedicated conditions and arousal index (polysomnography) were nominally higher in the orexin mutation-positive patients compared with the orexin mutation-negative patients ($P = 0.049$ and $P = 0.046$, respectively), suggesting that mutation-positive IH patients suffered more sleepiness and sleep instability. No significant association between narcolepsy (type 1 and type 2) and rs537376938 was observed. Two forms of orexin (orexin-A and -B) are generated by cleavage of one precursor peptide, prepro-orexin. A cleavage assay was performed using proprotein convertase subtilisin/kexin (PCSK) type 1 and PCSK2 to examine the differences in cleavage efficiency between wild-type (Gly-Lys-Arg; GKR) and mutant (Gly-Arg-Arg; GRR) peptides at the cleavage site of prepro-orexin. In both PCSK1 and PCSK2 assays, the mutant peptide was less processed than the wild-type peptide. We also confirmed that the prepro-orexin peptides themselves transmitted less signaling through orexin receptors than mature orexin-A and orexin-B peptides. These results indicate that a subgroup of IH is associated with decreased orexin signaling, which is believed to be a hallmark of narcolepsy type 1.

Molecular Effects of Genetic Variation Posters - Thursday

PB2500. A risk variant for Barrett's esophagus and esophageal adenocarcinoma at chr8p23.1 affects enhancer activity and implicates multiple gene targets

Authors:

M. Buas¹, M. Ali², J. Chen¹, X. Wang³, J. Dai³, T. Vaughan³, G. Casey²; ¹Mem. Sloan Kettering Cancer Ctr., New York, NY, ²Univ. of Virginia, Charlottesville, VA, ³Roswell Park Comprehensive Cancer Ctr., Buffalo, NY, ⁴Fred Hutchinson Cancer Res. Ctr., Seattle, WA

Abstract Body:

Nineteen genetic susceptibility loci for esophageal adenocarcinoma (EAC) and its precursor Barrett's esophagus (BE) have been identified through genome-wide association studies (GWAS). Clinical translation of such discoveries, however, has been hindered by the slow pace of discovery of functional/causal variants and gene targets at these loci. We previously developed a systematic informatics pipeline to prioritize candidate functional variants using functional potential scores, applied the pipeline to select high-scoring BE/EAC risk loci, and validated a functional variant at chr19p13.11 (rs10423674). Here, we selected two additional prioritized loci for experimental interrogation: chr3p13/rs1522552 and chr8p23.1/rs55896564. Candidate enhancer regions encompassing these variants were evaluated using luciferase reporter assays in two EAC cell lines. One of the two regions tested exhibited allele-specific enhancer activity - 8p23.1/rs55896564. CRISPR-mediated deletion of the putative enhancer in EAC cell lines correlated with reduced expression of three candidate gene targets: B lymphocyte kinase (*BLK*), nei like DNA glycosylase 2 (*NEIL2*), and cathepsin B (*CTSB*). Expression quantitative trait locus (eQTL) mapping in normal esophagus and stomach revealed strong associations between the BE/EAC risk allele at rs55896564 (G) and lower expression of *CTSB*, a protease gene implicated in epithelial wound repair. These results further support the utility of functional potential scores for GWAS variant prioritization, and provide the first experimental evidence of a functional variant and risk enhancer at the 8p23.1 GWAS locus. Identification of *CTSB*, *BLK*, and *NEIL2* as candidate gene targets suggests that altered expression of these genes may underlie the genetic risk association at 8p23.1 with BE/EAC.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2501. A single-nucleus transcriptome-wide association study implicates novel genes in depression pathogenesis

Authors:

L. Zeng; Columbia Univ. Irving Med. Ctr., New York, NY

Abstract Body:

Depression is a common psychiatric illness and global public health problem. However, our limited understanding of the biological basis of depression has hindered the development of novel treatments and interventions. To identify new candidate genes for therapeutic development, we integrated human single-nucleus RNA sequencing (snucRNAseq) data from the dorsolateral prefrontal cortex (N=424) in 7 cell types and 81 cell subtypes with depression genome-wide association study (GWAS) results (N=500,199). Namely, we performed a transcriptome-wide association study of depression followed by Mendelian randomization. We identified 67 causal genes in depression that have a role in specific neocortical cell subtypes snucRNAseq; 51/67 of them were novel compared to previous studies. Importantly, we demonstrate that, depression TWAS genes showed a cell type specific pattern, with the greatest enrichment being in neurons and astrocyte. Compared to lower genetic correlated traits (e.g., BMI) with depression, higher correlated traits (e.g., schizophrenia) have more common TWAS genes with depression. In parallel, we performed differential gene expression analysis in relation to depression in 92 cortical cell types, and we found that genes such as *CCDC6*, *MADD*, *TAOK3* and *MEF2A* are associated with depression in specific cell types. These two analyses illustrate the utility of large snucRNAseq data to uncover both genes whose expression is altered in specific cell subtypes in the context of depression and to enhance the interpretation of well-powered GWAS so that we can prioritize specific susceptibility genes for further analysis.

Molecular Effects of Genetic Variation Posters - Thursday

PB2502. A splicing variant found in the human myostatin gene encodes an isoform that inhibits myostatin

Authors:

K. Maeta, M. Farea, H. Nishio, M. Matsuo; Faculty of Rehabilitation, Kobe Gakuin Univ., Kobe, Japan

Abstract Body:

[Background] MSTN gene encodes myostatin that inhibits myocyte proliferation and is conserved across species. Although this gene has only three exons, splicing variants (SVs) have been identified in sheep and birds. Surprisingly, the isoform encoded by MSTN SV inhibited myostatin and suppressed muscle atrophy. Therefore, MSTN SV has attracted much attention as a myostatin inhibitory molecule. However, there is no report of MSTN SV in humans. In this study, by expanding the analysis of MSTN mRNA from the coding region to the 3' UTR, we succeeded in cloning MSTN SV in humans for the first time in the world. Furthermore, this MSTN SV encoded an isoform with myostatin inhibitory activity. [Methods] MSTN SV was identified by RT-PCR of MSTN mRNA from rhabdomyosarcoma (RMS) cells. Expression of MSTN SV was analyzed by RT-PCR amplification of myoblast- and skeletal muscle-derived RNA. Expressed MSTN SV and their myostatin inhibitory activity were evaluated by western blotting and SMAD-dependent luciferase reporter, respectively. [Results] PCR amplification of the coding region of MSTN mRNA amplified a single band of MSTN mRNA. However, when the PCR amplified region was expanded deep into the 3' UTR, a small amplification product was obtained in addition to the normal product. This product was a deletion of approximately 1,000 bases in the 5' end of exon 3. This SV was activated atypical splice acceptor site consisting of two bases of TG in the 3' UTR (MSTN-b). MSTN-b was amplified in myoblasts but not in skeletal muscle. Expression of MSTN-b resulted in the detection of a 40 kDa band that reacted with a myostatin N-terminal recognition antibody, and the same band was also detected in RMS cells. From the above, we concluded that the protein encoded by MSTN-b is a novel myostatin isoform (myostatin-b). Although myostatin-b is 15 amino acids shorter than the prodomain of myostatin, its expression inhibited myostatin signaling in RMS cells. However, it did not inhibit the signal elicited by recombinant GDF11. Thus, we conclude that myostatin-b is a novel myostatin inhibitor specific for myostatin. [Discussion] MSTN-b is thought to be previously undiscovered because it utilizes an atypical splice acceptor located deep in the 3'UTR. Since myostatin-b has myostatin-specific inhibitory activity, it is expected to be clinically applicable as an innovative myostatin inhibitor for the prevention and treatment of muscle atrophy.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2503. A structural variant of the C-terminal prion-like domain of TDP-43 causes vacuolar muscle degeneration.

Authors:

P. Ervilha Pereira¹, N. Schuermans¹, A. Meylemans², P. LeBlanc¹, L. Versluys¹, E. Debackere¹, O. Vanakker², S. Janssens², J. Baets³, K. Verhoeven⁴, M. Lammens⁵, S. Symoens², B. De Paepe², J. De Bleecker², E. Bogaert¹, B. Dermaut¹; ¹Ghent Univ., Gent, Belgium, ²Ghent Univ. Hosp., Gent, Belgium, ³Univ. of Antwerp, Wilrijk, Antwerp, Belgium, ⁴Sint-Jan Hosp. Bruges, Bruges, Belgium, ⁵Antwerp Univ. Hosp., Antwerp, Belgium

Abstract Body:

Neuronal TDP-43-positive inclusions are a hallmark lesion found in frontotemporal dementia (FTD) and amyotrophic lateral sclerosis (ALS), present in 45% and 97% of cases, respectively. Missense mutations in the C-terminal prion-like domain (PrLD) of TDP-43 are the main type of disease-causing mutations reported for ALS. This domain mediates self-interaction, and mutations of this region are thought to lead to aggregate formation. However, the scope of TDP-43 proteinopathies goes beyond neural tissues, with reports showing TDP-43 pathology in vacuolar myopathies. Nevertheless, genetic evidence for a primary role for TDP-43 in myopathies is still amiss. Here we identified a multigenerational family with an autosomal dominant rimmed vacuole myopathy. Whole exome sequencing and genome-wide linkage analysis mapped the disease to an 11bp deletion in TARDBP (LOD-score of 3.6), causing a frameshift mutation in the C-terminal domain (CTD) of TDP-43 (TDP-43^{p.Trp385IlefsTer10}). This constitutes a novel type among described TDP-43 mutations, which are predominantly missense mutations. Patient-derived muscle biopsies revealed the presence of p62/TDP-43-positive sarcoplasmic inclusions and nuclear depletion of TDP-43. Additionally, we verified higher numbers of autophagosomes and a transcriptomic signature indicative of reduced mitochondrial and lipid metabolism, alongside a switch in sarcomeric protein isoforms suggesting increased muscle regeneration. Together with these observations, functional assays in *D. melanogaster* showed that TDP-43^{p.Trp385IlefsTer10} retains normal function but has reduced toxic gain-of-function properties. By studying this unique variant of TDP-43 it is our goal to clarify the importance of the CTD of TDP-43 and how its remodeling can affect the formation of aggregates. Furthermore, these results genetically link TDP-43 to vacuolar muscle degeneration for the first time. This not only highlights the importance of the PrLD in pathological conditions in a tissue-specific manner, but it also expands the implications of TDP-43 proteinopathies, from a nearly neuronal-exclusive context into a broader spectrum encompassing myopathies as well.

Molecular Effects of Genetic Variation Posters - Thursday

PB2504*. A uniquely prevalent deleterious variant within *POMC* gene identified in Estonian Biobank cohort

Authors:

E. Abner, N. Taba, T. Nikopensius, T. Esko; Univ. of Tartu, Tartu, Estonia

Abstract Body:

Genome wide association studies based within specific population groups provide an excellent opportunity for pinpointing rare and high impact genomic variants in already well studied traits, such as body-mass index (BMI).

We performed an exploratory GWAS in Estonian biobank (EstBB) to describe BMI-affecting variants (185,429 participants, BMI as continuous trait). Our analysis identified 178 significant loci ($p < 5 \times 10^{-8}$; at least ± 1 Mb apart), of which a majority have previously been reported to associate with obesity-related traits. To pinpoint functionally relevant SNVs, we characterized individual variants by their consequence on protein-coding genes, in correlation to their CADD score and beta coefficient.

Among the most significant functional hits, a stop-gain variant rs202127120 (*POMC*:Glu206X) within the pro-opiomelanocortin (*POMC*) gene, was identified. This variant is present in 0.87% of EstBB participants, displaying to our knowledge a dramatically higher allele frequency in Estonia than in other global populations. The *POMC*:Glu206X variant results in an early truncation of the *POMC* prohormone and results in lower β -MSH and β -endorphin levels in the hypothalamic-pituitary-adrenal axis, thus resulting in an inadequate leptin-melanocortin pathway triggering.

POMC:Glu206X variant carriers display significantly higher BMI among all biobank participants ($+0.85$ kg/m²; $p = 9.2 \times 10^{-13}$), higher overall weight ($+2.70$ kg; $p = 3.8 \times 10^{-13}$), waist circumference ($+1.69$ cm; $p = 1.9 \times 10^{-5}$) and higher BMI among 18-39 year old participants ($+1.01$ kg/m²; $p = 1.5 \times 10^{-8}$). A PheWAS utilizing data from medical electronic health records confirmed the enrichment of obesity related diagnoses among the *POMC*:Glu206X variant carriers (Top hit: ICD-10 category E66 "Overweight and obesity", OR 1.42, $p = 8.3 \times 10^{-5}$). Although the variant was originally imputed based on Estonian specific genome reference panels, we reconfirmed the presence of *POMC*:Glu206X via Sanger sequencing and confirmed 183 heterozygous and 13 homozygous carriers (from total 198 EstBB participants). We currently are in process of verifying the carrier status of additional predicted $n=1,579$ biobank participants and will be measuring quantitatively the effect *POMC*:Glu206X has on *POMC*-derived peptides in plasma.

Here, we identified a remarkably prevalent stop-gain variant in *POMC* gene, which previously has been considered highly deleterious. We demonstrate that *POMC*:Glu206X significantly associates with risk of obesity and we will next be proposing clinical intervention trials to ameliorate the effect *POMC*:Glu206X has on the local population.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2505. *A2m1l*-Knockout Mouse as a Potential Model of Chronic Otitis Media

Authors:

C. Elling¹, S. hirsch¹, R. Santos-Cortez²; ¹Univ. of Colorado Anschutz Med. Campus, Aurora, CO, ²Univ. of Colorado, Dept of Otolaryngology, Aurora, CO

Abstract Body:

Inflammation and infection of the middle ear, known as otitis media (OM), is a leading cause of hearing loss and the most frequently diagnosed disease in children worldwide. Traditionally, mouse models for OM rely on inducing acute infection through inoculation of the middle ear, e.g. with the human otopathogen non-typeable *Haemophilus influenzae* (NTHi), with very few genetic models with spontaneous or chronic OM. *A2ML1* variants, including loss-of-function variants, are associated with susceptibility to OM in humans, but no animal model has been reported for OM. Here, we report our middle ear findings in a mouse line with a CRISPR-induced knockout (KO) of *A2m1l*. Mice were X-rayed prior to harvest to determine if there are craniofacial or skeletal abnormalities. Tissue from mouse middle ears, as well as other upper respiratory mucosal tissues, were harvested. The harvested middle ear bullae were examined under microscope for phenotypic indications of OM. RNA samples isolated from middle ear tissue were assayed for expression of genes correlated with *A2ML1* expression in humans. There were no significant craniofacial differences by genotype, however skeletal abnormalities that are concordant with phenotypes observed in *A2ML1*-related Noonan-like syndrome in humans were identified. Otomicroscopic findings in mice heterozygous for the *A2m1l*-KO are frequently indicative of otitis media, with tympanic membrane perforations or thickening, as well as cases of middle ear effusion or fluid. Gene expression studies are in progress and will be reported. Thus far, our preliminary results in this *A2m1l*-KO mouse line indicate spontaneous occurrence of OM in these mice without the need for NTHi inoculation.

Molecular Effects of Genetic Variation Posters - Thursday

PB2506*. Aberrant splicing prediction across human tissues.

Authors:

N. Wagner¹, M. Çelik², F. Hölzlwimmer¹, V. Yopez¹, C. Mertes³, H. Prokisch⁴, J. Gagneur¹; ¹Technical Univ. of Munich, Garching bei München, Germany, ²Univ. of California Irvine, Irvine, CA, ³Technical Univ. of Munich, Garching, Germany, ⁴Helmholtz Zentrum Muenchen, Neuherberg, Germany

Abstract Body:

Aberrant splicing is a major cause of genetic disorders but its direct detection in transcriptomes is limited to clinically accessible tissues such as skin or body fluids. While DNA-based machine learning models allow prioritizing rare variants for affecting splicing, their performance on predicting tissue-specific aberrant splicing remains unassessed. Here, we generated the first aberrant splicing benchmark dataset, by calling aberrant splicing events on 16,213 RNA-seq samples from 49 human tissues from the GTEx dataset, comprising 8.8 million rare variants in paired genotype data from 946 individuals. At 20% recall, state-of-the-art DNA-based models SpliceAI and MMSplice cap at 10% precision. We observed that many false predictions originated from inaccurate genome annotations. We constructed a tissue-specific splicing map (SpliceMap) by mapping and quantifying tissue-specific splice site usage transcriptome-wide and modeling isoform competition. Using SpliceMap together with SpliceAI and MMSplice in a combined model that we call AbSplice increased precision by three-fold at the same recall. These results replicated in two independent rare disease cohorts. Moreover, the GTEx dataset consists of post-mortem collected RNA-seq samples across a vast variety of tissues and thereby offers the unique opportunity to evaluate to what extent aberrant splicing in an accessible tissue reflects aberrant splicing of another tissue of interest. Integrating RNA-sequencing data of clinically accessible tissues brought precision to 60%. We provide precomputed AbSplice scores [1] for all possible single-nucleotide variants genome-wide and publicly available software [2] to score variants including indels directly from VCF files. Altogether, our results substantially contribute to non-coding loss-of-function variant identification and to genetic diagnostics design and analytics.

PB2507. Abnormal cell fate allocation in embryogenesis caused by *Zic3* loss-of-function

Authors:

A. Haaning, A. Phatak, H. M. Bellchambers, M. B. Padua, S. M. Ware; Herman B Wells Ctr. for Pediatric Res., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract Body:

Pathogenic variants in *ZIC3* cause X-linked heterotaxy, a laterality disorder caused by abnormal left-right (L-R) patterning. Laterality defects include congenital heart defects (CHD), but some CHD associated with *ZIC3* variants are isolated and/or not specifically related to laterality defects, such as ventricular non-compaction. Furthermore, the spectrum of CHD in *Zic3* null mice, which recapitulates laterality defects and CHD observed in humans with *ZIC3* variants, is broader and more severe than in another heterotaxy mouse model resulting from *Foxj1* loss-of-function. Whereas *Foxj1* is specifically expressed in and affects functionality of the L-R organizer, *Zic3* is broadly expressed during gastrulation and influences planar cell polarity (PCP), as well as cell fate transitions and pluripotency. We hypothesize that some CHD resulting from *Zic3* loss-of-function stem from abnormalities in cell fate allocation. To test this hypothesis, we used scRNA-seq analysis to investigate whether *Zic3* loss-of-function leads to abnormal cell lineage allocation in E8 embryos. We observed that proportions of several cell types in *Zic3* null embryos differed significantly from wildtype, and, notably, cardiac progenitor cell numbers were increased in *Zic3* nulls. Pseudo-bulk analysis identified genes that were differentially expressed in *Zic3* nulls. *Hmgal1* was downregulated in *Zic3* nulls in 11 of 15 cell type clusters and whole embryo pseudo-bulk datasets. HMGA proteins function as epigenetic regulators of transcription by binding chromatin at AT-rich sites, causing changes in chromatin conformation that impact transcription factor binding. *Hmgal1* is highly expressed in pluripotent cells and its silencing results in downregulation of pluripotency genes. Broad and consistent downregulation of *Hmgal1* in *Zic3* nulls suggests that *ZIC3* may have a role in epigenetic regulation of cell differentiation. Of the genes upregulated in *Zic3* nulls, three encode transcription factors in the Early Growth Response (EGR) family: EGR2, EGR3, and EGR4. EGR proteins respond to mitogenic signals in a variety of cells and impact cell growth and proliferation. Results of this study suggest that *ZIC3* is a regulator of cell differentiation, affecting cell lineage allocation, signifying a potential novel cell-fate mechanism underlying CHD.

Molecular Effects of Genetic Variation Posters - Thursday

PB2508. Abundance of immunoprotein CD99 affected by loss of chromosome Y

Authors:

J. Mattisson¹, M. Danielsson¹, M. Hammond¹, H. Davies¹, C. Gallant¹, J. Nordlund², A. Raine², M. Edén³, M. Ingelsson³, J. Dumanski^{1,4}, J. Halvardson¹, L. Forsberg^{1,5}; ¹Dept. of Immunology, Genetics and Pathology and Sci. for Life Lab., Uppsala Univ., Uppsala, Sweden, ²Dept. of Med. Sci. and Sci. for Life Lab., Uppsala Univ., Uppsala, Sweden, ³Dept. of Publ. Hlth. and Caring Sci. / Geriatrics, Uppsala Univ., Uppsala, Sweden, ⁴Faculty of Pharmacy and 3P Med. Lab., Intl. Res. Agendas Programme, Med. Univ. of Gdańsk, Gdańsk, Poland, ⁵The Beijer Lab., Uppsala Univ., Uppsala, Sweden

Abstract Body:

Aging men have an increasing risk of somatically losing the Y chromosome. This aneuploidy, known as mosaic loss of chromosome Y (LOY), is the most common somatic mutation in leukocytes of elderly men. LOY is also associated with increased all-cause mortality and disease risk, including Alzheimer's disease, autoimmune disease, cardiovascular disease and cancer. Most studies have thus far investigated the clinical associations of LOY, with the functional impacts of Y loss on a cellular level remaining largely unexplored. Here, we investigated CD99, a cell surface protein essential for a normal immune functionality of leukocytes. The *CD99* gene is located in the pseudoautosomal region of chromosome X and Y, and has previously been shown downregulated in association with Y loss. However, as transcription does not necessarily translate directly into protein levels, especially for cell surface proteins, we sought to investigate whether LOY also affects the cell surface abundance of CD99. This had to be done while accounting for cell type since many transcriptional effects of LOY have been reported to be cell type specific. We therefore used CITE-seq, a single cell technology that simultaneously quantifies RNA and protein levels, applying monoclonal antibodies to target the cell surface features of interest. Peripheral blood mononuclear cells (PBMCs) sampled from four elderly men were sequenced, targeting CD99 as well as CD4, CD8, CD14, CD16, CD19 and CD56. The six additional proteins are cell type markers commonly used to classify leukocytes found in PBMCs. Here, they allowed us to validate the performance of CITE-seq and also worked as controls that should be unaffected by LOY. We found an overall lower cell surface abundance of CD99 in cells affected by LOY. This CD99 decrease was significant in all of the studied cell types, with the largest effect found in B lymphocytes, corresponding to a loss of about 27% in CD99 cell surface abundance. In contrast, the abundance of the cell type markers, used as controls, were not significantly affected by LOY. Considering the critical role that CD99 plays in facilitating the immune response of leukocytes, its decreased cell surface abundance from LOY could influence disease vulnerability in affected men. This study is therefore the first to suggest a possible mechanism between LOY and disease on a protein level.

Molecular Effects of Genetic Variation Posters - Thursday

PB2510. All-but-one conditional analysis of eQTL isolation in peripheral blood sheds light onto causal variant prioritization.

Authors:

M. Brown¹, E. Greenwood¹, B. Zeng², G. Gibson³; ¹Georgia Inst. of Technology, Atlanta, GA, ²Mount Sinai, New York, NY, ³Georgia Tech, Atlanta, GA

Abstract Body:

Expression quantitative trait locus (eQTL) detection has become increasingly important for understanding how non-coding variants contribute to disease susceptibility and complex traits. The major challenge in eQTL fine-mapping and causal variant discovery relate to the impact of linkage disequilibrium on signals due to one or multiple functional variants that lie within a credible interval. We contrast eQTL fine-mapping using the all-but-one approach, which conditions each signal on all others detected in an interval, with results from forward stepwise conditional analysis as well as Bayesian localization method, all applied to the CAGE cohorts of microarray-based peripheral blood gene expression in 2,138 European-ancestry human adults. All-but-one conditioning significantly modifies effect-size estimates for 51% of 2,351 eQTL peaks, but has only a modest effect on credible interval size and location. On the other hand, both conditioning approaches result in unexpectedly low overlap with Bayesian credible intervals, with just 57% peak concordance and between 50% and 70% SNP sharing, leading us to caution the assumption that any one localization method is superior to another. We also cross referenced our results with ATAC-seq data, cell-type specific eQTL, and ABC-enhancers, leading to proposal of a 5-tier approach to further reduce credible interval sizes and prioritize likely causal variants for all known inflammatory bowel disease risk loci active in immune cells.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2511. Allele-specific expression in blood cells during aging

Authors:

M. Harwood^{1,2}, E. Bader^{1,2}, M. Agbessi¹, V. Bruat¹, M-J. Fave¹, P. Awadalla^{1,2}; ¹Ontario Inst. for Cancer Res., Toronto, ON, Canada, ²Univ. of Toronto, Toronto, ON, Canada

Abstract Body:

Gene expression changes during aging are associated with a decline in physical and cognitive abilities. Allele-specific expression (ASE) is the preferential expression of one of two alleles, and has been demonstrated to change based on increases in genetic and environmental variation. ASE can be caused by regulatory variation, post-transcriptional modifications, or environmental exposures, and has the potential to alter phenotype and disease risk. Although ASE is important in genetic regulation, it remains unknown how ASE contributes to variation in aging processes. Here, we use a population cohort, The Canadian Partnership for Tomorrow's Health, to evaluate ASE changes in blood cells during aging. Blood cell composition and functions are impacted by the aging process and some individuals retain healthy blood parameters as they age. Using age and a complete blood count risk score, we utilize whole genome sequencing and single-cell RNA sequencing from blood of 374 individuals who are i) young, healthy (n=90), ii) young, unhealthy (n=88), iii) aged, healthy (n=101), or iv) aged, unhealthy (n=95). We test for ASE at over 6,000 genomic loci in 9 blood cell types. We show an increase in ASE as individuals age, particularly in CD8⁺ T cells, which are important for killing cancerous or virally infected cells in the adaptive immune system. We identify four genes (RPS17, RPL13, HLA-B, HLA-DRB1) with consistent ASE between young and aged individuals, whereas >50 genes demonstrate differential ASE across age groups. We further classified ASE variants into common ASE (observed in >10 individuals), versus stochastic ASE (only observed in 1-2 individuals). Using gene set enrichment analyses, we identify that genes with common ASE are involved in genetic regulation, such as regulation of the immune system or differentiation, whereas genes with stochastic ASE are involved in cellular response, such as to stress or stimuli. We observe an increase in stochastic ASE in aged and young unhealthy individuals, which was particularly prominent in B cells. B cells are important for antibody production for response to viruses and bacteria, thus more stochastic ASE may be indicative of dysregulation in these older and unhealthy individuals. We also observe more stochastic ASE in CD4⁺ T cells in aged individuals, further suggesting a dysregulation in immune related cells during aging. Our results suggest that there is a reduction of genetic regulation through ASE during aging that may alter the immune response in unhealthy agers. This research identifies mechanisms for how genetic variation impacts aging processes, which can help identify negative effects of aging.

Molecular Effects of Genetic Variation Posters - Thursday

PB2512. Amplicon sequencing-based noninvasive fetal genotyping for RHD-Positive D antigen-negative alleles

Authors:

A. Hori^{1,2}, A. Sasaki³, K. Takahashi⁴, H. Ogata-Kawata¹, K. Taniguchi¹, O. Migita^{1,5}, A. Kawashima⁶, A. Okamoto⁴, A. Sekizawa⁶, H. Sago³, F. Takada⁷, K. Hata^{1,8}, K. Nakabayashi¹; ¹Natl. Res. Inst. for Child Hlth. and Dev., Tokyo, Japan, ²Nippon Med. Sch. Musashikosugi Hosp., Kanagawa, Japan, ³Natl. Ctr. for Child Hlth. and Dev., Tokyo, Japan, ⁴The Jikei Univ. Sch. of Med., Tokyo, Japan, ⁵Faculty of Med., Univ. of Tsukuba, Ibaraki, Japan, ⁶Showa Univ. Sch. of Med., Tokyo, Japan, ⁷Kitasato Univ. Graduate Sch. of Med. Sci., Kanagawa, Japan, ⁸Gunma Univ. Graduate Sch. of Med., Gunma, Japan

Abstract Body:

Fetal RHD genotyping using maternal cell-free DNA prevents unnecessary anti-D administration when RHD-negative women carry an RhD-negative fetus. In East Asian countries including Japan, fetal RHD genotyping is not performed for the pregnancies of Rh-negative women, and all cases are managed as RhD incompatible pregnancies. In Europeans, the frequency of the RHD gene deletion types among the RhD-negative alleles is more than 99%. However, in East Asians, about 25% of the RhD-negative alleles are non-deletion types. An alternative method to the qualitative PCR-based fetal RHD genotyping, which is widespread in Europe, was needed for East Asians. We have recently developed an amplicon-based noninvasive fetal genotyping method that distinguishes the wild-type RHD allele not only from the RHD-negative D antigen-negative allele (the RHD deletion allele), but also from RHD-positive D antigen-negative alleles. This method requires PCR amplification from four genomic intervals, upstream and downstream Rhesus boxes, RHD exon 9, and RHCE exon 9. Although two regions are co-amplified with one primer pair, each of the sequence reads obtained by the amplicon-sequencing using MiSeq can be accurately mapped to its origin because of one or two base differences between two regions. To distinguish the true absence of a fetal RHD-positive allele in maternal cell-free DNA and the false negative result due to a low fetal fraction (FF), it is important to determine FF for each of maternal cell-free DNA samples. Therefore, we tested whether simultaneous determination of the fetal RHD genotype and FF is possible by multiplex PCR using primers for RHD genotyping and a panel of multiplexed insertion/deletion polymorphisms for 35 loci, followed by amplicon-sequencing. In seven pregnancy cases of RhD-negative women carrying an RhD-positive fetus, we successfully detected a fetal RHD-positive allele (0.8 % ~ 8.6 %) and also determined a FF (3.8 % ~ 16.9 %) in all cases. In two pregnancy cases of RhD-negative women carrying an RhD-negative fetus, we detected the read counts for an RHD-positive allele below the background level determined using control samples and the FFs of 9.9 % and 7.8 %. In the latter cases, the FF data helped us assume the true absence of fetal RHD-positive allele in maternal cell-free DNA. Our fetal RHD genotyping method offers the first opportunity for East Asia countries to introduce a genotyping service for RhD-negative pregnant women and represents a model for other nonwhite countries to establish a genotyping strategy customized to the RHD-positive D antigen-negative alleles prevalent in each country.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2513. An African-specific Alzheimer disease-associated *ABCA7* frameshift deletion results in altered microglia functionality

Authors:

D. Dykxhoorn¹, B. DeRosa², J. Laverde-Paz², L. Adams², T. Starks³, J. Vance¹, M. Cuccaro⁴, J. Haines⁵, G. Byrd⁶, M. Pericak-Vance², H. Cukier²; ¹Univ. of Miami, Miami, FL, ²Univ. of Miami Miller Sch. of Med., Miami, FL, ³Wake Forest Sch. of Med., Winston-Salem, NC, ⁴John P. Hussman Inst. for Human Genomics, Miami, FL, ⁵Case Western Reserve Univ, Cleveland, OH, ⁶Wake Forest Univ., Winston-Salem, NC

Abstract Body:

The *ATP Binding Cassette Subfamily A Member 7 (ABCA7)* gene encodes for an ATP-binding cassette lipid transporter that has been implicated as a risk factor for Alzheimer's disease (AD) across different populations. However, the risk effect of *ABCA7* variants in African Americans (AAs) is stronger than in other populations, such as non-Hispanic whites (NHWs). We previously identified a 44 base pair deletion in *ABCA7* that is significantly associated with AD in AAs (frequency in cases=15.2%, controls=9.74%, $p=1.414 \times 10^{-5}$) and virtually absent in NHWs. The deletion is predicted to produce a frameshift mutation resulting in a truncated protein (p.Arg578Alafs). To further understand the impact of this *ABCA7* variant on AD pathogenesis, we developed induced pluripotent stem cell (iPSC) lines from two unrelated AA individuals with AD who are heterozygous for the deletion, as well as age-matched AA controls. These lines were validated for pluripotency, genomic stability and sequencing confirmation of the *ABCA7* deletion in the AD iPSC lines. The iPSC lines were differentiated into microglia, as recent studies have implicated a key role for *ABCA7* in amyloid- β ($A\beta$) clearance and cellular stress responses in the brain. Reverse transcription PCR analysis of cases demonstrate that a stable RNA transcript is expressed from the *ABCA7* deletion allele. Our preliminary results show that while patient-derived microglia have normal rates of phagocytosis, they are impaired in the uptake and clearance of fibrillar $A\beta$. Furthermore, when exposed to the proinflammatory stimulus lipopolysaccharide, patient-derived microglia have decreased cytokine responses. This *ABCA7* deletion is an ancestry-specific alteration in AD that may reduce the ability of microglia to clear $A\beta$ from the brain and impair responsiveness to proinflammatory signals. The generation of isogenic pairs of deletion bearing and CRISPR-corrected iPSC lines will help to comprehensively examine the contribution of this *ABCA7* deletion to AD pathology in AAs and refine the phenotypic analyses.

Molecular Effects of Genetic Variation Posters - Thursday

PB2514. An Alzheimer's disease risk variant in *TTC3* modifies the growth and transcriptional profile of iPSC-derived forebrain neurons

Authors:

H. Cukier, C. Duarte, J. Laverde-Paz, M. Del Mar Muniz, S. Simon, D. Van Booven, A. Miyares, J. Vance, M. Pericak-Vance, A. Griswold, D. Dykxhoorn; Univ. of Miami, Miami, FL

Abstract Body:

We identified a rare, nonsynonymous variant in the *tetratricopeptide repeat domain 3 (TTC3)* gene that segregated in all 11 Alzheimer disease (AD) individuals in a non-Hispanic white late onset Alzheimer disease (LOAD) family (Kohli, et al, 2016). This missense alteration, rs377155188 (p.S1038C), is predicted to be deleterious and extremely rare in the gnomAD database (allele frequency=3.231x10⁻⁵). Studies have reported that cortical *TTC3* expression is reduced in LOAD patients and negatively correlated with AD neuropathology. To understand the mechanism by which this *TTC3* variant may contribute to LOAD risk, CRISPR-based genome edited was performed to introduce this variant into induced pluripotent stem cells (iPSCs) from an unaffected individual. This resulted in a pair of isogenic iPSC lines which either lacked or were homozygous for the *TTC3* variant. These cells were validated for pluripotency, genomic stability, and potential off target effects from the CRISPR procedure (Laverde-Paz, et al, 2021). These isogenic lines were differentiated to forebrain neurons to examine cellular and transcriptional consequences of this variant. Quantitative PCR analysis demonstrated that *TTC3* levels were decreased in edited compared to unedited iPSCs, as well as differentiated neurons. Cellular motility was assessed in developing neuronal progenitor cells (NPCs) using a wound healing assay. The NPCs bearing the *TTC3* variant were quicker to migrate into the scratch but showed more disorganized movement than that of the parental iPSC-derived neurons. Since other groups have shown evidence that modulation of *TTC3* affects neurite growth, morphological measures of axon formation were assessed in differentiating neuronal cultures using the Incucyte Zoom. The *TTC3* variant bearing neurons had increased neurite outgrowth and branching. This effect of the *TTC3* variant on axon outgrowth phenocopies results found in rat hippocampal neurons in which *TTC3* expression has been silenced. RNA-seq of day 70 neurons identified 1,259 genes that were differentially expressed (FDR < 0.05) between isogenic lines. This included known AD genes (*BACE1*) and genes in AD GWAS loci (*ADAMTS1*, *MAF*, *ZKSCAN*). KEGG pathway analysis identified the PI3K-Akt signaling pathway, which *TTC3* has been previously implicated in, as well as the axon guidance pathway, the GABAergic synapse pathway, and the Wnt signaling pathway as differentially enriched between the parental and *TTC3* variant bearing cells. Combined, these results suggest that the *TTC3* p.S1038C variant acts through a loss of function mechanism.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2515. An integrated machine learning and functional analysis approach for resolution of variants of uncertain significance (VUS) in *PCDH19*.

Authors:

J. Calhoun¹, H. Mefford², S. Schnell³, V. Aguiar-Pulido⁴, M. Ross⁵, J. Parent⁶, L. Isom⁶, EpiMVP Consortium, G. Carvill¹; ¹Northwestern Univ., Chicago, IL, ²St. Jude Children's Res. Hosp., Memphis, TN, ³Univ. of Notre Dame, Notre Dame, IN, ⁴Univ. of Miami, Miami, FL, ⁵Weill Cornell Med., New York, NY, ⁶Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Variants of uncertain significance (VUS) pose a significant challenge for genetic diagnosis of epilepsy, in that these variants can be classified as neither pathogenic nor benign. In order to address this challenge, we established a highly integrated Epilepsy Multiplatform Variant Predictor (EpiMVP) Center Without Walls to develop precise, single-gene *in silico* pathogenicity prediction tools (EpiPred) for the most common epilepsy-associated genes. We are using supervised and unsupervised machine learning algorithms to discriminate pathogenic from benign variants. This approach will be bolstered by functional characterization of a subset of variants in multiple cellular and animal models. Functional data will then be incorporated into the machine learning model to improve classification performance in an iterative fashion. Herein we report our investigation of *PCDH19*, a protocadherin gene family member implicated in *PCDH19*-Epilepsy, that causes a female-limited epilepsy, except in the instances of mosaic males. We first curated a robust training set for the development of our classifier. This consisted of known benign or likely benign (BLB) missense *PCDH19* variants from the general population (gnomAD; n=129) and known pathogenic or likely pathogenic (PLP) missense *PCDH19* variants from multiple sources, including industry partners, Clinvar, and the literature (n=90). Variants were annotated with multiple features (n=39) using *in silico* measures related to evolutionary conservation, protein structure and stability, among others. Our approach employed standard unsupervised and supervised machine learning algorithms to develop an optimal single-gene classifier. Our classifier outputs a score ranging from PLP (high) to BLB (low) and was used to score *PCDH19* VUSs (n=267) collated from ClinVar and industry partners. Our classifier is successful at discriminating *PCDH19* missense BLB and PLP variants ($ROC_{AUC} > 0.9$). We selected representative variants for functional modeling in multiple cellular and animal models. The first iteration of our EpiPred classifier can distinguish between BLB and PLP variants with high specificity. After functional validation in the EpiMVP cellular and animal models, we will improve the predictive power of EpiPred and release this model to the wider scientific and epilepsy community for interpretation of VUS. Our overarching goal is to develop gene-specific classifiers for additional epilepsy-associated genes with an emphasis on non-ion channel genes with the highest volume of VUS and PLP variants identified in routine clinical genetic testing.

Molecular Effects of Genetic Variation Posters - Thursday

PB2516*. An updated genetic atlas of the plasma proteome: Findings from the UK Biobank Pharma Proteomics Project (UKB-PPP)

(Johnson & Johnson), Lansdale, PA, ¹⁹AstraZeneca, Cambridge, United Kingdom, ²⁰Regeneron Genetics Ctr., Tarrytown, NY, ²¹Regeneron, Piscataway, NJ, ²²Amgen, South San Francisco, CA, ²³Biogen Inc., Cambridge, MA

Abstract Body:

Genetic analyses of population biobanks are increasingly employed as tools for drug target discovery and validation. High-throughput, population-scale proteomics holds potential to bridge the gap between the human genome and human diseases, improving genetics-guided drug development. Here, we describe results from the first phase of the UK Biobank Pharma Proteomics Project (UKB-PPP); a public-private collaboration between the UK Biobank (UKB) and 13 biopharmaceutical companies profiling concentrations of an initial 1,463 plasma proteins across 54,306 UKB participants using the multiplex, antibody-based Olink™ Proximity Extension Assay. The study identifies 10,248 genetic associations with 1,377 proteins, including 1,163 protein quantitative trait loci (pQTLs) acting in *cis*- and 9,085 acting in *trans*. 85% of pQTLs are not previously described. We highlight the utility of these pQTL data for disease risk etiology and drug development through specific deep-dive examples, including: (i) validating and enhancing the Mendelian randomization derived relationships between PCSK9 concentration and lipid concentrations, cardiovascular disease and stroke; (ii) disentangling the contributions of lung-expressed proteins towards COVID-19 susceptibility; (iii) identifying a BAG3 missense variant affecting cardiac small heat shock protein complexing (BAG3-HSPB6), with downstream effects on blood biomarkers of heart failure (NT-proBNP and proBNP); (iv) underlining examples of complex network *trans* QTLs linking protein-protein interactions and biological pathways, including cytokine and complement pathways; and (v) highlighting long-range epistasis between ABO blood group (chr 9) and FUT2 secretor status (chr 19) on protein levels, with conserved expression in gastrointestinal tissues. We also make empirical estimates of how pQTL detection scales with sample size and number of proteins measured, providing context for current and future proteogenomic studies. Our private-public collaboration highlights the value of precompetitive investments in population biobanks, providing the scientific community with an open-access resource of unprecedented depth and breadth. Future UKB-PPP initiatives will further expand proteomic coverage, integrate additional longitudinal samples, and pilot other affinity- and mass spectrometry-based technologies, aiming to achieve more complete coverage of the plasma proteome and its genetic regulation at population scale.

Molecular Effects of Genetic Variation Posters - Thursday

PB2517. Antibody repertoire heavy chain gene usage is explained by common genetic variants in the immunoglobulin heavy chain locus.

Authors:

O. Rodriguez¹, Y. Safonova², C. Silver¹, K. Shields¹, W. Gibson¹, J. Kos¹, D. Tieri¹, H. Ke³, K. Jackson⁴, S. Boyd⁴, M. Smith¹, W. Marasco³, C. Watson¹; ¹Univ. of Louisville Sch. of Med., Louisville, KY, ²Johns Hopkins Univ., Baltimore, MD, ³Harvard Med. Sch., Boston, MA, ⁴Stanford Univ. Sch. of Med., Stanford, CA

Abstract Body:

Antibodies (Abs) are critical components of the adaptive immune system. The heavy chains of Abs are encoded by >100 variable (V), diversity (D), and joining (J) gene segments within the immunoglobulin heavy chain (IGH) locus. IGH is among the most structurally complex genomic regions, containing extensive haplotype diversity, with elevated numbers of single nucleotide variants (SNVs) and structural variants (SVs). Mounting evidence shows that IGH variants influence the expressed Ab repertoire, with potential consequences on Ab function in human health. However, due to the complexity of IGH, which has hindered the use of standard high-throughput sequencing and genotyping approaches, genetic variants contributing to Ab repertoire variation have not been fully characterized. To address this, we conducted the first genetic association study to identify IGH variants that impact expressed Ab repertoire signatures. Utilizing our novel targeted long read sequencing approach, we generated paired IGH haplotype and expressed Ab repertoire sequencing data in 154 healthy adults, the largest dataset of its kind. Variants identified included 27 SV alleles from 8 large (> 9Kb) SVs, ranging from 9.5 to 284 Kb, 966 indels and 71 small SVs (< 9 Kb), and 7,980 common SNVs, 5,057 (64%) of which were missing from or contained no allele frequency data in dbSNP. Our ability to characterize the full spectrum of genetic variants in IGH for the first time demonstrated the impact of accurate long reads for resolving complex loci. Our analysis revealed IGH genetic variants strongly influence the composition of the expressed Ab repertoire through both coding and non-coding SNPs, and large SVs. In total, 3,464 variants were associated with the usage of 58 (73%) IGH genes. This included genetic effects on either single genes, or multiple genes, demonstrating coordinated gene regulation. Importantly, associated SNVs overlapped GWAS variants, and were enriched in regulatory regions, including CTCF binding sites, a transcription factor involved in V(D)J recombination. These data provide the first robust links between IGH polymorphisms and the Ab repertoire, dispelling the long held belief that Ab diversity arises solely through stochastic processes. These datasets will (1) allow for the discovery of novel genomic factors and molecular mechanisms influencing Ab repertoire development and diversity, (2) facilitate better characterization of the Ab response in disease, and (3) inform the design of improved therapeutics, vaccines and implementation strategies.

Molecular Effects of Genetic Variation Posters - Thursday

PB2518. *APOE* Genotype Contributes to Distinct Profiles in Human iPSC Astrocytes and Neurons

Authors:

S. Clayton¹, R. Panitch², Y. You³, T. Ikezu³, L. Farrer⁴, G. Jun⁵; ¹Boston Univ., Brighton, MA, ²Boston Univ., potomac, MA, ³Mayo Clinic Florida, Jacksonville, FL, ⁴Boston Univ Sch Med, Boston, MA, ⁵Boston Univ., Boston, MA

Abstract Body:

The APOE gene is the major risk factor for Alzheimer disease (AD) risk, the $\epsilon 4$ allele increases while the $\epsilon 2$ allele decreases risk for AD. However, differential expression profiles between $\epsilon 2$ and $\epsilon 4$ alleles in neurons and astrocytes have not been well-characterized. We previously developed human isogenic APOE allele-specific induced pluripotent stem cells (iPSC)-derived excitatory neurons (iNeurons) and astrocytes (iAstrocytes) in a co-culture system (Jun, 2022). We conducted RNA-sequencing in 6 isogenic iNeurons and iAstrocytes from different APOE genotypes: APOE KO, $\epsilon 2/\epsilon 2$ (APOE2), $\epsilon 3/\epsilon 3$ (APOE3), and $\epsilon 4/\epsilon 4$ (APOE4). We conducted differential expression analysis using previously identified AD genes as well as transcriptome-wide data between APOE2 and APOE4 iPSCs separately in iNeurons and iAstrocytes. We conducted pathway enrichment analysis with significantly differentially expressed genes (DEG) with false discovery rate adjusted p (adjP) <0.05 between APOE2 and APOE4 iPSCs. APOE expression was highest in APOE2 iAstrocytes followed by APOE3 and APOE4 (log₂ of APOE2:APOE3:APOE4=9.28:8.81:8.50; p <0.05), while APOE expression in iNeurons was inconsistent (log₂ of APOE2:APOE3:APOE4=4.65:5.28:4.07; 0.05 $<p<0.2$). We also observed differentially expressed genes between APOE2 and APOE4 for the established AD genes with adjP <0.05 , including JAZF1, PRKD3, and ICA1 in iNeurons (best gene, JAZF1: log₂ fold change=-1.38, adjP=2.42E-8) and MAF, DOCK1, and C4A in iAstrocytes (best gene, MAF: log₂ fold change=1.06, adjP=1.81E-4). In transcriptome-wide analysis, we identified significantly DEGs between APOE2 and APOE4 genotypes including BMPER, SRY, and REEP5 in iNeurons whereas FEZF1, PCSK9, and NTRK1 in iAstrocytes with adjP <0.05 . Pathways significantly downregulated in APOE4 compared to APOE2 in iAstrocytes included pathways related to response to amyloid-beta, extracellular matrix structure and organization, and nervous system development (enrichment adjP <0.05). In iNeurons, pathways significantly upregulated in APOE4 include immune-related pathways, cellular senescence, and systemic lupus erythematosus (enrichment adjP <0.05). These results demonstrate that APOE genotype contributes to distinct expression profiles in iAstrocytes and iNeurons.

PB2519. Assessing the contribution of variants with functional effects on post-transcriptional regulation to genetics of psychiatric disease

Authors:

J. Gu, X. He; Univ. of Chicago, Chicago, IL

Abstract Body:

Identifying causal variants for complex traits remains challenging, as most GWAS identified variants are located in non-coding regions, without clear functions. A major challenge is thus to annotate functional effects of variants. Existing work along this line includes various experimental and computational approaches such as enhancer mapping, transcription factor binding site profiling and expression QTL studies. These efforts have been largely focused on putative transcriptional effects of variants. Numerous studies, however, have supported the importance of post-transcriptional regulatory (PTR) processes in development and diseases, such as RNA splicing, N⁶-methyladenosine (m6A) modification, and alternative polyadenylation. Nevertheless, the importance of variants with possible PTR effects in genetics of complex traits remains largely unexplored. This is particularly the case for m6A modification, which is a key process regulating RNA stability and translation. There have been very few studies directly linking m6A modification to human genetic variations.

To fill these gaps, we annotated GWAS SNPs with putative PTR effects using two sources of data. We collected m6A profiles of human fetal tissues from a recent study and computed scores for splicing effects using two deep-learning based prediction tools, Spidex and SpliceAI. Applying Stratified-LD score regression to Schizophrenia (SCZ) GWAS, we found that m6A sites from fetal brains show ~9-fold enrichment with disease heritability. The predicted splice variants, on the other hand, show no significant enrichments. We estimate that transcriptional features, defined by open chromatin regions from neuronal cells explain about 24.9% of SCZ heritability, while fetal m6A sites explain about 4.5% heritability. These results thus suggest that m6A features make a substantial contribution to disease genetics. The lack of enrichment of splicing features, may reflect the limitation of current splicing prediction tools to accurately predict splicing effects of variants.

Molecular Effects of Genetic Variation Posters - Thursday

PB2520. Assessing the genetic control of whole blood RNA editing and its role in modulating risk of common diseases.

Authors:

D. Stacey¹, E. Aiton¹, C. Acciari¹, A. Nath^{1,2}, E. Persyn¹, J. Marten¹, T. Vanderstichele³, K. Walter³, K. Kundu³, D. Roberts⁴, E. Di Angelantonio¹, J. Danesh¹, A. Butterworth¹, N. Soranzo³, E. E. Davenport³, M. Inouye^{1,2}, D. S. Paul^{1,5}; ¹Univ. of Cambridge, Cambridge, United Kingdom, ²Baker Heart and Diabetes Inst., Melbourne, Australia, ³Wellcome Trust Sanger Inst., Hinxton, United Kingdom, ⁴Univ. of Oxford, Oxford, United Kingdom, ⁵AstraZeneca, Cambridge, United Kingdom

Abstract Body:

RNA editing is a naturally occurring mechanism by which nucleotides in RNA sequence are chemically modified. This leads to nucleotide changes in RNA that potentially impact gene function, but that are not detectable by DNA sequencing. RNA editing is a vastly under-explored area, with major gaps in knowledge concerning (i) the functional effects of non-coding RNA edit sites and (ii) the molecular chain of events by which RNA edit sites might impact disease.

Using linked RNA-sequence and whole-genome sequence data from 2,918 whole blood samples from healthy participants of the INTERVAL study, we have called a 'high-confidence' set of 2,575 RNA edit sites. In accordance with previously published datasets, these high-confidence sites are enriched in Alu elements, they reside primarily in 3' UTRs, and are depleted of recoding (i.e., protein-altering) events. About 20% are currently not annotated in REDIportal, the largest database cataloguing known RNA edit sites. Furthermore, in support of the validity of our RNA edit dataset, we found that higher whole blood mRNA levels of *ADARI* - which encodes the key enzyme involved in catalysing RNA editing in blood cells - are significantly ($p < 2 \times 10^{-16}$) associated with higher overall editing levels.

To assess the genetic control of RNA editing, we have performed preliminary edit QTL analyses using matrix eQTL, with the high-confidence edit sites as outcome variables. We have uncovered significant ($p < 1.29 \times 10^{-12}$) associations at 3,415 independent loci. Approximately one third of these associations relate to edit sites at the immunoglobulin locus on chromosome 2, suggesting a genetically controlled role for RNA editing in modulating immunoglobulins produced by B cells. A pheWAS indicated that of the 3,415 independent loci, 269 are associated with at least one disease or trait at genome-wide significance. We aim to assess the extent to which these loci might play a causal role in disease by performing statistical colocalization and Mendelian randomization analyses. Finally, we aim to leverage the multiomic data available in the INTERVAL study to better define the causal chain of events leading to disease risk. We anticipate our findings will enhance our understanding of the genetic regulation of RNA editing and the role it plays in disease.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2521. Assessment of genotype-phenotype correlation of human *TEX11* variants associated with non-obstructive azoospermia in mouse

Authors:

J. Hardy¹, C. Doungkamchan¹, N. Pollock², J. Kuong², K. Tran¹, Y. Sheng², T. Jaffe³, M. Olszewska⁴, M. Kurpisz⁴, F. Tuttelmann⁵, M. Brieno-Enriquez¹, K. Orwig¹, A. Yatsenko¹; ¹Univ. of Pittsburgh, Pittsburgh, PA, ²Univ. of Pittsburgh Med. Ctr., Pittsburgh, PA, ³West Virginia Univ., Morgantown, WV, ⁴Polish Academy of Sci., Poznan, Poland, ⁵Univ. of Munster, Munster, Germany

Abstract Body:

Introduction Approximately 10% of infertile men suffer from azoospermia or complete absence of mature spermatozoa in the ejaculate. To date, as much as 50% of all male infertility cases are estimated to be the result of genetic abnormalities. Variants in *TEX11*, a testis specific gene involved in meiosis are posited to account for ~2% of all non-obstructive (w/o physical impairment to the reproductive tract) azoospermia (NOA) cases. A 214kb deletion in the 224kb mouse *Tex11* orthologue was shown to cause early meiotic arrest yet pathogenicity and functional consequence of variants associated with human male infertility have yet to be validated. Here we utilized a similar transgenic mouse model approach to assess causality of *TEX11* point mutations and indels associated with NOA in humans.

Methods CRISPR/Cas9 technology was used to introduce 3 likely pathogenic *TEX11* variants, one splice site in the meiosis specific SPO22 domain, one frameshift leading to a premature stop in the 2nd structural tetratricopeptide repeat (TPR) motif, and one missense in the 3rd TPR into the homologous mouse gene. Fertility status, testis morphology, seminiferous tubule histology, immunohistochemistry, in situ hybridization, and prophase I analysis were assessed using standard and advanced molecular techniques.

Results In 12-week old, BL6/D2 F1 mice, each of the 3 variants resulted in testicular phenotypes that at least partially mimicked the human condition. The frameshift variant which caused infertility due to arrest in pachynema most strongly resembled the human phenotype of complete meiotic arrest though mouse spermatocytes were able to progress to metaphase. Both point mutations did not result in infertility at this age/generation though defects in spermatocyte chromosome segregation similar to the knockout were noted. By the F3 generation, mice harboring the splice site variant had a statistically reduced epididymal sperm count and testis weight began trending toward significance (p=0.053402).

Conclusion Human *TEX11* shares 74% sequence identity with the mouse orthologue. The unique 26% could plausibly account for the disparity in spermatozoa production observed with human *TEX11* variants versus the mouse complement. Additionally, the 15% of the total genome that is not shared could allow for a compensatory mechanism in mouse. Alternatively, *TEX11* induced NOA may be a progressive disorder with increasing severity due to age and/or transgenerational effect. Long term analysis of germ cell dynamics in mouse may provide additional insight into the consequence and mechanism of identified variants. This work was supported by P50 HD096723 to KEO and ANY and T32 HD087194 to JJH.

Molecular Effects of Genetic Variation Posters - Thursday

PB2522. Association of GWAS and candidate gene loci of dopaminergic system with major depression, schizophrenia and bipolar disorder in the Pakistani population

Authors:

A. Hashmi¹, R. Dharejo², R. Taj³, M. Ajmal¹, Z. Agha⁴, R. Qamar⁵, M. Azam⁶; ¹Comsats Univ. islamabad, Islamabad, Pakistan, ²WAPDA Administrative Staff Coll., Lahore, Pakistan, ³Pakistan Inst. of Med. Sci., Islamabad, Pakistan, ⁴COMSATS Univ. ISLAMABAD, ISLAMABAD, Pakistan, ⁵Sci. and Technology Sector, ICESCO,, Rabat, Morocco, ⁶COMSATS Univ. Islamabad, Islamabad, Pakistan

Abstract Body:

Background: The dopaminergic pathways control neural signals that modulate mood and behaviour along and have a vital role in the aetiology of major depression (MDD), schizophrenia (SHZ) and bipolar disorder (BD). Genome-wide association studies (GWAS) have reported several dopaminergic pathway's and other genetic loci's association with these disorders however, no such comprehensive data was available regarding the Pakistani population. **Aim:** the present study was conducted to analyse the GWAS and candidate gene loci of the dopaminergic and cognitive system genes in MDD, SHZ, and BD, in the Pakistani population. **Methods:** A total of 1237 subjects [MDD n=479; BD n=222; SHZ n=146; and controls n=390], were screened for eleven genetic variants through polymerase chain reaction (PCR) techniques. Univariate followed by multivariate logistic regression analysis were applied to determine the genetic association. **Results:** Significant risk associations were observed for rs4532 and rs1799732 with MDD; and rs1006737 and rs2238056 with BD. However, after applying multiple test corrections rs4532 and rs1799732 association did not remain significant for MDD. Moreover, a protective association was found for three variants; DRD4-120bp, rs10033951 and rs2388334 in the current cohort. **Conclusion:** The current study revealed the risk association of SNPs rs1006737 and rs2238056 with BD and the protective effect of the DRD4-120bp variant in MDD and BD, of rs2388334 in BD and of rs10033951 in MDD, BD, and SHZ in the current Pakistani cohort. Thus, the study is valuable in understanding the genetic basis of MDD, BD and SHZ in the Pakistani population, which may pave the way for future functional studies.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2523. Association of MTHFR C677T polymorphism with obesity in women: A case-control study and meta-analysis

Authors:

M. Irfan, R. Rani; Pir Mehr Ali Shah, Arid Agriculture Univ., Rawalpindi, Pakistan

Abstract Body:

Methylenetetrahydrofolate reductase (MTHFR) is an enzyme that stimulates and modulates folate metabolism in the body. The main and specific function of MTHFR is to convert 5, 10-Methylenetetrahydrofolate into 5-Methylenetetrahydrofolate (5-MTHF), which is active folate. 5-MTHF is a key component in the synthesis of nucleotides for the production of RNA and DNA by methylation reactions; production of S-Adenosylmethionine (SAM); methylation of DNA, proteins, neurotransmitters (NTs), & phospholipids; and also the conversion of homocysteine into methionine by remethylation reaction. Many genetic variations in the MTHFR enzyme are recognized and reported which alter the folate metabolism hence methylation and overall health. Numerous studies have shown that low folate levels lead to an increased body mass index. Therefore, in the present study was hypothesized that the genetic polymorphisms of the MTHFR gene might be related to obesity resulting in decreased levels of active folate. The objective of this study was to determine the association of a specific MTHFR C677T polymorphism with obesity in obese women. Blood samples (5ml) along with the data on sociodemographic, physical health and lifestyle aspects were also collected. DNA was extracted from the blood samples by using a standard phenol-chloroform method and stored at -20°C. The specific primers were designed and optimized for the gene. The PCR amplified products were digested by a specific restriction enzyme (Hinf I) to determine polymorphisms. The digested product was electrophoresed on agarose gel with ethidium bromide staining which was then visualized through ultraviolet transillumination. The fragments of wild type and mutated DNA were obtained on the gel. The allele frequency of the C to T polymorphism was determined by counting alleles through electrophoresis gel analysis. Chi-square analysis was used to determine the Hardy-Weinberg equilibrium of the alleles in the population. The association of the polymorphism with obesity was determined by logistic regression analysis adjusting the effects of confounding factors i.e. age, socioeconomic factors and lifestyle. A p-value of < 0.05 was considered statistically significant. We found no association of MTHFR C677T with obesity in women. Furthermore, the meta-analysis also confirmed our result of no association between obesity in women and MTHFR C677T.

Molecular Effects of Genetic Variation Posters - Thursday

PB2524. Bayesian fine-mapping of sex-specific gene regulation during neurodevelopment shows link to neurodevelopmental disorders

Authors:

J. Lalli¹, S. Pochareddy², D. Liang², R. Kovner², J-Y. An³, N. Sestan², S. Sanders⁴, D. Werling¹; ¹Univ. of Wisconsin-Madison, Madison, WI, ²Yale Univ., New Haven, CT, ³Korea Univ., Seoul, Korea, Republic of, ⁴Univ. of California - San Francisco, San Francisco, CA

Abstract Body:

Autism spectrum disorder (ASD) is diagnosed more commonly in males than females, and multiple lines of evidence suggest that individuals with the same autosomal genetic background are more likely to be diagnosed with ASD if they are male. While it is possible that female sex has a neuroprotective effect against ASD during early neurodevelopment, our understanding of this phenomenon is hampered by limited knowledge of the effect of sex on gene regulation during neurodevelopment.

To address this problem, we utilized a previously published dataset of bulk RNA-seq and whole genome DNA sequences from the dorsolateral prefrontal cortices (DLPFCs) of 81 human fetuses with gestational ages of 14 to 21 weeks, when sex hormone levels peak during development. To determine if a SNP was significantly associated with a nearby gene's expression level, we compared the use of FDR correction, permutation analysis, and Bonferroni correction using the of effective tests performed per gene as determined by eigenvector decomposition. We ultimately applied a previously published Bayesian fine-mapping technique to all SNPs in cis with expressed genes in our dataset.

We identified 335 credible sets of SNPs that affect the expression of 297 nearby genes in a sex-specific manner. Gene ontology analysis suggests that these genes are significantly associated with neurodevelopmental disorders, and are associated with E2F1 and EGR1 regulatory pathways - critical for neuroprogenitor proliferation and brain plasticity, respectively. Our work suggests that genes important for neurodevelopment are differentially regulated in male and female DLPFCs during a critical period, providing a potential mechanism for the sex-biased prevalence of some neurodevelopmental disorders.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2525. Body mass index as an environmental context in functional genomic annotations.

Authors:

R. Signer¹, A. de Pins¹, H. Young¹, A. Cote², C. Seah¹, J. Johnson¹, L. Huckins¹; ¹Icahn Sch. of Med. at Mount Sinai, New York, NY, ²Icahn Sch. of Med., New York, NY

Abstract Body:

Background Genome-wide association studies (GWAS) have succeeded in identifying numerous disease risk loci while expression quantitative trait loci (eQTL) studies have annotated tissue-specific functional effects across the genome. Despite advances in recruitment and annotation, significant challenges remain translating estimates learned from the population back to the individual. Body mass index (BMI) represents a physiologic state with psychiatric and non-psychiatric disorder associations and is a source of variability amongst cases and controls. Additionally, BMI plays a critical and poorly understood role in eating disorder diagnosis, treatment, and genomic models. Here, we explore the dynamic nature of eQTLs in the context of BMI, test for associations with phenotypes including anorexia nervosa (AN), and define the utility of including physiologic measures in functional genomics to advance precision medicine.

Methods We used matched whole genome- and transcriptome-sequencing from 46 tissues in the Genotype-Tissue Expression (GTEx) project (Including all tissues with > 100 samples; N_{total}=950) to identify BMI-dynamic eQTL and eGenes. We first considered a continuous BMI and tested for a BMI*SNP interaction effect. BMI-dynamic eGenes had at least one SNP with a significant interaction after applying a Bonferroni correction for N_{SNPs} in the cis-eGene window. We next considered categorical BMI and called eQTL within BMI quintile. Finally, we imputed gene expression from psychiatric, immune, and other BMI-associated disorder summary statistics using S-prediXcan and tested for overlap with BMI-dynamic eGenes.

Results We identified 9,750 BMI-dynamic eGenes across all tissues (39.9% of all eGenes tested). Tissues with the most BMI-dynamic eGenes included four brain regions: cortex, caudate, nucleus accumbens, putamen and four digestive tissues: small intestine, salivary gland, transverse colon, and gastroesophageal junction. Minor salivary gland emerged as a BMI-responsive immune organ, with eGenes enriched for innate immune response (p=1.50x10⁻⁰⁴) and interferon signaling (p=2.01x10⁻⁰⁴). BMI-dynamic eGene-tissue pairs overlap with significant AN-associated eGenes at loci including *MGMT*-Lymphocytes. BMI-responsive eGenes were enriched in ovary (p=0.0020) amongst nominally significant AN-associated eGenes.

Conclusion Our results show the dynamic nature of eQTL across the BMI spectrum and demonstrate the relevance of BMI in characterizing functional loci within psychiatry. These data support the inclusion of individual environmental measures in complex disorder risk models to enhance precision of effect estimates.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2526. Calibration set for high throughput functional assay for *RYR1* Variants.

Authors:

J. Johnston¹, A. Douglass¹, R. T. Dirksen², K. Stowell³, L. G. Biesecker¹; ¹NHGRI, NIH, Bethesda, MD, ²Univ. of Rochester Med. Sch., Rochester, NY, ³Massey Univ, Palmerston North, New Zealand

Abstract Body:

The ClinGen malignant hyperthermia susceptibility (MHS) variant curation expert panel specified the ACMG/AMP criteria for *RYR1*-related MHS and classified 335 *RYR1* variants. Sixty-five percent of these variants (218) were classified as variants of uncertain significance (VUS) due to limited evidence supporting pathogenicity. Prioritization of functional studies is needed to resolve the large number of VUS classifications and allow for appropriate risk assessment. However, Brnich et al. (2020) concluded that functional studies often do not have adequate controls to support using the data in the ACMG classification scheme. For supporting strength, according to the Bayesian model of combining the ACMG criteria (Tavtigian et al. 2018), the evidence should support an odds of pathogenicity of 2.08:1 and for moderate strength an odds of pathogenicity of 4.3:1, based on likelihood ratios derived from experimental datasets. *RYR1* is a calcium release channel and numerous functional studies are available to measure the release of calcium in response to agonist. However, few benign variants have been analyzed, limiting the strength of the functional evidence. In this work, we set out to design a validation set of *RYR1* variants that will allow calibration of *RYR1* functional assays. The calibration set comprises 17 *RYR1* variants classified as benign and six *RYR1* variants classified as pathogenic (5) or likely pathogenic (1). Variants were introduced into the full length human *RYR1* cDNA using standard subcloning and site directed mutagenesis. All variants were verified for sequence integrity. Stable expressing cell lines were generated in HEK293 cells using the pcDNA5/FRT mammalian expression vector (ThermoFisher Scientific). Caffeine concentration-response curves will be determined using the Flexstation 3 Plate Reader (Molecular Devices) with the goal of validating this assay for use in ACMG pathogenicity classification. These variants will also be used to develop a large-scale functional assay for *RYR1*. In summary, we have prioritized functional studies in *RYR1* to resolve the large number of VUS classifications. This validation set will support calibration of functional assays using objective data, contributing to the transition of variant classification from an art to a science.

Molecular Effects of Genetic Variation Posters - Thursday

PB2527. CD4⁺ T cell gene expression influences COVID-19 severity and susceptibility: results from single cell sequencing and Mendelian randomization

Authors:

J. Willett^{1,2}, T. Lu^{1,2}, S. Yoshiji^{1,2}, T. Nakanishi^{1,2}, G. Butler-Laporte^{3,2}, S. Zhou¹, Y. Farjoun⁴, B. Richards^{1,2}; ¹McGill Univ., Montreal, QC, Canada, ²Lady Davis Inst., Montreal, QC, Canada, ³McGill Univ., Montréal, QC, Canada, ⁴Lady Davis Inst., JGH, Montreal, QC, Canada

Abstract Body:

Background: Severe COVID-19 is due, in part, to immune hyperstimulation. The dynamics of this immune response are poorly understood. Using cis-expression quantitative loci (cis-eQTL) from single-cell RNA (sc-RNA) sequencing of CD4⁺ T-cells before and after experimental stimulation, we hypothesized colocalization of these dynamic cis-eQTLs with COVID-19 outcomes would identify targets for disease prevention and treatment. We assessed transcripts detectable before and during infection and in cells relevant regardless of one's previous exposure to antigen (naïve and memory cells).

Methods: We colocalized q-value corrected ($q < 0.1$) cis-eQTLs from CD4⁺ sc-RNA T-cell data from 119 healthy, British ancestry individuals against 87 loci in European-stratified Host Genetics Initiative (HGI) release 7 summary statistics for COVID-19 outcomes (very severe, defined as death or requiring ICU care, severe requiring hospitalization, or susceptibility). We identified estimated causal genes among pre- (CD4⁺ naïve and memory) and post-Leiden algorithm clustered (T naïve, T effector memory, T central memory, T regulatory) cell populations, defined by strong colocalization (posterior probability ≥ 0.8) and passing sensitivity testing. We conducted Mendelian randomization (MR) with sensitivity and directionality testing for strong colocalization examples.

Results: T regulatory cell expression did not colocalize for any outcome. Three genes colocalized to all outcomes (NAPSA, CAT, RALGDS). NAPSA colocalized in whole-blood bulk-RNA sequenced GTEx v8 EUR-stratified data, corresponding to a noninfectious state. It was not expressed in sc-RNA CD4⁺ cells pre-stimulation. NAPSA expression in T effector memory cells 40 hours post-stimulation, per MR, influenced all outcomes (95% confidence interval odds ratio (OR) very severe 1.18 [1.10, 1.27], severe 1.15 [1.10, 1.20], susceptibility 1.04 [1.03, 1.06]). Pre-stimulation CD4⁺ naïve catalase expression influenced very severe and severe COVID-19 (OR 1.21 [1.08, 1.40] and 1.13 [1.01, 1.28]). RALGDS expression 16 hours post-stimulation in T effector memory cells was protective for all outcomes (OR very severe 0.78 [0.71, 0.87], severe 0.87 [0.79, 0.96], susceptibility 0.88 [0.86, 0.90]). Another gene, RAB2A, influenced severe COVID-19 in CD4⁺ memory cells 40 hours post-stimulation (OR 1.67 [1.38, 2.01]). NAPSA expression can be inhibited by pepstatin A, CAT can be inhibited by fomepizole and cannabidiol, and RALGDS can be stimulated by STAT3 signalling.

Conclusions: These results implicate specific cell types, cell states and transcripts that influence COVID-19 severity and susceptibility.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2528. Cellular consequences of Hirschsprung disease-associated *RET* variants studied utilizing CRISPR-mediated genome engineering.

Authors:

L. Fries, A. Chakravarti, S. Chatterjee; NYU Grossman Sch. of Med., New York, NY

Abstract Body:

Genome sequencing studies have led to vast catalogs of disease-associated genes and variants, but biological studies of how they mediate disease are lagging. This is in part owing to a lack of targeted functional screens that can quantify the effects of variants on specific cellular processes underlying the disorders.

Hirschsprung disease (HSCR), a developmental disorder, arises due to the inability of enteric neural crest derived cells to proliferate and migrate to form a functional enteric nervous system. Despite extensive gene and variant heterogeneity, ~50% patients harbor coding and enhancer variants at the receptor tyrosine kinase gene *RET*. Therefore this study focuses on understanding how *RET* variants lead to aganglionosis. CRISPR-based prime editing was used to engineer multiple HSCR-associated rare coding *RET* variants in the neuroblastoma cell line CHP-212. Three tyrosine variants, with varying degrees of predicted pathogenicity, spanning the entire protein were made: Y204X, Y791F, and Y981X. Quantitative functional screens to measure proliferation and migration in stable heterozygous mutant lines demonstrated that all variants decreased ability of cells to perform these functions, reflective of a HSCR phenotype; with Y204X, Y791F and Y981X leading to 60%, 45%, and 30% ($P < 0.001$ for all) reduced migration, respectively. Thus, earlier protein truncation is associated with a more severe cellular effect, though missense mutations can be as severe as nonsense changes.

Additionally, the effect of the HSCR associated common enhancer variant rs2435357 in *RET* intron 1 was studied by engineering mice via CRISPR based deletion of the homologous region. This mutant was crossed to create a compound mutant carrying two deletions, in the *Ret* gene and the enhancer, modeling HSCR patients with both coding and non-coding variants. An allelic series was created, demonstrating mice carrying homozygous enhancer deletion showed a 20% ($P < 0.001$) reduction in *Ret* expression in the embryonic gut at E14.5 compared to the wildtype, 50% ($P < 0.001$) reduction in heterozygous *Ret* knockout, and a 60% ($P < 0.001$) reduction in the compound mutant. Single cell RNA-sequencing was completed on these mutants in conjunction with immunohistochemistry to examine specific neuronal cell types altered.

These functional screens demonstrate that coding and noncoding variants have additive effects on gene expression leading to variable cellular phenotypes that don't necessarily parallel predicted pathogenic risk scores. These assays provide a route to functionally quantify pathogenicity of variants discovered in patients of HSCR and other neurodevelopmental motility disorders.

Molecular Effects of Genetic Variation Posters - Thursday

PB2529. Characterization of a leaky splice mutation in *AIRE*, associated with milder phenotype and late debut of autoimmune polyendocrine syndrome type 1.

Authors:

A. Berger¹, B. E. Oftedal¹, E. Bratland^{1,2}, S. Johansson^{2,1}, E. S. Husebye^{1,2}; ¹Univ. of Bergen, Bergen, Norway, ²Haukeland Univ. Hosp., Bergen, Norway

Abstract Body:

Autoimmune Polyendocrine Syndrome type 1 (APS-1) is a rare monogenic autoimmune disorder caused by mutations in the gene *AIRE*. *AIRE* or the Autoimmune Regulator acts as a transcriptional regulator in the thymus, facilitating the expression of thousands of genes important for the process of negative T-cell selection and immunological tolerance against self. Most APS-1 causative mutations in *AIRE* result in a quite severe phenotype with the three main manifestations being autoimmune Addison's disease, hypoparathyroidism and chronic mucocutaneous candidiasis, although many patients also exhibit a variety of other autoimmune manifestations. However, not all mutations lead to a severe phenotype which is illustrated by a cohort of four patients with a mutation in the canonical donor splice site of exon 7, c.879+1G>A, exhibiting a milder phenotype with relatively late debut. Utilizing a C57BL/6 crispr knock-in mouse model we investigate the transcriptional impact of c.879+1G>A with bulk RNA sequencing of FACS sorted medullary thymic epithelial (mTEC) cells, with cells from wildtype mice and mice homozygous for the nonsense mutation p.C313X as controls. We confirm the exon skipping effect of c.879+1G>A without frameshift of the open reading frame, leading to a shortened *AIRE* without the amino acids 267 to 293, encoded by exon7. However, this splicing effect may be leaky and while substantially reduced, there are mRNA reads within exon 7 which may be evidence of some full-length *AIRE* expression. On the transcriptional level the effect of c.879+1G>A is less severe than that exhibited by p.C313X showing an intermediate pattern compared to wildtype *AIRE* with higher relative and absolute expression of *AIRE*-regulated genes compared to p.C313X and fewer significantly downregulated genes (among wildtype *AIRE* regulated genes) in total. This transcriptional effect may either be caused by the aforementioned leaky expression of some full-length *AIRE* or by some residual effect of *AIRE* lacking amino acids 267-293. We confirm that the milder phenotype exhibited by APS-1 patients with the c.879+1G>A mutation in *AIRE* correlates to a less severe effect on the transcriptional level in the mTEC cells of the thymus of mice carrying the corresponding mutation, compared to other known deleterious *AIRE* mutations.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2530. Characterization of haplotype diversity in the human immunoglobulin heavy chain constant region using long-read sequencing

Authors:

U. Jana¹, O. Rodriguez², A. Dorgham¹, W. Gibson¹, K. Shields¹, C. Silver³, M. Emery³, G. Deikus³, R. Sebra⁴, E. Eichler⁵, M. Smith³, C. Watson³; ¹Univ. of Louisville, Louisville, KY, ²Univ. of Louisville Sch. of Med., Louisville, KY, ³Icahn Sch. of Med. at Mount Sinai, New York, NY, ⁵Univ of Washington, Seattle, WA

Abstract Body:

The heavy chain constant region of antibodies (Ab) mediates immune function by playing a pivotal role in neutralization and elimination of antigens through various effector functions. Critically, these functions are mediated by different Ab isotypes (IgM, IgG, IgA, IgE and IgD) each encoded by genes within the immunoglobulin heavy chain constant (IGHC) locus located near the telomeric end of chromosome 14. Despite previous studies highlighting extreme allelic and structural variation within human IGH, our knowledge of haplotype diversity remains limited. This stems from technical barriers that have hindered the use of standard next-generation sequencing for resolving these complex loci, stressing the need for improved genomic resources and tools for more effectively characterizing IGH diversity. Here, we leveraged targeted long-read sequencing (Pacific Biosciences) of genomic DNA and fosmid clones to generate high quality haploid resolved assemblies spanning the IGH region for 7 individuals of different African, East Asian and European descent to effectively capture IGH diversity. From these assemblies, we identify novel SNVs and large SVs (n=12) ranging in size up to 100 Kb and include duplications, deletions and inversions. These SVs are resolved for the first time at nucleotide resolution, leading to the discovery of novel IG genes and alleles (n=70). In addition, we use these assemblies to benchmark our high-throughput targeted long-read sequencing protocol and bioinformatics pipeline, revealing that our novel approach can generate accurate assemblies and genotype callsets, outperforming alternative methods. These data provide a more complete understanding of IGH haplotype diversity and provide a set of vetted and curated reference assemblies for this locus. The availability of these haplotype resources will facilitate the design of novel high-throughput approaches for more accurately interrogating IGH polymorphisms, further improving the characterization of IGH gene diversity at the genome and population-level. This will be critical for delineating the roles of germline variation in Ab effector functions in disease and clinical phenotypes.

Molecular Effects of Genetic Variation Posters - Thursday

PB2531. Characterization of mutants in *SOS1* in an endothelial cell model of lymphatic anomaly

Authors:

L. Matsuoka¹, M. March², D. Li³, S. Sheppard⁴, R. Pellegrino⁵, J. Garifallou², C. Vaccaro⁶, C. Kao⁷, H. Hakonarson³; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Children's Hosp. of Philadelphia, Philadelphia, PA, ³Children's Hosp. of Philadelphia, Philadelphia, PA, ⁴Eunice Kennedy Shriver Natl. Inst. of Child Hlth. and Human Dev., Rockville, MD, ⁵The Children's Hosp. of Philadelphia, Philadelphia, PA, ⁶The Children's Hosp. of Philadelphia, Philadelphia, PA, ⁷Ctr. for Applied Genomics, Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

Mutations in *SOS1* are known causes of conditions that involve anomalies in the development of the lymphatic system, most notably Noonan syndrome. As part of our ongoing efforts to functionally characterize mutations that contribute to vascular and lymphatic anomalies, we have undertaken efforts to examine the effects of *SOS1* mutations in primary human dermal lymphatic endothelial cells (HDLECs). A known pathogenic mutation (E846K) and a variant of unknown significance were expressed in HDLECs via retroviral transduction, and the effects on intracellular signaling were examined via western blotting of relevant substrates. Additionally, the ability of the variant of unknown significance to activate Ras was determined through an *in vitro* Ras activation assay. The functional consequences of expression of *SOS1* mutants in HDLECs was determined through an established spheroid sprouting assay, previously used to describe the effects of *ARAF*, *KRAS*, and *NRAS* mutations. The role of *SOS1* as a guanine nucleotide exchange factor for RAS family GTPases places it in a position where it may regulate signaling through MAP kinase, PI-3-kinase, and mTOR pathways. In addition to the information we derived from the biochemical studies, inhibitors of each of the indicated pathways were tested for their ability to reverse the effects of *SOS1* mutants in the functional spheroid sprouting assay. The results of these experiments elucidate the role of *SOS1* specifically in lymphatic endothelial cells, inform as to the appropriate pathways to target therapeutically, and reveal the effects of a variant of unknown significance in *SOS1*.

PB2532. Characterizing a novel missense variant in the methionine salvage gene *MRI1* that conveys protection for type 2 diabetes.

Authors:

K. Bandesh, M. Traurig, L. Baier; Phoenix Epidemiology and Clinical Res. Branch, Natl. Inst. of Diabetes and Digestive and Kidney Diseases, NIH, Phoenix, AZ

Abstract Body:

Methionine is an essential amino acid which is strictly recycled in the body. Dietary methionine is needed for cellular processes including methylation and DNA repair, but it may also influence metabolic disease. Dietary restriction of methionine prevents hyperglycemia and improves hepatic insulin response in mice; in humans higher blood methionine levels associate with increased type 2 diabetes (T2D). In a prior genome-wide association study for T2D among 7,200 American Indians, an Arg149Cys (rs551664067) in the methionine salvage enzyme *MRI1* was the strongest missense association; individuals carrying the Cys allele had a lower T2D prevalence ($P=1.2 \times 10^{-6}$, Odds ratio= 0.43) and a later age of T2D onset ($P=1.6 \times 10^{-5}$; carriers 51.2 yrs, noncarriers 46.2 yrs). The Arg149Cys is very rare in all ethnic groups except Americans Indians (Cys allele frequency in TOPMED cohort= 0.00001 vs 0.02 in American Indians). *MRI1*, which has never been implicated in T2D, is expressed in all human tissues and recycles methionine from a primary byproduct by the universally conserved methionine salvage pathway. The Arg149Cys resides in a conserved protein domain necessary for *MRI1* salvage activity. We assessed the stabilities of the two *MRI1* proteins by predicting the change in free energy (ΔG); the variant Cys149 protein was less stable ($\Delta G=-0.74$ kcal/mol) with reduced solvent accessibility (69%, Cys149 vs 75%, Arg149). Using the available crystal structure of *MRI1* (PDB ID: 4LDQ) as a template, we generated the structure of Cys149 protein by homology modeling; superimposition of the two proteins revealed close structural similarity (RMSD= 1.77Å). However, the Cys149 protein revealed a smaller, more compact ligand-binding pocket than the Arg149 (38 and 76 residues respectively). We investigated the binding of both forms of *MRI1* to its ligand, Methylthioribose-1-P, by molecular docking and found that both forms of *MRI1* have catalytic activity. However, the Cys149 protein had an improved ligand binding ($\Delta G=-6.1$ kcal/mol, Cys149; -5.8 kcal/mol, Arg149) where the ligand uniquely formed a salt-bridge with residue Arg98 leading to a higher enzymatic activity. We are validating the observed ligand-binding energetics using ^1H -Nuclear Magnetic Resonance (NMR) spectroscopy; our preliminary results confirm that the Cys149 protein is an active enzyme. To verify differential ligand-binding, we are studying the catalytic turnover of the two proteins over a reaction time of 24-hours by comparing the peak intensities of the ligand and the product obtained in a real-time NMR setting. Our work provides insight into novel metabolic process that confer protection for T2D.

Molecular Effects of Genetic Variation Posters - Thursday

PB2533. Characterizing the effects of a novel *RDH12* donor splice site variant using *in vivo*, *in vitro*, and *in silico* methods

Authors:

M-Y. Chung^{1,2}, Y-C. Chen³, S-J. Chen³; ¹Dept. of Life Sci. and Inst. of Genome Sci., Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan, ²Dept. of Med. Res., Taipei Veterans Gen. Hosp., Taipei, Taiwan, ³Dept. of Ophthalmology, Taipei Veterans Gen. Hosp., Taipei, Taiwan

Abstract Body:

Retinol dehydrogenase 12 (*RDH12*), a member of the dual-function retinoid dehydrogenase/reductase family, catalyzes the conversion of 11- *cis*-retinal to vitamin A in the rod and cone photoreceptors. *RDH12* has been implicated in a number of autosomal recessive retinal dystrophies, including early onset Leber congenital amaurosis and adolescent-onset macular dystrophy. Objective: Whole exome sequencing revealed a proband affected with Leber congenital amaurosis were a compound heterozygote of a known nonsense mutation, c.187C>T (p.Arg62Ter) in exon 4, and a novel variant at donor splice site of intron 6, c.448+4_448+7del (clinical significance unknown and MAF=1.32x10⁻⁵, based on gnomAD v.3.1.2). We characterized this novel *RDH12* donor splice site variant using *in vivo*, *in vitro* and *in silico* methods. Methods: The effect of the variant was initially predicted by four bioinformatics tools. In addition, we analyzed transcripts isolated from peripheral blood leukocytes of the proband and parents by RT-PCR and sequencing as well as minigene assay to quantify the ratio between the wild-type and mutant transcripts resulting from this variant. Results: The results revealed that two out of the four bioinformatic tools score the variant below the threshold for a typical human donor splice site, and that, from both *in vivo* and *in vitro* studies, about 85% of the *RDH12* transcript carrying the variant had skipped the exon 6 and the translated product would be in frame deletion of 35 amino acids. Conclusion: Based on the nature and relative amounts of aberrant and wild-type transcripts, this variant is very likely pathogenic.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2534*. Chromatin conformation during CD4+ T cell activation implicates putative autoimmune disease candidate genes

Authors:

M. Pahl¹, P. Sharma¹, R. M. Thomas¹, Z. Thompson¹, J. Pippin¹, C. Su¹, S. F. A. Grant², A. D. Wells³; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Children's Hosp. of Philadelphia/Univ. of Pennsylvania, Philadelphia, PA, ³Children's Hosp. of Philadelphia and Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

The majority of genetic variants identified by genome-wide association studies (GWAS), including for autoimmune traits, are located in non-coding regions and contribute to disease risk by modulating cis-regulatory element (cRE) activity to influence gene expression. To determine how these variants contribute to disease risk, it is essential to define both the cREs where causal variants reside and their target effector genes. As cRE function is dynamic across tissue types and cellular states, characterizing the dynamic epigenetic status of cREs across several physiological processes should provide additional insight into disease-relevant variants. Here we investigated 822 signals from 15 autoimmune GWAS in the context of cREs active in naïve CD4+ T cells during TCR-CD28 costimulation. CD4+ T cells coordinate adaptive immune responses, and the mechanisms that contribute to gene regulation in this cell type are crucial for balancing effective immunity with the maintenance of self-tolerance. To characterize how dynamic changes in gene expression correlate with dynamic vs. stable cRE activity, we performed RNA-seq, ATAC-seq, and HiC to capture the gene expression, chromatin accessibility, and chromatin conformation across three phases (0hr, 8hr, 24hr) of naïve CD4+ T cells activation. We found enrichment of transcription factor motifs for *KLF2*, *FOXO3*, *JUN*, and *IKZF1* at cREs in contact with promoters that may influence gene expression to restrain vs. promote CD4+ T cell activation. We further integrated CD4+ T cell cREs with autoimmune GWAS signals and found that most of the autoimmune traits enriched in cREs connected to early differential genes, while SLE enriched for genes dynamic at later timepoints. We finally prioritized 423 signals and identified 1,836 (1,200 protein-coding) genes contacted with these signals with a median distance of 103kb. These putative disease-relevant genes are enriched for expression of quantitative trait loci (eQTLs) and genes previously implicated in CD4+ T cell proliferation and function by high-throughput screens and other studies, suggesting that autoimmune diseases may disproportionately influence processes involved in CD4+ T cell proliferation and activation. A subset of these genes can be prioritized based on potential pharmacological evidence, which in turn should prove useful for repurposing efforts.

Molecular Effects of Genetic Variation Posters - Thursday

PB2535. Clonal hematopoiesis of indeterminate potential and kidney function decline in the general population

Authors:

C. Vlasschaert¹, B. Kestenbaum², A. Bick³, P. Natarajan⁴, N. Franceschini⁵, A. Kottgen⁶, M. Lanktree⁷, M. Rauh¹, C. Robinson-Cohen³; ¹Queen's Univ., Kingston, ON, Canada, ²Univ. of Washington, Seattle, WA, ³Vanderbilt Univ. Med. Ctr., Nashville, TN, ⁴Broad Inst., Cambridge, MA, ⁵Univ North Carolina at Chapel Hill, Chapel Hill, NC, ⁶Univ Hosp Freiburg, Freiburg, Germany, ⁷McMaster Univ., Hamilton, ON, Canada

Abstract Body:

Introduction: Clonal hematopoiesis of indeterminate potential (CHIP) is a common age-related process whereby somatic mutations in select driver genes lead to the biased production of leukocytes that exhibit dysregulated inflammation. CHIP affects at least 10% of individuals aged 65 and older and has been associated with increased mortality and multi-system morbidity, including the progression of chronic kidney disease. We tested the hypothesis that CHIP is associated with kidney function decline in the general population.

Study Design: Cohort Study

Setting and Participants: 11,941 individuals from three community-based cohorts in the TOPMed Consortium

Exposure: CHIP status from blood DNA-derived whole genome or exome sequences

Outcome: Incident 30% decline in estimated glomerular filtration rate (eGFR) after CHIP determination.

Analytical approach: Cox proportional hazards models for 30% decline endpoint. Study-specific estimates were combined using fixed-effects meta-analysis.

Results: Median baseline eGFR was 87 ml/min/1.73m² and median baseline age was 63 years. Prevalence of CHIP was 5.0%, 7.8% and 12.3% in persons 50-60, 60-70 and >70 years old, respectively. Over a median follow-up of 9 years, 2020 kidney function decline events occurred, with an event rate of 2.0 per 100-person-years among CHIP carriers and 1.8 per 100-person-years among those without CHIP. In meta-analysis adjusting for age, age², sex, baseline eGFR, self-reported race and diabetes status, CHIP was associated with a 22% higher risk of kidney function decline (95% CI: 5% to 41% higher; p-value=0.008).

Conclusions: We detected an association between CHIP and kidney function decline in three general population cohorts. Further studies are needed to investigate this novel condition.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2536. Clustering of missense mutations follows a non-random distribution across the human genome and correlates with specific classes of genes

Authors:

C. Rivolta^{1,2,3}, M. Quinodoz^{1,2,3}, V. G. Peter^{1,2,3,4}, K. Cisarova⁵, B. Royer-Bertrand⁵, P. Stenson⁶, D. Cooper⁶, S. Unger⁵, A. Superti-Furga⁵; ¹Inst. of Molecular and Clinical Ophthalmology Basel, Basel, Switzerland, ²Univ. of Basel, Basel, Switzerland, ³Univ. of Leicester, Leicester, United Kingdom, ⁴Lausanne Univ. Hosp. (CHUV), Lausanne, Switzerland, ⁵Univ. of Lausanne and Lausanne Univ. Hosp. (CHUV), Lausanne, Switzerland, ⁶Cardiff Univ., Cardiff, United Kingdom

Abstract Body:

Using a machine learning approach, we analyzed the distribution of missense variants observed in genetic conditions and cancer, and discovered that within-gene clustering of mutations is widespread across the human genome, significantly deviating from a random distribution in as many as 46% of all well-characterized disease genes from ClinVar. We took advantage from these findings to develop a pathogenicity predictor, MutScore, which integrates qualitative features of DNA substitutions with this new additional information on clustering. In its first four months of activity, MutScore's website received more than 2,000 queries from the scientific community. This prompted us to assess its performance on additional, more recent ClinVar submissions, as well as to expand our research on variant clustering. With a global area under the curve (AUC) value of more than 0.95 for sensitivity vs. specificity, MutScore showed an even better predictive power on these novel variants than previously reported.

In addition, we investigated further the biological relevance of degrees of mutational clusters, by assessing whether the within-gene distribution of pathogenic variants would correlate with specific classes of genes. We found that genes with high clustering of mutations within small regions were significantly more likely to encode for proteins (1) having DNA-binding properties, (2) being transcription factors, and (3) localizing in the nucleus, whereas enzymes were significantly underrepresented in this category. Conversely, proteins encoded by genes with no relevant mutational clustering were enriched in enzymes and depleted in transcription factors, at a statistically significant level. These findings very likely reflect the molecular mechanisms shaping pathogenicity at the protein level for both genetic diseases and cancer. For instance, DNA-binding domains that characterize transcription factors and other regulatory proteins are in general relatively small (20-100 aa residues), and therefore pathogenic variants would tend to be restricted to such domains, leading in turn to dense mutational clusters at the DNA level. Conversely, functional domains of enzymes are larger, giving rise to stretches of medium clustering.

In conclusion, our analyses confirm MutScore's high predictive power and identify a new and significant link between degrees of mutational clustering and protein function, across the whole human genome.

Molecular Effects of Genetic Variation Posters - Thursday

PB2537. COL9A1 and FLNB: Variants corresponding to complex clinical phenotype.

Authors:

J. Vázquez¹, M. Santos², C. Velez³, G. Serrano⁴, S. Carlo⁵, F. Vélez-Bartolomei⁶, A. Cornier⁷; ¹Genetic Diagnostic Group, Bayamón, PR, ²Univ. of Puerto Rico Med. Sci. Campus, Sch. of Publ. Hlth., Calle Antosnsanti #1607 San Juan, Puerto Rico, ³PUCPR, Ponce, PR, Puerto Rico, ⁴Genetic Diagnostic Group/Ponce Hlth.Sci. Univ., San Juan, PR, ⁵Ponce Hlth.Sci. Univ., Cabo Rojo, PR, ⁶San Jorge Children's Hosp./Genetic Diagnostic Group, San Juan, PR, ⁷San Jorge Children s Hosp./ Ponce Hlth.Sci. Univ., San Juan, PR

Abstract Body:

We are presenting the case of an 18-year-old male that was referred to genetics by cardiology due to skin striae and to rule out a connective tissue disorder (CTD). During the physical examination there was evidence of pronounced joint hyperlaxity, striae on the back and on the lower extremities, arachnodactyly and chest asymmetry. The patient also presented with scoliosis that was documented by spine X-rays and mitral valve prolapse that was documented by an echocardiogram. Due to clinical symptoms such as tenderness in the lower extremities, recurrent headaches and evidence of Marfanoid habitus a comprehensive connective tissue disorder gene panel was requested. The results of the CTD gene panel indicated that the patient is heterozygous for variants in two genes: *COL9A1* and *FLNB*. The *COL9A1* gene codes for a specific part of the type IX collagen protein. A sequence variant *c.1636G>A* was recorded in this patient. This nucleotide change is predicted to cause an amino acid substitution designated as *p.Asp546Asn*. Pathogenic variants of the *COL9A1* gene has been associated with autosomal recessive Stickler syndrome IV and autosomal dominant multiple epiphyseal dysplasia 6. The *FLNB* gene is responsible for providing the blueprint to produce a protein called filamin B. This protein is important because it provides a scaffold that binds to actin in order to form a network that is known as the cytoskeleton of the cell. Filamin B is of major importance because it plays a role in skeleton development before birth and it is a protein expressed by chondrocytes. A sequence variant *c.4447T>C* in the *FLNB* gene was documented in this patient. This change is predicted to result in an amino acid substitution *p.Phe1483Leu*. Pathogenic variants of *FLNB* are associated with autosomal recessive spondylocarpotarsal synostosis syndrome, autosomal dominant ateloteggenesis type 1 and type 3, Boomerang dysplasia and Larsen syndrome. The *COL9A1* and the *FLNB* variants have never been reported in the scientific literature. We are presenting a case of a patient with a genetic variant in the *COL9A1* gene that has not been associated before to Stickler syndrome type 4 and may be responsible of the patient's phenotype. *FLNB* variant may be responsible for some of this patient's phenotype, resembling an atypical presentation of Larsen syndrome which has a wide range of phenotypic variability. Both genes have a dominant effect on phenotype and these variants have not been reported in the literature before. Functional proteomic studies would be useful in order to define the degree of involvement of these proteins, and this would further characterize the molecular pathophysiology of these genetic gene variants.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2538. Colocalization of blood cell traits GWAS associations and variation in *PU.1* genomic occupancy prioritizes causal noncoding regulatory variants

Authors:

R. Jeong^{1,2}, M. L. Bulyk^{1,2}; ¹Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, ²Harvard Univ., Cambridge, MA

Abstract Body:

Although genome-wide association studies (GWAS) uncovered numerous trait-associated loci across the human genome, most are located in noncoding regions and are often hard to fine-map to individual causal variants because of widespread linkage disequilibrium (LD). To address this challenge, we present a strategy utilizing transcription factor (TF) binding quantitative trait loci (bQTLs) for colocalization analysis to identify genetic associations potentially mediated by TF occupancy variation and to pinpoint likely causal variants. To demonstrate, we sought to identify blood cell trait GWAS loci that may be mediated by *PU.1*, a hematopoietic master regulator. We analyzed available *PU.1* ChIP-seq data in 49 genotyped lymphoblastoid cell lines (LCLs), detected genetic variants associated with *PU.1* occupancy levels, and tested colocalization with overlapping blood cell trait GWAS signals. 69 significantly colocalized blood cell trait associated loci are potentially driven by *PU.1* occupancy variation. We identified *PU.1* motif-altering variants at 55 of them, which we nominate as the likely shared causal variants for the colocalized blood cell trait associations. We also demonstrate the regulatory impact of two such variants, using available reporter assay results. The ability to hone in on variants altering a particular TF motif facilitated pinpointing a likely causal regulatory variant at a locus, as well as highlighting the likely direct regulatory impact of the variant. This work motivates the use of TF bQTL data to elucidate GWAS associations to various complex traits, where relevant TFs are known.

Molecular Effects of Genetic Variation Posters - Thursday

PB2539. Combining human genetics and functional genomics identifies regulators of the lysosomal lipid BMP.

Authors:

D. Leto, S. V. Andrews, S. S. Davis, A. Rana, R. Ghosh, T. Logan, R. D. Maciuca, J. Suh, T. Sandmann, G. Di Paolo, A. G. Henry; Denali Therapeutics, South San Francisco, CA

Abstract Body:

Background: The phospholipid bis(monoacylglycerol)phosphate (BMP) is highly enriched in the endo-lysosomal system, where it facilitates cholesterol egress and sphingolipid degradation. BMP dysregulation is observed in many lysosomal storage disorders, although it is unclear whether this lipid is a driver or marker of disease. Elevated levels of BMP are also observed in urine from carriers of the Parkinson's Disease (PD) risk variant G2019S in LRRK2, a protein implicated in the regulation of lysosomal function. Early-stage clinical data has shown that LRRK2 inhibition reduces urine BMP in a dose-dependent manner. Despite its function in maintaining lysosomal health and its connection to disease, the genes that control BMP metabolism remain poorly understood.

Methods: We used two complementary approaches to identify genetic regulators of BMP: (1) we performed GWAS of four BMP species using WGS and urine BMP measurements from the Parkinson's Progression Markers Initiative (PPMI) and the Accelerating Medicines Partnerships - Parkinson's Disease (AMP-PD) (N = 634 samples). We nominated causal genes via eQTL and chromatin interaction data and examined overlap with regions identified in PD GWAS of European samples. (2) We conducted a targeted CRISPR-knockout (KO) screen in mouse bone marrow-derived macrophages (BMDMs). We assessed the effects of deleting 129 genes, nominated either as causal genes in the BMP GWAS or selected through literature curation, on the intracellular levels of five different BMP species via LC/MS.

Results: In the BMP GWAS study, the LRRK2 G2019S variant was a genome-wide significant ($p < 5E-8$) quantitative trait locus for all four BMP species. Gene set enrichment analysis of putative causal genes in loci reaching a suggestive association threshold ($p < 1E-5$) with BMP levels implicated endocytosis and phospholipid transport pathways. Two loci overlapped with regions identified in PD GWAS, including the ANK2/CAMK2D/LARP7 region on chromosome 4. The BMP CRISPR-KO screen identified gene knockouts that affected the total abundance or composition of the intracellular BMP pool ($Z\text{-score} \geq 2$). In addition to validating known modifiers of intracellular BMP, the screen also identified genes that have not previously been implicated in BMP regulation, including causal genes nominated in the BMP GWAS.

Conclusion: Combining human genetics and functional genomics approaches is an effective method for identifying and prioritizing putative regulators of clinical biomarkers.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2540. Comparative titin gene frequencies and distributions across four population cohorts.

Authors:

P-S. Lai, R. Lim, J. Koo, J. Rao, G. Tan; Natl. Univ. of Singapore, Singapore, Singapore, Singapore

Abstract Body:

Mutations in the titin gene (*TTN*) are known to cause a wide spectrum of genetic diseases, ranging from cardiomyopathies to skeletal muscle diseases. *TTN* gene, spanning 363 exons, encodes for titin, the largest human protein which spans four domains, namely I-, A- and M-bands, and Z-disk. The increasing use of next-gen sequencing (NGS) has led to a surge in discovery of numerous *TTN* variants, many of which are rare and unique. In this study, we investigated the frequency and spectrum of *TTN* variants in a cohort of 60 local neuromuscular (NMD) patients and compared these against variants in public domains from three other populations, namely cardiomyopathies, titinopathies and healthy individuals. Variants in the NMD cohort were identified from standard NGS pipelines using whole genomes sequenced at an average 30X coverage. Pathogenicity classification was performed according to the American College of Medical Genetics and Genomics (ACMG) guidelines. A total of 15,757 *TTN* variants was observed from the 60 NMD cases, with more than half being novel or rare in the general population. Most of the variants (90.60%) were non-synonymous, of which 1.05% of these were truncating (TTNtv). Missense variants make up the majority of the exonic variants (59.39%) followed by synonymous variants (32.74%) and non-frameshift indels (4.57%). Rare or novel variants accounted for 698 out of 934 unique variants in coding regions. Among the 38 *TTN* variants curated as clinically pathogenic in the 60 NMD cases, 25 were novel. In terms of frequencies and distributions among the titin domains, titin I-band and M-band had the highest TTNtv densities at 0.525 and 0.547 variants/kb. In contrast, TTNtv variants were enriched in the A and M-bands more than the I-band or Z-disk for healthy, titinopathies and cardiomyopathies cohorts. Overall, all the disease cohorts had significantly higher TTNtv densities compared to the general population ($p = 0.0478$). These results highlight the challenge in interpreting the clinical significance of *TTN* variants especially with the frequent presence of rare and unique variants across all populations. The high percentage of novel and rare TTNtv variants identified in this study also indicate the need for further understanding on the distribution of these variants to help in the identification of pathogenic variants.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2541. Comparison of pedigree-based graph workflow to more traditional workflows for rare candidate variant analysis

Authors:

B. Pusey¹, J. Fu¹, W. N. Gahl², D. R. Adams³; ¹Natl Human Genome Res. Inst., Bethesda, MD, ²NHGRI (NIH), Bethesda, MD, ³NIH, Bethesda, MD

Abstract Body:

The NIH Undiagnosed Diseases Program (UDP), a subgroup of the Undiagnosed Diseases Network (UDN), was established with the goal of conducting research for patients with significant illnesses that remain undiagnosed despite extensive medical evaluation. Genome sequencing approaches became available around the same time that the UDP started and are important tools for making diagnoses in some cases. Given the increasing prevalence of exome and genome sequencing in standard medical care, many current UDP applicants have been evaluated with this technology before they apply. As a result, a major focus of UDP genomic analyses is the assessment and prioritization of variants of unknown significance, often in genes not currently associated with human disease. This work often requires an “agnostic” approach, maximizing the sensitivity and scope of variant analysis. A recently described FASTQ to filtered-variant alignment pipeline (VG-Pipeline, Markello et al, 2022, PMID 35483961) was developed in part with UDP cases. We present a descriptive head-to-head comparison of the VG-Pedigree analysis pipeline with our prior GATK-derived pipelines. The comparison cohort contains approximately 200 nuclear families with a wide variety of clinical presentations. We conclude by highlighting the strengths and weakness of each approach along with considerations for future work.

Molecular Effects of Genetic Variation Posters - Thursday

PB2542. Comprehensive detection of trans-regulatory signal from scRNA-seq and perturbation datasets

Authors:

N. Babushkin, X. Liu; Univ. of Chicago, Chicago, IL

Abstract Body:

Single cell RNA-sequencing (scRNA-seq) coupled with effective CRISPR/Cas9-mediated perturbations offers the ability to functionally map regulatory elements of gene regulation, including trans-gene regulation. Recently, several studies (Xie 2019 Cell Rep; Gasperini 2019 Cell and Morris 2021 bioRxiv) generated large scale scRNA-seq perturbation datasets to study cis-regulatory effects. However, most focused on detecting cis-regulatory effects, probably because of the computational and statistical challenges of detecting trans-signals, including low statistical power and high false positive rates. Short RNA-sequencing reads mapped to multiple homologous locations on the genome lead to more than 75% of the false positive trans-signals in bulk RNA-seq data. Similarly, we found that around 70% of trans-signals in scRNA-seq perturbation data are likely false positives due to an analogous multi-mapping issue. However, using the solution for bulk RNA-seq, which involves removing suspicious trans-signals that are cross-mappable, is overly stringent in scRNA-seq data and results in substantial loss of true signal. In this study, we carefully addressed the multi-mapping issue in order to reduce false trans-signals while preserving power in scRNA-seq perturbation data. More specifically, we thoroughly removed scRNA-seq reads mapped to genomic regions of low mappability, such as repeat regions, before quantifying gene expression in each cell. Using this approach, we processed a collection of scRNA-seq and perturbation datasets, targeting more than 6,500 regulatory elements and profiling expression in more than 370,000 cells. We then applied the state-of-the-art association method SCEPTRE (Barry 2021 Genome Biology) to the datasets to detect trans-signals. Our work will produce an unprecedented, comprehensive and high-quality set of trans-regulatory signals from scRNA-seq and perturbation datasets.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2543. Comprehensive signal identification highlights the contribution of protein QTLs to complex trait genetics

Authors:

J. Chiou, H. Kim, UK Biobank Pharma Proteomics Project, FinnGen, E. Fauman, M. Miller; Pfizer, Cambridge, MA

Abstract Body:

Large-scale protein quantitative trait loci (pQTL) mapping presents opportunities for unraveling biological mechanisms underlying the genetic risk of complex diseases. However, comprehensive signal identification, especially at the oft-ignored major histocompatibility complex (MHC) and X chromosome, is necessary to leverage the full potential of pQTL datasets. In this study, we identified 28,867 conditionally independent pQTL signals of 1,424 plasma proteins measured across 35,306 individuals from the UK Biobank Pharma Proteomics Project using SuSiE regression. Cis regions were more likely to contain multiple independent signals (cis: 88.1%, trans: 17.5% of regions), contained more signals on average (cis: 5.7, trans: 1.3 signals), and had better resolved fine-mapping (cis: 9.5, trans: 43.1 credible set variants). In the extended MHC locus, we observed 1,265 independent signals, 78.3% of which mapped outside of the MHC class I/II genes. Joint tagging between two or more causal variants boosted the significance of non-causal variants in 3.3% of regions, where the index variant from the marginal association was not identified in any of the conditional credible sets. Strong primary signals masked the effects of 5.6% of independent signals, which had attenuated significance in the marginal association. We highlight the contribution of independent pQTL signals to complex trait genetics through specific examples on the X chromosome, including (1) a causal relationship between increased circulating CD40 ligand levels and risk for autoimmune diseases using Mendelian randomization (OR=1.05, 95% CI=1.01-1.08) and (2) colocalization between a single (out of 6 distinct signals) non-primary cis pQTL signal that reduces ACE2 levels and a rare variant (rs190509934) that decreases COVID-19 susceptibility. We are currently broadening the scope of our independent pQTL signal to GWAS integration and expect to report high-level findings from these analyses. These results underscore the importance of modeling all variants in associated regions for accurate signal identification and demonstrate how pQTLs can support therapeutic hypotheses of disease risk mechanisms in understudied genomic regions.

Molecular Effects of Genetic Variation Posters - Thursday

PB2544*. Conditionally distinct adipose eQTL signals in 2,256 individuals identify hundreds of colocalized genes for cardiometabolic traits

Authors:

S. Brotman¹, L. Guan², J. El-Sayed Moustafa³, A. Jackson⁴, K. Broadaway¹, D. Wang³, K. Currin¹, A. Roberts³, C. Raulerson¹, M. Erdos⁵, N. Narisu⁵, H. Stringham⁴, M. Boehnke⁴, F. Collins⁵, P. Abstract Body:

GWAS have implicated thousands of loci in disease, yet most underlying genes remain unknown. To detect genetic variants associated with both disease risk and gene expression level, we colocalized GWAS signals with expression quantitative trait loci (eQTL) signals in subcutaneous adipose tissue from 2,256 individuals in 5 studies. While most previous eQTL studies focused on primary eQTL signals, we used conditional analysis to detect non-primary signals. Of 28,346 genes tested in ≥ 2 studies, 17,969 (63%) had ≥ 1 significant eQTL ($P \leq 1e-06$); fewer genes (8,113-11,254) were detected in individual studies. Of the 17,969 genes, 50% had ≥ 2 eQTL signals and 21% had ≥ 3 signals. Among genes with ≥ 4 eQTL signals, non-primary eQTL had lower median effect sizes: 0.38, 0.27, 0.21, and 0.19 for 1st, 2nd, 3rd and 4th-10th signals, respectively. Additionally, the distances of lead eQTL variants from their transcription start sites were a median of 31, 39, 48 and 68 kb for 1st, 2nd, 3rd and 4th-10th signals, respectively. Adipose eQTL variants for the 1st-4th signals were enriched in both promoters and enhancers ($P < 2.5e-3$), however the levels of enrichment (particularly for promoters) were successively lower with increasing order of signal discovery. Gene expression levels in TwinsUK showed a median heritability estimate of 0.19 for eGenes and 0.07 for genes without an eQTL; heritability increased with the number of eQTL signals per gene, independent of gene expression level. Preliminary analyses using proportions of 4 cell types in TwinsUK showed 0.42% of 1st signals had an interaction with adipocyte proportion, compared to 0.35, 0.27 and 0.33% of 2nd, 3rd, and 4th signals, respectively. We compared the adipose eQTL to a 10-fold larger study in blood ($n = 31,684$): among 24,666 significant adipose gene-signal pairs tested in eQTLGen, only 15,622 (63%) were had a $P \leq 1e-06$, highlighting the value of disease-relevant tissues. Finally, we used *coloc* ($PP4 \geq 0.5$) and LD ($r^2 \geq 0.5$) to identify adipose eQTL colocalizing with GWAS loci from 3 cardiometabolic traits. We identified 158 colocalized signals for T2D, 186 for WHR, and 237 for WHRadjBMI, corresponding to 150, 176, and 224 genes, respectively. Of 581 total colocalized GWAS-eQTL signals, 31% were from non-primary eQTL and would have been missed if distinct signals were not identified. Colocalizations include allelic series where ≥ 2 GWAS signals colocalized with ≥ 2 eQTL signals for the same gene, further supporting the role of these genes in disease. Together, we found that half of genes with an eQTL have at least 2 signals and that GWAS colocalization with non-primary signals greatly expanded the number of candidate genes for common traits.

PB2545. Congenital Myasthenic Syndrome Due to *DOCK7* Gene Mutation Case Study Report

Authors:

A. Lebron Ilarraza^{1,2}, G. Serrano Rodriguez³, J. Pascual³, G. Arroyo Figueroa^{1,2}, S. Carlo^{3,1}, F. Velez¹, N. Arciniegas³, A. Cornier⁴; ¹San Jorge Children's Hosp., San Juan, PR, ²Univ. of Puerto Rico Piedras Campus, San Juan, PR, ³Ponce Hlth.Sci. Univ., Ponce, PR, ⁴San Jorge Children s Hosp./ Ponce Hlth.Sci. Univ., San Juan, PR

Abstract Body:

Congenital myasthenic syndrome (CMS) are rare genetic conditions resulting from a defect at the junction where your nerve stimulates muscle activity. To date, few cases of CMS due to the *DOCK7* gene mutation have been documented, but it must remain within the differential diagnosis for patients with muscular weakness and other neurological problems. We found a missense change in Exon 14 that replaced valine with alanine at codon 539 of the *DOCK7* protein, which has not been reported and may be deleterious. A 20-year-old male presents himself with a history of generalized muscular weakness, asthma, fatigue, ptosis, intestinal dysmotility, dysphagia (upper dysmotility), and other conditions like non-epileptic events, intense headaches, and multiple osseous fractures. The intriguing facts about this case are that, aside from the low frequency, the manifestation of the symptoms can be non-specific, and it may imitate other pathologies. This case could represent a novel way of identifying individuals with congenital myasthenia that could have passed unnoticed or misdiagnosed due to *DOCK7* gene mutations.

PB2546. Connecting rare variation to extremes of plasma protein levels

Authors:

X. Xie¹, T. Li², C. Benner¹, J. Irudayanathan¹, B. van de Geijn¹, R. Pendergrass¹, A. Mahajan¹, A. Battle³, M. McCarthy¹; ¹Genentech, South San Francisco, CA, ²Johns Hopkins Sch. of Med., Baltimore, MD, ³Johns Hopkins Univ., Baltimore, MD

Abstract Body:

The emergence of large scale high-throughput proteomic data enables integrative analysis of the relationships between genetic variation and plasma proteins: these can provide insights into regulatory mechanisms and biomarkers relevant to disease. While genome-wide association studies (GWAS) on plasma proteomics have identified many common variants associated with plasma protein levels, rare variants, which are collectively abundant in the human genome, are inefficiently tagged in GWAS. Here, we focus on characterizing the relationship between rare variants and extreme plasma protein levels. We used measures of 1463 plasma proteins generated, using the OLINK platform, on 54306 UK Biobank participants (another 1500 proteins will be available shortly). In the pilot analyses with 16991 baseline UKB participants, we assessed the prevalence of rare coding variants (MAF<0.1%) amongst protein level outliers (defined as individuals with expression values >3SD from the average expression level of the cognate protein). We adjusted the protein levels by known covariates, such as sex, age, and study sites, plus 100 PEER factors to account for hidden confounders. Amongst individuals who were outliers for a given protein, we found a marked excess of rare coding variants in the cognate gene, consistent with our hypothesis that rare coding variants underlie extremes of protein abundance. We found that, compared to non-outliers, outliers are 2.31 times more likely to be rare variant carriers ($p=8.51e-88$): this enrichment increased to 2.49 ($p=1.08e-42$) and 2.52 ($p=1.90e-21$) when more stringent thresholds (>4SD and >5SD) were used to define outliers. The magnitude of this enrichment signal decreased as the number of PEER factors was reduced (from OR=2.31 with 100, to 2.09 with 50 and 1.83), confirming PEER factors' effectiveness in capturing the hidden confounding variables in measured proteomics. Other mechanisms that may lead to extreme protein levels, including artefacts related to differential antibody binding, will be assessed in further analysis. Access to whole-genome sequence data from UKB will allow us to extend these analyses to include rare variants in non-coding space. We are developing a hierarchical Bayesian model, Watershed, to synthesize genomic annotations and observed outlier signals across proteins in trans to prioritize rare variants and interrogate their effects on disease risk given UKB's extensive phenotype data. The ultimate goal is to establish the value of plasma protein profiling as a valuable tool to sequence-based diagnostics, which can improve interpretation of rare variants and identification of causal genes for complex traits.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2547*. Consequences of loss of function burden effects on the human plasma proteome in 54,306 UK Biobank participants

Authors:

C. Whelan¹, S. Loomis², N. Okugawa¹, H. McLaughlin¹, T. Trinh¹, H. Runz³, S. Engle¹, A. Chen¹, B. Sun²; ¹Biogen Inc., Boston, MA, ²Biogen, Cambridge, MA, ³Biogen Inc., Cambridge, MA

Abstract Body:

Proteins are the functional modules underlying biological processes and the main targets of drugs. To date, studies of genetic determinants of plasma protein levels have primarily focused on single variant associations, most of which are non-coding. Here, we directly assessed the effects of gene-based protein truncating variant (PTV) burden (19,209 genes; PTV MAF <1%) on 1,463 plasma proteins measured in 54,306 individuals in the UK Biobank using the Olink Explore assay. We identified 1,642 significant PTV associations with circulating proteins ($p < 2.6 \times 10^{-6}$), including 584 genes associated with the encoded protein (*cis*) and 1,058 associations with genes other than for the encoded proteins (*trans*). For 38% (223) of *cis* gene PTV-burden associations, we did not find any associations within the corresponding gene in genome-wide single variant pQTL analyses, demonstrating that PTV burden can help refine candidate genes at single-variant pQTL loci. 99% of *cis* PTV effects led to decreased protein levels (mean $\text{abs}(\beta) = 1.67$); *trans* PTV effects were on average weaker (mean $\text{abs}(\beta) = 0.78$, $p = 6.6 \times 10^{-153}$) and more evenly distributed in direction (40% decreased, 60% increased protein levels). *Trans* effects highlighted pleiotropic loss of function effects at genes that may act as master regulators of protein pathways and networks. For example, PTV burden at *TET2* was associated with perturbations of several immune pathway proteins, including decreased concentrations of CCL5, CLC, FLT3LG, KIR2DL3, KIR3DL1 and LCN2, and increased levels of CD1C, CD200R1, CD207, CD33, CLEC4C, FCGR2A, FLT3, LILRB2 and TNFSF13B. We also found *IGF2R* PTV burden leads to decreased IGF2R levels and downstream increases in multiple cathepsin levels, reflecting the role of IGF2R in lysosomal transport of cathepsins. Additionally, we illustrated how PTV gene burden can mimic effects of inhibitory drugs, in cases such as PCSK9 and ANGPTL3. Finally, we experimentally validated two putative loss-of-function variants at *APP*, revealing reduced plasma protein and corresponding, genotype-dependent reductions in iPSC mRNA and protein levels for two stop gained variants at exon 7. Our study highlights how PTV burden can be linked to protein levels to help implicate specific genes in driving proteome expression, highlight associations and networks missed at the single-variant level, and directly elucidate physiological implications of inhibitory drugs on disease.

PB2548. CRISPR perturbation screens identify predicted regulatory sequences and genes within GWAS loci associated with erythrocyte density traits

Authors:

N. Brosseau¹, T. Pincez², K. Sin Lo¹, M. Beaudoin³, G. Lettre⁴; ¹Montreal Heart Institute, Montréal, QC, Canada, ²Université de Montréal, Montréal, QC, Canada, ³Montreal Heart Inst, Montreal, QC, Canada, ⁴Université de Montréal, Montreal, QC, Canada

Abstract Body:

GWAS have identified hundreds of loci robustly associated with red blood cell (RBC) traits such as mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC). These traits influence complications in several hematological diseases such as sickle cell disease and malaria, and a better understanding of the genetic regulation of these traits could provide new drug targets for these pathologies. Most of the sentinel SNPs identified are in non-coding regions of the genome. This suggests these genomic regions have a regulatory effect on RBC phenotypes. In this study, we created a library of sgRNA targeting the sentinel SNPs identified by GWAS and their strong linkage disequilibrium variant proxies, as well as potential regulated genes based on proximity and other genes of interest. We used an immortalized CD34⁺ erythroid-like cell line (HUDEP-2) to assess the effect of the sgRNAs on cell density. Three different cell lines stably expressing either Cas9 (CRISPR KO), dCas9-KRAB (CRISPRi), and dCas9-VP64 (CRISPRa) were transduced with our sgRNA library. Cells were then separated according to their density using a Percoll gradient as density combines the effect of changes of MCV and MCHC. Cells were collected at each fraction of the gradient, and the abundance of each sgRNA was assessed using Illumina next-generation DNA sequencing. The expected results are that the sgRNAs that increase the density of the cells will be more abundant in the lower fractions, and sgRNA decreasing the density of the cell will be less abundant in the lower fractions compared to safe sgRNAs. Using this method, we were able to identify (at a false discovery rate <10%) 21 genomic targets with CRISPR KO, 22 with CRISPRi, and about 10 times more with CRISPRa. After validation and further characterization, these findings should provide a better understanding of the genetic regulation of erythrocyte volume.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2549. CRISPR/Cas9-mediated knockout and cDNA rescue using sgRNAs that target exon-intron junctions in *Drosophila* enable functional analysis of pathogenic variants in a tissue-specific manner.

Authors:

W. Yoon, M. Chilian, K. Vargas Parra, A. Sandoval, J. Ramirez; Oklahoma Med. Res. Fndn., Oklahoma City, OK

Abstract Body:

Functional studies of genetic variants in undiagnosed patients in humans require model organisms such as *Drosophila*. Studies of disease-associated variants in *Drosophila* often need to be performed in a tissue-specific manner, especially in cases where human genes have multiple paralogs, one of which is expressed in a specific tissue, while *Drosophila* single orthologs are expressed ubiquitously. OxoGlutrate DeHydrogenase-Like (OGDHL) is one such gene and is mainly expressed in the human brain. In contrast, *dOgdh*, the *Drosophila* single ortholog, is expressed ubiquitously. In this study, we take CRISPR/Cas9 and Gal4/UAS approaches to achieve tissue-specific knockout in parallel with the rescue of the knockout by cDNA expression in *Drosophila*. We demonstrated that neuronal-specific expression of Cas9 with the sgRNA that targets the exon-intron junction of *dOgdh* (sgRNA_{dOgdh}) leads to knockout of the endogenous *dOgdh* gene, but not UAS-*dOgdh* cDNA transgene. This approach enabled us to determine the pathogenicity of nine missense variants in OGDHL identified from individuals with neurological phenotypes. We anticipate that this new approach will be widely used to study the tissue-specific roles of numerous human disease-associated variants as well as gene function studies in *Drosophila*.

Molecular Effects of Genetic Variation Posters - Thursday

PB2550. Cryptic AS-NMD elements harbor relevant variants in probands with early onset genetic disease.

Authors:

S. Felker¹, J. M. J. Lawlor¹, D. R. Latner¹, M. L. Thompson¹, S. M. Hiatt¹, C. R. Finnila¹, K. M. Bowling², Z. T. Bonnstetter¹, W. V. Kelley¹, A. C. Hurst³, M. A. Kelly⁴, G. Nakouzi⁴, G. M. Cooper¹; ¹HudsonAlpha Inst. For Biotechnology, Huntsville, AL, ²Washington Univ. Sch. of Med., Saint Louis, MO, ³Univ. of Alabama in Birmingham, Birmingham, AL, ⁴HudsonAlpha Clinical Services Lab., Huntsville, AL

Abstract Body:

Families of children with early-onset genetic disease often undertake arduous diagnostic odysseys that can take a considerable emotional and financial toll. Despite advancements in genomic medicine and research, rates of causal variant discovery in these probands remain low. One contributor to this deficiency is that variants in poorly annotated functional genomic elements are often overlooked in conventional analysis. Examples of this are “poison exons” which are non-coding, noncanonical exons in transcripts that are alternatively spliced and result in nonsense-mediated decay (AS-NMD) via the inclusion of a premature termination codon. Such AS-NMD transcripts are difficult to capture and annotate because they may only be expressed at an early developmental or embryonic timepoint. As variants within these cryptic regions have been previously associated with disease, we conducted a genome-wide screen for variants in AS-NMD elements in probands without a molecular diagnosis. Variants from genomes and exomes of 4001 probands with early-onset genetic disease were intersected with elements curated from published studies of differential AS-NMD. The allele frequency, conservation, and CADD score of resulting variants were examined with regard to patient phenotype and mode of inheritance. Variant pathogenicity was determined using ACMG/AMP Standards and Guidelines. This analysis has resulted in likely pathogenic and VUS variants in probands with no previously returned results from conventional analysis. Two novel VUS variants were identified in highly conserved regions of intron 20 of *SCN1A*. This intron contains the well-described 20N poison exon within which several variants associated with Dravet Syndrome and Dravet-like epilepsy phenotype have been found. Another variant was found within the poison exon of *SNRPB*, a gene associated with cerebro-costo-mandibular syndrome (CCMS) which causes abnormal skeletal morphologies and cardiac defects consistent with the proband’s phenotype. This variant had been determined causative for CCMS in earlier publications from other cohorts, so there was sufficient evidence to return as likely pathogenic. This AS-NMD directed variant investigation has resulted in returnable variants in probands who had no molecular diagnosis. The inclusion of cryptic AS-NMD elements in variant analysis pipelines would result in few additional variants per proband, with minimal, if any, added labor from scientists. In conclusion, this investigation has shown that incorporation of AS-NMD elements in genomic analysis would improve diagnostic yield in rare disease.

PB2551. CYP2C19 Polymorphism in Ischemic Heart Disease Patients Taking Clopidogrel after Percutaneous Coronary Intervention in Egypt

Authors:

M. El-Zawahri; MUST, Giza, Egypt

Abstract Body:

CYP2C19 Polymorphism in Ischemic Heart Disease Patients Taking Clopidogrel after Percutaneous Coronary Intervention in Egypt El-Zawahry M¹ Shawky A² Sabit H^{3†} Baraka K^{4†}

¹Department of Medical Biotechnology, College of Biotechnology, Misr University for Science and Technology, ²Department of Cardiology, College of Medicine, Helwan University, Cairo, Egypt³Department of Environmental Biotechnology, College of Biotechnology, Misr University for Science and Technology, P. O. Box 77, Giza, Egypt⁴Department of Cardiology, College of Medicine, Minia University, Egypt P. O. Box 77, Giza, Egypt†Corresponding author:

hussein.sabit@must.edu.eg. **Abstract Background:** Cardiovascular diseases (CVDs) are considered a leading cause of death worldwide. Allelic variation in the CYP2C19 gene leads to a dysfunctional enzyme, and patients with this loss-of-function allele will have an impaired clopidogrel metabolism, which eventually results in major adverse cardiovascular events (MACE). Ischemic heart disease patients (n=102) who underwent percutaneous cardiac intervention (PCI) followed by clopidogrel were enrolled in the present study. **Methods:** The genetic variations in the CYP2C19 gene were identified using the TaqMan chemistry-based qPCR technique. Patients were followed up for one year to monitor MACE, and the correlations between the allelic variations in CYP2C19 and MACE were recorded. **Results:** During the follow-up, we reported 64 patients without MACE (29 with unstable angina (UA), 8 with myocardial infarction (MI), one patient with non-STEMI, and one patient with ischemic dilated cardiomyopathy (IDC)). Genotyping of CYP2C19 in the patients underwent PCI and treated with clopidogrel revealed that 50 patients (49%) were normal metabolizers for clopidogrel with genotype CYP2C19*1/*1 and 52 patients (51%) were abnormal metabolizers, with genotypes CYP2C19*1/*2 (n=15), CYP2C19*1/*3 (n=1), CYP2C19*1/*17 (n=35), and CYP2C19*2/*17 (n=1). Demographic data indicated that age and residency were significantly associated with abnormal clopidogrel metabolism. Moreover, diabetes, hypertension, and cigarette smoking were significantly associated with the abnormal metabolism of clopidogrel. These data shed light on the inter-ethnic variation in metabolizing clopidogrel based on the CYP2C19 allelic distribution. **Conclusion:** This study, along with other studies that address genotype variation of clopidogrel-metabolizing enzymes, might pave the way for further understanding of the pharmacogenetic background of CVD-related drugs. **Keywords:** Cardiovascular; PCI; Clopidogrel; Egyptian; CYP2C19; Genotyping

Molecular Effects of Genetic Variation Posters - Thursday

PB2552*. Defining the effects of noncoding genetic variation on human regulatory element activity

Authors:

K. Strouse, G. Johnson, K. Siklenka, A. Barrera, W. Majoros, A. Allen, T. Reddy; Duke Univ., Durham, NC

Abstract Body:

Millions of noncoding genetic variants are associated with common human traits and disease. As a step towards understanding how noncoding variants contribute to disease, we are generating a population-scale atlas of the effects of 40 million genetic variants on gene regulatory element activity. To do so, we are assaying regulatory activity genome-wide across 300 individuals from diverse populations using the high-throughput reporter assay STARR-seq. We have developed a pooling approach to whole-genome STARR-seq allowing for comprehensive assaying of regulatory variation across five individuals at once. With those measurements, we will estimate the effects of >40 million variants using a Bayesian model of allele-specific STARR-seq signal. To maximize the number of genetic variants we assay, we have prioritized the genomes of individuals with African ancestry, but still include representation from diverse ancestries.

We have completed genome-wide STARR-seq assays for the first five human genomes in our study. Our assay libraries each contain four billion unique DNA fragments, covering the human genome at 300x per individual. We are already able to detect hundreds of sites with allele-specific regulatory activity in that data using our BIRD model. In total, we will assay all common, most rare, and millions of personal noncoding variants. We expect the insights gained from this work will make the identification of causal genetic variants and mechanisms more routine, allowing researchers to prioritize genes as potential therapeutic targets.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2553*. Deletion mapping of regulatory elements for *GATA3* reveals a distal T helper 2 cell enhancer involved in allergic diseases.

Authors:

G. McVicker¹, H. V. Chen¹, P. C. Fiaux², A. Sen¹, I. Luthra³, A. J. Ho¹, A. R. Chen¹, K. Guruvayurappan¹, M. H. Lorenzini¹, C. O'Connor¹; ¹Salk Inst. for Biological Studies, La Jolla, CA, ²Univ. of California San Diego, La Jolla, CA, ³Univ. of British Columbia, Vancouver, CA, Canada

Abstract Body:

The *GATA3* gene is essential for T cell differentiation and is surrounded by risk variants for immune traits. Interpretation of these variants is challenging because the regulatory landscape of *GATA3* is complex with dozens of potential enhancers spread across a large topological associating domain (TAD). Furthermore, gene expression quantitative trait locus (eQTL) studies provide limited evidence for the function of GWAS variants at this locus potentially due to small effect sizes and limited power. To address these issues, we performed a tiling deletion screen of a 2 MB region surrounding the gene in Jurkat T cells to identify 23 candidate regulatory elements for *GATA3*. Using small deletions in primary T helper 2 (Th2) cells, we validated the function of five of these elements, two of which contain risk variants for asthma and allergic diseases. We fine-mapped genome-wide association study (GWAS) signals in a distal regulatory element, 1 Mb downstream, to identify 14 candidate causal variants. Small deletions spanning candidate rs725861 decrease *GATA3* expression in Th2 cells suggesting a causal mechanism for this variant in allergic diseases. Our study demonstrates the power of integrating GWAS signals with deletion mapping and identifies critical regulatory sequences for *GATA3*.

Molecular Effects of Genetic Variation Posters - Thursday

PB2554. Detection of rare Synaptogyrin 3 (*SYNGR3*) gene missense mutations in patients with schizophrenia.

Authors:

M-C. Cheng, L-Y. Ping, K-H. Lin, T-M. Hu, S-H. Hsu, H-Y. Tsai; Yuli Branch, Taipei Veterans Gen. Hosp., Hualient Country, Taiwan

Abstract Body:

Objective: Schizophrenia is a severe psychiatric illness experienced by approximately 1% of individuals worldwide and has a debilitating impact on perception, cognition, and social function. The heritability of schizophrenia is estimated at 80% on average. Synaptic vesicle-related genes significantly regulate synaptic transmission and play a critical role in various psychiatric diseases. Synaptogyrin 3 (*SYNGR3*) is a transmembrane protein of presynaptic vesicle that warrant genetic and functional analysis for the pathogenesis of schizophrenia. **Methods:** For pathogenic mutation identification, we sequenced the exonic regions of the *SYNGR3* gene in 516 unrelated patients with schizophrenia from Taiwan. We analyzed the *SYNGR3* protein function of the identified missense mutants via immunoblotting and post-translational modification analysis. **Results:** We identified four missense mutations, and *in silico* analysis indicated that these were rare, damaging, or pathological based on putative protein function. The functional studies demonstrated that the *SYNGR3*^{p.Ala81Pro} mutant as a loss-of-function mutant in HEK-293 cells. We also showed that the two missense mutations (*SYNGR3*^{p.Ser190Arg} and *SYNGR3*^{p.Ser210Asn}) abolish the potential serine protein kinase C phosphorylation sites in the C-terminal cytoplasmic tail and one missense mutation (*SYNGR3*^{p.Pro197Thr}) create a potential threonine phosphorylation site. **Conclusion:** The results suggest that the *SYNGR3* gene harbors rare and functional disrupting mutations in some patients with schizophrenia, supporting contributing rare coding variants to the genetic architecture of schizophrenia. Of particular interest is three missense mutations (*SYNGR3*^{p.Ser190Arg}, *SYNGR3*^{p.Pro197Thr}, and *SYNGR3*^{p.Ser210Asn}) might be involved in the regulation of protein kinase C (PKC) function. Thus, more studies using a proper neuronal model are required to characterize the association between schizophrenia-associated *SYNGR3* mutants and PKC changes.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2555. Determining the rate of unintended on-target and off-target effects induced by CRISPR-Cas gene editing in iPSC clones

Authors:

C. Shum¹, Y. Han¹, B. Thiruvahindrapuram¹, Z. Wang¹, B. Zhang¹, M. Sundberg², E. Buttermore², N. Makhortova², C. Chen², M. Sahin², S. Scherer¹; ¹The Hosp. for Sick Children, Toronto, ON, Canada, ²Boston Children's Hosp., Boston, MA

Abstract Body:

CRISPR-Cas usage for genome editing can be hindered by undesired genomic changes, though the prevalence and types of these unintended edits remain poorly understood. To address this, we investigated unintended effects in induced pluripotent stem cells (iPSCs) after homology-directed repair (HDR) of disease-associated mutations using whole genome sequencing (WGS). We developed Off-Flow, a bioinformatic workflow that generates a comprehensive list of predicted off-target sites from 4 prediction programs (CHOPCHOP, Cas-Offinder, CRISPRitz, CRISPR-Offinder) based on the specific guide RNA and Cas enzyme used. We analyzed WGS data from 15 clones generated after CRISPR-Cas9 or -Cas12a editing of 6 separate genomic regions within 3 genes (*KCNQ2*, *ASH1L*, *GNAQ*). In 5 regions, CRISPR-Cas9/Cas12a was used to repair a disease-associated mutation in patient iPSC lines. In the remaining region, CRISPR-Cas9 was used to introduce a disease-associated mutation in a control iPSC line. Cell line-specific variants were intersected with predicted off-target sites from Off-Flow to assess the impact of the gene editing process. We identified a substitution and mono-allelic deletions at or near the target loci in 3 clones. A 3-bp substitution resulting in an amino acid change (p.T234L) was observed at the target locus in an edited clone after CRISPR-Cas9 repair of the target mutation *KCNQ2* c.766G>T, p.G256W. A 1,857bp mono-allelic deletion (chr20:62,068,445-62,070,301, hg19) was observed near the target locus in an edited clone after CRISPR-Cas9 repair of *KCNQ2* (c.821C>T, p.T274M). A 329bp (chr9:80412512-80412841) mono-allelic deletion was observed at the target locus after CRISPR-Cas9 introduction of *GNAQ* c.548G>A, p.R183Q. We identified 20 editing-induced missense variants at other genomic loci in 10 edited and unedited or HDR-failed clones. One such variant, *CACNA1E* c.G669T, p.Q223H, was observed in an edited clone after CRISPR-Cas9 editing of *KCNQ2* c.875_877delTCCinsCCT, p.L292_L293delinsPF. This clinically relevant gene is associated with epileptic encephalopathy and predicted to be likely damaging, thus may have functional consequences. On-target substitution and deletions had escaped standard PCR and Sanger sequencing analysis, while missense variants had escaped Off-Flow. In summary, we identified on-target substitution and deletions and off-target missense variants following CRISPR-Cas9/Cas12a HDR in iPSCs. We propose a standard for quality control of iPSC clones that have undergone gene editing by rigorous analysis of WGS data or the use of multiple edited and control unedited clones to facilitate the integrity of iPSC-based studies.

Molecular Effects of Genetic Variation Posters - Thursday

PB2556. Development of a multiplexed assay of variant effects for the DNA repair gene *MUTYH*

Authors:

S. Hemker, B. Burugula, G. Clark, S. Jayakody, J. Kitzman; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Disruption of *MUTYH* causes MYH-associated polyposis, a recessive condition for which up to 1:50 individuals are carriers, depending upon ancestry group. Nearly 800 missense mutations in *MUTYH* have been reported in ClinVar, 95% of which are classified as variants of uncertain significance (VUS), reflecting the difficulty of classifying missense variants, which can range in effect from wildtype-like to complete functional impairment. To resolve these reported VUS, and as-yet unseen patient variants in *MUTYH*, we are developing a multiplexed assay of variant effects (MAVE) to predict pathogenicity of all *MUTYH* missense variants. The normal function of *MUTYH* is to repair A:8oxoG lesions, a product of oxidative damage. We have developed an optimized cell-based reporter assay for *MUTYH* variant function, in which proper A:8oxoG to C:G repair initiated by *MUTYH* yields fluorescent protein expression. To perform this assay, we generated a CRISPR-induced *MUTYH* knockout human cell line and then introduced different *MUTYH* variants: a wildtype (WT) copy, a truncating nonsense variant (Q363X), and two pathogenic missense variants - one previously demonstrated to have partial loss of function (G368D) and one with nearly total loss of function (Y151C). The Q363X variant exhibited practically no repair of the 8oxoG lesion, while the Y151C and G368D variants were able to repair the lesion at approximately 5% and 30% of WT levels, respectively. Thus, this assay has the dynamic range to distinguish between various levels of functional impairment, and is amenable to high-throughput screens such as deep mutational scans. Using this reporter as a functional read-out, we will complement *MUTYH* knockout cells with libraries comprising every *MUTYH* missense mutation (n=9,899). The pathogenicity predictions of these assays will be 1) compared to clinically identified variants from ClinVar, 2) refined based upon evolutionary conservation, and 3) used to identify structural mechanisms underlying hotspots of functional constraint by mapping data to 3D structure.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2557. Development of a yQTL Discovery Pipeline Applicable for Both Unrelated and Related Individuals

Authors:

M. Li¹, Z. Song², A. Gurinovich³, P. Sebastiani³, S. Monti¹; ¹Boston Univ., Boston, MA, ²Boston Univ. Sch. of Publ. Hlth., Boston, MA, ³Tufts Med. Ctr., Boston, MA

Abstract Body:

Quantitative trait loci (QTL) are DNA sequence variants, such as SNPs, that influence the level of a quantitative trait, for example, gene expression. QTL discovery analysis consists of multiple steps, including genome-wide principal component analysis (PCA), genome-wide association test, as well as downstream analyses such as plotting and result annotations. In order to facilitate and automate the process, we developed yQTL discovery pipeline tool, which is agnostic to the nature of the dependent variable (y) to be modeled. In the genome-wide association step, the pipeline supports two different analysis modalities: i) one using standard linear models based on the use of the R package *matrixQTL*, which is optimized to process hundreds of phenotypes at once and yields QTL results at a high speed, but does not support the incorporation of family structure information, thus adequate only when unrelated subjects are analyzed; ii) one based on the R package *GENESIS* that supports the estimation of genetic relationship matrix (GRM) and include it in linear mixed effect models, thus able to analyze related subjects. Both modalities include the genome-wide PCA and the incorporation of user-specified covariates. Through the adoption of the workflow management tool Nextflow, the pipeline parallelizes the analysis steps. We have tested the pipeline using proteomics and metabolomics data from the New England Centenarian Study and publicly available multi-omics datasets.

Molecular Effects of Genetic Variation Posters - Thursday

PB2558. Discovery and finemapping of eGFR loci in metaanalysis GWAS of 80K African ancestry individuals

Authors:

C. Kintu¹, O. Soremekun², M. Richard³, J. Daudi³, C. Tinashe⁴, S. Fatumo⁵; ¹Dept. of Immunology and Molecular Biology, Sch. of BioMed. Sci., Makerere Univ. Coll. of Hlth.Sci., Kampala, Uganda, ²The African Computational Genomics (TACG) Res. Group, Kampala, Uganda, ³Makerere Univ., Kampala, Uganda, ⁴MRC/Wits Dev.al Pathways for Hlth.Res. Unit, Dept. of Paediatrics, Faculty of Hlth.Sci., Univ. of the Witwatersrand, Witwatersrand, South Africa, ⁵Dept. of Non-Communicable Disease Epidemiology, London Sch. of Hygiene and Tropical Med. (LSHTM), London, United Kingdom

Abstract Body:

Background: Chronic kidney disease is defined by reduced glomerular filtration rate. Genome-wide association studies of over 1 million individuals have already identified 424 loci harboring common variants that are associated with estimated glomerular filtration rate (eGFR). These studies, however, only analyzed data of European ancestry. **Methods:** To enhance the power to identify eGFR associated loci African ancestry (AA) individuals, we conducted a meta-analysis of creatinine-based eGFR in 80,027 AA participants from three global population-based cohorts: The Chronic Kidney Disease Genetics consortium (CKDGen, n = 16474 cases), UK Biobank (UKBB, n = 6217 cases), and the Million Veteran Program (MVP, n = 57336). A fixed-effect inverse-variance weighted meta-analysis was performed using METAL. For each lead variant, we computed a 99% credible set through finemapping and further performed functional analysis to map variants to tissues of importance for kidney function. **Results:** Of the 799 single nucleotide polymorphism (SNPs) that reached genome wide significant threshold of ($p < 5 \times 10^{-8}$), 17 SNPs were identified as the lead SNPs. Further downstream analysis showed that rs3798156 and rs2486272 mapping to genes *SLC22A2* and *GATM* have not been previously reported to be associated with eGFR. Bulk tissue gene expression analysis revealed that these two genes are highly differentially expressed in the kidney-medulla and kidney-cortex. Fine mapping of rs3798156 and rs2486272 showed that there were 4 and 31 credible sets with posterior probability of 71% and 36% respectively. **Conclusion:** These results provide insight into the biological mechanisms of kidney function by identifying two novel variants potentially influencing metabolic functions of the kidney unique to individuals of African ancestry.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2559. Disease-specific analysis improves prioritization of non-coding genetic variants

Authors:

Q. Liang¹, D. Kostka²; ¹Univ. of Pittsburgh, Pittsburgh, PA, ²Univ of Pittsburgh, Pittsburgh, PA

Abstract Body:

There is increasing interest in non-protein-coding genetic variants, and in their role as genetic causes of human disease. In-silico variant prioritization methods quantify a variant's severity, and commonly used instances are single (i.e., organism-wide) scores, as well as methods that summarize a variant's impact specifically in certain tissues and/or cell-types. Because variants causing one disease may have different characteristics from those causing another disease, disease-specific variant prioritization schemes represent a complementary approach. In this study we assess variant scores' ability to prioritize disease-associated non-coding variants. We propose a simple logistic regression approach for converting tissue/cell-type specific variant scores into disease-specific scores, which also enables calculation of disease similarities based on disease-relevant tissues and cell-types.

Using ~63k non-coding variants from the NHGRI-EBI GWAS catalog with associations spanning 111 disease terms, we find that organism-wide scores (GenoCanyon, LINSIGHT, GWAVA, eigen, CADD) are only moderately successful in predicting disease associations (average precision across scores: 0.129; baseline=0.09), and disease-specific aggregation of tissue/cell-type specific scores (GenoSkyline, FitCons2, DNA accessibility) significantly improves performance (average precision across scores: 0.151; baseline=0.09). Disease similarities based on learned aggregation weights highlight meaningful disease groups (e.g., immune system related diseases and mental/behavioral disorders), while providing information on tissues and cell-types that drive similarities (e.g., lymphoblastoid T-cells for immune-system related diseases). We also show that learned similarities are complementary to purely genetic similarities as quantified by genetic correlation. Overall, this analysis makes the case for disease-specific variant prioritization; our aggregation approach leads to a gain in performance, and it enables interpretable disease models that carry information that is complementary to purely genetic similarities.

Molecular Effects of Genetic Variation Posters - Thursday

PB2560. Dissecting the downstream effects of IL-6 signaling on atheroprotection: a proteome-wide Mendelian randomization study

Authors:

M. Georgakis^{1,2,3}, S. Prapiadou¹, C. Anderson^{4,3}; ¹Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA, ²Inst. for Stroke and Dementia Res., LMU Munich, Munich, Germany, ³Broad Inst. of MIT and Harvard, Cambridge, MA, ⁴Brigham and Women's Hosp., Boston, MA

Abstract Body:

Introduction: Genetic and experimental studies support a causal involvement of interleukin-6 (IL-6) signaling in atheroprotection. While clinical trials targeting IL-6 signaling for lowering the burden of cardiovascular disease are currently underway, any atheroprotective benefits must be balanced against an impaired host immune response, thus highlighting a need for discovery of more specific targets.

Dissecting the downstream mechanisms driving the effects of IL-6 signaling on atherosclerosis could offer insights about novel drug targets with more specific effects.

Methods: Leveraging data from 522,681 individuals of European ancestry in the CHARGE Consortium and UK Biobank, we constructed a genetic instrument of 26 variants in the vicinity of the gene encoding IL-6 receptor that proxied the effects of pharmacological IL-6 receptor inhibition. We explored in Mendelian randomization (MR) the effects of these variants on 3,622 plasma proteins quantified with an aptamer-based multiplex protein assay (SOMAscan) in 3,301 individuals in the INTERVAL cohort. In a mediation MR framework, we explored potential mediators in the effects of genetically proxied IL-6 signaling on cardiovascular disease endpoints (coronary artery disease, large artery atherosclerotic stroke, peripheral artery disease) in disease-specific consortia.

Results: After correction for multiple comparisons, we found significant effects of genetically proxied IL-6 signaling on 83 circulating proteins. A gene ontology enrichment analysis identified immune response, cytokine production and regulation, and cell differentiation pathways. From these 83, the genetically predicted levels of 25 proteins also showed directionally consistent significant associations with risk of coronary artery disease, large artery atherosclerotic stroke, or peripheral artery disease. Genetically predicted circulating levels of CXCL10, a chemokine involved in T cell recruitment and experimentally implicated in atheroprotection, was associated with significantly higher risk of all three endpoints. Mediation analyses revealed that a significant proportion of the effects of IL-6 signaling on cardiovascular disease endpoints were mediated by increases in CXCL10 levels.

Conclusions: Integrating genomic and proteomic data, we found a proteomic signature of IL-6 signaling activation and mediators of its effect on cardiovascular disease. Our analyses suggest CXCL10 to be a potentially causal mediator for atherosclerotic endpoints in three different vascular beds and as such might serve as a promising drug target for atheroprotection.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2561. *Drosophila* assays for variant interpretation in the polycomb repressive complex 2 related syndromes

Authors:

S. Cyrus^{1,2}, W. T. Gibson^{3,1,2}, S. Medina Giró⁴, T. Lian⁴, D. W. Allan^{4,5}; ¹Dept. of Med. Genetics, Univ. of British Columbia, Vancouver, British Columbia, Canada, Vancouver, BC, Canada, ²BC Children's Hosp. Res. Inst., Vancouver, BC, Canada, ³BC Children's Hosp., Vancouver, BC, Canada, ⁴Dept. of Cellular and Physiological Sci., Life Sci. Inst., Univ. of British Columbia, Vancouver, BC, Canada, ⁵Djavad Mowafaghian Ctr. for Brain Hlth., Univ. of British Columbia, Vancouver, BC, Canada

Abstract Body:

Variants of unknown significance pose a challenge for clinical laboratories, physicians and patients. The creation of well-calibrated assays, that accurately predict functional impact of variants, will help resolve these challenges.

The polycomb repressive complex 2 (PRC2) is an epigenetic reader/writer that catalyzes the mono-, di-, and trimethylation of H3K27. Mutations in PRC2 members *EZH2*, *EED* and *SUZ12* cause overgrowth and intellectual disability syndromes, namely Weaver syndrome, Cohen-Gibson syndrome, and Imagawa-Matsumoto syndrome respectively. Pathogenic PRC2 mutations manifest variable expressivity, conferring a wide range of phenotypic effects. Notably, 2.4% of the general population will have a rare missense or nonsense variant in one of these 3 genes. Therefore, attributing or excluding disease causality for rare coding variants may have implications for common complex diseases, in addition to rare syndromes. We have taken advantage of the powerful genetic strategies in *Drosophila* to develop inexpensive and robust assays that can screen hundreds of naturally-occurring variants seen in human populations. Our combination of strategies includes CRISPR/CAS9-based genome editing, Recombination Mediated Cassette Exchange and phiC31 integrase-mediated transgenesis to develop reagents that can test variants in *EZH2*, *EED* and *SUZ12*, including:

- (i) Mimics of the human variant in the fly's orthologous gene (fly mimetics)
- (ii) Direct expression of the human gene variant in the fly

Our assays test the ability of human PRC2 variants to rescue null phenotypes, or to cause known PRC2 phenotypes in *Drosophila*.

Fly mutants in the ortholog *esc* that mimic 6 pathogenic *EED* human variants caused early lethality, or classical *esc* phenotypes such as extra sex combs in males, but 2 benign *EED* mimetic variants displayed wildtype phenotypes. Differences in the severity of phenotypes suggest that our approach may be capable of quantifying the relative functional impact of *EED* variants. Similarly, creating a knock-in allele in the ortholog *E(z)* that mimics a pathogenic human *EZH2* variant generated a lethal phenotype.

Additionally, direct expression of wildtype human *EZH2* and a pathogenic variant in *Drosophila* demonstrated a reduced ability for the variant to cause transcriptional silencing, in a classical position effect variegation assay of the white gene. However, further work is needed to determine if this approach will be as successful as fly mimetics.

Our work to date demonstrates the utility of numerous approaches to functional characterization of *EED* and *EZH2* variants, and in the future *SUZ12* variants, using the *Drosophila* assay platform.

Molecular Effects of Genetic Variation Posters - Thursday

PB2562. Dual inhibition of mTORC1 and mTORC2 activation effectively rescues hyperproliferative lymphatic sprouting in a cell-based model system of complex lymphatic anomalies

Authors:

M. Battig¹, M. E. March¹, L. S. Matsuoka¹, S. E. Sheppard², C. Kao¹, C. Seiler¹, D. Li¹, H. Hakonarson¹; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Eunice Kennedy Shriver Natl. Inst. of Child Hlth.and Human Dev., Rockville, MD

Abstract Body:

Generalized lymphatic anomaly (GLA) and kaposiform lymphangiomatosis (KLA) are intractable diseases of micro/macrocystic lymphatic malformations in the bones, viscera, and abdominal and thoracic cavities, which can result in respiratory compromise, multiorgan failure, and death. Recently, somatic activating mutations in *PIK3CA* and in *NRAS* have been identified in patients with GLA and/or KLA. *PIK3CA* encodes the PI3K catalytic subunit p110 α while *NRAS* encodes the GTPase N-ras, both of which are strong mediators of cell proliferation. However, despite the identification of these genes, the molecular mechanisms by which these genetic mutations drive the pathogenesis of GLA and KLA are not well understood. Towards this end, we conducted functional characterization using an *in vitro* spheroid-sprouting assay with human dermal lymphatic endothelial cells expressing variants of *PIK3CA* (p.H1047L) or *NRAS* (p.Q61R) that have previously been implicated in these diseases. In comparison to its wild-type control, *PIK3CA*(H1047L) expression resulted in significantly greater lymphangiogenic sprouting, as determined by the cumulative sprout length (1381 μ m vs. 2666 μ m, $p = 0.029$). Similarly, greater lymphangiogenic sprouting was observed when spheroids expressing *NRAS*(Q61R) were compared to its wild-type counterpart (2134 μ m vs. 4750 μ m, $p = 0.0012$). Further analyses *via* immunoblotting revealed over-activation of mTORC1 and mTORC2 targets led to the increased lymphangiogenic activity. Suppression of mTOR activation in mutant cells was tested with OSI-027 (dual mTORC1 and mTORC2 inhibitor) or rapamycin (mTORC1 inhibitor). OSI-027 was as effective as rapamycin in rescuing the hyperproliferative phenotype caused by either mutation, as evidenced by decreases in both the number and the length of capillary-like sprouts to basal levels. Immunoblotting confirmed OSI-027 inhibited lymphangiogenic sprouting by targeting both mTORC1 and mTORC2. These findings demonstrate that somatic activating mutations in *PIK3CA* and in *NRAS* act through over-activation of AKT/mTOR signaling, and inhibitor-based therapy may benefit individuals affected with complex lymphatic anomalies, particularly when multiple signaling pathways are targeted.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2563. Ehlers-Danlos Syndrome: A Likely Pathogenic Variant Found in *COL5A1* gene

Authors:

C. Rodriguez Rodriguez¹, S. Carlo², F. Velez-Bartolomei³, G. Serrano⁴, J. Pascual⁵, A. Cornier⁶; ¹Univ. Autonoma de Guadalajara Sch. of Med., Guadalajara, Mexico, ²Ponce Hlth.Sci. Univ., Cabo Rojo, PR, ³San Jorge Children and Women's Hosp., San Juan, PR, ⁴Ponce Hlth.Sci. Univ. Sch. of Med., Guadalajara, Mexico, ⁵Ponce Hlth.Sci. Univ. Sch. of Med., Ponce, PR, ⁶San Jorge Children s Hosp./ Ponce Hlth.Sci. Univ., San Juan, PR

Abstract Body:

Ehlers-Danlos syndrome is a connective tissue disorder characterized by joint hypermobility, skin hyperextensibility and may also be associated with joint dislocation and berry aneurysm among others. EDS can be subdivided on multiple types depending on inheritance and can express different degrees of severity of symptoms. The *COL5A1* gene, is in charge of the synthesis of pro-alpha 1, a component necessary for the production of type V collagen and a key component in collagen synthesis. Mutations / variations in this gene causes a form of Autosomal Dominant Ehlers-Danlos syndrome, known as the classic type, characterized by the development of soft and hyperextensible skin, and hypermobility of joints. More than 100 *COL5A1* gene mutations have been identified in people affected with EDS. The mutation in *COL5A1* affects the amount of Pro-alpha1 that a cell produces leading to fibrils that contain type V and type I collagen in the skin that are unorganized and larger than usual weakening the connective tissue and causing the clinical manifestations that characterized the disease. We are presenting the case of a 24-year-old female referred to genetic services due to signs of hyperextensible skin, hypermobility of joints and epistaxis. Patient was first referred at age 11, however she did not return for follow-up visits, rendering further testing impossible. Upon returning at the age 22, an Ehlers-Danlos gene panel test, evaluating more than 15 genes related to the disease, was performed. Results showed a pathogenic variant identified as *c.4465G>A(p.Gly1489Arg)*. This sequence replaces glycine with arginine at Codon 189 of the *COL5A1* protein (*p.Gly1489Arg*). Glycine residues are required for the structure and stability of fibrillar collagen. This variant has been observed in people affected with EDS classic type, however it is not present in population databases. Our patient presents most of the classical phenotypical findings consistent with EDS hyperflexible type making this variant a pathogenic one.

Molecular Effects of Genetic Variation Posters - Thursday

PB2564. Elucidating genomic disease associations using transcriptomic, proteomic and metabolomic data in 4,732 individuals

Authors:

E. Persyn¹, A. P. Nath^{1,2}, A. Tokolyi³, J. Marten¹, K. Burnham³, S. C. Ritchie¹, Y. Xu¹, T. Vanderstichele³, S. Lambert¹, INTERVAL Study, D. J. Roberts⁴, E. Di Angelantonio¹, J. Danesh¹, A. S. Butterworth¹, E. E. Davenport³, M. Inouye^{1,2}, D. S. Paul⁵; ¹Dept. of Publ. Hlth. and Primary Care, Univ. of Cambridge, Cambridge, United Kingdom, ²Cambridge Baker Systems Genomics Initiative, Baker Heart and Diabetes Inst., Melbourne, Australia, ³Dept. of Human Genetics, Wellcome Sanger Inst., Cambridge, United Kingdom, ⁴Radcliffe Dept. of Med., Univ. of Oxford, Oxford, United Kingdom, ⁵Ctr. for Genomics Res., Discovery Sci., BioPharmaceuticals R&D, AstraZeneca, Cambridge, United Kingdom

Abstract Body:

Defining the biological mechanisms underlying the genetic associations with diseases is a major challenge in human genetics. The integration of genomic data with dynamic -omics data (e.g., transcriptomic, proteomic, metabolomic) provides a scalable and systematic approach to identifying candidate causal genes and molecular pathways underlying genetic disease loci. In this study, we generated and analyzed RNA-sequencing data from peripheral blood samples of 4,732 healthy participants in the INTERVAL study. We aimed to (1) identify the genetic determinants regulating gene expression in *cis* and *trans*, (2) integrate dynamic -omics data in INTERVAL to identify candidate causal genes and pathways, and (3) advance the understanding of the mechanisms involving these genes and pathways.

We mapped *cis*-gene expression quantitative loci (*cis*-eQTL), identifying 17,233 *cis*-eGenes (~90% of tested autosomal genes). We further investigated independent signals from *cis*-eGenes with a *trans*-eQTL analysis, discovering 2,058 *trans*-eGenes. The 2,498 *cis*-eGenes with an eSNP in a *trans*-association were enriched in transcription regulation and immune response gene pathways. We also found that 14% of these *cis*-eGenes were transcription factors including many zinc-finger proteins. We further explored the relationship between *cis*-eQTLs and other -omics datasets in INTERVAL by performing colocalization analysis to identify genes whose expression shares genetic regulation with protein and/or metabolite levels. We identified colocalized signals with 185 protein QTLs from the SomaScan platform, 41 protein QTLs from the Olink assay and 223 metabolite QTLs from the Nightingale platform. For example, we found colocalized signals between eQTLs and protein QTLs for genes associated with type I diabetes mellitus, such as *CTSH*, *NCR3* and *SIRPG*. The eQTL data presented here have been integrated into the OMICSPRED database (<https://www.omicspred.org/>), a resource to predict multi-omics data using genotype data and polygenic scores.

Future analyses will further delineate the relationship between molecular QTLs and disease associations through mediation analyses. In summary, the availability of concomitant genomic and multi-omic data in the same individuals provides an opportunity for translating genomic discoveries into therapeutic hypotheses.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2565. Elucidating mechanisms of genetic interactions and oligogenic inheritance in Autism Spectrum Disorder.

Authors:

A. Sertie¹, A. Teles e Silva¹, B. Y. Yokota¹, I. S. Nobrega¹, B. L. Zampieri¹, M. Passos-Bueno²; ¹Hosp. Israelita Albert Einstein, Sao Paulo, Brazil, ²Univ.e de Sao Paulo, Sao Paulo, Brazil

Abstract Body:

Background: Oligogenic inheritance of autism spectrum disorder (ASD) has been supported by several studies showing that a single patient can carry gene-disruptive variants in more than one gene that combined confer a higher risk for disease than their individual risk. However, little is known about how these risk variants interact and converge on causative neurobiological pathways. We identified in an ASD proband deleterious compound heterozygous missense variants in the Reelin (*RELN*) gene, and a *de novo* splicing variant in the Cav3.2 calcium channel (*CACNA1H*) gene. Using induced pluripotent stem cell (iPSC)-derived neural progenitor cells from this proband, we showed that the variants in *RELN* and *CACNA1H* are deleterious and that there is an abnormal interaction between these mutated genes via the mTORC1 pathway. Furthermore, analysis of the sequencing data from two ASD cohorts - a Brazilian cohort of 861 samples, 291 with ASD; the MSSNG cohort of 11,181 samples, 5,102 with ASD - revealed a significantly increased burden of co-occurring risk variants in both alleles of Reelin pathway genes and in one allele of calcium channel genes in ASD (PMID:35668055). However, it is still unknown how these mutated genes alter brain development and lead to ASD. **Objectives:** explore molecular and cellular phenotypes affected by the synergistic action of *RELN* and *CACNA1H* disruptive variants and those that are unique to either one of the alleles by using CRISPR-Cas9 gene editing and cerebral organoids. **Results:** We designed and cloned guide RNAs (gRNAs) to introduce into control iPSC lines the pathogenic variants of *RELN* and *CACNA1H* identified in the ASD proband, and selected the gRNAs with the highest editing rates. These gRNAs will be used for transfection of iPSCs, generating 3 gene-edited iPSC lines (either in *RELN* or *CACNA1H*, as well as in the two genes simultaneously). The edited and isogenic cell lines will then be used to generate cerebral organoids. We generated cerebral organoids from a control iPSC line that model early developmental events in the human forebrain, including the organization of neural progenitor zones similar to the ventricular and subventricular zones, and programmed differentiation of glutamatergic and GABAergic neurons and astrocytes. **Conclusion:** This work integrates risk-variant identification and functional genomics, and will provide further insight into the mechanisms of gene interactions and oligogenicity in ASD.

Molecular Effects of Genetic Variation Posters - Thursday

PB2566. Elucidating the mechanism of a neurological syndrome caused by germline mutations in *H3F3A* and *H3F3B*.

Authors:

A. Sangre^{1,2}, L. Bryant², D. Layo-Carris², R. Angireddy², E. Lubin^{3,2}, D. Brooks¹, K. Musunuru¹, E. Bhoj²; ¹Univ. of Pennsylvania, Philadelphia, PA, ²Children's Hosp. of Philadelphia, Philadelphia, PA, ³Perelman Sch. of Med./Univ. of Pennsylv, Philadelphia, PA

Abstract Body:

Histones are fundamental proteins with key architectural and gene regulatory roles. Histone H3.3, a replication-independent variant of the canonical H3.1 and H3.2, is encoded for by two genes *H3F3A* and *H3F3B*. Among its many functions, H3.3 marks active genes and maintains genome integrity during mammalian development. Highly tumor type specific somatic mutations in H3.3 drive pediatric glioblastoma and chondroblastoma, indicating that H3.3 residues, mutations and genes have distinct functions. Recently, *de novo* missense germline mutations in *H3F3A* and *H3F3B* were identified in a cohort of 56 unrelated patients with progressive neurologic dysfunction and congenital anomalies. Unlike with the cancer variants, there is not a single causative mutation, but rather 31 unique mutations in *H3F3A* and 11 in *H3F3B*, all resulting in phenotypes of varying levels of severity. Interestingly, *H3F3A* and *H3F3B* have been shown to be independently dispensable for development in *Drosophila* and *H3F3A* or *H3F3B* null mice are overtly normal and fertile, suggesting that these missense mutations are not loss of function (LOF).

An overarching question is whether pathology is caused by each specific mutation, or rather by a more global dysregulation of H3.3. It is also not well understood at what level (protein, RNA, or both) this dysregulation is occurring. Given the breadth and distribution of mutations, as well as the apparent lack of genotype-phenotype correlation, large-scale genomic modalities and focused follow-ups are necessary to understand the dysfunction arising in this patient cohort, as well as a more general understanding of the role of missense, synonymous and LOF mutations in histones and their subsequent effects on genome organization and development. We set out to functionally classify the effect of every missense mutation in H3.3 and elucidate the contribution of *H3F3A* and *H3F3B* RNA and H3.3 protein on function in cells. We will use CRISPR technologies to study these mutations in their native contexts in a scalable and unbiased manner to both elucidate how individual mutations, and missense mutations as a broader class, affect H3.3 function. We will also disentangle the importance of RNA and protein on the function of H3.3 in cells to study the specific effects of RNA perturbation. We anticipate that this work will fill key gaps in the field's understanding of the role of histone RNA and protein in the context of development and genome regulation and will also be fundamental in developing a therapy to improve the lives of patients affected by this severe syndrome.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2567. Epigenomic and transcriptomic analyses define core cell types, genes and targetable mechanisms for kidney disease

Authors:

H. Liu¹, T. Doke¹, D. Guo², X. Sheng¹, Z. Ma¹, J. Park¹, H. Vy³, G. Nadkarni³, A. Abedini¹, Z. Miao¹, M. Palmer¹, B. Voight¹, H. Li¹, C. Brown¹, M. Ritchie¹, Y. Shu², K. Susztak¹; ¹Univ. of Pennsylvania, Philadelphia, PA, ²Univ. of Maryland at Baltimore, Baltimore, MD, ³Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

More than 800 million people suffer from kidney disease, yet the mechanism of kidney dysfunction is poorly understood. The epigenome could provide critical insight into disease understanding as it integrates genetic and environmental signals. Here we define the genetic association with kidney function in 1.5 million individuals and identify 878 (126 novel) loci. We map the genotype effect on the methylome (methylation quantitative trait loci, meQTL) in 443 human kidneys, on the transcriptome (eQTL) in 686 samples, and on single cell open chromatin in 57,282 human kidney cells. Integrated analysis of these omics data reveal that methylation variation explains a larger fraction of GWAS heritability than gene expression. We present a multi-stage prioritization strategy based on Bayesian multiple-trait colocalization, mendelian randomization, single cell co-accessibility and enhancer-promoter contacts. Target genes are assigned for 87% of GWAS loci, but the closest gene is only prioritized 34% of the time. We highlight the key role of proximal tubules and metabolism in kidney function regulation. Further, the causal role of *SLC47A1* in kidney disease is defined in mice with genetic loss of *Slc47a1* and in human individuals carrying loss-of-function variants. Our findings emphasize the key role of bulk and single-cell epigenomic information in translating genome-wide association studies into identifying causal genes, cellular origins and mechanisms of complex traits.

Molecular Effects of Genetic Variation Posters - Thursday

PB2568. Epitranscriptomic m6A alterations in *C9orf72* ALS cerebellum

Authors:

J. Ross^{1,2}, D. Rochefort^{1,2}, H. Catoire^{1,2}, C-E. Castonguay^{1,2}, D. Spiegelman^{1,2}, M. Strong³, P. Dion^{1,2}, G. Rouleau^{4,1}, ¹McGill Univ., Montreal, QC, Canada, ²Montreal Neurological Inst. and Hosp., Montreal, QC, Canada, ³Robarts Res. Inst., Western Univ., London, ON, Canada, ⁴Montreal Neurological Inst.-Hosp., Montreal, QC, Canada

Abstract Body:

Background: One of the most common causes of amyotrophic lateral sclerosis (ALS) is an intronic hexanucleotide repeat expansion in *C9orf72*. Widespread RNA dysregulation has been observed in multiple brain regions in *C9orf72*-associated ALS. Mature RNA is chemically modified as a means to modulate gene expression in the cell. The most abundant modification, N6-methyladenosine (m6A), results in altered RNA half-life and potentially overall expression levels. As m6A RNA methylation regulates the amount and duration of transcripts, it may be that alterations to the epitranscriptome are also present in *C9orf72* ALS. We hypothesized that in addition to gene expression and splicing changes in *C9orf72* ALS, m6A RNA methylation might be altered. Further, we hypothesized that the genes in which m6A is altered might point to common pathways that could better explain the pathogenic effect of *C9orf72* expansion. **Methods:** Total RNA was extracted from the cerebellum of five ALS patients and five unaffected controls. m6A RNA was immunoprecipitated and enriched using meRIP-seq, and sequenced in parallel with paired total RNA. Regions with m6A enrichment were detected using clipper following the ENCODE eCLIP pipeline. Differential gene expression and alternative splicing were analyzed using DESeq2 and SUPPA2, respectively. Pathway enrichment analyses were conducted with the R package enrichR. **Results:** We observed substantial amounts of differentially expressed and spliced genes, consistent with previous *C9orf72* cerebellum studies. However, a striking number of regions (891) had significantly downregulated m6A in ALS cases (FDR < 0.05). Very few m6A regions were increased in *C9orf72* cerebellums (44), suggesting a global decrease in m6A methylation due to the repeat expansion. Differentially expressed genes in *C9orf72* cases did not often overlap with differentially methylated m6A regions, suggesting that m6A alterations are independent of gene expression levels. Further, pathway enrichment analysis of genes with downregulated m6A levels showed an enrichment of transcription regulation (padj = 5.53E-06). *C9orf72* itself contained a differentially m6A-methylated region near the ALS-associated expansion, while concurrently being downregulated in ALS cases. **Discussion:** The *C9orf72* expansion causes alterations in transcription that likely lead to or contribute to ALS pathology. Identifying alterations to m6A RNA modifications present in *C9orf72* ALS increases the complexity of this paradigm. Our results could explain the means by which transcriptional alterations are generated by *C9orf72*.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2569*. Escape from Nonsense-Mediated Decay: Annotation of Transcripts with Protein Truncating Variants

Authors:

J. Klonowski¹, Q. Liang¹, Z. Coban Akdemir², C. Lo¹, D. Kostka¹; ¹Univ. of Pittsburgh, Pittsburgh, PA, ²UTHlth.Sch. of Publ. Hlth., Houston, TX

Abstract Body:

Protein truncated variants (PTVs) are genetic variants that shorten the coding sequence of transcripts, thereby changing the protein. They comprise approximately 42% of pathogenic variants in ClinVar, and one-third of transcripts that cause human genetic conditions and cancer mediate their pathogenicity through PTVs. PTVs arise from introduction of premature termination codons (PTCs), generating proteins that are typically degraded by nonsense-mediated decay (NMD), causing loss-of-function (LoF). However, some transcripts with PTCs escape NMD, resulting in translation of altered proteins that may cause a gain-of-function (GoF). While well-established rules have been identified to predict escape from NMD for transcripts with PTVs, there are currently no easy-to-use bioinformatics tools to annotate NMD escape comprehensively.

Here we present a user-friendly software tool for annotating of PTC variants at scale, applying canonical and non-canonical rules for NMD escape. Specifically, annotation is performed not only for canonical but for all variant-overlapping transcripts, resulting in a comprehensive annotation of NMD escape. In addition, we explicitly construct the alternative version of the protein for each PTV and transcript combination. This enables incorporation of indel size and nucleotide content, which leads to more principled application of distance-based rules for NMD escape, compared to methods using pre-computed indices based on reference annotation alone. We provide both a command-line interface that integrates well with variant processing workflows, as well as a web-based interface intended for interactive annotation of variants of interest.

We apply our software to all high-confidence transcripts currently annotated in Ensembl, and we will report results for NMD escape annotation considering variants from two sources. First, to study NMD-escaping transcript-variant pairs on the population level, we consider variants called across approximately 140,000 individuals in gnomAD (version 2.1.1). Second, variants from the NHGRI-EBI GWAS catalog will be investigated for the prevalence of GoF PTVs in the context of complex disease. Overall, our software enables geneticists to better leverage large-scale NMD-escape annotation of PTVs. Given that NMD escape can exert GoF effects, PTV annotation using this new bioinformatics tool may uncover disease causing variants missed by current approaches.

PB2570. Establishing a deep mutational scan for functional classification of MSH6 missense variants

Authors:

A. Scott^{1,2}, S. Jayakody¹, B. Burugula¹, J. O. Kitzman^{1,3}; ¹Dept. of Human Genetics, Univ. of Michigan, Ann Arbor, MI, ²Dept. of Internal Med., Univ. of Michigan, Ann Arbor, MI, ³Dept. of Computational Med. & Bioinformatics, Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Lynch Syndrome is a dominantly inherited colorectal and gynecological cancer predisposition syndrome caused by loss-of-function variants in genes encoding DNA mismatch repair (MMR) factors. *MSH6* is one of the key MMR factors implicated in Lynch Syndrome, and is notable in particular for its high penetrance for endometrial cancer risk. Actionability of clinical MSH6 testing is limited by the burden of missense variant interpretation as demonstrated by MSH6 missense variants in the NCBI ClinVar database, nearly all of which (2745/2802, 98.0%) are either unclassified (i.e., variants of uncertain significance) or have conflicting interpretations. To address this unmet clinical need, we applied deep mutational scanning (DMS) to systematically generate functional data to support variant classification. We have established a DMS-based platform to systematically test missense variants across MSH6, and here we describe proof-of-principle experiments targeting a 50-residue segment of MSH6 (codons 1054-1103). We generated a saturation mutagenesis library representing all 950 distinct missense variants within this region, and introduced these one at a time into human HAP1 *MSH6* knockout cells. These cells are then treated with the nucleotide analog 6-thioguanine, which selects against intact MMR activity, to deplete neutral *MSH6* variants and enrich for pathogenic variants, resulting in a loss of function (LoF) score to quantify MMR activity. Consistent with known functional constraint in this region, 18.8% of missense variants have a deleterious LoF score, especially around the critical p.R1076 residue, and among proline substitutions in regions of secondary structure. The LoF scores of this pilot tile were 100% concordant with known clinical pathogenic (4/4) and benign (5/5) classifications, and are well correlated with effects observed at the equivalent residues in the binding partner and distant paralog MSH2 in a previous DMS study from our group. These experiments demonstrate the feasibility of deep mutational scanning of all possible MSH6 missense variants, toward their prospective interpretation.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2571. Establishment of *in vitro* assay system for evaluating of *RERE* variants

Authors:

B-J. Kim¹, D. Scott²; ¹Baylor Coll. Med., Houston, TX, ²Baylor Coll. Med, Houston, TX

Abstract Body:

Deletions of chromosome 1p36 are the most common terminal deletions in humans. The arginine-glutamic acid dipeptide repeats gene (*RERE*) is located in the proximal critical region on chromosome 1p36. *RERE* is a nuclear receptor coregulator that positively regulates retinoic acid signaling by binding to transcriptional complex of nuclear receptors in the developing embryo. Pathogenic loss-of function variants in *RERE* have been shown to cause many of the defects seen in individuals with proximal 1p36 deletions. Recently, we have demonstrated that genotype/phenotype correlations exist with some *RERE* missense variants causing more severe and/or unusual phenotypes that are not seen in individuals who carry *RERE* loss-of-function variants. For example, the c.4313_4318dupTCCACC [p.Leu1438_His1439dup] variant consistently causes phenotypes that are commonly associated with CHARGE syndrome. Other rare variants have been found to cause congenital diaphragmatic hernia. To determine if these variants function as loss-of-function, dominant negative, or gain-of-function alleles, we are generating a series of variant-specific *RERE* expression plasmids. To date, we have successfully cloned plasmids carrying three truncating variants seen in humans: c.2278C>T, [p.Gln760*], c.3122delC [p.Pro1041Lysfs*], and c.4552C>T, [p.Gln1518*]. Variant *RERE* proteins generated using these plasmids were of expected molecular weight. We then determined the effects of these variants in a functional assay in which the transcription of a luciferase gene is driven by retinoic acid responsible elements (RARE) derived from the promoter of retinoic acid receptor β 2 (RAR β 2DR5-Luc). Overexpression of wild type *RERE* robustly increased luciferase activity when co-transfection of RAR β 2DR5-Luc plasmids in 293T cells. In contrast, luciferase activity was significantly reduced in 293T cells expressing the *RERE* truncating variants. These data provide evidence that the functional assay system we have developed can be used to evaluate the effects of human variants on *RERE*-mediated transcription.

Molecular Effects of Genetic Variation Posters - Thursday

PB2572. Estimating Diagnostic Noise in Panel-Based Genomic Analysis

Authors:

R. Beaumont¹, C. Wright²; ¹Univ. of Exeter Med. Sch., Exeter, United Kingdom, ²Univ. of Exeter, Exeter, United Kingdom

Abstract Body:

Background: Gene panels with a series of strict variant filtering rules are often used for clinical analysis of exomes and genomes. Panels vary in size, which affects the sensitivity and specificity of the test. We sought to investigate the background rate of candidate diagnostic variants in a population setting using gene panels developed to diagnose a range of heterogeneous monogenic diseases. **Methods:** We used the Genotype-2-Phenotype database with the Variant Effect Predictor plugin to identify rare non-synonymous variants in exome sequence data from 200,643 individuals in UK Biobank. We evaluated five clinically curated gene panels: developmental disorders (DD; 1708 genes), heritable eye disease (536 genes), skin disorders (293 genes), cancer syndromes (91 genes) and cardiac conditions (49 genes). We further tested the DD panel in 9,860 proband-parent trios from the Deciphering Developmental Disorders (DDD) study. **Results:** As expected, bigger gene panels resulted in more variants being prioritised, varying from an average of ~0.3 per person in the smallest panels, to ~3.5 variants per person using the largest panel. The number of individuals with prioritised variants varied linearly with coding sequence length for monoallelic disease genes (~300 individuals per 1000 base pairs) and quadratically for biallelic disease genes, with some notable outliers. Based on cancer registry data from UK Biobank, there was no detectable difference between cases and controls in the number of individuals with prioritised variants using the cancer panel, presumably due to the predominance of sporadic disease. However, we observed a marked increase in the number of prioritised variants in the DD panel in the DDD study (~5 variants per proband). Phasing of compound heterozygotes in biallelic genes resulted in a modest reduction in the number of prioritised variants. **Conclusions:** Although large gene panels may be the best strategy to maximize diagnostic yield in genetically heterogeneous diseases, they will frequently prioritise false positive candidate variants potentially requiring additional clinical follow-up. Most individuals will have at least one rare nonsynonymous variant in panels containing more than 500 monogenic disease genes. Extreme caution should therefore be applied when interpreting potentially pathogenic variants found in the absence of relevant phenotypes.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2573. Evaluation of regulatory potential of European ancestry *APOE* ϵ 3 *TOMM40-523*' repeat haplotypes with differential risk effects.

Authors:

M. Lipkin Vasquez, P. Bussies, F. RAJABLI, K. Hamilton, A. Griswold, M. Pericak-Vance, J. young, J. Vance, K. Nuytemans; John P. Hussman Inst. for Human Genomics, Univ. of Miami, Miami, FL

Abstract Body:

Introduction: We showed that poly-T repeat length in *TOMM40* (*TOMM40-523*') is associated with AD risk in individuals carrying *APOE* ϵ 3 on European local ancestry (LA). 'Very long' repeats (VL, >29T) have a protective effect compared to 'short' repeats (S, <19T). We hypothesized that variants in linkage disequilibrium (LD) with *TOMM40-523*' on the European LA *APOE* ϵ 3 haplotype can modify risk for AD, potentially through *APOE* regulation. **Methods:** We used the short tandem repeat detection bioinformatics algorithm HipSTR and whole genome sequencing data of individuals homozygous for the *APOE* ϵ 3 European LA haplotype to type S and VL repeats. Frequency of variants on 16 S and 14 VL haplotypes were compared to determine LD with the repeat. We assessed effect on expression of VL versus S haplotypes in the *APOE* promoter region with or without the known enhancer in *TOMM40* intron 2 using luciferase reporter assays in astrocytes, microglia and neurons. **Results:** We identified a 16kb LD block surrounding *TOMM40-523*' harboring 21 variants in strong LD ($r^2 > 0.9$) with the repeat (hg19, chr19:45,395-45,411k); including the *APOE* promoter and several potential enhancer regions. Preliminary data indicate the S promoter and VL enhancer infer higher activity in microglia and astrocytes, common combinations of promoter and enhancer haplotypes (S-S) versus (VL-VL) do not differ significantly in activity. Additional analyses including other potential enhancer regions, comprising the repeat itself, are currently ongoing to investigate other cumulative effects. **Discussion:** Our results indicate that differential activity of promoter and enhancer is dependent on the repeat length haplotype, potentially contributing to the AD risk difference. These regulatory regions may be target of future therapies that could help a large amount of people, given *APOE* ϵ 3's frequency in the general population.

Molecular Effects of Genetic Variation Posters - Thursday

PB2574. Evaluation of the ACMG PM5 variant pathogenicity evidence guideline.

Authors:

G. Maston; Quest Diagnostics, Secaucus, NJ

Abstract Body:

Background: Interpreting the clinical significance of sequence variants remains one of the most challenging tasks in clinical genetic testing. One of the recommended criteria for pathogenicity states “Novel missense change at an amino acid residue where a different missense change determined to be pathogenic has been seen before” (ACMG evidence code PM5). This line of evidence is given moderate weight, but to date no formal evaluation of the reliability of this line of evidence has been published. Here, the strength of this guideline is examined using high-throughput functional data (Findlay GM, Daza RM, Martin B, et al. Accurate classification of *BRCA1* variants with saturation genome editing. *Nature*. 2018;562(7726):217-222). **Methods:** In the Findlay study, saturation genome editing was used to produce 1,839 missense changes from 326 different codons located in 2 regions of the *BRCA1* protein and tested them in a cell survival-based assay to determine their functional impact. Functional results were classified as damaging, non-damaging, or intermediate. The study produced 96.5% of all possible single nucleotide variants in these regions, generating data for an average of 5.6 missense changes per codon. The data were re-examined in this study to calculate the proportions of damaging and non-damaging changes within each codon.

Results: At least 1 missense change was functionally damaging at 156 out of 326 (47.85%) codons examined, while 101 sites had 2 or more damaging variants. From these data, we estimate the probability of there being a 2nd damaging variant in a codon given that there was at least 1 damaging variant is 64.74%, which is a 1.35-fold enrichment compared to the number of codons where any damaging variants were found. However, 133 of 156 sites with at least 1 damaging variant also had at least 1 non-damaging variant. In fact, damaging variants are only marginally more common than non-damaging variants at these sites: there was an average of 2.59 damaging variants but also 2.47 non-damaging variants.

Conclusions: These data suggest that this line of evidence needs to be re-examined for its utility, or possibly that the amount of weight it is given be re-calibrated on a gene-by-gene basis. Notably, these data come from 2 regions of the *BRCA1* protein that have known functions (RING domain and BRCT domains), thus there is likely a higher proportion of damaging variants in these data than would be expected in other regions of a protein. Further study is needed, including testing in other regions of the *BRCA1* protein and also in other proteins, to determine if these patterns are universal or unique to the domains of *BRCA1* that were studied.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2575. Evidence from a massively parallel reporter assay and genome engineering for non-coding variants at 1q32-*IRF6* that directly influence risk for orofacial cleft

Authors:

P. Kumari^{1,2}, R. Friedman³, L. Pi⁴, S. Curtis⁵, K. Paraiso⁶, A. Visel^{6,7,8}, E. Leslie⁵, M. White³, B. Cohen³, R. A. Cornell^{1,2}; ¹Current address: Dept. of Oral Hlth.Sci., Univ. of Washington, Seattle, WA, ²Dept. of Anatomy and Cell Biology, Univ. of Iowa, Iowa City, IA, ³Dept. of Genetics, Washington Univ. in St. Louis, St. Louis, MO, ⁴PharmaLex, 1700 District Ave, Burlington, MA, ⁵Dept. of Human Genetics, Emory Univ. Sch. of Med., Atlanta, GA, ⁶Environmental Genomics and Systems Biology Div., Lawrence Berkeley Lab., Berkeley, CA, ⁷U.S. Dept. of Energy Joint Genome Inst., Lawrence Berkeley Lab., Berkeley, CA, ⁸Univ. of California, Merced, CA

Abstract Body:

Variation at the 1q32/*IRF6* locus accounts for about 12% of genetic contribution to isolated orofacial cleft, the most at any single locus. To identify the functional subset of single nucleotide polymorphisms (SNPs) at 1q32 and 7 other loci we conducted a massively parallel reporter assay in a human foetal oral epithelium cell line. SNPs from multiple loci yielded allele-specific effects in this assay. We pursued ten such SNPs at the 1q32/*IRF6* locus with luciferase reporter assays. For two such SNPs, one 10 kilobases upstream, and the other 21 kilobases upstream of the *IRF6* transcription start site, we separately engineered cell clones to be homozygous for the risk-associated allele or the non-risk associated allele. Interestingly, for both SNPs, the expression level of *IRF6* was relatively lower in the former. The *IRF6* - 21kb SNP had allele-specific effects on binding of transcription factor ETS2, nominating *ETS2*, or a paralogue of it, as an OFC risk gene. Conditional analyses suggest that the *IRF6*-10kb and *IRF6*-21kb SNPs together account for most or all of the association signal at 1q32/*IRF6* for cleft lip only and for cleft lip with or without cleft palate. These experiments identify non-coding variants that directly affect risk for orofacial cleft. The methods are generalizable whenever an appropriate cell line is available. Funded by NIH DE027362, USA.

Molecular Effects of Genetic Variation Posters - Thursday

PB2576. Evolutionary study and variant analysis in the *mcph1* gene in patients diagnosed with non-syndromic hearing impairment

Authors:

O. Oluwole¹, K. James¹, A. Wonkam²; ¹Univ. of Cape Town, Cape Town, South Africa, ²Univ Cape Town, Cape Town, South Africa

Abstract Body:

The genetic causes of Hearing impairment (HL) in Africa are unknown despite increasing number of cases. We investigated human mouse orthologous HL genes in patients to identify rare pathogenic variants with possible causal effects in the African individuals. The study identified a homozygous mutation in the exon 13 BRCT2 of microcephalin1 (*MCPHI*) gene in a Cameroonian patient diagnosed with non-syndromic hearing impairment (NSHI). The present study combined evolutionary analyses with DNA sequencing to screened multiplex family; ninety (n=90) NSHI patients and 106 controls recruited from Cameroon and South Africa. The estimated mode of inheritance of NSHI in the cohort was 34.8% autosomal recessive, 34.8% autosomal dominant, 21.74% mitochondrial, and 8.66% X-linked. The approaches include whole exome sequencing, Sanger Sequencing and High-Resolution Melt analyses. We identified rare variants in the investigated genes. However, four rare missense variants and seven novel variants were identified in the candidate gene (*MCPHI*). The variants *MCPHI* c.2222G>A p.(R741Q) (Alt Allele A=0.0000) and novel homozygous *MCPHI* c.2234A>C p.(H745P) identified were absent in the 106 ethnically matched controls. The evolutionary analyses revealed that the *MCPHI* protein evolved in 150 taxa while about 28 condensed in a phylogeny cluster that indicated similar substitution rates, divergent lengths, and positive selections, particularly in the two closest taxa to humans (chimpanzee and gorilla). The protein modelling and surface hydrophobicity analyses suggest a change in atomic charges at the helix-loop that mediates dimerization and DNA binding, such that the wildtype equilibrates at 0.072 nm while the mutant equilibrates at 0.042 nm. The algorithms used also detects an increase in hydrophobicity *in-silico*. Our study suggests a further understanding of the roles of *MCPHI* gene in NSHI using functional assays.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2577. Examination of predicted loss of function (pLoF) variants in the general population reveals high rates of rescue and artifacts

Authors:

S. Gudmundsson^{1,2,3}, M. Singer-Berk¹, N. Watts¹, J. Goodrich¹, M. Wilson¹, Genome Aggregation Database Consortium, S. Baxter¹, H. Rehm^{1,3,4}, D. MacArthur^{1,5,6}, A. O'Donnell-Luria^{1,2,3}; ¹Program in Med. and Population Genetics, Broad Inst. of MIT and Harvard, Cambridge, MA, ²Div. of Genetics and Genomics, Boston Children's Hosp., Boston, MA, ³Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA, ⁴Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA, ⁵Ctr. for Population Genomics, Garvan Inst. of Med. Res. and UNSW Sydney, Sydney, New South Wales, Australia, ⁶Ctr. for Population Genomics, Murdoch Children's Res. Inst., Melbourne, MA

Abstract Body:

One of the most surprising outcomes from genome sequencing of apparently healthy individuals is the prevalence of gene-disrupting variants that are expected to cause severe disease. This could suggest that incomplete penetrance (the proportion of individuals who carry a genotype but do not develop the associated disorder) may be a common feature of human disease. However, it is also possible for such variants to arise from incorrect prediction of functional impact. We investigate this by large-scale analysis of disease-associated predicted loss of function (pLoF) variants in 76,156 genomes from the Genome Aggregation Database (gnomAD).

We assessed all pLoF variants (n=899), in 77 haploinsufficiency genes causing severe, early-onset, highly penetrant disorders expected to be excluded from gnomAD. Variants had passed gnomAD quality control pipelines, and were determined high-confidence by the Loss-Of-Function Transcript Effect Estimator (LOFTEE). We identified evidence for LoF evasion in 595 of 899 variants (66%). Of 595 variants, 49% displayed known mechanisms of rescue, with the top reasons being escape of nonsense-mediated decay because of location in the last exon (22%), location at a site with low per-base expression (pext; 11%), rescue because of being part of a multi-nucleotide variant or in phase with frame-restoring indels (8%), and splice variants with predicted cryptic splice rescues (5%). An additional 17% were filtered as artifacts or of lesser biological importance, with the top reasons being presence in a non-coding transcript (7%), being somatic (allele balance below 25%; 5%), location in a homopolymer (3%), or location in a region with known mapping difficulties (2.7%). The remaining 33% of variants had more than one reason identified, with the most common combinations being last exon with low pext score or low allele balance. Of the remaining 304 pLoF variants, 131 variants were predicted to cause true LoF with no known rescue mechanisms identified. We are now exploring if high-impact splice(s)- and expression(e)- qualitative trait loci (QTL), structural or regulatory variants could explain their incomplete penetrance.

Our results demonstrate the importance of extending LoF assessment beyond standard annotation and reveal the challenges of variant interpretation in general population sequencing. We caution the direct use of pLoF variants, particularly when identified in settings where the prior probability of pathogenicity is low such as genomic screening programs of healthy individuals. Further analysis will be required to understand how LoF variants predicted to cause true loss do not cause disease in these individuals.

Molecular Effects of Genetic Variation Posters - Thursday

PB2578. Exome analysis for bronchial asthma in the Mennonite population reveals an association with *NOTCH4* polymorphisms

Authors:

I. Bucco¹, V. L. Carvalho¹, C. G. Meissner¹, L. C. Oliveira¹, P. I. dos Santos¹, Regeneron Genetics Center, F. McMahon², F. L. Lopes³, A. B. W. Boldt¹, G. C. Kretzschmar¹; ¹Federal Univ. of Paraná, Curitiba, Brazil, ²NIH/NIMH, Bethesda, MD, ³Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract Body:

Mennonites are a Christian Anabaptist group with cc. 500 years genetic isolation and a closed community structure which, added to three bottleneck events, reduced their genetic diversity and increased their susceptibility to chronic diseases, including bronchial asthma (BA). We screened 213 South-Brazilian Mennonites from Colônia Nova (CON), 157 from Colônia Witmarsum (CWI), and 185 from Curitiba (CWB) for BA and compared the exomes of 49 Mennonites that had BA or reported first-degree affected relatives with 41 that were unaffected and reported unaffected relatives, evaluating the results with multivariate logistic regression. Cc. 12% of the interviewed Mennonites had BA (CON: 8.1%, CWI: 15%, CWB: 14.3%), compared with 4.5% among Brazilians. Thirty-four variants were associated with a dominant effect for BA ($p < 0.005$) in the exome-wide analysis. Among these, 22 are associated with mRNA levels in the lungs/whole blood (GTEx), 8 replace amino acids, and 14 modify CpG sites. Twenty-two (73%) were associated with protection from BA ($p < 0.0005$), but 54% present a lower frequency among Mennonites ($p < 0.006$), compared with those in the non-Finnish Europeans and/or Brazilians. Thus, the higher BA prevalence in Mennonites is associated with a founder effect decreasing the frequency of protective alleles. Among the risk polymorphisms, we genotyped rs423023 of the *NOTCH4* gene with PCR-SSP in an increased sample of 261 Mennonites. This variant breaks a CpG site and is associated with the reduction of gene expression and with the alternative processing of its pre-mRNA in the lung. We genotyped it with another SNP at 5' (rs520803) by PCR-SSP, and found that the *rs520803_rs423023*AG*, with 30.6% frequency was also associated with an additive effect for BA susceptibility (OR = 2.15; CI95% = 1.08 - 4.39; $p = 0.031$), confirming the association previously identified in the exomes. Although the complexity of this genomic region, with high HLA linkage disequilibrium, implies difficulty in identifying a causal haplotype, we suggest that *rs520803_rs423023*AG* contributes to BA susceptibility through alternative splicing and greater expression of common *NOTCH4* transcripts in the lung, increasing the activation of inflammatory pathways.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2579. Exome-wide association analyses of 1,463 proteins in 31k participants of the UK Biobank reveal the spectrum of coding variant effects on protein levels.

Authors:

H. Kim, J. Chiou, UK Biobank Pharma Proteomics Project, E. B. Fauman, M. R. Miller; Internal Med. Res. Unit, Pfizer, Cambridge, MA

Abstract Body:

Circulating proteins are valuable biomarkers of health and disease and can be attractive targets for therapeutic modulation. While genome-wide association studies using imputed variants have identified numerous protein quantitative trait loci (pQTLs), the effects of rare coding variants on protein levels have not been extensively studied. To characterize the genetic architecture of circulating proteins by rare coding variants, we performed exome-wide association analyses of 1,463 proteins quantified by Olink Explore 1563 platform in 30,838 unrelated individuals of European ancestry from the UK Biobank. We identified 4,613 significant cis-pQTLs by coding variants (hereafter referred to as “coding cis-pQTLs”) for 993 proteins (P-value < 2.9e-7). The class of variants predicted to have more severe consequences had higher proportions of variants with significant cis-pQTLs and greater median effect magnitudes in the following order: 1) predicted loss-of-function variants, including frameshift, stop-gain, splice acceptor/donor, and start-loss variants (5.1%, -2.1 sd), 2) in-frame insertion/deletion variants (3.5%, -1.3 sd), 3) missense variants (2.6%, -0.5 sd), and 4) synonymous variants (2.4%, -0.1 sd). The effect magnitudes were also inversely correlated with the minor allele frequency, and for missense variants, positively correlated with the number of algorithms that predicted them to be deleterious. Of the 4,613 coding cis-pQTLs, 3,774 (82%) remained significant when adjusted for GWAS cis-pQTLs within +/-500kb of the gene, and the overall pattern remained comparable.

One challenge in interpreting coding cis-pQTLs arises from the possibility that coding variants may directly alter the binding of antibodies used for protein quantification. Given that coding variants are unlikely to affect the quantification of other proteins in this manner, the presence of trans-pQTLs by the same coding variants can add credibility to the observed coding cis-pQTLs. Of the 4,606 coding variants with cis-pQTLs, 3,622 variants (79%) had at least one significant trans-pQTL (P-value < 8.3e-9), supporting the reliability of 3,629 cis-pQTLs by those variants.

In summary, our study provides a reference for coding variant effects on protein levels and suggests an approach to increase the confidence in cis-pQTLs by coding variants. We are further exploring ways to incorporate the observed effects of coding variants on protein levels into gene burden association test to boost statistical power for disease gene discovery.

Molecular Effects of Genetic Variation Posters - Thursday

PB2580. Expanding the rare *DHCR24*-related sterol biosynthesis disorder: genotype -phenotype correlation.

Authors:

D. Cocciadiferro¹, D. Vecchio², V. Lanari¹, E. Agolini¹, A. Villani¹, F. Petrizzelli³, T. Biagini³, T. Mazza³, D. Martinelli⁴, M. Macchiaiolo², A. Bartuli², A. Novelli¹; ¹Translational Cytogenomics Res. Unit, Bambino Gesù Children's Hosp., IRCCS, Rome, Italy, Rome, Italy, ²Rare Diseases and Med. Genetics Unit, Academic Dept. of Pediatrics, Bambino Gesù Children's Hosp., IRCCS, Rome, Italy, Rome, Italy, ³Bioinformatics Unit, Fondazione IRCCS Casa Sollievo della Sofferenza, S. Giovanni Rotondo (FG), Italy, Rome, Italy, ⁴Dept. of Pediatric Subspecialties, Div. of Metabolic Diseases, Bambino Gesù Children's Hosp. IRCCS, Rome, Italy, Rome, Italy

Abstract Body:

Desmosterolosis is a rare sterol biosynthesis disorder characterized by multiple congenital anomalies, failure to thrive, intellectual disability and elevated levels of desmosterol caused by biallelic mutations of *DHCR24* encoding 3- β -hydroxysterol Δ -24-reductase. In brain cholesterol synthetic metabolism, *DHCR24* protein is known as the heavily key synthetase in cholesterol synthesis, catalyzing the reduction of the delta-24 double bond of sterol intermediates during cholesterol biosynthesis. Until date, less than 10 *DHCR24* pathogenic variants have been identified in association with desmosterolosis. Here, we describe a patient with developmental delay, epileptic encephalopathy, spastic tetraparesis, ventriculomegaly, epicanthus, elevated desmosterol levels, cataract and dolichocephaly harboring the never described before missense variant c.506T>C (p.Met169Thr) in *DHCR24*. Using molecular dynamics simulation techniques, we have investigated the impact of this mutation on the protein's stability and interaction network and preliminary assessed its pathogenic role. In conclusion, this report expands the clinical and molecular spectrum of *DHCR24* related disorder, reporting a novel *DHCR24* variant associated with desmosterolosis syndrome.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2581. Expansion of the histidine-rich domain of *DYRK1A* in a patient with developmental delay, short stature, and microcephaly: A case report.

Authors:

R. Fox, G. Hortopan, E. Yusko, G. Mendiratta-Vij, R. Zimmerman, A. Birch, L. Edelmann; Sema4, Stamford, CT

Abstract Body:

Background: *DYRK1A*-related intellectual disability syndrome is a dominant disorder caused by *de novo* pathogenic variants in the *DYRK1A* gene. It is characterized by intellectual disability, developmental, speech and language delays, microcephaly and facial dysmorphism. We report a novel expansion of the histidine-rich domain (HRD) of the *DYRK1A* gene in a female patient with unexplained developmental delay, short stature, and microcephaly. Our findings provide the first evidence of a critical role for the size of the HRD in the *DYRK1A*-intellectual disability syndrome. **Methods:** Next generation sequencing was performed using a 228-gene autism panel. Sanger sequencing was used for variant confirmation in the proband and parents. Variant analysis was performed using the Agilent Alissa software and variant classification was determined using ACMG and ClinGen recommendations. Consent was obtained to deidentify this sample and use it for research purposes. **Results:** We identified a novel heterozygous in frame duplication variant in the coding region of exon 11 of the *DYRK1A* gene, NM_130436.2:c.1801_1830dup, p.His601_His610dup. The mutation was absent in the mother and father, indicating that this variant is *de novo* in this individual. *DYRK1A* encodes a dual specificity tyrosine-phosphorylation-regulated kinase 1A, that contains a highly conserved HRD that consists of 13 consecutive histidines in the C-terminus. Functional studies of the HRD have shown that it is important for nuclear speckle localization and phosphorylation of serine and threonine residues on exogenous substrates and its own kinase domain. To date, 84.5% of individuals reported with *DYRK1A*-related intellectual disability syndrome have a *de novo* variant. Per ACMG criteria, small in-frame deletions/insertions in repetitive regions without a known function are less likely to be pathogenic. However, this region is not highly polymorphic in the Genome Aggregation Database (<http://gnomad.broadinstitute.org>) with observed duplications not exceeding 2 amino acids. Biochemical characterization of missense mutations occurring in the HRD result in altered DYRK1A catalytic activity. No pathogenic expansions of the HRD have been reported in patients. **Conclusion:** Here, we report a rare duplication variant in the HRD of the *DYRK1A* gene in a female with developmental delay, short stature, and microcephaly. Based on the clinical presentation and family history, the confirmed *de novo* in frame duplication p.601_p.610 in the HRD in *DYRK1A* was classified to be likely pathogenic and disease causing. To our knowledge, this is the first report of a repeat expansion in *DYRK1A* causing this disorder.

PB2582. Explicable prioritization of genetic variants by integration of rule-based and deep learning algorithms for diagnosis of rare Mendelian disorders.

Authors:

K. Lee, H. Lee, J. Woo, D-w. Kim, G. Seo; 3billion, Seoul, Korea, Republic of

Abstract Body:

Using exome, genome and even transcriptome sequencing for making a molecular diagnosis for patients with rare Mendelian disorders has become a common clinical practice. However, determining variant pathogenicity is not a simple task and therefore many variants remain of uncertain significance albeit numerous in silico tools being developed to predict how damaging the variants could be. Here, we report a comprehensive algorithm that prioritizes variants with higher sensitivity than other publicly available tools with added capabilities of annotating variants with the evidence that was used for the prioritization. We integrated three different scores into EVIDENCE, an internally developed variant annotation and classification tool. First, the Bayesian score is based on the 28 criteria defined by the ACMG/AMP variant interpretation guidelines. Second, the symptom similarity score quantifies the semantic similarity between the known symptoms of a specific disorder and those observed in the patient. Third, 3Cnet score, generated by a trained deep-learning model, provides the likelihood of a given amino-acid change impacting the protein function. 3Cnet scores add extra refinement to the variant classification made by the first two scores.

Using an in-house dataset of 1,817 WES patient samples, we compared how our model performs compared to other prioritization algorithms. Our method was able to find the causal gene within the top-5 genes at a recall rate of 93.5 %, while LIRICAL and Exomiser did so at recall rates of 73.9 % and 73.4 % respectively. Reflecting this result, our algorithm performed best in the recent CAGI6 SickKids challenge by successfully identifying ten out of fourteen causal genes. Among them, two genes that showed decreased gene expression in RNA-seq data, *CASK* and *HDAC8*, were identified with the estimated probabilities over 0.96 and 0.93 respectively. Although our tool does not directly calculate the likelihood of a variant affecting gene expression level, we were able to correctly predict that the variants in these two genes might result in decreased expression. These results show that the gene prioritization algorithms can be explicable yet sensitive by integrating rule-based algorithms and machine learning algorithms.

PB2583. Exploiting a human stem cell-based modeling approach to functionally characterize loss-of-function of lncRNA RMST as a cause of Kallmann Syndrome.

Authors:

L. Stanton, G. Ali, G. Alkhadairi, W. Habbab, Y. Park; Qatar BioMed. Res. Inst., Doha, Qatar

Abstract Body:

Human genetics identified mutations in several genes that cause isolated GnRH deficiency (IGD), a rare Mendelian disorder (1) manifested by abnormal puberty, hypogonadotropism, infertility, and anosmia in Kallmann Syndrome, a phenotypic subset of IGD. A balanced translocation in a KS proband disrupted the gene for the long noncoding RNA (lncRNA) RMST thus implicating it as a genetic regulator of GnRH neuronal development (2). Previously we showed that RMST regulates neuronal development through a physical interaction with SOX transcription factors during neurogenesis (3).

To establish a model system to characterize the role of RMST, we have used Crispr gene editing to delete RMST in human embryonic stem cells (ESC). Small (5kb) and large (40kb) genetic deletions of both alleles of RMST were created to mimic the disruption of RMST resulting from a balanced translocation observed in a KS patient. Several independent, gene edited ESC lines have been generated. Genetic loss of RMST was confirmed by DNA sequencing and absence of RMST transcripts. The RMST mutant ESC lines were shown to retain pluripotency as assessed by conventional means.

The ESC lines with RMST deletion have been differentiated *in vitro* to human neural progenitors and subsequently into human GnRH neurons. We demonstrated that RMST mutant lines generate neural progenitors and GnRH neurons using our directed *in vitro* differentiation protocols. The electrophysiological activity of the mutant neurons relative to wild-type neurons is now being evaluated. To understand the molecular basis of RMST knockout we are performing RNA-seq on wild-type and mutant neural progenitors and neurons.

We will update on the progress of using this *in vitro* model of Kallmann syndrome to dissect the molecular mechanism of RMST in neuronal development and the pathological manifestations of its loss of function on GnRH neurons.

PB2584. Fast Forward - is Multiomics a resurgence of old?

Authors:

M. Hegde¹, F. Guo², C. Collins³, L. Bean¹, B. Nallamilli¹, N. Guraju¹, H. Liu¹; ¹PerkinElmer, Waltham, MA, ²PerkinElmer Genomics, Pittsburgh, PA, ³PerkinElmer, Boston, MA

Abstract Body:

Multiomics including genome, proteome, transcriptome, and epigenome is an approach to collectively assessing and analyzing data sets. One of the challenges for next-generation sequencing (NGS) based tests is to understand the disease mechanism of the variants of uncertain significance (VOUS) in known Mendelian genes, and newly discovered genes. . Incorporating data generated by RNA sequencing, and biochemical testing, we have reclassified variants from uncertain significance to disease-causing (DMD c.4806T>A; DYSF duplication of exons 10-35; GAA c.1796C>A; ABCD1 c.598G>A). Among 81 cases for GAA enzyme activity and molecular testing, 26 cases with biallelic pathogenic variants in GAA showed over 50% the reduction of the lysosomal alpha-glucosidase enzyme activity (0.42 $\mu\text{mol/L/hr}$; normal range: $\geq 2.10 \mu\text{mol/L/hr}$), despite the GAA variants is associated with mild or severe Pompe disease. Nineteen individuals carrying one pathogenic GAA variant demonstrated average enzyme activity of 1.63 $\mu\text{mol/L/hr}$. The remaining 36 individuals carried two VOUS, or one VOUS and one pseudodeficiency allele, or two pseudodeficiency alleles, or negative. The enzyme activity ranged from 0.72-5.53 $\mu\text{mol/L/hr}$. Similar correlations between the enzyme activity and biallelic pathogenic variants were observed in 36 cases for GBA testing, of which 27 individuals carrying biallelic GBA pathogenic variants with significantly decreased enzyme activity (0.26-0.78; normal range: $\geq 1.60 \mu\text{mol/L/hr}$). Among these 27 individuals, 23 presented increased lyso-Gb1 (19.19->200; normal range: $\leq 17.41 \text{ ng/mL}$) whereas the other 4 in normal range. A remarkable reduction of GLA enzyme with an average of 0.53 $\mu\text{mol/L/hr}$ (normal range: $\geq 1.10 \mu\text{mol/L/hr}$) was observed in 20 out of 33 males tested for Fabry disease. The GLA variants correlated with less severe symptoms and reduced penetrance were associated with close to the normal range of Lyso-Gb3 ($< \text{ or } = 1.11 \text{ ng/ml}$). Our data shed light on the correlation between biochemical results and molecular findings, as well as the genotype-phenotype relationship in some lysosomal storage disorders. These methodologies have been widely used in clinical laboratories for over two decades. The recent technological advances in multiomics approaches will aid in improving the diagnostic performance to tailor personalized treatment, but it's required datasets from multiple measurements, large reference databases for different genes and diseases, integrated analysis methods, and a strong computational infrastructure.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2585*. Fine-mapping causal tissues and genes at disease-associated loci

Authors:

B. Strober, T. Amariuta, M. Zhang, A. Price; Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA

Abstract Body:

Heritable diseases often manifest in a highly tissue-specific manner; this knowledge is fundamental to our understanding of disease biology and can provide insights into tissue-mediated mechanisms of disease (Hekselman et al. 2020 Nat Rev Genet). Previous studies have generally prioritized relevant tissues for disease based on genome-wide patterns of disease enrichment. However, disease effects at different GWAS loci may be mediated by different tissues, motivating efforts to identify relevant tissues at individual GWAS loci.

Here, we introduce a new statistical method, Tissue-Gene Fine-Mapping (TGFM), to infer the posterior probability that each tissue and gene mediate a given disease association based on GWAS summary statistics and expression quantitative trait loci (eQTL) from diverse tissues. TGFM consists of two steps. First, TGFM estimates gene expression-disease effects for each tissue and gene while accounting for co-regulation (correlations of cis-regulatory SNP effects) across tissues and genes; this step makes use of transcriptome-wide association study (TWAS) statistics, which quantify marginal effects of genetically predicted gene expression on disease (without accounting for co-regulation). Second, TGFM estimates the posterior probability that a specific disease-associated locus is mediated through each tissue and gene given the gene expression-disease effect estimates from the first step. TGFM improves tissue and gene fine-mapping accuracy by incorporating genome-wide estimates of the contribution of gene expression in each tissue to disease as tissue-level priors, and also accommodates gene-level priors.

We apply TGFM to a broad set of 36 diseases/traits and 38 GTEx tissues to fine-map hundreds of disease loci to causal tissues and genes. We evaluate TGFM using 10 independent diseases/traits whose biology is widely believed to involve a single causal tissue. For white blood cell count, TGFM correctly maps 31.3% of GWAS loci to whole blood tissue, vs. 6.4% of loci for a baseline approach that compares tissue-specific probabilities computed by coloc, a widely used gene expression-disease colocalization method. For diastolic blood pressure, TGFM correctly maps 25.4% of GWAS loci to artery tibial tissue, vs. 5.2% of loci for the baseline approach. Despite outperforming the coloc-based baseline, TGFM still fails to correctly fine-map the causal tissue at the majority of disease loci, reflecting the difficulty of this challenge given existing genomic data. In summary, we have developed and evaluated a statistically principled method for fine-mapping the causal tissue and gene at individual GWAS loci.

Abstract Body:

Craniofacial microsomia (CFM also known as Goldenhar syndrome), is a craniofacial developmental disorder of variable expressivity and severity with a recognizable set of abnormalities. These birth defects are associated with structures derived from the first and second branchial arches, can occur unilaterally and include ear dysplasia, microtia, preauricular tags and pits, facial asymmetry and other malformations. The inheritance pattern is controversial, and the molecular etiology of this syndrome is largely unknown. 670 patients belonging to unrelated pedigrees with European and Chinese ancestry with CFM, were investigated. We identified 18 likely pathogenic variants in 21 probands in FOXI3 (3.1%). Biochemical and cellular analyses in HEK-293T cells, and 4 different knock-in mouse data support the involvement of FOXI3 in CFM. Our findings indicate autosomal dominant inheritance with reduced penetrance, and/or autosomal recessive inheritance. The phenotypic expression of the FOXI3 variants is variable. The penetrance of the likely pathogenic variants in the seemingly dominant form is reduced, since a considerable number of such variants in affected individuals were inherited from non-affected parents. There is suggestive evidence that common variation in the FOXI3 allele in trans with the pathogenic variant could modify the phenotypic severity and penetrance.

PB2587. Fragile X related genes and Dlg4 gene are involved in process formation in neuronal cells

Authors:

H. Shimizu, H. Hohjoh; Natl. Inst NeuroSci., Kodaira, Japan

Abstract Body:

Fragile X syndrome (FXS) is an inherited disorder caused by mutant *Fragile X mental retardation 1 (FMR1)* genes carrying abnormally expanded CGG triplet repeats: aberrant CGG repeats inhibit the expression of *FMR1*. The protein encoded by *FMR1* (FMRP) is an RNA binding protein and involved in the stabilization and translational regulation of mRNAs. FMRP is present in dendrites and dendritic spines of neurons and plays an important role in local translation of mRNAs. Previous studies suggested that FMRP was involved in neuronal development. The decrease in dendritic spines and the reduction of basal dendrite length and branching were observed in *Fmr1* knockout mice. Thus, FXS may have some adverse effects on neurite formation, but the mechanism is not yet fully understood. In this study, to examine the effects of *Fmr1* (FMRP) on process formation, we generated *Fmr1*-deficient cell lines with mouse neuroblastoma Neuro2a (N2a) cells: *Fmr1* was knocked out by gene editing using CRISPR-Cas9. Western blot indicated little or no expression of FMRP in *Fmr1*-deficient N2a cell lines. The *Fmr1*-deficient cells showed impairment of process formation under differentiation conditions. However, supplementation of retinoic acid restored process formation in *Fmr1*-deficient N2a cells. Since FMRP is known to be associated with the *DLG4* mRNA and FXR1 protein, we examined the effects of *Dlg4* and *Fxr1* on process formation. Gene silencing against *Dlg4* and *Fxr1* by RNAi was carried out in naïve N2a cells and *Fmr1*-deficient N2a cells. The knockdown cells exhibited impairment of process formation even under retinoic acid-containing differentiation conditions. In addition, the *Dlg4* mRNA could be detected by qRT-PCR, but the protein was hardly detected in N2a cells by western blotting. Gene silencing against *Dlg4* and *Fxr1* by RNAi in primary mouse hippocampal neurons was also performed. The knockdown neurons exhibited impairment of neurite outgrowth as in N2a cells. We further examined associations between FXR1 protein and *Dlg4* mRNA in *Fmr1*-deficient N2a cells by immunoprecipitation with FXR1 antibody. As a result, the association between *Fxr1* and *Dlg4* mRNA was observed. Taken together, our current findings suggest that the FXR1 protein and *Dlg4* mRNA may be involved in process formation independently of FMRP.

Molecular Effects of Genetic Variation Posters - Thursday

PB2588. Full penetrance of a hypomorphic TYR gene variation in oculocutaneous albinism.

Authors:

C. Velez¹, J. Vazquez², S. Carlo³, F. Velez-Bartolomei¹, A. Cornier⁴; ¹Genetic Diagnostic Group, San Juan, PR, ²Biology, Univ. of Puerto Rico Rio Piedras Campus, San Juan, PR, ³Ponce Hlth.Sci. Univ., Cabo Rojo, PR, ⁴San Jorge Children s Hosp./ Ponce Hlth.Sci. Univ., San Juan, PR

Abstract Body:

We are presenting the case of an 11-year-old male patient referred to genetics due to abnormal metabolic laboratory findings including deficient carnitine levels. Upon physical examination, mild joint hyperlaxity, decreased muscle tone and facial hypoplasia was ascertained. In addition to displaying lack of skin pigmentation, light colored hair and nystagmus. Therefore, an albinism gene panel was requested. Albinism gene panel identified two variants of potential clinical relevance in the *TYR* gene with an autosomal inheritance and heterozygosity for both variants. The *TYR* gene is bounded to the production of tyrosinase and melanin, which affects hair, skin and eyes pigmentation. Mutations in the *TYR* gene have been associated with oculocutaneous albinism (OCA) types IA and IB, and autosomal recessive Waarderburg syndrome type 2 (WS2-OA). The likely pathogenic variant sequence c.140G>A was identified in the patient with a prediction of missense mutation of Gly to Asp at codon 47 in exon 1 of the *TYR* gene. Whereas variant sequence c.1205G>A is classified as a reduced penetrant, hypomorphic pathogenic variant with a missense mutation of Arg to Gln at codon 402 in exon 4 of the *TYR* gene. The amino acid substitutions have been linked with OCA1 and OCA respectively, which is characterized by decreased or absent pigmentation in the hair, skin and eyes. Although reports indicate no clinically significant sequences were identified, and specify only a potential clinical relevance was shown, this patient does meet all the classical clinical criteria for a diagnosis of oculocutaneous albinism due to *TYR* gene mutations.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2589. Functional analysis of genetic variations found in clinical exomes of ASD patients.

Authors:

A. Bhattacharya¹, P. Parlanti¹, L. Cavallo¹, E. Farrow², T. M. Spivey², M. Manzini³; ¹Rutgers Univ. (Child Hlth.Inst.), New Brunswick, NJ, ²George Washington Univ., DC, DC, ³Rutgers Robert Wood Johnson Med. Sch., New Brunswick, NJ

Abstract Body:

Autism Spectrum Disorder (ASD) and Intellectual Disability (ID) represent genetically heterogeneous neurodevelopmental disorders that are often comorbid and caused by single gene mutations of large effect. The involvement of multiple genes, each affecting a relatively few patients, complicates diagnosis. Genome-wide profiling studies produce an array of 'variants of uncertain significance' (mostly missense) which fail to provide clinicians with any specific cues for managing the disease. We sought to develop a framework to characterize these variations using Coiled-coil and C2 domains containing 1A (CC2D1A; MIM *610055, UniProtKB Q24K25), a candidate gene for ASD identified through family studies. We included four ASD/ID cases with compound heterozygous missense mutations [c.980C>T(p.Ser327Leu)/c.1345G>A(p.Val449Met), c.980C>T(p.Ser327Leu)/c.1322G>T(p.Gly441Val), c.956C>T(p.Pro319Leu)/c.2728G>A(p.Glu910Lys), c.1739C>T(p.Thr580Ile)/c.2657G>A,T(p.Arg886His)]. CC2D1A regulates the protein kinase A (PKA)/CREB pathway by repressing phosphodiesterase 4D (PDE4D), via an interaction mediated by its unique DM14 domains. We hypothesized that missense variants in the DM14 region disrupt binding and repression of PDE4D. When wildtype (WT) CC2D1A is overexpressed, PDE4D is repressed leading to an increase in PKA/CREB activity while the missense variants release repression, increasing cAMP degradation and reducing CREB activation. To test this, we cloned and overexpressed WT and mutant CC2D1A (individually and in patient combination) in HEK293 cells. Overexpression of mutant CC2D1A neither affected protein stability nor the survival of the transfected cells at 24 and 48hrs. By employing luciferase reporter assay, we quantified CREB activation 24hrs after transfection with 6hrs forskolin treatment. Compared to the WT, four DM variants G441V, V449M, P319L and T580I lead to blunted response to forskolin induced CREB activation (p=0.0313, N=6-7, Wilcoxon matched pairs signed rank test), suggesting these are most likely loss of function. S327L, V449M, P319L, T580I and R886H also have a concomitant reduction in cAMP levels (p<0.05, N=6, Wilcoxon matched-pairs signed rank test). Our work suggests mutations in the DM14 domain affect CC2D1A binding to PDE4D and disrupts signaling.

Molecular Effects of Genetic Variation Posters - Thursday

PB2590. Functional and *in silico* analyses of variants found in mitochondrial trifunctional protein deficiency patients

Authors:

E. Vieira Neto^{1,2}, M. Wang², A-W. Mohsen¹, Y. Wang¹, C. Van't Land¹, E. Koppes¹, T. S. Anthonymuthu¹, H. Bayir^{1,2}, J. Vockley^{1,2}; ¹Univ. of Pittsburgh, Pittsburgh, PA, ²UPMC Children's Hosp. of Pittsburgh, Pittsburgh, PA

Abstract Body:

Background: Mitochondrial trifunctional protein (TFP) catalyzes the last three steps of the β -oxidation spiral for long-chain fatty acids as well as an unrelated step in cardiolipin metabolism. It is a heteromeric enzyme composed of two α and two β -subunits, encoded by *HADHA* and *HADHB* genes, respectively. More than 150 mutations in *HADHA* and *HADHB* are reported, typically resulting in complete TFP deficiency, while a common *HADHA* missense mutation (p.E510Q) usually leads to an isolated LCHAD deficiency. TFP/LCHAD deficiency shows a wide variety of clinical phenotypes that may range from severe, fatal neonatal to late onset with recurrent rhabdomyolysis. We previously showed defective cardiolipin remodeling and mitochondrial bioenergetics in this disorder. Our objective here is to address its genetic heterogeneity correlating it with cardiolipin profile and bioenergetics function. Methods: Genotype was confirmed by sequencing of DNA from skin fibroblasts. α and β -TFP proteins were analyzed by western blot (WB). Reverse-transcription droplet digital PCR (RT-ddPCR) was used to evaluate mRNA expression. Structure analysis of the variant proteins was performed by the Insight II (2000) software package using TFP atomic coordinates. Mitochondrial bioenergetics were measured with a Seahorse Analyzer. Cardiolipins (CLs) and monolyso-CLs were quantified by LC-MS/MS. The databases HGMD, ClinVar, and gnomAD were consulted. The *in silico* predictive tools PROVEAN, SIFT, PolyPhen-2, and Mutation Taster were applied. Results: WB of cells with truncating variants in *HADHA* or *HADHB* revealed significant decrease in levels of both subunits. Genotypes comprising *HADHA* or *HADHB* missense mutations had protein levels comparable to controls. Truncating variants had variable effects on mRNA levels. Structure analysis of the variant proteins predicted disruption of catalytic sites, substrate binding and destabilization of subunit interaction. Mitochondria from cells with genotypes homozygous for p.E510Q or having truncating variants in *HADHA* and *HADHB* presented increased levels of oxidized CLs and/or monolyso-CLs. These same cells presented mitochondrial dysfunction reflected in clear reduction of maximal respiration and spare respiratory capacity. Conclusion: Genotypes with truncating mutations were the most affected in terms of protein expression, but their impact on mRNA levels varied. These genotypes plus homozygous p.E510Q were also very deleterious for mitochondrial function and cardiolipin metabolism. There was a high level of concordance between the results of these functional analyses, and *in silico* structure analysis, and predictive tools.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2591*. Functional characterization of a heat shock regulated enhancer at coronary artery disease associated locus that controls *CALCRL* expression in endothelial cells

Authors:

I. Selvarajan¹, J. Li², P. Pölönen³, T. Örd¹, K. Öunap¹, K. Mäklin¹, A. Toropainen¹, L. Stolze⁴, C. ROMANOSKI⁴, M. Heinäniemi³, Y. Fang², M. Kaikkonen¹; ¹A. I. Virtanen Inst. for Molecular Sci., Univ. of Eastern Finland, Kuopio, Finland, ²Dept. of Med., The Univ. of Chicago, Chicago, IL, ³Inst. of Biomedicine, Univ. of Eastern Finland, Kuopio, Finland, ⁴The Univ. of Arizona, Tucson, AZ

Abstract Body:

Coronary artery disease (CAD) is one of the major causes of mortality worldwide. Recent genome-wide association studies have started to unravel the genetic architecture of the disease. Such efforts have identified Calcitonin receptor-like (*CALCRL*), an important mediator of the endothelial fluid shear stress response, associated with CAD risk variants. Better understanding of *CALCRL* gene regulation and the role of SNPs in modulation of *CALCRL* activity could provide important steps towards understanding genetic predisposition in shear stress. In this study we functionally characterized the non-coding regulatory elements carrying CAD risks SNPs and studied their role in the regulation of *CALCRL* expression in endothelial cells. We demonstrated that rs880890-harboring regulatory element exhibits high enhancer activity and significant allelic bias with A allele showing 40% more activity than G allele. We also observed that under shear stress the A allele of rs880890 is favored over the G allele. CRISPR deletion of rs880890-enhancer resulted in downregulation of *CALCRL* expression. EMSA showed that heat shock factors are binding to the enhancer with a preference to A allele compared to G allele. Interestingly, HSF1 knockdown under shear stress showed a significant decrease in *CALCRL* expression. RNA-Seq of *CALCRL* knockdown and enhancer deletion results confirmed the role of *CALCRL* in eNOS, apelin, adrenomedullin and angiotensin signaling pathways while Real-Time Cell Analyzer (RTCA) based assay further showed decrease in cell proliferation and tube formation. Overall, our results demonstrate the existence of an endothelial-specific heat shock factor regulated transcriptional enhancer carrying a CAD risk SNP rs880890 that regulates *CALCRL* expression.

Molecular Effects of Genetic Variation Posters - Thursday

PB2592. Functional characterization of new non-coding pathogenic variants creating upstream Open Reading Frames in the 5'UTR of the Endoglin gene and causing Hereditary Hemorrhagic Telangiectasia.

Authors:

O. Soukarieh¹, E. Tillet², C. Proust¹, F. Soubrier³, A. Goyenville⁴, M. Eyries³, D-A. Trégouët¹; ¹INSERM UMR 1219, Bordeaux Population Hlth.Res. Ctr., Université de Bordeaux, Bordeaux, France, ²INSERM UMR U1292, laboratoire BIOSANTE, Université Grenoble Alpes, Inserm, CEA, Grenoble, France, ³Département de génétique, Hôpital Pitié-Salpêtrière, Sorbonne Université, Assistance Publique-Hôpitaux de Paris, Paris, France, ⁴Université Paris-Saclay, UVSQ, Inserm, END-ICAP, Versailles, France

Abstract Body:

Hereditary Hemorrhagic Telangiectasia (HHT) is a rare vascular disorder causing abnormal vessel formation and characterized by autosomal dominant transmission and considerable variability in symptoms and clinical severity. In clinical diagnosis, 3 main genes, *ALK1*, *ENG* and *SMAD4* are routinely screened for pathogenic variants at the origin of HHT. About 80% of HHT cases are caused by pathogenic coding mutations in *ALK1* and *ENG*. However, at least 15% remain with no molecular explanations in the 3 main genes.

We here report the identification of 2 new variants, c.-79C>T and c.-68G>A, in the 5'UTR of *ENG* in 2 unrelated HHT patients. These 2 variants are predicted to create Open Reading Frames located upstream (upORF) of the CoDing Sequence (CDS). upORF are naturally present in human transcripts and result from the presence of an upstream translation initiation site (uTIS) located within the 5'UTR. The association of an uTIS with a stop codon located within the 5'UTR leads to a fully upstream ORF (uORF). Elongated CDS (eCDS) and overlapping ORF (oORF) result from uTIS being in-frame and out-of-frame with the CDS, respectively.

Interestingly, 4 additional upORF-creating variants in the 5'UTR of *ENG* have been previously reported in HHT patients (c.-142A>T, c.-127C>T, c.-10C>T and c.-9G>A), without extensive functional investigations of their pathogenicity. To assess the potential effect of all of these 6 variants (5 oORF- and 1 eCDS-creating variants) on *ENG*, we performed *in vitro* functional assays based on the expression of wild-type and mutant constructs in human cells. We found that all were associated with a decrease of protein levels in HeLa and HUVECs cell lines. A comparison of our experimental results with patients' clinical characteristics suggests that oORF-creating variants leading to *ENG* protein levels less than 40% *in vitro* would be associated with a severe form of HHT whereas eCDS-creating ones, at the origin of *ENG* levels around 80% would lead to a mild form of HHT. Additional experiments relying on artificial deletions in our mutated constructs revealed that some, but not all, created upORF could be translated into small encoded peptides. We are now using a dedicated functional assay to explore the effect of these 6 *ENG* variants on the signaling activity of *ALK1* in response to BMP9, a mandatory element before providing a definitive molecular diagnosis.

Overall, we here identified two never reported 5'UTR *ENG* variations in HHT patients and shed new lights on the role of upORF on *ENG* regulation. Our findings contribute to ameliorate molecular diagnosis in HHT.

PB2593. Functional Characterization of Novel UBE3A Variants Associated with Angelman Syndrome

Authors:

M. Cousin^{1,2}, G. E. Boyum^{1,3,4}, T. L. Schwab^{1,3}, C. T. Schmitz^{1,3}, A. Jain⁵, E. C. Wirrell⁶, J-M. Tillema⁶, D. Babovic-Vuksanovic^{1,7}, B. C. Lanpher^{1,7}, R. H. Gavrilo^{1,6,7}, K. J. Clark^{1,3}, E. W. Klee^{1,2,7}; ¹Ctr. for Individualized Med., Mayo Clinic, Rochester, MN, ²Dept. of Quantitative Hlth.Sci., Mayo Clinic, Rochester, MN, ³Dept. of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, ⁴Univ. of Wisconsin-Madison Genetics Training Program, Madison, WI, ⁵Mayo Clinic Graduate Sch. of BioMed. Sci., Jacksonville, FL, ⁶Dept. of Neurology, Mayo Clinic, Rochester, MN, ⁷Dept. of Clinical Genomics, Mayo Clinic, Rochester, MN

Abstract Body:

Angelman syndrome (AS, MIM: 105830) is a rare neurodevelopmental disorder characterized by developmental delay or intellectual disability, speech impairment, gait ataxia, limb tremor, microcephaly, seizures, and a happy demeanor with frequent laughing, smiling, and excitability. AS is caused by alterations of the 15q11-13 chromosomal region with a subset caused by pathogenic variants within the paternally imprinted *UBE3A* (MIM: 601623, NM_130838.2) gene. Mechanisms of *UBE3A* variant pathogenesis include loss of the nuclear isoform or abnormal catalytic activity by the encoded E6-associated protein (E6AP) ubiquitin-protein ligase. We identified and functionally characterized novel *UBE3A* variants in 3 unrelated individuals with a neurodevelopmental disorder consistent with AS. Proband 1 has a maternally inherited c.91G>A; p.(Glu11Lys) variant which was not found in the maternal grandmother. Proband 1 is female with a history of an abnormal brain MRI, intractable epilepsy, absent speech, a hemiparetic gait disorder, and a happy demeanor. Proband 2 has a maternally inherited c.1772T>C; p.(Leu591Pro) variant occurring de novo in the mother. Proband 2 is male and has global developmental delay, language delay, abnormal gait with uplifted arms flexed at the elbow, frequent smiling, history of GI reflux, sleep disturbance, and a light complexion. Proband 3 has a de novo c.2360C>T; p.(Thr787Met) variant. Proband 3 is female with a clinical diagnosis of Landau-Kleffner syndrome with intractable seizures, development and speech delays, language regression, auditory agnosia, abnormal movement, sleep disturbance, and hyperactivity. Two additional entries for this variant have since been deposited in ClinVar as a VUS associated with AS. All variants are extremely rare in the population (gnomAD) and affect highly conserved residues. The p.(Glu11Lys) lies in the AZUL domain and the p.(Leu591Pro) and p.(Thr787Met) fall in the N-lobe and C-lobe, respectively, of the HECT domain. By expressing GFP-tagged wild-type or variant *UBE3A* in HEK293 cells, we demonstrate that p.(Glu11Lys) and p.(Leu591Pro) variants are associated with almost complete loss of nuclear localization and the p.(Thr787Met) variant with reduced nuclear localization. Using ligase-dead in comparison to ligase-active constructs we show p.(Glu11Lys) has no effect on protein stability, where p.(Leu591Pro) was unstable and p.(Thr787Met) had reduced protein with ligase-active construct only suggesting ligase hyperactivity. This study demonstrates the functional characterization of these novel *UBE3A* variants confirming they are disease causal.

Molecular Effects of Genetic Variation Posters - Thursday

PB2594. Functional characterization of polycystic ovary syndrome-associated risk loci identifies genetic regulatory regions

Authors:

L. Sankaranarayanan¹, G. Johnson¹, A. Barrera¹, A. Dunai², T. Reddy¹; ¹Duke Univ., Durham, NC, ²Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Polycystic ovary syndrome (PCOS) is a leading cause of infertility and type 2 diabetes and affects 10-15% of menstruating people worldwide. PCOS is characterized by increased circulating testosterone levels, ovulatory dysfunction and increased insulin resistance. Recent genome wide association studies (GWAS) have identified ~20 PCOS susceptibility loci in European and Han Chinese cohorts. The identified loci are implicated in neuroendocrine, reproductive, and metabolic function. The associated variants are predominantly non-coding. Rare non-coding variants in the *DENNDIA* locus have also been found in ~50% of families with PCOS by whole genome sequencing. Together, these associations suggest non-coding genetic contributions to PCOS.

We tested the hypothesis that PCOS-associated non-coding genetic variants contribute to PCOS pathogenesis by altering gene regulation. We first identified ~1400 functioning regulatory elements across the PCOS-associated loci using a high throughput reporter assay, STARR-seq, in a cell line model of testosterone production. Adding to evidence that the identified regulatory regions have function, ~60% of the identified regions are in previously documented open chromatin regions from DNase-seq and ATAC-seq studies.

To then investigate the effects of noncoding genetic variants in these regulatory regions, we tested for allele specific regulatory activity in a multi-ethnic pool of five genomes from healthy individuals. *DENNDIA* codes for a protein of the connectin family functioning as guanine nucleotide exchange factors for the GTPase Rab35. *DENNDIA* has also been identified as a regulator of androgen biosynthesis in ovarian cells. We identified 35 genetic variants that alter regulatory activity in the *DENNDIA* locus, including one that is ancestry specific. About half of the identified variants reside in previously documented open chromatin regions. Four of those genetic variants (rs12237685, rs28441318, rs10120705 and rs10117455) are also eQTLs for *DENNDIA* from the GTEx project and reside within open chromatin regions or annotated as ENCODE candidate cis-regulatory elements.

Taken together, these studies suggest a new mechanism for PCOS where rare and common genetic variants cause altered gene expression, including altered *DENNDIA* expression; and in which some of those variants may contribute in an ancestry-specific genetic risk for PCOS.

Molecular Effects of Genetic Variation Posters - Thursday

PB2595. Functional impact of rare variants and sex across the x chromosome and autosomes

Authors:

R. Ungar¹, T. Li², N. Ersaro¹, N. Gates Vetr¹, A. Battle³, S. Montgomery⁴; ¹Stanford, Stanford, CA, ²Johns Hopkins Sch. of Med., Baltimore, MD, ³Johns Hopkins Univ., Baltimore, MD, ⁴Stanford Univ., Stanford, CA

Abstract Body:

Sex differences are widespread in humans, 37% of genes are sex biased in at least one tissue across the autosomes and X-chromosome (Oliva et al. Science. 2020). Yet many studies fail to analyze sex as a biological variable, and the X-chromosome is largely ignored; 67% of genome-wide association studies exclude the X-chromosome (Wise et al. AJHG 2013). Furthermore, these studies typically consider only common variants excluding rare variants despite their abundance and potential for larger effect sizes. We have hypothesized that understanding how rare variants functionally operate on the X and in a sex-stratified manner across the X and autosomes can provide novel insight into the biological underpinnings of sex differences in complex traits and diseases.

We use the GTEx resource of population-scale, multi-tissue gene expression to extend analyses of rare variant associated gene expression outliers to identify effects present on the X or masked by sex. We identified 109 multi-tissue gene expression outliers on the X-chromosome. We further identified 27 multi-tissue outliers that were only detectable at $abs(Z) > 2.5$ in one of the sexes and masked in a joint sex analysis. Per individual, we observed approximately 0.20 outliers per individual on the X while autosomal chromosomes range from 0.09 to 0.66 outliers. Males averaged 0.05 more outliers on the X than females and were notably more enriched for outlier-associated rare variants compared to females on the X. Sex masking of outlier effects also highlighted specific genes. We identified an individual with a rare variant at a frequency of $1.5e-5$ in the gene ADGRD2 that has a z-score of 1.6 in a combined-sex distribution but a z-score of 3.1 when stratifying to a female-only distribution. ADGRD2 has been implicated to predict uterine corpus endometrial carcinoma survival (Lei et al. International Immunopharmacology 2022), and truncating mutations cause congenital bilateral absence of vas deferens (Patat et al. AJHG 2016). We leveraged both observed outlier status and genomic annotations to prioritize 124,325 rare variants on the X-chromosome using a Bayesian hierarchical model. When assessing sex-specific distribution of rare variant posteriors we found CD99L2, which reduces inflammatory response in mice knockouts (Rutledge et al. Experimental & Molecular Pathology 2015), showed higher splicing posteriors in females. Our study demonstrates that while rare variants are by definition difficult to individually study, providing detailed generalizations of effects in a sex-specific manner is an important step in understanding biological underpinnings of sex differences and their role in personalized genomics.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2596. Gene discovery and pathogenic mechanisms of disease in worms, flies, and fish: The Model Organisms Screening Center for the Undiagnosed Diseases Network

Authors:

M. Wangler¹, D. Baldrige², H. Bellen¹, A. Bowman², S. Pak², J. Postlethwait³, T. Schedl⁴, L. Solnica-Krezel², M. Westerfield³, S. Yamamoto⁵; ¹Baylor Coll. of Med., Houston, TX, ²Washington Univ. in St Louis, St Louis, MO, ³Univ. of Oregon, Eugene, OR, ⁴Washington Univ. Sch. of Med., St Louis, MO, ⁵Baylor Coll. of Med., HOUSTON, TX

Abstract Body:

Model organisms allow for functional studies of human genetic variants that are candidates for disease while also providing avenues to explore in depth pathogenic mechanisms. The Undiagnosed Diseases Network (UDN) has incorporated a Model Organisms Screening Center (MOSC), and for the past four years the MOSC has conducted studies on UDN cases in Phase II of the project. Undiagnosed human subjects undergo sequencing and variant interpretation in the UDN, and candidate variants are nominated for the MOSC for further evaluation. The MOSC human genetics team initially evaluates each variant using available gene- and variant-level human genetic data, after which, clinicians nominating the UDN cases interface with model organism investigators at monthly video conferences. Subsequently, variants are experimentally studied by experts in *C. elegans*, *Drosophila melanogaster* and Zebrafish. Over the course of Phase II, 243 variants in 173 genes from 158 human subjects have been nominated for MOSC studies. Laboratory based model organism studies in Worm, Fly and Fish have been or are being conducted for 26, 55 and 35 variants, respectively (48% of nominated variants in total). MOSC studies to date in Phase II have yielded data for 33 genes in favor of variant causality across all three organisms and for 24 genes no evidence for variant causality after thorough study. These studies also allow for in depth mechanistic studies; for example, *Drosophila* studies of a novel *MRTFB de novo* variant determine this gene's role in neurodevelopmental disease and actin binding. These MOSC studies have led to additional new disease gene discoveries from Phase II, including *CDK19*, *BICRA*, *TOMM70*, *RAB5B*, and *TNPO2*. This model organism work ultimately aids in diagnosing otherwise undiagnosed patients by providing support for pathogenicity of candidate disease-causing variants. In summary, the MOSC is a uniquely collaborative effort which brings clinicians seeing undiagnosed patients into collaboration with basic scientists in model system labs. In addition, model organism studies of newly uncovered rare disease provide opportunities to exploring molecular mechanisms and future therapeutic approaches.

Molecular Effects of Genetic Variation Posters - Thursday

PB2597. Gene expression profiling with direct long-read RNA sequencing uncovers functional variation affecting transcripts production.

Authors:

A. Real¹, C. Borel², N. M. R. Lykoskoufis¹, G. PugaYung^{1,3}, J. D. Seebach^{1,3}, A. Brown⁴, E. T. Dermitzakis¹, A. Viñuela⁵, A. Ramisch¹; ¹Univ. of Geneva, Geneva, Switzerland, ²Univ. of Geneva, Geneva 4, Switzerland, ³Univ. Hosp. Geneva (HUG), Geneva, Switzerland, ⁴Univ. of Dundee, Dundee, United Kingdom, ⁵Newcastle Univ., Newcastle, United Kingdom

Abstract Body:

Expression quantitative trait loci (eQTLs) studies have uncovered thousands of genetic effects acting on gene expression. However, the current short-read RNA-seq technologies do not characterize transcripts in their full-length form, leaving us incomplete information to understand the molecular regulatory mechanisms of eQTLs. In this study, we produced long-read native poly(A) RNA-seq data using the Oxford Nanopore Technologies (ONT) platform for 60 genetically different lymphoblastoid cell lines (LCLs) from the 1000 Genomes/Geuvadis project. We identified 11,154 protein-coding genes and lincRNAs expressed in at least 50% of the samples, for which we see a good agreement with published gene expression quantifications of the same samples based on Illumina short-read sequencing (pairwise sample correlation 0.61-0.79). We identified 48,539 transcripts using the FLAIR pipeline (Tang, 2020), of which 39% are already annotated based on GENCODE version 19. While 35% of these annotated transcripts were expressed in each of the 60 LCL samples, this was true only for 7% of unannotated ones. A genome-wide QTL analysis on the 14,447 annotated transcripts expressed in at least 50% of samples identified 72 transcript QTLs (trQTLs) (FDR 5%) of which 71 are novel compared to the published list of eQTLs from the larger Illumina dataset (317 samples). Based on the gene-level quantifications from our long-read data, we detected 45 eQTLs of which 12 were also trQTLs. We observed that eQTL genes had a significantly lower number of annotated transcripts than genes with trQTLs (Wilcoxon test p -value = $5.23e-05$), suggesting that genetic effects on genes with higher transcript diversity were missed using gene-level quantifications. Overall, we were able to identify new trQTLs with a small number of samples, whose effect on expression were missed when using short read technology. Hence, we could show that by using long-read data to analyze transcriptomes, we are one step closer to understand the key role of genetic variants on transcription abundance and structure, which might also improve the characterization of disease-associated variants.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2598. Gene prioritization for rare diseases integrating genotype, RNA-seq and phenotype - lessons from a CAGI 6 challenger team

Authors:

V. Yépez¹, C. Mertes², N. H. Smith³, I. F. Scheller¹, J. Gagneur¹; ¹Technical Univ. of Munich, Garching bei München, Germany, ²Technical Univ. of Munich, Garching, Germany, ³Technical Univ. of Munich, München, Germany

Abstract Body:

RNA sequencing has emerged as a complementary tool to DNA sequencing for rare disease diagnostics. However, gene prioritization methods integrating genotype, RNA-seq and phenotype have been lacking. To address this need, the SickKids Genome Clinic released a CAGI6 diagnostics challenge and provided nearly 80 genomes and RNA-seq samples [1] from children suffering from a rare genetic disorder. We developed a gene prioritization model integrating mono-allelic expression, gene expression [2] and splicing outliers [3] extracted through the workflow DROP [4] together with variant annotations and HPO-encoded phenotypes. For the samples without genetic data, we called the variants from the RNA-seq data using GATK. The model is a gradient boosting machine implemented using XGboost trained on a cohort of 209 mitochondrial disease patients [5] from which half are diagnosed. Our model prioritizes the causal gene first for almost half of the diagnosed cases, and among the top 5 in more than 70% of them. Application to the CAGI6 SickKids cohort revealed a known splice-disrupting pathogenic variant and reported several promising candidates. Our approach and publicly available software [6] can help find and prioritize candidate genes found by DNA and RNA sequencing and can be especially useful to reduce the burden of manual inspection in cohorts of hundreds of samples.

Molecular Effects of Genetic Variation Posters - Thursday

PB2599. Genetic control of mRNA splicing as a potential driver for incomplete penetrance of coding variants

Authors:

J. Einson¹, D. Glino², S. Castel², P. Mohammadi³, T. Lappalainen⁴; ¹Columbia Univ., New York, NY, ²New York Genome Ctr., New York, NY, ³Scripps Res., La Jolla, CA, ⁴KTH Royal Inst. of Technology & NY Genome Cntr, New York, NY

Abstract Body:

Alternative splicing is a fundamental molecular process that can be influenced by common genetic variants across individuals and populations. In this study, we propose a model where common splicing quantitative trait loci (ψ QTLs) affect the dosage of rare coding variants (cSNPs) in their target exons, which consequently reduces the cSNP's penetrance. We hypothesize that haplotype configurations undergo selective pressure against those that increase penetrance in the general population, and that this can be inferred from the perspective of purifying selection. This model may explain some instances of incomplete penetrance, and could ultimately help predict the clinical severity of carrying a putatively damaging variant. First, we calculated exon PSI scores from bulk RNA-seq data across 18 GTEx tissues. We found that PSI Z-scores were significantly different between exons carrying deleterious (N = 19,178) and non-deleterious (N = 49,575) rare variants (Mann-Whitney U-Test: $p = 2.577e-4$), with exons carrying deleterious rare variants spliced in less often, on average. To test if this result was potentially driven by regulatory variants, we cataloged ψ QTLs (N = 5,196 across 18 tissues), which use exon PSI as a molecular phenotype. We developed an enrichment test for haplotype combinations that takes into account ψ QTL allele frequencies. The test outputs " ϵ ", where the sign represents if high penetrance haplotypes are depleted or enriched in a dataset, and an associated p-value. We first applied our test to phased WGS data in GTEx V8, and observed a depletion of putative high-penetrance haplotypes ($\epsilon = -0.0156$, $p = 1.006e-6$). When splitting the data into groups based on synonymous vs. non-synonymous status of the cSNP, we did not observe a significant difference in depletion between for high-penetrance configurations. We next tested our model in donors from the Simons Simplex Collection (SSC), to investigate if high penetrance haplotypes are associated with autism spectrum disorder (ASD). Across ASD associated genes in probands, deleterious high-penetrance haplotypes were depleted ($\epsilon = -0.055$, B.P. $p = 0.046$). The result was similar in parents, but did not reach significance ($\epsilon = -0.028$, B.P. $p = 0.11$). This indicates that splicing modifiers may provide some protection in families with evidence of heritable autism risk variants. Overall, we have demonstrated a relationship between common splice-regulatory variants and rare pathogenic cSNPs, two typically separate areas of study.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2600*. Genetic determinants of blood transcript splicing and impact on molecular phenotypes in 4732 healthy individuals

Authors:

A. Tokolyi¹, E. Persyn², K. Burnham¹, A. Nath^{2,3}, J. Marten², INTERVAL Study, D. Roberts⁴, E. Di Angelantonio², J. Danesh², A. Butterworth², M. Inouye^{2,3}, D. Paul^{2,5}, E. Davenport¹; ¹Wellcome Sanger Inst., Hinxton, United Kingdom, ²Univ. of Cambridge, Cambridge, United Kingdom, ³Baker Heart and Diabetes Inst., Melbourne, Australia, ⁴Univ. of Oxford, Oxford, United Kingdom, ⁵AstraZeneca, Cambridge, United Kingdom

Abstract Body:

Untangling the pathways by which genetic variants modulate molecular phenotypes and disease risk requires comprehensive integrated analyses in large, deeply phenotyped cohorts of individuals. Splicing quantitative trait loci (sQTLs) are major contributors to complex traits, with a similar contribution as those affecting gene expression levels. However, the mechanisms that link these variants to downstream molecular and disease phenotypes through transcript splicing remain to be explored. INTERVAL is a deeply phenotyped cohort of healthy blood donors across England, including 4,732 individuals with matched genotypes and whole-blood RNA-seq, as well as proteomic, lipidomic, and metabolic measurements.

Here we utilize the split reads present in RNA-seq to describe the genetic architecture of splicing in whole blood, yielding 31,319 sQTLs (at FDR<0.05) across 8,799 genes. Comparing and colocalizing these sQTLs to expression QTLs (eQTLs) mapped in the same individuals reveals both commonalities and differences, with 9422 splice events (in 47.9% of tested genes) possessing a colocalizing eQTL. Splicing also appears to share genetic regulation with plasma protein QTLs (pQTLs), assayed by SOMAscan, with 544 splice events having genetic signals colocalizing with pQTLs (in 50.3% of 346 proteins) after conditional association analysis. These colocalizations demonstrate a genetic basis for known splicing differences impacting the plasma levels of proteins, such as the solubility of FAS, as well as revealing many other splicing events through which genetic variants may impact downstream plasma protein levels. Subsequent colocalization of sQTLs and pQTLs with COVID-19 HGI summary statistics recapitulates established associations of splicing and protein levels with disease risk in *OAS1*, as well as providing novel splicing associations in risk genes such as *IFNAR2* and *OAS3*.

This largest to-date splicing QTL catalog and associated preliminary analyses will be a useful resource for future study of the genetic architecture of transcript splicing and the subsequent impact on molecular phenotypes and disease risk.

Molecular Effects of Genetic Variation Posters - Thursday

PB2601. Genetic determination of fetal hemoglobin levels in patients with sickle cell disease

Authors:

O. Ojewunmi¹, T. Adeyemo^{2,3}, A. Oyetunji⁴, A. Akinrodoye⁴, H. Patel¹, H. Rooks¹, C. Grace⁵, A. Goel⁶, H. Ahmad⁷, O. Nnodu⁸, J. Strouboulis¹, S. Menzel¹; ¹King's Coll. London, London, United Kingdom, ²Univ. of Lagos, Lagos, Nigeria, ³Lagos Univ. Teaching Hosp., Lagos, Nigeria, ⁴Sickle Cell Fndn. Nigeria, Lagos, Nigeria, ⁵Oxford Univ., Oxford, Oxfordshire, United Kingdom, ⁶Univ Oxford, Oxford, Oxfordshire, United Kingdom, ⁷Ahmadu Bello Univ. Teaching Hosp., Zaria, Nigeria, ⁸Univ. of Abuja, Abuja, Nigeria

Abstract Body:

Sickle cell disease is an inherited blood disorder caused by a point mutation in the β -globin. It is a major cause of childhood disability and mortality in sub-Saharan Africa. A major modifier of sickle cell disease (SCD) is fetal hemoglobin (HbF). HbF ($\alpha_2\gamma_2$) is heritable and persistent HbF ameliorates the disease severity and improves survival. Previously, genetic polymorphisms in three loci, *BCL11A*, *HMIP*, and β -globin like cluster have been associated with high HbF in healthy persons and in individuals with SCD. Nigeria has the largest population of SCD patients world-wide, enabling the assembly of powerful study cohorts to discover new disease modifier loci.

In this study, we recruited 1,117 SCD patients (HbSS/HbS β^0) comprising three major ethnic groups in Nigeria to conduct the first genome-wide association study of HbF in Nigeria.

Our aim was to identify new loci and perform fine-mapping to discover causal variants in persons with SCD. Genotyping was performed using H3Africa Illumina chip array and imputation using 1000 Genomes Phase 5 version 3. Association with HbF was analyzed using a linear regression model assuming an additive allele effect (adjusting for age, sex, and population structure).

Our preliminary results of 379 patients confirmed *BCL11A* rs7606173 (EAF: effect allele frequency = 0.43, $\beta = -0.461$, $p = 7.19 \times 10^{-15}$) showing the strongest association with HbF. We also identified two novel *BCL11A* SNPs: rs62142644 (EAF = 0.35, $\beta = -0.429$, $p = 9.9 \times 10^{-14}$) and rs72962585 (EAF = 0.21, $\beta = -0.378$, $p = 2.43 \times 10^{-8}$). In addition, we found a novel locus on chromosome 9: rs13284968 (EAF = 0.25, $\beta = -0.345$, $p = 2.54 \times 10^{-8}$). Regional association plot revealed two credible SNPs (rs6706648 and rs62142644) in linkage disequilibrium with rs7606173 (R^2 : 0.911 and 0.738 respectively). Stepwise conditional regression analysis on rs7606173 indicated rs45595933 ($p = 1.07 \times 10^{-4}$) as an independent signal. A third conditional analysis using rs7606173 and rs45595933 identified rs1427407 ($p = 0.0024$). The HbF-boosting genotypes of rs7606173 (GG) and rs1427407 (TT) are always inherited together, but they have independent genetic effect on HbF levels. Providing further insight into the contribution of rs1427407 (T/G), rs7606173 (G/C), and rs45595933 (G/A) to the *BCL11A* HbF association signal, haplotype analysis showed that haplotype TGA was associated with the highest HbF ($\beta = 0.391$, 95%CI: 0.16 - 0.62, $p = 0.001$). Functional Genome-wide Complex Trait Analysis suggests functional role for rs7606173 as it is contained within enhancers characterized by histone modification patterns in HUDEP-2 cells. This region is enriched with sites for GATA-1, POLR2A, and TAL-1 binding.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2602. Genetic effects on chromatin accessibility and nucleosome positioning using snATAC data across 284 skeletal muscle biopsies

Authors:

X. Wang¹, C. C. Robertson^{1,2}, A. Varshney¹, N. Manickam¹, P. Orchard¹, M. Laakso^{3,4}, J. Tuomilehto⁵, T. A. Lakka³, K. L. Mohlke⁶, M. Boehnke¹, L. Scott¹, H. A. Koistinen⁵, F. Collins², S. C. J. Parker¹; ¹Univ. of Michigan, Ann Arbor, MI, ²NIH, Bethesda, MD, ³Univ of Eastern Finland, Kuopio, Finland, ⁴Kuopio Univ Hosp., Kuopio, Finland, ⁵Finnish Inst for Hlth.and Welfare, Helsinki, Finland, ⁶Univ North Carolina, Chapel Hill, NC

Abstract Body:

Insulin resistance in skeletal muscle is a central process contributing to type 2 diabetes (T2D) and related metabolic traits. Among 13 cell types we have identified in snRNA and snATAC data from skeletal muscle, type 1 muscle fiber is the most abundant. Studying genetic variants that affect chromatin accessibility and nucleosome positioning in type 1 muscle fiber can provide mechanistic insights at GWAS signals for T2D and related trait, and allow for causal inference of local chromatin dynamics (i.e. which transcription factors (TFs) causally position nucleosomes?). We profiled the chromatin landscape using snATAC of muscle from 284 individuals and focused our analyses on type 1 fibers. Using a hidden markov model (HMMRATAC), we inferred nucleosome free regions (NFR, N=44,763 peaks), which represent TF-occupied regions, and their adjacent nucleosomal chromatin regions (N=89,526 peaks, two per NFR), which represent nucleosomal phasing that may be induced by a primary TF-binding event. For each of the 284 samples, we used Multi-Otsu statistical thresholding on the observed ATAC-seq fragment length distribution to classify fragments as originating from NFR or nucleosomal regions. Using QTLtools, we performed a cis-QTL analysis (cis window of 100kb) on both chromatin accessibility (caQTL) and nucleosome positioning (nucQTL). We identified 10,203 caQTLs and 5,292 nucQTLs at 5% FDR. The same lead variant was shared across 968 caQTL and nucQTL signals. For 2,543 out of 5,292 (48%) nucQTLs, the lead variant was in strong linkage disequilibrium ($r^2 > 0.8$) with a caQTL lead variant. The remaining 2,749 (52%) nucQTLs may represent independent nucleosomal signals that would not be identified in a standard QTL scan with ATAC-seq data. We are now performing formal colocalization analyses of the overlapping caQTL and nucQTL signals and T2D and related trait GWAS signals, followed by Mendelian Randomization, to infer causal directional effects. Motif enrichment analyses may reveal specific TFs that causally affect nucleosome positioning. Overall, these analyses expand our understanding of regulatory mechanisms in skeletal muscle underlying T2D and related trait genetic risk.

Molecular Effects of Genetic Variation Posters - Thursday

PB2603. Genetic inactivation of zinc transporter SLC39A5 improves liver function and hyperglycemia in obesogenic settings

Authors:

S. Chim¹, K. Howell¹, J. Dronzek¹, W. Weizhen², C. Van Hout¹, M. Ferreira¹, B. Ye¹, A. Li¹, S. Brydges², V. Arunachalam¹, A. Marcketta¹, A. Locke¹, J. Bovijn¹, N. Verweij¹, T. De¹, L. Lotta¹, L. Mitnau¹, M. LeBlanc¹, Regeneron Genetics Center, GHS-RGC DiscovEHR Collaboration, D. Carey³, O. Melander⁴, A. Shuldiner¹, H. Nistala¹, K. Karalis¹, A. Economides¹; ¹Regeneron Genetics Ctr., Tarrytown, NY, ²Regeneron Pharmaceuticals, Tarrytown, NY, ³Geisinger Hlth.System, Danville, PA, ⁴Lund Univ., Malmo, Sweden

Abstract Body:

Recent studies have revealed a role for zinc in insulin secretion and glucose homeostasis. Randomized placebo-controlled zinc supplementation trials have demonstrated improved glycemic traits in patients with type II diabetes (T2D). Moreover, rare loss-of-function variants in the zinc efflux transporter *SLC30A8* reduce T2D risk. Despite this accumulated evidence, mechanistic understanding of how zinc influences systemic glucose homeostasis and consequently T2D risk remains unclear. We explored the relationship between zinc and metabolic traits by searching the exome database of the Regeneron Genetics Center-Geisinger Health System DiscovEHR cohort for genes that regulate zinc levels and associate with changes in metabolic traits. We previously reported that rare loss-of-function (LOF) variants (MAF<1%) in Solute Carrier Family 39, Member 5 (*SLC39A5*) associated with increased circulating zinc ($p=4.9 \times 10^{-4}$). Trans-ancestry meta-analysis across four studies exhibited nominal association of *SLC39A5* LOF variants with decreased T2D risk. To explore the mechanisms underlying these associations, we generated mice lacking *Slc39a5*. *Slc39a5*^{-/-} mice display improved liver function and reduced hyperglycemia when challenged with congenital or diet-induced obesity. Furthermore, our recent findings showed that under conditions of diet-induced non-alcoholic steatohepatitis (NASH), *Slc39a5*^{-/-} mice display significantly attenuated fibrosis and inflammation. We also show that *Slc39a5*^{-/-} mice, in addition to their elevated hepatic zinc levels, have activation of hepatic AMPK and AKT signaling, at least in part due to zinc mediated inhibition of hepatic protein phosphatase activity. Taken together, these results suggest SLC39A5 maybe considered as a potential therapeutic target for non-alcoholic fatty liver disease (NAFLD) and its associated metabolic derangements including T2D.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2604. Genetic regulation of OAS1 nonsense-mediated decay underlies association with COVID-19 hospitalization in patients of European and African ancestries

Authors:

Abstract Body:

COVID-19 is an infectious disease caused by the virus SARS-CoV-2 and, as in any other infectious disease, its clinical outcomes are determined by a complex interplay between host and pathogen factors. Heterogeneity in the clinical outcomes of COVID-19 strongly suggests the involvement of genetic factors in its pathogenesis. Genome-wide association studies (GWAS) have reported a series of genetic variants in distinct loci associated with COVID-19 susceptibility. One of these associated loci is the chr12q24.13, which harbors three genes encoding antiviral 2',5'-oligoadenylate synthetase (OAS) enzymes: OAS1, OAS2, and OAS3. While these associations were performed by comparing patients with COVID-19 and the general population, the interindividual variability in response to SARS-CoV-2 infection ranging from asymptomatic to fatal disease remains poorly understood. To address this critical gap, we have provided genetic, functional, and clinical insights into this locus in relation to COVID-19 severity. We analyzed patients of European (n=2249) and African (n=835) ancestries with hospitalized vs. non-hospitalized COVID-19. Patients were recruited by the COVNET Consortium. COVID-19 status was defined as non-hospitalized (mild), hospitalized moderate (not requiring mechanical ventilation), or hospitalized severe (mechanical ventilation or death due to COVID-19). In both ancestries, protection from hospitalized disease was consistently associated with one ancestral/introgressed Neandertal haplotype comprising several OAS1 markers. Since OAS1 is an interferon-induced antiviral protease, we further tested the haplotypes in a clinical trial with pegIFN- λ 1 and found that the OAS1 haplotypes were also associated with SARS-CoV-2 clearance. We then carried out in vitro functional studies of OAS1 with specific haplotypes and demonstrated that the combined effect of the associated splicing rs10774671 and missense rs1131454 markers increased OAS1 protein abundance through the regulation of splicing and nonsense-mediated decay. Our results suggest that the OAS1 expression is elevated in the presence of genetic variants or due to treatment with interferons, improving SARS-CoV-2 clearance and decreasing the risk of hospitalization for COVID-19 in patients of European and African ancestries.

PB2605. Genetic regulation of splicing in macular and peripheral retina reveals novel molecular mechanisms for age-related macular degeneration

Authors:

P. A. Mehta^{1,2,3}, J. M. Rouhana^{1,2,3}, A. R. Hamel^{1,2,3}, S. Mehrotra^{1,2,3}, J. Advani⁴, M. English⁴, D. A. Ferrington⁵, A. Swaroop⁴, A. V. Segrè^{1,2,3}; ¹Massachusetts Eye and Ear, Boston, MA, ²Harvard Med. Sch., Boston, MA, ³Broad Inst. of Harvard and MIT, Cambridge, MA, ⁴NIH (NIH), Natl. Eye Inst. (NEI), Bethesda, MD, ⁵Doheny Eye Inst., Univ. of California Los Angeles, Pasadena, CA

Abstract Body:

Alternative splicing of mRNA that increases diversity of the transcriptome and proteome is highly complex in the retina. The molecular mechanisms underlying 52 known genetic associations with age-related macular degeneration (AMD), a leading cause of central vision loss in the elderly, are not well understood. We hypothesized that genetic variants that alter splicing in the retina may also contribute to AMD risk. We therefore performed RNA-sequencing of 185 macular and 403 peripheral retina samples from postmortem healthy and AMD cases, and imputed the donor's genotype data to GTEx v8 whole genome sequencing variant calls. Following quality control, we used LeafCutter to detect and quantify splicing events based on reads spanning splice junctions. We identified 98,616 splice events for 12,720 genes with 76% overlap between macula and peripheral retina. About 25% of the splice events were specific to the retina compared to 49 GTEx tissues. We identified 34 splice events in 24 genes that were significantly altered between advanced AMD and healthy macula samples (Wilcoxon rank sum test $P=4E-05$). These genes were enriched in cytoskeletal protein binding and cell adhesion ($FDR<0.05$). Using FastQTL and a regression model that corrects for sex, age, AMD grade, top genotype principal components, and intron excision covariates (PEERs), we uncovered variants associated in *cis* (1Mb) with alternative splicing (splicing quantitative trait loci, sQTLs) for 1,390 and 2,850 genes in macula and peripheral retina, respectively ($FDR<5\%$); the sGenes showed enrichment of respiratory electron transport, photoreceptor outer segment, and phototransduction ($FDR<0.01$). The sQTLs were most significantly enriched in splice donor/acceptor sites, followed by missense, synonymous, and intron variants (TORUS). Using colocalization analysis (eCAVIAR) between retina sQTLs that overlapped any of the 34 AMD genome-wide association study (GWAS) loci, we detected significant colocalization for 6 loci, which included a *TBC1D23* sQTL and an sQTL acting on *BLOC1S1-RDH5* transcripts that we are experimentally inspecting. Analyzing AMD associations beyond genome-wide significance, we found that macular and peripheral sQTLs were enriched for AMD associations (QTLEnrich $P<1E-05$), to a larger extent than the retina eQTLs. Notably, the target genes of retina sQTLs with AMD GWAS $P<0.05$ were enriched for rare inherited retinal degeneration (IRD) genes ($P=8E-05$), suggesting a link between alternative splicing of Mendelian disease genes and AMD. Our study suggests that regulation of splicing may play an important role in AMD susceptibility and propose new therapeutic targets.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2606*. Genetically Decreased CPS1 Activity Attenuates Atherosclerosis in Humans and Mice Through Sexually Dimorphic Patterns

Authors:

J. Hilser¹, N. Woodward², P. Huang¹, J. Gukasyan³, Z. Fouladian¹, S. Charugundla⁴, A. Lusic⁵, L. Ma⁶, J. Bjorkegren⁶, Z. Wang⁷, W. Tang⁷, S. Hazen⁷, H. N. Hodis¹, W. Mack¹, J. Hartiala⁸, H. Allayee⁹; ¹Univ. of Southern California, Los Angeles, CA, ²Univ. of Southern California, Los Angeles, CA, ³USC, Van Nuys, CA, ⁴Univ. of California Los Angeles, Los Angeles, CA, ⁵UCLA, Los Angeles, CA, ⁶Mount Sinai Sch. of Med., New York, NY, ⁷Cleveland Clinic, Cleveland, OH, ⁸Univ of Southern California, Los Angeles, CA, ⁹USC Keck Sch. of Med., Los Angeles, CA

Abstract Body:

Background: We previously reported that a variant (rs715) of *CPS1*, the rate-limiting enzyme of the urea cycle, exhibited a female-specific pattern of association with lower urea cycle metabolite levels and decreased risk of coronary artery disease (CAD). In the present study, we sought to independently replicate these findings in multi-ancestry cohorts and genetically modified mice. **Results:** Consistent with prior observations, rs715 was significantly associated with decreased risk of CAD in women in the UK Biobank (OR=0.96, 95% CI 0.94-0.99; $p=4.2 \times 10^{-3}$) and Biobank Japan (OR=0.91, 95% CI 0.87-0.95; $p=3.0 \times 10^{-4}$). This association increased in significance when meta-analyzed together (OR=0.94, 95% CI 0.92-0.96; $p=8.3 \times 10^{-8}$) along with data from the CARDIoGRAM+C4D Consortium. A similar meta-analysis in men did not reveal association of rs715 with CAD (OR=0.99, 95% CI 0.98-1.01; $p=0.21$). A meta-analysis with several hormone or nutraceutical clinical trials in women also revealed cross-sectional association between rs715 and decreased carotid intima-media thickness ($\beta=-0.046$, SE=0.011 $p=1.6 \times 10^{-5}$). To complement these studies, we characterized heterozygous *Cps1* deficient (*Cps1*^{+/-}) mice, which exhibited the same pattern of metabolomics associations observed in humans. On a hyperlipidemic background, genetically decreased *Cps1* activity also significantly decreased aortic lesions in male mice compared to wildtype (WT) ($452,855 \pm 23,550$ vs $343,481 \pm 29,752 \mu\text{m}^2/\text{section}$; $p=0.009$). A similar male-specific pattern was observed when atherosclerosis was assessed along the entire aorta by *en face* analysis in WT and *Cps1*^{+/-} mice (6.4 ± 1.2 vs $2.3 \pm 0.6\%$; $p=0.01$). By comparison, *Cps1* deficiency had no effects on atherosclerotic plaque development in female mice. Gene expression analysis in humans revealed that women have ~20% lower hepatic *CPS1* expression compared to men (828 ± 385 vs 1024 ± 582 TPM; $p=4.6 \times 10^{-6}$) regardless of rs715 genotype whereas the opposite pattern is observed in WT mice with males exhibiting ~50% lower hepatic *Cps1* expression than WT females (0.73 ± 0.22 vs 1.3 ± 0.37 ru; $p=1.6 \times 10^{-4}$). Thus, human females and male mice have naturally lower *CPS1* expression, which taken together with our genetic and atherosclerosis analyses, provide an explanation for the opposite but sexually dimorphic pattern of associations observed in the two species. **Conclusions:** Our results provide further evidence for the causal and sex-specific relevance of *CPS1* to atherosclerosis in both humans and mice. Further studies will be needed to elucidate the biological mechanism for the atheroprotective effect of genetically decreased *CPS1* activity.

Molecular Effects of Genetic Variation Posters - Thursday

PB2607. Genome-First Approach to Explore Prevalence and Cancer Risk of Adults with Pathogenic and Likely Pathogenic Variants in RASopathy Genes

Authors:

E. Astiazaran Symonds¹, G. M. Ney¹, J. Kim¹, J. S. Haley², M. N. Frone¹, A. Pemov¹, M. E. Yohe³, A. M. Gross³, D. Collaboration², N. T. Strande², H. Rao², M. Shadrina⁴, D. J. Carey², B. D. Gelb^{4,5}, D. R. Stewart¹; ¹Clinical Genetics Branch, Div. of Cancer Epidemiology and Genetics, Natl. Cancer Inst., Rockville, MD, ²Geisinger Clinic, Danville, PA, ³Pediatric Oncology Branch, Ctr. for Cancer Res., Natl. Cancer Inst., Bethesda, MD, ⁴Dept.s of Pediatrics and Genetics and Genomic Sci., Icahn Sch. of Med., New York, NY, ⁵Mindich Child Hlth.and Dev. Inst., Icahn Sch. of Med., New York, NY

Abstract Body:

The RASopathies are a group of disorders with multisystemic manifestations, including tumor predisposition, arising from germline pathogenic/likely pathogenic variants (GPVs) in RAS-MAPK pathway genes. Estimations of prevalence and penetrance have been focused on pediatric populations and are limited by syndrome rarity and incomplete ascertainment. To address these limitations, a genome-first approach was used to analyze exome sequencing and phenotypic data from electronic health records (EHRs) from 1) Mount Sinai's BioMe (n=32,344), 2) the UK Biobank (UKB, n=200,600) and 3) Geisinger MyCode Community Health Initiative (n=175,499). We focused on 24 genes from the ClinGen RASopathy Gene Curation Expert Panel (EP) and applied the ClinGen RASopathy Variant Curation EP's methods to identify individuals with heterozygous (VAF>25%) GPVs. We retrieved ICD codes from EHRs for 1) RASopathies and 2) neoplasms. We identified 32 individuals with GPVs in BioMe (1:1,011), 112 in UKB (1:1,791) and 139 in MyCode (1:1,262). Overall, we found a prevalence of 1:1,745 for heterozygotes for GPVs associated with Noonan syndrome (NS), 1:12,762 for Legius syndrome (LS), 1:68,065 for cardiofaciocutaneous (CFC) syndrome and 1:40,839 for *LZTR1*-related schwannomatosis. The prevalence of GPVs for any RASopathy across all cohorts was 1:1,433. Subsequently, we performed analyses to estimate cancer risk in MyCode individuals with GPVs using phecodes, a strategy that groups different ICD codes into meaningful phenotypes. We saw significantly elevated relative risks (RRs) for acute and chronic myeloid leukemia (9.2, 95% CI 2.3-36.5 and 14.4, 95% CI 3.6-57.7), myeloproliferative disease (4.2, 95% CI 2.3-7.7) and brain cancer (3.4, 95% CI 1.6-7.5) in NS, for melanoma (12, 95% CI 3.5 to 41.4) in CFC, and for bone cancer (5.2, 95% CI=1.2-20) and reticulosarcoma (4.7, 95% CI 1.5-14.6) in *LZTR1* heterozygotes. When combining all individuals with GPVs in RASopathy genes, associations with testicular cancer (7.4, 95% CI 1.8-29.7), and cancer of nasal cavities (5.0, 95% CI=1.3-20.2) were uncovered. The ICD code that includes NS (Q87.19) was linked to only 4.6% of heterozygotes. This genome-first approach identified heterozygotes of RASopathy gene GPVs while mitigating ascertainment bias and providing more precise prevalence estimates. Additionally, we describe for the first time the spectrum of cancers in adult RASopathy gene heterozygotes, including new associations to confirm in larger studies. A substantial number of individuals identified had not been diagnosed with a RASopathy, suggesting the potential for improved and earlier detection and treatment using this approach.

PB2608. Genome-wide association study of serum metabolites and lipids in Multiple Sclerosis

Authors:

C. Yang¹, E. Marshall¹, N. Sadhu¹, F. B. Briggs², K. C. Fitzgerald³, H-H. Tsai¹, K. Trinh¹, H. Mclaughlin¹, C. Singh¹, R. Wei¹, D. Conway⁴, M. Comabella⁵, H. Wiendl⁶, E. M. Mowry³, P. Calabresi³, S. Belachew¹, S. John¹, C. Shen¹, H. Runz¹, A. Gafson¹, P. G. Bronson¹; ¹Biogen, Cambridge, MA, ²Case Western Reserve Univ., Cleveland, OH, ³Johns Hopkins Univ., Baltimore, MD, ⁴Cleveland Clinic, Cleveland, OH, ⁵Vall d'Hebron Univ. Hosp., Barcelona, Spain, ⁶Univ. of Münster, Münster, Germany

Abstract Body:

Introduction: Multiple sclerosis (MS), a neurodegenerative disease, affects millions worldwide. Dysregulation of cellular metabolism and abnormal metabolite levels have been reported in MS. An individual's metabolic phenotype is influenced by multiple levels of biologic interaction including genetics. Metabolite levels can serve as intermediate traits between genotype and disease phenotype. We aim to identify single nucleotide polymorphisms (SNPs) associated with metabolite levels (mQTLs), which may highlight causal pathways in MS.

Methods: MS PATHS (Partners Advancing Technology and Health Solutions) is a longitudinal study collecting clinical and MRI data in >20,000 persons with MS (pwMS). We profiled 663 metabolites (Biocrates platforms: MxP Quant 500, Eicosanoid, Oxysterol) in non-fasting serum from 863 MS PATHS participants of European ancestry (n = 863). Inclusion criteria: availability of serum and genetic data. Exclusion criteria: hypercholesterolemia, statin use. After stringent quality control, we integrated metabolomics with genetics to identify mQTLs. We tested 517 metabolites and 10.6 million SNPs with linear regression, including age, sex, and the top 10 principal components for ancestry. After Bonferroni correction for multiple testing ($5 \times 10^{-8}/517$), the significance threshold was $P < 9.7 \times 10^{-11}$. Colocalization analyses with MS risk, UK Biobank traits, methylation QTLs, and known mQTLs were conducted for our significant mQTLs.

Results: We identified 17 significant ($P < 9.7 \times 10^{-11}$) associations between SNPs and metabolites, of which five were novel: three triacyl glyceride metabolites [*FADS2*], ceramide [*BANF2*], and phosphatidylcholine [*MYRF*]. *MYRF* regulates differentiation of myelinating cells (oligodendrocytes). Three known mQTLs had evidence for shared causal variants (PP4>0.95). *CPS1* rs1047891*A (missense) and *SLC16A9* rs1171617*T (intronic) were associated with increased glycine and carnitine, respectively, as well as increased fat-free mass traits. *ASPG* rs2282377*G (intronic) was associated with increased asparagine and reduced methylation.

Conclusions: This is the first large-scale mQTL study in pwMS. We identified 17 significant mQTLs, of which five were novel, including an mQTL for phosphatidylcholine that mapped to *MYRF*. We replicated 12 mQTLs, including mQTLs for the amino acid neurotransmitters glycine and asparagine. Next steps include replicating our novel mQTLs, and testing whether loci for longitudinal MRI traits in MS share a causal variant with our mQTLs. Understanding genetic predictors of metabolite levels may provide biological insight into MS pathogenic mechanisms.

Molecular Effects of Genetic Variation Posters - Thursday

PB2609. Genome-wide characterization of selective constraint on variation within CTCF Binding Sites.

Authors:

C. Tubbs¹, M. Benton², E. McArthur¹, J. Capra³, D. Ruderfer⁴; ¹Vanderbilt Univ., Nashville, TN, ²Baylor Univ., Waco, TX, ³Univ. of California San Francisco, San Francisco, CA, ⁴Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract Body:

Background: CCCTC-binding factor (CTCF) binds DNA at tens of thousands of conserved sequence motifs. These CTCF Binding Sites (CBSs) facilitate gene expression by regulating 3D genome organization. Mutations in CBSs have clinical impact; their disruption has been linked to the etiologies of both rare and common disorders. However, we currently lack a comprehensive understanding of when and how CBS variation contributes to disease. We hypothesize that mutations that disrupt CBSs will be enriched for deleterious effects and carry signals of purifying selection. **Methods:** To test our hypothesis, we assessed the allele frequency (AF) of genetic variation at CBSs from 76k whole-genome sequenced samples representing diverse global ancestries. We defined CBSs by considering all genomic regions that have significant match to the 19 bp CTCF core binding motif (JASPAR, MA0139.1). To characterize the AF spectrum of variants at these sites, we queried the gnomAD database (v3.1.2) for all overlapping, mono allelic SNVs. Finally, we classified our CBSs by their genomic context and putative regulatory role in the genome by annotating whether they cluster, associate with insulatory boundary regions, overlap an ENCODE candidate cis-regulatory element, or act as a chromatin loop anchor. **Results:** We defined 767,259 CBSs that possess a significant ($p < 10^{-5}$) sequence match to the CTCF binding motif and 153,535 with functional support using the JASPAR and ENCODE databases. We identified 3.41M overlapping SNVs (mean AF=0.00363) in total and detected significantly lower AF (mean AF=0.00358, $p=2.62 * 10^{-11}$) for those that overlapped a CBS with a putative functional annotation. We further observed variants that overlapped chromatin loop anchors to be the most depleted of variation. We next hypothesized that a SNV's predicted impact on the binding affinity of a CBS would further modulate its frequency in the population. We stratified variants by their position in the CBS motif and calculated their impact on binding affinity by taking the difference in motif scores for the reference and alternate alleles. We observed lower AF (mean AF=0.00327, $p=5 * 10^{-3}$) for variants that significantly modify the binding motif compared to those that do not (mean AF=0.00381). **Conclusion:** Currently, we lack a framework for interpreting the effects of variants that disrupt CBSs. Here, we present an approach that integrates population genetic data with regulatory genome annotations to characterize the constraint on CBSs. This work represents an important first step in characterizing the contribution of CBS variation to human disease and will allow for future interpretation of their pathogenicity.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2610. Genome-wide microRNA expression quantitative trait loci from 596 adult brains

Authors:

S. Vattathil¹, S. Canon¹, A. Lori¹, E. S. Gerasimov¹, Y. Liu¹, D. A. Bennett², T. S. Wingo¹, A. P. Wingo^{1,3}; ¹Emory Univ., Atlanta, GA, ²Rush Univ. Med. Ctr., Chicago, IL, ³VA Atlanta Hlth.Care System, Decatur, GA

Abstract Body:

MicroRNAs (miRNAs) are essential post-transcriptional regulators that suppress gene expression by binding complementary mRNA sequences and causing either transcript degradation or translation repression. These non-coding RNAs are too small (~22 nucleotides) to be captured in RNA sequencing experiments targeting protein-coding transcripts, and while expression quantitative trait loci (eQTL) for protein-coding genes have been profiled across human tissues, to date there have been few large studies focusing on miRNA eQTLs (miR-QTLs). In this study, we aimed to map and characterize miR-QTLs in adult human brain tissue. Brain dorsolateral prefrontal cortex specimens were collected after autopsy of participants from the Religious Order Study (ROS) or the Rush Memory and Aging Project (MAP). Both studies are U.S.-based longitudinal community-based cohort studies of cognitive decline and aging. The 596 ROS/MAP participants included here were all of European ancestry and mean age at death was 90.3 years (standard deviation 6.2 years). MiRNA abundance was quantified using small-RNA sequencing, and genotypes were called from whole-genome sequencing or imputed from SNP array genotypes. We focused on common (minor allele frequency > 5%) single nucleotide polymorphisms (SNPs) within 500 Kb of miRNA genes. For each miRNA, we used linear regression to test for association between SNP genotype and miRNA abundance while controlling for the effect of age at death, sex, clinical diagnosis, post-mortem interval, RNA integrity number (RIN), sequencing batch, genetic principal components, and surrogate variables estimated from the miRNA data. We found miR-QTLs for 310 miRNAs (50% of 623 tested miRNAs) at false discovery rate < 1%. After LD-based clumping of SNPs for each miRNA (e.g. pruning SNPs with $R^2 > 0.5$ in 250 Kb windows), the results include 2,419 index miR-QTLs. Among these, 8 miR-QTLs are located within the corresponding miRNA gene, and another 938 miR-QTLs (~40% of index miR-QTLs) are located within 50 Kb of the gene. MiR-QTLs are enriched for SNPs that overlap brain promoters compared to non-miR-QTL SNPs (Mantel-Haenszel common odds ratio 1.44, p-value 5.6×10^{-9}), and a subset of miR-QTLs overlap promoters predicted to regulate the specific associated miRNA. To our knowledge, this is the first genome-wide adult brain miR-QTL study. This miR-QTL catalog complements existing and future miRNA analyses in other tissues, developmental stages, and cohorts, and the results may be integrated with transcriptomic, proteomic and phenotypic data to better understand the contribution of miRNAs to pathogenesis of brain illnesses.

Molecular Effects of Genetic Variation Posters - Thursday

PB2611*. Genome-wide pleiotropy study identifies association of *PDGFB* with Age-Related Macular Degeneration and COVID-19 infection outcomes.

Authors:

X. Sun¹, J. Chung², V. Vig¹, X. Han¹, G. O'Connor¹, X. Chen¹, M. DeAngelis³, M. Subramanian¹, L. Farrer⁴; ¹Boston Univ. Sch. of Med., Boston, MA, ²Boston Univ., Boston, MA, ³Jacobs Sch. of Med. and BioMed. Sci., Buffalo, NY, ⁴Boston Univ Sch Med, Boston, MA

Abstract Body:

Background Patients with age-related macular degeneration (AMD) have been shown to be at higher risk of infection and complications of COVID-19. We leverage large-scale data of genome-wide association studies (GWAS) for AMD and COVID-19 to assess the relationship between the two diseases and identify shared genetic susceptibilities between AMD and COVID-19. **Methods** We evaluated the genetic architecture shared between AMD (n = 33,976) and three COVID-19 outcomes (n ≥ 1,388,342) including critical illness, hospitalization, and infections by assessing genetic correlations and conducting a pleiotropy analysis of these two diseases using the previous GWAS summaries and Multi-Trait Analysis of GWAS (MTAG) software. The functional relevance of our most significant finding was examined by analyses of gene expression and DNA methylation quantitative trait locus (eQTL), transcriptome datasets for AMD and COVID-19, and Mendelian randomization (MR). **Results** A modest, but significant, genetic correlation of AMD was observed with COVID-19 infection ($r_G = 0.10$, $P = 0.02$). Our pleiotropy analysis for the two diseases identified one novel genome-wide significant ($P < 5 \times 10^{-8}$) association with several single nucleotide polymorphisms (SNPs) located 18.1kbp upstream of *PDGFB* (best SNP: rs130651; MTAG $P = 2.4 \times 10^{-8}$; AMD OR = 0.96, $P = 1.4 \times 10^{-7}$; COVID-19 OR = 0.90, $P = 0.02$). The rs130651 disease risk allele was significantly associated with increased *PDGFB* expression in multiple tissues (best eQTL, $P = 1.8 \times 10^{-11}$ in blood) and decreased DNA methylations in the *PDGFB* promoter region (best mQTL, cg11247378, $P = 9.74 \times 10^{-64}$). Moreover, *PDGFB* expression was higher in AMD cases than AMD controls ($p = 0.067$), as well as in the peak COVID-19 symptom stage (11-20 days after onset) compared to early/progressive stage (0-10 days) among COVID-19 patients over age 40 ($P = 0.03$). Our MR analysis found that the liability to AMD risk derived from the complement system dysfunction (OR [95% CI]; hospitalization = 1.02 [1.01- 1.03], infection = 1.02 [1.01-1.03]) and the increased levels of serum cytokine PDGF-BB (β [95% CI]; critical illness = 0.07 [0.02-0.11]) are significantly associated with the COVID-19 outcomes. **Conclusion** Our study demonstrated that AMD is associated with an increased risk of COVID-19 infection and *PDGFB* may be responsible for the severe clinical outcomes of COVID-19 among the AMD patients. Our findings may provide some insights about pathophysiology and potential interventions for these disorders.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2612. Genome-wide transcriptome correlation analysis identifies shared pathways between coronary heart disease and hematologic traits

Authors:

H. Abe¹, E. Gamazon²; ¹Vanderbilt Univ., NASHVILLE, TN, ²VUMC Clare Hall, Univ. of Cambridge, Nashville, TN

Abstract Body:

Recent studies have reported an increased risk of developing coronary heart disease (CHD) in patients who have undergone treatment for hematologic malignancies. Furthermore, clonal hematopoiesis of indeterminate potential (CHIP), a pre-malignant condition that results from clonal expansion of blood or immune cells, has been shown to increase risk of both coronary heart disease (CHD) and hematologic malignancies. Nevertheless, our understanding of the underlying biology and of the specific genes involved in the shared etiology of CHD and hematologic traits remains limited. Evaluation of gene expression regulation may identify novel genes and pathways that can serve as targets for therapeutic application and functional analysis.

Here, we curated genome-wide association summary statistics from large cohorts such as the UK Biobank and examined the shared genetics between CHD (N= 32926), 8 hematologic malignancies (N range= from 209 to 2279) and 23 blood cell traits(N= 427154). We apply PrediXcan/TWAS, which estimates the genetically regulated expression (GReX) of a gene and tests its association with traits. Specifically, we use the recently developed joint-tissue imputation (JTI) models that leverage tissue similarity of gene expression and the regulatory information from reference functional genomic resources such as GTEx and Roadmap to estimate GReX. Using the zscore estimates from this method, we calculated the correlation of the genetically regulated effect spanning 1800 biological pathways. This allows us to examine the extent to which pathways associated with hematologic traits have similar effects on CHD. Our results identified pathways, including the MAP kinase activation and mTORC1 mediated signaling, as strongly correlated between CHD and hematologic malignancies at the level of GReX. Moreover, we observed inflammation, cell division, DNA replication, as well as mitochondrial fatty acid oxidation, as the top shared pathways across the blood cellular traits. Our results highlight potentially causal molecular mechanisms and genes whose phenotypic effect on disease classes is mediated mainly through gene expression. The approach we present has broad implications for the search for genetic relationships between other cardiovascular and hematologic traits.

Molecular Effects of Genetic Variation Posters - Thursday

PB2613. Genomic characterization of the immunoglobulin light chain lambda locus from individuals of European, Asian and African origin.

Authors:

Abstract Body:

The adaptive immune system relies on a diverse set of over one hundred immunoglobulin (IG) genes across three genomic loci that are variably combined to form antibodies (Ab). Studies show that the IG loci are highly variable between individuals and populations. However, the complexity of the IG loci severely limits the effective use of standard short read sequencing, limiting our knowledge of population diversity in these loci. We leveraged existing long read whole-genome sequencing (WGS) data, fosmid technology, and targeted long-fragment DNA capture (IG-cap) combined with single molecule, real time (SMRT) long read sequencing (Pacific Biosciences) to create haplotype-resolved assemblies of the IG Lambda (IGL) locus from 6 ethnically diverse individuals. In addition, we generated 10 diploid assemblies of IGL utilizing IG-cap combined with SMRT sequencing from a diverse cohort of individuals. These data represent highly accurate base-level assemblies of the IGL region. From these 16 individuals, we identified significant allelic diversity, including 37 novel IGLV alleles. In addition, we observed highly elevated single nucleotide variation (SNV) in IGLV genes relative to average IGL intergenic and genomic background SNV density. By comparing SNV calls between our high quality assemblies and existing short read datasets from the same individuals, we show a high propensity for false-positives in the short read datasets. Finally, for the first time we haplotype-resolved, at nucleotide resolution, common 5-10 Kb duplications in the IGL constant region that contain functional IGLJ and IGLC genes. Together these data represent a significant advancement in our understanding of genetic variation and population diversity in the IGL locus.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2614*. Glucocorticoids unmask silent non-coding genetic risk variants for common diseases.

Authors:

T. Nguyen, H. Gao, D. Liu, Z. Ye, J-H. Lee, G. Shi, K. Copenhaver, L. Zhang, L. Wei, J. Yu, Z. Cheng, H. Li, L. Wang, T. Ordog, R. Weinshilboum; Mayo Clinic, Rochester, MN

Abstract Body:

Most disease-associated sequence variants are non-coding, and understanding their function remains a major challenge for biology. Many diseases are the result of complex gene-by-environment interactions, increasing the difficulty in understanding mechanistic function of variants. Using the glucocorticoid signaling system, we discovered and exhaustively characterized environment-responsive genetic variants. We first identified 134 glucocorticoid receptor (GR)-mediated expression quantitative trait loci (eQTL) across 30 human B-lymphoblastoid cell lines (LCLs) with exposure to a GR agonist and antagonist. Using machine learning-based chromatin modeling to integrate 16 LCL epigenomic datasets, we predicted that three-quarters of the GR-modulated SNPs mapped to enhancers, half of which with promoter-looping properties. This observation fits with current knowledge of GR being primarily an enhancer mediator.

Based on these predictions, we utilized a massively parallel reporter assay to directly test variant x stimulus interactions by determining transcriptional activities of all GR-mediated loci across different drug treatments and cell lines. Up to 81% of the loci displayed allele-specific transcriptional activity in response to drugs, with high consistency across two tested cell lines. To understand the regulatory architecture of these variants, we performed H3K27ac HiChIP before and after GR activation. We observed that in 75% of SNP-gene pairs in active enhancers, GR either induced the connections between SNP-gene pairs, or mediated transcription of already established loops.

Lastly, we investigated disease risk SNP mechanisms overlapping with GR-mediated eQTLs, identifying 30 associations with GR-related diseases across autoimmunity, metabolism, mood disorders, osteoporosis and cancer. Without “unmasking” of variant function after glucocorticoid exposure, the causal variants and their target genes would have been overlooked. For example, SNPs previously associated with obesity mediated cortisol-responsive expression of *FBXL19*, an adipogenesis-controlling gene, and *HSD3B7*, a cholesterol metabolizing enzyme. We validated a GR-mediated eQTL for breast cancer with GR-targeted ChIP-seq, RNA-seq and H3K27ac HiChIP in breast cancer cell line and observed similar interaction between the risk SNP and the novel risk gene *MAST4* identified originally in LCLs. Furthermore, *MAST4* expression was dramatically repressed in breast cancer tissue and predictive of treatment outcome. Together, these results provide a mechanistic framework for understanding the function of non-coding genetic variants across environments.

PB2615*. Hematopoietic Loss of Y Chromosome Leads to Cardiac Fibrosis and Heart Failure Mortality

Authors:

L. Forsberg¹, S. Sano², K. Horitani², H. Ogawa², J. Halvardson¹, N. Chavkin², J. Mattisson¹, M. Danielsson¹, A. Zaghlool¹, K. Walsh²; ¹Uppsala Univ., Uppsala, Sweden, ²Univ. of Virginia Sch. of Med., Charlottesville, VA

Abstract Body:

Mosaic loss of chromosome Y (mLOY) in blood is the most common acquired human mutation and detectable in more than 10% of blood leukocytes in at least 5%, 20% and 40% of 50, 60 and 70 year old men, respectively. Remarkably, mLOY is associated with a diverse and growing list of diseases, notably many forms of hematological and non-hematological cancers, Alzheimer's disease, cardiovascular events, autoimmune conditions, age-related macular degeneration and type 2 diabetes. While associated with the most common causes of death in general populations; men with mLOY display increased mortality in prospective analyses. As a common and male specific somatic mutation, mLOY helps explain why men in the entire world live shorter lives compared with women. Beyond the risk factor of age itself, genomewide association studies (GWAS) identifies germline risk loci located near genes involved in cell-cycle regulation and genome instability. A polygenic score suggest that individuals with high genetic risk could be up to five times more likely to be affected during aging. Furthermore, mLOY often co-occur with point mutations associated with clonal hematopoiesis of indeterminate potential (CHIP). A number of preventable risk factors for mLOY such as smoking, air pollution and other environmental exposures has also been described. Despite recent attention, the causal relationship between mLOY in leukocytes and disease manifesting in other organs have been largely unknown. Using mouse models reconstituted with bone marrow cells lacking the Y chromosome by CRIPR-Cas9 editing, we here describe a causal link between hematopoietic mLOY and age-dependent cardiac dysfunction. We found that Y chromosome-deficient cardiac macrophages over-activate a profibrotic signaling network, leading to cardiac fibroblast proliferation and activation, excessive matrix production, and diminished heart function. We also found that a neutralizing TGF β antibody reversed the pathological cardiac phenotypes caused by mLOY in the mouse model. Consistent with this, survival analyses of men in the UK Biobank showed that mLOY in leukocytes at study entry is associated with risk for death caused by cardiovascular disease overall during follow up; an association mainly driven by heart failure, hypertensive heart disease and aortic aneurysm. Tissue fibrosis is a hallmark of aging and estimated to contribute to 45% of deaths in industrialized countries. In view of recent efforts to treat heart failure, idiopathic pulmonary fibrosis, and some cancers with antifibrotic approaches, men with mLOY could represent a patient subpopulation that exhibits a superior response to this class of therapeutic agents.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2616. Human genetic variation reveals regulators of *Yersinia pestis* cellular Infection.

Authors:

R. Keener, L. Wang, D. Ko; Duke Univ., Durham, NC

Abstract Body:

Yersinia (Y.) pestis is the gram-negative pathogenic bacterium responsible for the deadliest pandemic in recorded human history, the Black Death. This pathogen causes such catastrophic pandemics because of its variable 30-100% mortality rate in infected humans when antibiotic intervention is unavailable. Factors like time to treatment and nutrition can cause some of this variation but, like other infectious diseases, we hypothesize host genetic variation also plays a role. These genetic differences can normally be identified by human challenge studies or genome-wide association studies (GWAS) of natural infection. Both quantify disease symptoms, physiology, and outcomes then compare these phenotypes to the genetics of the individual. Unfortunately, using these techniques for *Y. pestis* is difficult: high lethality makes human challenges unethical, and the infrequency of present-day *Y. pestis* outbreaks coupled with non-random population exposure make GWAS too underpowered and confounded. To overcome these hurdles, we developed a genetically diverse cellular GWAS approach. This method, called Hi-HOST (high-throughput human *in vitro* susceptibility testing), is unhindered by pre-existing conditions, medical care access, diet, or other environmental and life history confounders found in traditional human disease related GWAS. Additionally, Hi-HOST previously identified variation in *VAC14* and *ARHGEF26* loci that modulate *Salmonella* infection. For *Y. pestis* Hi-HOST, we infected LCLs (lymphoblastoid cell lines; immortalized B cells) from 978 genetically distinct individuals in eight global populations with GFP-tagged *Y. pestis*. Using flow cytometry, we measured percent infection (proportion of cells that are GFP+) as well as bacterial burden (median fluorescence of GFP+ cells). Each phenotype was tested for association with approximately 15 million single nucleotide polymorphisms (SNPs), using family-based association to control for population stratification while also allowing for heritability estimates. This uncovered a genome-wide significant hit ($p = 3 \times 10^{-9}$) in the intracellular survival phenotype. We hypothesize the gene containing this SNP helps modulate the intracellular niche of *Y. pestis*. Additionally, stratifying for likely functional variants revealed a nonsynonymous SNP associated with 24-hour percent infection with greater significance ($p=3.5 \times 10^{-07}$) than expected based on the neutral distribution. Experimental follow-up studies suggest the protein product of this gene acts as a previously unrecognized receptor for *Y. pestis* in lymphoid lineage cells, regulating *Y. pestis* attachment and uptake.

PB2617. Human pancreatic islet microRNAs implicated in diabetes and related traits by large-scale genetic analysis

Authors:

H. Taylor^{1,2}, Y-H. Hung³, N. Narisu¹, M. Erdos¹, M. Kanke³, T. Yan¹, C. Grenko¹, A. Swift¹, L. Bonnycastle¹, P. Sethupathy³, F. Collins¹, D. Taylor¹; ¹Ctr. for Precision Hlth.Res., Natl. Human Genome Res. Inst., NIH, Bethesda, MD, ²Cardiovascular Epidemiology Unit, Dept. of Publ. Hlth.and Primary Care, Univ. of Cambridge, Cambridge, United Kingdom, ³Dept. of BioMed. Sci., Coll. of Vet. Med., Cornell Univ., Ithaca, NY

Abstract Body:

Genetic studies have identified ≥ 240 loci associated with risk of type 2 diabetes (T2D), yet most of these loci lie in non-coding regions, masking the underlying molecular mechanisms. Recent studies investigating mRNA expression in human pancreatic islets have yielded important insights into the molecular drivers of normal islet function and T2D pathophysiology. However, similar studies investigating microRNA (miRNA) expression remain limited. Here, we present data from 63 individuals, representing the largest sequencing-based analysis of miRNA expression in human islets to date. We characterize the genetic regulation of miRNA expression by decomposing the expression of highly heritable miRNAs into *cis*- and *trans*-acting genetic components and mapping *cis*-acting loci associated with miRNA expression (miRNA-eQTLs). We find (i) 81 heritable miRNAs, primarily regulated by *trans*-acting genetic effects, and (ii) 5 miRNA-eQTLs. We also use several different strategies to identify T2D-associated miRNAs. First, we colocalize miRNA-eQTLs with genetic loci associated with T2D and multiple glycemic traits, identifying one miRNA, miR-1908, that shares genetic signals for blood glucose and glycated hemoglobin (HbA1c). Next, we intersect miRNA seed regions and predicted target sites with credible set SNPs associated with T2D and glycemic traits and find 32 miRNAs that may have altered binding and function due to disrupted seed regions. Finally, we perform differential expression analysis and identify 13 miRNAs associated with T2D status—including miR-187-3p, miR-21-5p, miR-668, and miR-199b-5p—and 4 miRNAs associated with a polygenic score for HbA1c levels—miR-216a, miR-25, miR-30a-3p, and miR-30a-5p.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2618. Hypotonia due to homozygous mutation of *NALCN*

Authors:

O. Ope^{1,2}; ¹St. George Univ. Sch. of Med., Detroit, MI, ²Ascension St. John Hosp., Detroit, MI

Abstract Body:

NALCN encodes a sodium ion leak channel expressed in the nervous system. As a leak channel, it conducts a persistent influx of sodium ions to facilitate formation of action potentials. Homozygous or compound heterozygous loss of function variants in *NALCN* cause infantile hypotonia with psychomotor retardation and characteristic facies-1 (IHPRF1; OMIM 615419). Through exome sequencing, we identified homozygous *NALCN* p.Arg735Ter pathogenic variants in two siblings of Afro-Caribbean ancestry. Both individuals had failure to thrive, severe hypotonia, and dolichocephaly. Diagnosis was obtained as a result of a successful international collaboration originating from a resource limited setting on a small Caribbean island. Due to its geographical isolation and low socioeconomic status, the island lacks many specialty medical services, including clinical genetics. As with many rare syndromes, individuals of Afro-Caribbean ancestry with *NALCN* variants are rarely reported in the medical literature. This is an especially important genetic diagnosis, as it is associated with sudden cardiac death, and the older sibling in this family died suddenly without a known etiology after evaluation but before molecular diagnosis.

Molecular Effects of Genetic Variation Posters - Thursday

PB2619. Identification of bidirectional regulatory regions for *FADS1* and *FADS2*

Authors:

S. Yang, H. Zhang, K. Ye; Univ. of Georgia, Athens, GA

Abstract Body:

The *FADS1* and *FADS2* genes encode two rate-limiting enzymes in the biosynthesis process of long-chain polyunsaturated fatty acids (LC-PUFAs). These two genes are located adjacent to each other in a head-to-head orientation, resulting in a potential shared regulatory region between them. However, whether and how the shared region affects their expression is still largely unknown. Using GTEx data, many eQTLs in this region were found to be associated in opposite directions with *FADS1* and *FADS2* expression. By integrating ChIP-seq data in HepG2 cell lines from ENCODE, we revealed that two causal variants for *FADS* expression, rs174557 and rs968567, both lie in binding sites for transcription factor SP1 and SREBP1c. Our reporter assay showed that overexpression of SP1 and SREBP1c enhances promoter or enhancer activities of the shared regulatory regions. We will apply CRISPRi approach to interfere their binding sites in these regions to investigate the potential competition on transcription factors between *FADS1* and *FADS2*. In addition, by analyzing genotypes of rs174557 and rs968567 in 5005 individuals across multiple human populations, we found that A allele of rs174557 and T allele of rs968567 do not appear together; the two alleles increase the transcription of *FADS1* and *FADS2*, respectively. To examine if the combinations of alleles at these two SNPs are sufficient to explain the bidirectional regulation on *FADS1* and *FADS2*, we will apply prime editing in HepG2 cell lines. Taken together, findings from this study will enhance our understanding of *FADS* expressions and facilitate the development of genome-informed LC-PUFAs supplementation for preventing associated complex diseases.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2620. Identification of polyadenylation signals relevant to Mendelian disease variant interpretation.

Authors:

H. Shiferaw¹, C. Hong², J. Johnston³, L. Biesecker⁴; ¹NIH, Bethesda, MD, ²Natl. Inst.S OF HEALTH, BETHESDA, MD, ³NIH, Rockville, MD, ⁴NIH NHGRI, Bethesda, MD

Abstract Body:

Polyadenylation is essential in maintaining nascent mRNA stability. Variants in polyadenylation signal hexamers (PASH) can result in reduced polyadenylation at associated polyA sites and lead to altered gene expression. Only 31 PASH variants in 22 genes have been associated with Mendelian disorders. Of the 22 genes, 14 genes have at least one PASH variant listed as disease causing ('DM') in HGMD. We hypothesize that this is an under-representation of this class of variant. Here, we aimed to identify clinically important PASH by examining the usage of polyA sites and the traits of associated PASH. Polyadenylated 3' UTRs from EST data were collected from the PolyA Site 2.0 database, re-annotated, and examined for predominant polyA site usage activity (defined by >50% of overall EST representation). Associated PASH were selected based on the relative location to the predominant polyA site and the strength of the hexamer motif. We identified 15,212 predominant PASH for further examination. To understand constraint in the identified predominant PASH, we compared the frequency of variants in the predominant PASH vs. control sequences by examining variants in gnomAD. The predominant PASH were significantly more constrained than control sequences ($p < 0.001$, Mann-Whitney U test). Additionally, distribution of deleteriousness scores from *in-silico* predictors (FATHMM-MKL and CADD) for potential variants in predominant PASH were predicted to be more deleterious than potential variants in control sequences ($p < 0.001$, Mann-Whitney U test). To understand the effects of variants occurring in PASH, RNA sequencing and 3' end sequencing was performed on 76 ClinSeq[®] individuals with variants in these hexamers. Twenty-five of 64 genes with predominant PASH variants showed alternative polyadenylation, which suggests that variants in predominant PASH may lead to altered gene function. Toward pathogenicity classification of PASH variants, 30 PASH variants identified in HGMD were annotated for evidence that supports pathogenicity according to ACMG/AMP criteria adapted for polyadenylation variants. Sixteen variants had sufficient evidence to support a classification of pathogenic or likely pathogenic. We suggest that classification of PASH variants as pathogenic or likely pathogenic is limited by patient data and could be aided by *in vitro* functional studies not typically pursued for PASH variants. These data reinforce that PASH sequences are critical in polyadenylation and that variants in these sequences should be considered and assessed as candidates for pathogenic, disease-associated variation.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2622. Identification of susceptibility loci for frailty through a genome-wide scans and genetic association study of aging-related variants in Korean population

Authors:

Y. Kwak¹, S. Yang², M. Yuk¹, J. Lee¹, J. Youn², N. Song²; ¹Coll. of Pharmacy, Chungbuk Natl. Univ., Cheongju-si, Korea, Republic of, ²Coll. of Pharmacy, Chungbuk Natl. Univ., Cheongju, Korea, Republic of

Abstract Body:

BACKGROUND: Although frailty occurs with chronological aging with a state of increased physiologic vulnerability for adverse health outcomes, the genetic mechanisms underlying frailty were not understood. Genome-wide association studies (GWAS) have identified approximately 1,300 single-nucleotide polymorphisms (SNPs) for aging but their involvement in frailty has not been evaluated and GWAS of frailty has not identified the susceptibility SNPs with a nominal genome-wide significance. Thus, we performed GWAS to identify SNP of frailty and evaluated whether GWAS-identified aging susceptibility SNPs are associated with frailty in Korean population. **METHODS:** Among 8,840 study participants from the Korean Genome and Epidemiology Study (KoGES)_Ansan and Ansung study with genome-wide SNP data, 1,690 participants with frailty data which was defined as the short-physical performance battery (SPPB) score were selected. The 344,928 and 459,909 SNPs, genotyped by Affymetrix 5.0 and Korean Biobank Array (K-CHIP), were analyzed in GWAS, respectively. GWAS was performed to identify novel SNPs associated with frailty using multivariable logistic regression model after adjustment for age, sex, and history of diabetes and hyperlipidemia. The 283 previous GWAS-identified aging susceptibility SNPs ($P \leq 5 \times 10^{-8}$) were selected to evaluate the association with frailty. **RESULTS:** Among 1,690 study participants (age, years: mean=70.08, sd=6.14), frailty was observed in 89 (5.27%) participants. In the current GWAS, the most significantly associated SNPs with the frailty ($P < 1 \times 10^{-5}$) were rs10119203 (TTLL11, OR=3.88, 95% CI=2.17-6.94, $P=4.83 \times 10^{-6}$), rs17075127 (LOC107986479, OR=4.34, 95% CI=2.31-8.16, $P=5.13 \times 10^{-6}$), rs12532855 (HECW1, OR=10.36, 95% CI=3.77-28.47, $P=5.73 \times 10^{-6}$), rs6558938 (CSMD1, OR=5.68, 95% CI=2.64-12.22, $P=8.65 \times 10^{-6}$), rs117280191 (RBFOX1, OR=9.87, 95% CI=3.59-27.17, $P=9.39 \times 10^{-6}$), and rs16977369 (SLC39A11, OR=5.86, 95% CI=2.75-12.66, $P=6.60 \times 10^{-6}$). Among the 283 GWAS-identified aging susceptibility SNPs, 14 SNPs (rs1008084, rs1159806, rs2069837, rs2075650, rs2736100, rs3959554, rs4420638, rs4838595, rs6224, rs72738736, rs7412, rs7705526, rs8089807, and rs9386796) were associated with frailty ($P < 0.05$). **CONCLUSION:** Although the current study results did not satisfy the nominal genome-wide significance threshold ($P < 5 \times 10^{-8}$), we identified novel and strong genetic susceptibility loci associated with the frailty in Korea population. Furthermore, we found that 14 GWAS-identified aging susceptibility SNPs were also associated with frailty suggesting that aging and frailty may have shared biological mechanisms.

Molecular Effects of Genetic Variation Posters - Thursday

PB2623. Identifying context-specific genetically regulated expression changes in monocytes associated with resilience to Alzheimer's Disease

Authors:

Y. Mustafa¹, W. Bush², A. Naj³, J. Below⁴, T. Hohman⁵, L. Dumitrescu⁶; ¹Case Western Reserve Univ., Cleveland, OH, ²Case Western Reserve Univ, Cleveland, OH, ³Univ. of Pennsylvania, Philadelphia, PA, ⁴Vanderbilt Univ Med Ctr., Nashville, TN, ⁵Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract Body:

Alzheimer's Disease (AD) is a complex, multifactorial disease and remains the most common form of dementia worldwide. Previous AD genetic research, particularly genome-wide association studies (GWAS), have focused on the identification of genetic risk variants; however, the effect of each variant is small and biologically difficult to interpret. Transcriptome-wide association studies (TWAS) aggregate genetic variants in a gene-based association approach, capturing greater variation and generating concrete mechanistic hypotheses bridging the association. We conducted a TWAS of circulating monocytes to test the hypothesis that variation in genetically regulated gene expression (GR_{EX}) alters their function and response during inflammation, leading to differences in AD pathogenesis. Monocyte genetic data (Fairfax et al, 2014) imputed against the Haplotype Reference Consortium (HRC r1.1) on the Michigan Imputation Server, and corresponding expression data of monocytes in a naïve state, 12 and 24 hours after LPS stimulation, and 24 hours after stimulation with IFN- γ from ArrayExpress served as our reference. We trained elastic-net regression models of GR_{EX} on the basis of the surrounding *cis*-regulatory SNP profile for all genes. We then imputed GR_{EX} levels of 5108 individuals from an AD resilience GWAS (Dumitrescu et al, 2020) based on summary statistics, and tested for association between GR_{EX} and AD using the MetaXcan software suite. The results of the *cis*-eQTL analysis showed concordance between our results and those of the Fairfax group, including variants with a context-specific direction of effect—illustrating the importance of studying these cells in an appropriate environment. The TWAS analysis revealed three genes with GR_{EX} significantly associated with cognitive and global resilience to AD symptoms: *CRISPLD2*, *NETO2*, and *DHRS9*, in IFN- γ , LPS-24h, and LPS-2h, respectively. We contribute evidence of potentially novel genetic associations between components of the innate immune system and AD in a time-, cell-, and context-specific manner. Further, we expand the available tissues and cell types for TWAS of AD by generating reference panels that account for the dynamic biology of monocytes in different states. These panels enable analyses that may have importance for Alzheimer's Disease, cancer, autoimmune conditions and more; moreover, they may provide concrete biological hypotheses as to how genetic variation can influence these complex phenotypes through monocyte activity.

Sci., The Univ. of Yaoundé I, Yaoundé, Cameroon, ⁸Dept. of Biology, Addis Ababa Univ., Addis Ababa, Ethiopia, ⁹Ctr. for Global Genomics and Hlth.Equity, Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

African populations have high levels of genomic and phenotypic diversity. To increase our knowledge of African genomic diversity, we analyzed a novel high coverage whole genome sequencing dataset consisting of 180 individuals from 12 indigenous African populations and identified more than 30 million SNPs. We identified candidate loci that may be targets of local adaptation to diverse environments by using a population differentiation-based analysis (Di) to identify alleles showing highly differentiated frequencies between populations. We selected the top 0.1% of SNPs based on Di values (Di-SNPs) and studied genomic functional enrichment of nearby genes using GREAT (genomic regions enrichment of annotations tool). Interestingly, we observed an enrichment of SNPs near genes involved in heart development in the Hadza hunter-gatherers from Tanzania, possibly due to local adaptation. We observed that 9,325 (99.5%) of the 9,370 total Hadza Di-SNPs locate in non-coding regions, only 45 (0.5%) locate in coding regions, and no nonsynonymous variants are found in heart-related genes. To find putative regulatory variants associated with heart function, we overlapped Hadza Di-SNPs with genomic regions predicted to be functional regulatory regions, based on human heart-derived DNase-seq and ATAC-seq, as well as ChIP-seq for the cardiac transcription factors GATA4, TBX5, and NKX2.5. Intersection of these data sets identified Hadza Di-SNPs located within predicated enhancer regions close to genes important for heart development. Specifically, we identify a variant common only in the Hadza population (allele frequency of 46.7% in the Hadza but <6.7% in global populations) located in a predicted heart-specific enhancer of the HAND2 (heart and neural crest derivatives expressed 2) gene, a key transcription factor for cardiac morphogenesis. We demonstrate that this variant impacts enhancer activity in cardiomyocytes. We are employing CRISPR genome editing in human pluripotent stem cell-derived cardiomyocytes to determine the impact of this variant on cardiac development. This study demonstrates an approach for identifying functionally important variants that may play a role in local adaptation. Funded by NIH grant 1U01HG012047-01, 1R35GM134957, R01AR076241 and ADA 1-19-VSN-02.

Molecular Effects of Genetic Variation Posters - Thursday

PB2625. Impact of rare heterozygous mutations of *PCSK1* on obesity: implication for treatment with MC4R agonists.

Authors:

M. Baron¹, L. Folon¹, M. Derhourhi¹, B. Balkau², G. Charpentier³, S. Franc³, R. Roussel⁴, M. Canouil¹, P. Froguel^{1,5}, A. Bonnefond^{1,5}; ¹Inserm UMR1283, CNRS UMR8199, Lille, France, ²Inserm U1018, Villejuif, France, ³CERITD, Evry, France, ⁴Inserm U1138, Paris, France, ⁵Imperial Coll. London, London, United Kingdom

Abstract Body:

Background and aims: Pathogenic mutations in key genes involved in the leptin-melanocortin pathway are well-established causes of monogenic forms of obesity. Recently, the melanocortin-4 receptor (MC4R) agonist setmelanotide has been developed to efficiently treat obese patients with homozygous mutations in *POMC* and *LEPR*. Its relevance to other forms of monogenic obesity is currently under investigation. Among those forms is *PCSK1* deficiency. Bi-allelic pathogenic mutations in *PCSK1* lead to early-onset obesity associated with severe endocrinopathy, but the clinical impact of heterozygous pathogenic *PCSK1* mutations on obesity is still elusive. We performed large-scale functional genetic studies to clarify the link between heterozygous *PCSK1* mutations and obesity. **Material and methods:** All 14 coding exons of *PCSK1* were sequenced in 10,000 individuals (including obese and/or diabetic patients) by next-generation sequencing. The detected heterozygous variants were created by mutagenesis and inserted into plasmids. Functional assays of each variant were performed in HEK293 cells: enzymatic activity was analysed using a fluorescent PC1/3 substrate. **Results:** We identified 66 rare heterozygous variants of *PCSK1* (minor allele frequency < 1%). The variants were clustered into 5 groups (A-E) based on their enzymatic activity. The 17 variants in group A had complete loss of enzymatic activity whereas group B included 11 variants with partial loss of enzymatic activity. They strongly affect the structure of the protein preventing the expression of the mature active form of PC1/3. We found that class A variants increased the risk of developing obesity by 6-fold in both children ($P=0.097$; OR=6.0) and adults ($P=0.038$; OR=5.6). In contrast, class B variants were not associated with obesity risk ($P=0.86$; OR=1.1). Importantly, we observed a lack of sensibility and specificity of the largely used *in silico* tools predicting putative heterozygous pathogenic *PCSK1* mutations. Indeed, the pathogenic variants predicted by REVEL showed 4 false negatives and 11 false positives compared to the results of *in vitro* functional assays. **Conclusion:** Our results strongly suggest that only obese individuals carrying *PCSK1* heterozygous mutations proven pathogenic through *in vitro* functional testing (*i.e.* category A, 25%) should be eligible for putative setmelanotide treatment, but not the carriers of mutations with only intermediate *in vitro* deleterious effect. Therefore, *in vitro* tests are required following the molecular diagnosis of rare heterozygous *PCSK1* mutations before initiating expensive medication.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2626. Improving generalizability of gene expression prediction models from African-ancestry populations.

Authors:

Campus, Aurora, CO, ²Univ. of Colorado, Aurora, CO, ³Univ. of the West Indies, Bridgetown, Barbados, ⁴Johns Hopkins Univ., Baltimore, MD, ⁵Johns Hopkins Univ., Sch. of Med., Baltimore, MD, ⁶Icahn Sch. of Med. at Mt Sinai, New York, NY

Abstract Body:

Prior gene expression prediction studies demonstrated that differences in out-of-sample prediction across populations of different ancestries were related to genetic differentiation between source populations. Therefore, we aimed to quantify the relationship between population genetic differentiation and gene expression prediction performance to develop more generalizable gene expression prediction models. Previously, we used the PrediXcan suite of tools to create a database of SNPs that contribute to significant prediction of unstimulated CD4+T cell gene expression among 260 African-ancestry individuals participating in the Barbados Asthma Genetics Study. This database was used to predict CD4+T gene expression in subjects from the 1000 Genomes Project (TGP), of African (AA: YRI, N=86) and European (EA: CEU, FIN, & GRB N=276) ancestry who also have cell line RNA sequencing measures. Prediction accuracy (R²) for each gene (N=3,279) was calculated as the square of the Pearson correlation coefficient between predicted versus observed values. We tested whether prediction accuracy differed across AA and EA populations using a Wilcoxon rank sum test. Next, we used the R package KRIS to summarize the pairwise genetic fixation index (F_{st}) for each SNP between AA and EA populations in TGP. We averaged the F_{st} for all SNPs used to predict a gene's CD4T expression as a measure of population differentiation and tested whether average F_{st} was associated with prediction performance using Pearson's correlation. Average prediction performance for the 3,227 genes was like prior studies applying prediction models developed in one ancestry to an out- f-ancestry or multi-ancestry population, with median R²=0.00631 (IQR=0.001, 0.027). Prediction performance was significantly better (p<0.001) in the AA population with a median R²=0.0155 (IQR=0.003, 0.052, max=0.91) compared to the EA population median R²=0.00597 (IQR=0.001, 0.026, max=0.82). The mean F_{st} of SNPs used to predict CD4+T gene expression was not significantly associated with increased difference in prediction performance between AA and EA (rho=0.0166, p=0.35), and no association with prediction performance among the AA or EA population (p>0.05). We showed that prediction accuracy of gene expression from SNP data was increased among subjects from the same ancestry as the model training dataset compared to the out-of-ancestry subjects, but this difference in prediction accuracy was not significantly association with mean F_{st}. Ongoing work evaluates the improvement in generalizability of gene expression prediction models through restriction of eligible SNP predictors by ancestry specific MAF.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2627. Inhibiting aurora kinase A in the HMC3 immortalized human microglia cell line increases phagocytosis of amyloid beta *in-vitro*.

Authors:

K. Cook¹, S. H. Littleton², J. A. Pippin¹, E. A. Burton³, S. A. Anderson¹, A. Chesi², S. F. A. Grant⁴; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Univ. of Pennsylvania, Philadelphia, PA, ³The Univ. of Pennsylvania, Philadelphia, PA, ⁴Children's Hosp. of Philadelphia/Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Alzheimer's Disease (AD) represents the leading cause of dementia worldwide. Despite its increasing prevalence and burden on public health, there are still not widely available and efficacious therapeutics. This relative dearth of available pharmaceutical interventions is a result of the multi-factorial nature of AD associated neurodegeneration. Among the key contributors to AD pathology is neuroinflammatory processes, and central to those mechanisms are the microglia, representing the central nervous system's resident macrophage. Integrating reported AD GWAS statistics with our combined ATAC-seq/high-resolution promoter-focused Capture-C datasets has implicated microglial genes in the pathophysiology of the disease. Among the targets resulting from our variant-to-gene efforts for this disease is the gene encoding Aurora Kinase A (*AURKA*). *AURKA* is a serine/threonine kinase involved in NFkB signaling, as well as involved in the promotion of M1 pro-inflammatory polarization in macrophages. To investigate the effects of *AURKA* inhibition on key aspects of AD pathology we have obtained a research grade inhibitor (MK8475) and applied it to the human microglial HMC3 model system. Cells exposed to MK8475 following stimulation with AB displayed a 30% ($P=0.0033$) increased uptake of fluorescently conjugated Amyloid Beta (AB_{42}). Following up on this functional phenotype we sought to characterize the transcriptome of cells treated with MK8475 using RNA-seq. We found key GO analysis terms associated with the gene module upregulated in cells treated with the inhibitor after exposure to AB_{42} to be 'organonitrogen compound metabolic processes' ($P=1.5 \times 10^{-6}$), 'interferon type I response' ($P=1.63 \times 10^{-7}$), and 'cellular response to cytokine signaling' ($P=1.19 \times 10^{-11}$). Indeed, these categories have been previously implicated as dysregulated in AD pathology. Additionally, the transcriptomic profile of drug treated cells displayed upregulation of genes previously published as enriched in the transcriptomic profile of microglia actively phagocytosing fibrillar AB (Grubman *et al.* 2021). Taken together, results from a FLOW cytometry-based phagocytosis assay, as well as transcriptomic profiling, reveal that inhibition of *AURKA* is a promising therapeutic avenue for promoting microglial phenotypes and holds promise for ameliorating AD pathology.

Molecular Effects of Genetic Variation Posters - Thursday

PB2628. Integrated analysis of retinal eQTLs, meQTLs and eQTM identifies target genes and epigenetic mechanisms contributing to age-related macular degeneration.

Authors:

J. Advani¹, A. R. Hamel^{2,3}, S. Mehrotra^{2,3}, C. Kiel⁴, T. Strunz⁴, J. Rouhana^{2,3}, M. Kwicklis¹, F. V. Asten¹, R. Ratnapriya¹, X. Corso-Díaz¹, D. G. Hernandez⁵, R. J. Kappahn⁶, D. Eye Inst., NIH, Bethesda, MD, ²Ocular Genomics Inst., Dept. of Ophthalmology, Massachusetts Eye and Ear, Harvard Med. Sch., Boston, MA, ³The Broad Inst. of MIT and Harvard, Cambridge, MA, ⁴Inst. of Human Genetics, Univ. of Regensburg, Regensburg, Germany, ⁵Lab. of Neurogenetics, Natl. Inst. of Aging, NIH, Bethesda, MD, ⁶Dept. of Ophthalmology and Visual NeuroSci.s, Univ. of Minnesota, Minneapolis, MN, ⁷Inst. of Clinical Human Genetics, Univ. Hosp. Regensburg, Regensburg, Germany

Abstract Body:

Age related macular degeneration (AMD) is a multifactorial progressive neurodegenerative disease and a leading cause of blindness in people with advanced age globally. A large genome-wide association study (GWAS) has previously identified 52 genetic variants at 34 AMD susceptibility loci (Fritsche et al., *Nat. Genet.* 2016). However, a vast majority of associated variants localize to non-coding genome and causal genes remain largely undetermined at most loci. Our previous retinal eQTL and TWAS analyses have uncovered several candidate genes in AMD GWAS loci (Ratnapriya et al., *Nat. Genet.* 2019; Strunz et al., *PLoS Genet.* 2020). However, complex traits, such as AMD, are affected by environmental and genetic factors, epigenetic mechanisms and their genetic regulation can help dissect the impact of aging and environment on disease onset and severity. In this study, we defined the inter-relationship among gene expression, genetic variability, and DNA methylation in the human retina and investigated their potential causal effect on AMD. We performed DNA methylation profiling of postmortem retina from 152 controls and AMD cases using Illumina MethylationEPIC bead chip. Applying QTLtools to methylation and imputed genotype data, we identified 37,453 variants associated in *cis* (<1 Mb) with CpG sites (methylation quantitative trait loci, meQTLs) (FDR≤0.05). Gene ontology analysis of mGenes identified genes involved in regulation of GTPase activity, actin filament and synaptic signaling. Applying colocalization analyses with eCAVIAR and Summary data-based Mendelian Randomization (SMR) between meQTL and eQTL or AMD GWAS signals have revealed meQTLs that may impact 9 disease-associated loci; e.g., meQTLs mapped to *CFH*, *ARMS2/HTRA1* or *LINC01004*, and 10,246 meQTLs that may mediate expression of 2,637 genes, e.g., *NLRP2* or *NDUFA10*. Furthermore, integration of expression with methylation identified 13,747 expression quantitative trait methylation (eQTMs) (FDR≤0.05). Notably, eQTM target genes were enriched in oxidative phosphorylation, electron transport chain and translational initiation. Thus, our study, for the first time, describes relationship between genetic regulation and DNA methylation in the retina, and association of meQTLs with AMD. The high correlation of genetic effects between methylation and gene expression highlights the target genes that may mediate the effect of aging and/or environmental factors on AMD. Future incorporation of age, environment or lifestyle factors, such as smoking, to meQTL and eQTM detection, can potentially augment understanding of complex interplays among divergent components contributing to AMD pathology.

Molecular Effects of Genetic Variation Posters - Thursday

PB2629. Integrative 3D structural analysis of *de novo* missense variants and their associated protein structures inferred by AlphaFold2 identifies the importance of β -strand/sheet features for congenital heart disease

Authors:

Y. Xie¹, Y. Yang², C. Moth³, B. Li³, J. Gu¹, W. Dong¹, J. Capra⁴, S. Jin⁵, W. Zheng², H. Zhao¹; ¹Yale Univ., New Haven, CT, ²Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, ³Vanderbilt Univ., Nashville, TN, ⁴Univ. of California San Francisco, San Francisco, CA, ⁵Washington Univ. Sch. of Med., St. Louis, MO

Abstract Body:

Multiple studies have been conducted to characterize the association between missense variants and protein structures using data from Protein Data Bank (PDB). However, only 35% of human proteins map to a PDB entry, and in many cases the structure covers only a portion of the protein sequences, not the whole proteins. The release of protein structures from AlphaFold2 (AF2) covers 98.5% of human proteins, with 58% of them with high confidence.

In this study, we surveyed the associations between congenital heart disease (CHD) *de novo* missense variants and structural features using protein structures from both PDB and AF2. Compared with *de novo* missense variants from healthy controls, we identified a significant association of β -strand/sheet (a three-class secondary structure) with CHD *de novo* missense variants after multiple testing adjustments (marginal $p=0.0019$). Structural features including α , π , 3_{10} -helix and core (relative solvent accessible area $<5\%$) are marginally significant (marginal $p<0.05$). If we only include PDB structures in the analysis, all features are not significant.

Under the assumption that the AF2 predicted structures included in our analysis are accurate, our preliminary results 1) show the increased power of extending protein structure information using AF2; 2) call upon novel statistical methods that can integrate protein structural features with *de novo* variants; and 3) may shed new light on the relationship between molecular effects of *de novo* missense variants and CHD.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2630*. Investigating the impact of non-coding structural variants flanking epilepsy-associated gene, *FOXG1* on chromatin architecture and gene regulation.

Authors:

A. Ramamurthy¹, J. Calhoun¹, M. Bandouil¹, M. Nobrega², G. Carvill¹; ¹Northwestern Univ., Chicago, IL, ²Univ. of Chicago, Chicago, IL

Abstract Body:

Structural variants (SVs) are genetic variants ranging from 50 bases to a few megabases in size and include deletions, duplications, insertions, inversions and translocations. Epilepsy is a heterogeneous neurological disorder characterized by recurrent seizures. Up to 12% of genetic epilepsies can be explained by SVs that disrupt the coding regions of the genome, causing epilepsy through gene dosage effects. SVs in non-coding genomic regions can perturb *cis*-regulatory elements (CREs) and/or topologically associated domains (TADs). These loci are important for 3D genome architecture and gene regulation. Whether SVs in these loci cause epilepsy and the associated putative pathogenic mechanisms are unknown. The goal of this study is to define the molecular mechanisms by which SVs in non-coding regions influence epilepsy susceptibility. We identified microdeletions in the *14q12* genomic region flanking the gene, *FOXG1*, in individuals with epilepsy and associated neurodevelopmental disorders. This gene encodes the Forkhead Box G1 protein, a transcription factor essential for mammalian cerebral corticogenesis, and *FOXG1* haploinsufficiency is associated with epilepsy. We hypothesized that the *14q12* microdeletions flanking *FOXG1* alter gene expression. We utilized induced pluripotent stem cell (iPSC) derived neuronal models for our studies, as *FOXG1* expression is highest in neuronal cell types. We introduced the microdeletions via CRISPR based genome editing to create stable iPSC lines and reprogrammed the iPSCs to neural progenitor cells (NPCs). Our preliminary findings demonstrate reduced *FOXG1* expression and protein abundance in NPCs harboring the microdeletion downstream of *FOXG1*, compared to our isogenic controls. Additionally, during the selection of CRISPR edited iPSCs, we identified iPSC clones which harbored an inversion of the region of the intended microdeletion downstream of *FOXG1*. Interestingly, NPCs derived from this iPSC line demonstrate increased *FOXG1* expression. Further validation of these findings is currently ongoing. Future steps will involve evaluating TAD architecture and CRE interactions as well as assessing changes in neuronal phenotypes in the presence of the proposed microdeletions. This study will be the first to explore molecular mechanisms of non-coding SVs associated with epilepsy. A comprehensive understanding of genome wide SVs in the non-coding regions associated with epilepsy will enable the identification of misregulated genes that can function as potential targets of pharmacological agents and aid the development of therapy for those individuals with active genetic epilepsies.

Molecular Effects of Genetic Variation Posters - Thursday

PB2631. Investigating the molecular and cellular effects of pathogenic variants of *GNAI1* in developmental and epileptic encephalopathy

Authors:

E. Fathi¹, H. Chen², E. Almanza Fuerte¹, H. Mefford³; ¹St. Jude Children's Res. Hosp., Memphis, TN, ²St. Jude Children's Res. Hosp., Memphis, TN, ³St. Jude Children's Res. Hosp., Memphis, TN

Abstract Body:

Developmental and epileptic encephalopathies (DEE) are characterized by intellectual disability, significant developmental delay, intractable seizures, and autistic features. Recently our group identified 16 unique *de novo* mutations in *GNAI1* (G protein subunit alpha I1) in 24 individuals with DEE. *GNAI1* encodes $G\alpha_{i1}$, a G-protein subunit that binds to and hydrolyzes GTP and interacts with a variety of downstream effectors in signaling cascades inside the cell. However, the effect of the identified variants on $G\alpha_{i1}$ functions such as GDP/GTP binding, GTP hydrolysis, and affecting downstream signaling pathways is not known. Although *GNAI1* is predicted to be intolerant to loss-of-function variants, only a single disease-causing variant has been studied to date. Therefore, there is an urgent need to determine the molecular and cellular consequences of disease-causing variants and develop a cellular model in which to study disease and test potential therapies. To investigate the molecular and cellular function of *GNAI1* disease-causing variants, we selected four pathogenic mutations, each found in two or more patients, including three missense variants in different positions of the GDP binding domain (Gly40Cys, Thr48Lys, Lys270Arg), and one single amino acid deletion just outside of the GDP binding domain (Gln172del). We designed a series of *GNAI1* mutations in pcDNA3.1 vector with a flag tag using site-directed mutagenesis. We also designed one early termination (Thr48Ter) as a control for haploinsufficiency and loss of function effects. In addition, we are generating CRISPR-engineered cells with the same selected variants and have patient cells for three variants. We are investigating the effect of disease-related $G\alpha_{i1}$ variants on protein localization, protein-protein interactions, GTP binding and downstream pathways. We transiently transfected HEK-293T cells with each mutant construct (Gly40Cys, Thr48Lys, Lys270Arg, Gln172del, Thr48Ter). We showed that the protein expression of all five *GNAI1* mutant constructs is significantly decreased compared with wild type (WT) control in HEK-293T cells. Preliminary results suggest that the Lys270Arg and Gln172del variants disrupt protein localization compared with control. Our engineered and patient-derived cells represent a valuable tool for studying the role of *GNAI1* mutations in the pathogenesis of $G\alpha_{i1}$ mutant proteins. We will validate our preliminary results from *in vitro* studies in 3D brain organoids from patient cells, which will serve as a beneficial disease model to investigate molecular and cellular function of $G\alpha_{i1}$ variants and to test promising therapeutic strategies for *GNAI1*-related DEE.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2632. Investigating the potential roles of Importin-7 and Importin- β in LINE-1 retrotransposition.

Authors:

S. Mortimer, J. V. Moran; Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract Body:

Sequences derived from Long Interspersed Element-1 (LINE-1 or L1) retrotransposons comprise ~17% of human genomic DNA. The L1 retrotransposition cycle begins with transcription of a full-length bicistronic L1 RNA, which exits the nucleus and undergoes translation to generate the L1-encoded proteins (ORF1p and ORF2p). Both ORF1p, an RNA binding protein, and ORF2p, which has endonuclease and reverse transcriptase activities, preferentially associate with their encoding RNA transcript to form a ribonucleoprotein (RNP) particle by a process known as cis-preference. Components of the L1 RNP then must gain access to genomic DNA, where the ORF2p endonuclease activity generates a single strand endonucleolytic nick in genomic DNA to expose a 3'-hydroxyl group (3'-OH) that is used as a primer by the ORF2p reverse transcriptase activity to initiate the reverse transcription of L1 RNA. However, how the L1 RNP enters the nucleus requires elucidation. A 2006 study (Kubo et al. PNAS) demonstrated that L1 retrotransposition can occur in G1/S arrested cells, indicating that components of the L1 RNP can cross an intact nuclear membrane. Additionally, a 2019 study (Miyoshi et al. Molecular Cell), which used an immunoprecipitation-mass spectrometry screen in HEK293T cells, identified the nuclear import proteins Importin-7 (Imp-7) and Importin- β (Imp- β) as putative L1 ORF2p interaction partners. Here, I describe progress toward investigating whether Imp-7 and/or Imp- β might play a role in L1 retrotransposition. My preliminary results suggest that Imp-7 siRNA knockdown leads to a modest reduction in retrotransposition as compared to mock siRNA treatment in HEK293T cells, but not in HeLa-JVM cells. Ongoing experiments will determine whether Imp- β knockdown has a similar effect on L1 retrotransposition and whether co-immunoprecipitation experiments provide evidence for ORF2p/Imp-7 and/or ORF2p/Imp- β interactions.

Molecular Effects of Genetic Variation Posters - Thursday

PB2633. KDM5A, a chromatin remodeler and newly identified autism gene, has a cell type-specific function in the hippocampus.

Authors:

L. El Hayek, D. DeVries, K. Kaur, M. Chahrour; Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract Body:

Autism spectrum disorder (ASD) is a constellation of neurodevelopmental disorders with high clinical and genetic heterogeneity. It is characterized by impaired communication skills, social behavior deficits, restricted interests, and repetitive behaviors. Although 1 in 44 children are diagnosed with ASD, the causative genes that have been identified to date account for only 30% of cases, with no single gene individually contributing to more than 1% of cases. Therefore, the genetic architecture of ASD suggests that it is a collection of individually rare disorders. Designing targeted therapeutics for these rare genetic subtypes of ASD will require mechanistic understanding of the disrupted pathways. Importantly, insights into the normal function of ASD genes continue to inform the mechanisms underlying neurodevelopment. Epigenetic chromatin regulation is essential for proper gene expression and for brain development, and is a key pathway disrupted in ASD with causative mutations identified in several genes encoding chromatin remodelers (e.g. *ARID1B*, *CHD8*, *SETD5*). We identified a novel ASD gene, *KDM5A*, and showed that its loss results in neurobehavioral abnormalities and transcriptional dysregulation in the cortex and hippocampus. *KDM5A* is a chromatin regulator that belongs to the *KDM5* family of lysine-specific histone H3 demethylases. Consistent with its function, we found that loss of *KDM5A* results in global increase in trimethylated H3 lysine 4 (H3K4Me3) in the cortex. Thus, evidence from our studies suggests that *KDM5A* is critical for brain development and function. It has been shown that ASD genes are enriched in specific cell types in the brain during development and that changes in gene regulatory networks in ASD occur in a cell type-specific manner in the brain. *KDM5A* is ubiquitously expressed across cell types in the brain, its expression pattern throughout development is dynamic, and it is differentially expressed at different stages of cell lineage birth and maturation, indicating that *KDM5A* function in the brain is likely to be cell type-specific. We performed single-nuclei isolation and RNA sequencing from hippocampal tissue from wildtype and *Kdm5a* knockout mice and identified specific subtypes of excitatory and inhibitory neurons that are particularly vulnerable to *KDM5A* loss of function. These cell types have common and distinct transcriptional networks that are disrupted upon loss of *KDM5A*. Our findings define a cell type-specific role for *KDM5A* in the hippocampus and more broadly, advance our knowledge of the role chromatin regulation plays in brain development and function.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2634. KMT5B is required for early motor development.

Authors:

H. Feser Stessman, J. Hulen, D. Kenny, R. Black, J. Hallgren, K. Hammond, E. Bredahl, R. Wickramasekara, P. Abel; Creighton Univ., Omaha, NE

Abstract Body:

Heterozygous disruptive variants in lysine methyl transferase 5B (*KMT5B/SUV420H1*) have been identified as likely-pathogenic among humans with developmental delays, intellectual disability, and autism spectrum disorder phenotypes. Interestingly, this patient population presents with high rates of motor deficits (i.e., hypotonia and motor delays); however, the role that KMT5B plays in early motor development is largely unknown. Using a mouse gene trapping strategy, we have previously reported early motor reflex deficits and reduced body size in the germline *Kmt5b* heterozygous (HET) state compared to wild-type (WT) littermates. The goal of this study was to further characterize the developmental motor phenotype in the HET condition to better understand the effects of KMT5B haploinsufficiency on skeletal muscle growth and maturation. Using our gene trap model, we assessed neuromuscular strength, skeletal muscle weight (i.e., muscle mass), neuromuscular junction (NMJ) structure, and myofiber type, size, and distribution in both sexes and at two developmental times (postnatal days P17 and P44) to compare juvenile to adult skeletal muscle structures. Data were collected in hindlimb soleus (SOL) and extensor digitorum longus (EDL) muscles to compare slow- to fast-twitch muscle types, respectively. Prior to the onset of puberty at P17, slow-twitch SOL muscle weight was significantly reduced in HET compared to WT males ($p = 0.0072$; Tukey's test) but not females suggesting sexual dimorphism at this developmental stage. At the young adult stage (P44), we identified decreased neuromuscular strength ($p = 0.0367$; 2-way ANOVA) and increased NMJ fragmentation in the SOL ($p = 0.0157$; 2-way ANOVA) in HET animals. Further, skeletal muscle weights were significantly decreased at P44 in both the HET SOL ($p = 0.0015$; 2-way ANOVA) and EDL ($p < 0.0001$; 2-way ANOVA) muscles. HET muscle weight remained lower than WT even after correcting for known body weight differences; this was not found among other body organs suggesting skeletal muscle specificity. Smaller HET muscles were composed of a significantly increased numbers of fast-twitch myofibers, yet the overall size of myofibers was significantly smaller in P44 muscles ($p < 0.05$; 2-way ANOVA). We conclude that KMT5B haploinsufficiency results in a skeletal muscle developmental deficit causing reduced muscle mass and body weight (i.e., hypotonia) that phenocopies the KMT5B patient population.

Molecular Effects of Genetic Variation Posters - Thursday

PB2635. Large-scale integrative analysis of 1.5 million single cells across diverse human tissues and immune cell types reveals dynamic regulatory effects on *HLA* gene expression.

Authors:

J. Kang^{1,2,3}, A. Z. Shen^{1,2,3}, Y. Luo^{1,2,3}, S. Sakaue^{1,2,3}, S. Gurajala^{1,2,3}, A. Nathan^{1,2,3}, V. R. C. Aguiar^{2,3,4}, C. Valencia^{1,2,3}, L. Rumker^{1,2,3}, F. Zhang^{1,2,3}, A. Jonsson^{1,2}, S. Yazar⁵, J. Alquicira-Hernandez⁵, K. Dey^{6,3}, K. Jagadeesh^{6,3}, Accelerating Med. Partnership (AMP): Rheumatoid Arthritis and Systemic Lupus Erythematosus Network, J. E. Powell⁵, M. Gutierrez-Arcelus^{2,3,4}, D. A. Rao^{1,2}, L. Donlin^{7,8}, J. Anolik⁹, M. B. Brenner^{1,2}, S. Raychaudhuri^{1,2,3}; ¹Brigham and Women's Hosp., Boston, MA, ²Harvard Med. Sch., Boston, MA, ³Broad Inst. of MIT and Harvard, Cambridge, MA, ⁴Boston Children's Hosp., Boston, MA, ⁵Garvan Inst. of Med. Res., Sydney, NSW, Australia, ⁶Harvard T. H. Chan Sch. of Publ. Hlth., Boston, MA, ⁷Hosp. for Special Surgery, New York, NY, ⁸Weill Cornell Med., New York, NY, ⁹Univ. of Rochester Med. Ctr., Rochester, NY

Abstract Body:

The major histocompatibility (MHC) region on chromosome 6, containing the human leukocyte antigen (*HLA*) and ~260 other genes, has the strongest genetic associations with immune-mediated diseases. However, the exact molecular mechanisms behind MHC disease risk are yet unsolved. Previous research has extensively explored how *HLA* coding variation contributes to disease risk, but altered *HLA* expression might also confer disease risk, for example through higher levels of antigen presentation to autoreactive T cells.

--

Here, we hypothesize that MHC genetic variants modulate *HLA* expression in a cell-state-dependent manner. Single-cell RNA-seq enables modeling expression quantitative trait loci (eQTLs) at the single-cell level in disease-relevant tissues and dynamic cell states. To this end, we collected and uniformly processed genotype and transcriptional data from four existing datasets in total comprising >1,495,000 single-cell profiles from 1,073 individuals: inflamed synovial tissue from rheumatoid arthritis patients and controls (n=69), inflamed intestinal tissue from ulcerative colitis patients and controls (n=22), peripheral blood mononuclear cells (PBMCs) treated *in vitro* with influenza A and controls (n=73), and PBMCs from a population cohort (n=909).

--

Because standard expression quantification pipelines are confounded by the polymorphic nature of *HLA* genes, we developed a personalized read alignment strategy that imputes 4-digit classical *HLA* alleles (*HLA-A, B, C, DPB1/B1, DQA1/B1, DRB1*) per individual then quantifies single-cell expression using a personalized genome. We find that *HLA* class II expression is more variable across cell states within a given cell type compared to class I and is present in both professional antigen-presenting cells as well as other cell states, such as proliferating T cells. We then performed a single-cell eQTL analysis across the MHC to identify variants regulating classical *HLA* gene expression in myeloid, B, and T cells. First, we aggregated cohorts together to increase power and used a pseudobulk linear model, identifying eQTLs for all eight *HLA* genes in every cell type (all lead P-vals < 4e-9). Then, we demonstrated multiple cases where *HLA* regulatory variants are cell-state-dependent by modeling the eQTLs at single-cell resolution using a negative binomial mixed effects model that includes interaction terms with continuously defined cell states. For example, a T cell *HLA-DQA1* eQTL (rs3104371) becomes strongest in cytotoxic T cells (interaction P = 6e-322). This work offers a large-scale, cross-tissue atlas of *HLA* expression and its genetic regulation across diverse disease-relevant cell states.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2636. Leveraging Mosaic Epileptogenic Human Brain Tissue to Study Cell-type Specific Transcriptional Changes Associated with a Pathogenic *PIK3CA* Variant

Authors:

M. Gade, D. Lai, E. Heinzen; Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract Body:

Post-zygotically acquired mutations that arise during embryonic cortical development can lead to abnormal neuron morphology and/or migration defects, both of which can often result in seizures and developmental disabilities. Somatic mutations that cause abnormal activation of proteins in the PI3K-AKT-mTOR signaling pathway have been implicated in focal cortical dysplasia type 2 and hemimegalencephaly (HMEG). Surgically resected mosaic brain tissue from affected individuals offers a unique opportunity to determine the burden of mutations and transcriptional effects of the mutations across cell types. To tease apart the transcriptional effects of the mutation within cell types, we modified the G&Tseq¹ protocol to simultaneously perform single-cell genotyping and transcriptomic profiling to identify the comprehensive transcriptomic signature of mutation-positive and mutation-negative nuclei. We benchmarked the protocol by comparing nuclei isolated from surgically resected brain tissue of a patient with HMEG harboring a pathogenic somatic variant in *PIK3CA* (E545K) to an age-matched control. We used a fluorescently labeled NeuN antibody to sort neuronal and non-neuronal nuclei for bulk (n=20,000 nuclei/total nuclei) and single-cell (n=44 NeuN+ nuclei/sample) preparations. RNA extracted from bulk (NeuN+ and NeuN-) and single NeuN+ nuclei for both cases and controls was sequenced at a depth of 15 million (MM) reads/sample. In parallel, DNA was genotyped in mutation-positive bulk and single nuclei using droplet digital PCR and TaqMan genotyping assay, respectively. A variant allele fraction of 30% (NeuN+) and 35% (NeuN-) was observed in bulk samples from the mosaic *PIK3CA* tissue, which correlated with that observed in single nuclei. RNA from bulk nuclei populations consistently yielded ~10 MM uniquely mapped reads (UMR) while RNA from single nuclei yielded ~5-10 MM UMR. Transcriptomic analysis of bulk nuclei (NeuN- & NeuN+) and single nuclei (NeuN+) confirmed the activation of the mTOR pathway. We also observed transcriptomic signature associated with *PIK3CA* variants specific to NeuN+ bulk and single nuclei; namely, the CREB phosphorylation pathway and an upregulation of *SPDYE5*, a gene implicated in low-grade glioma. Analyses of genotype-informed single nuclei RNAseq are currently underway. This approach will allow for novel insights into the impact of pathogenic somatic mutations on cell-autonomous and non-cell-autonomous functions, high-resolution assessments of cell-type-specific mutation burden, and may help identify antiseizure targets for treating mTOR related intractable seizures.

Molecular Effects of Genetic Variation Posters - Thursday

PB2637. Limited overlap of eQTLs and GWAS hits due to systematic differences in discovery

Authors:

H. Mostafavi, J. Spence, S. Naqvi, J. Pritchard; Stanford Univ., Stanford, CA

Abstract Body:

Most signals in genome-wide association studies (GWAS) of complex traits point to noncoding genetic variants with putative gene regulatory effects. However, currently identified expression quantitative trait loci (eQTLs) explain only a small fraction of GWAS signals. By analyzing GWAS hits for complex traits in the UK Biobank, and cis-eQTLs from the GTEx consortium, we show that these assays systematically discover different types of genes and variants: eQTLs cluster strongly near transcription start sites, while GWAS hits do not. Genes near GWAS hits are enriched in numerous functional annotations, are under strong selective constraint and have a complex regulatory landscape across different tissue/cell types, while genes near eQTLs are depleted of most functional annotations, show relaxed constraint, and have simpler regulatory landscapes. We describe a model to understand these observations, including how natural selection on complex traits hinders discovery of functionally-relevant eQTLs. Our results imply that GWAS and eQTL studies are systematically biased toward different types of variants, and support the use of complementary functional approaches alongside the next generation of eQTL studies.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2638. Long-chain fatty acid oxidation disorder gene variants identified through a gene panel sponsored program: a diverse gene variant landscape.

Authors:

V. Rangel Miller¹, H. McLaughlin², D. Marsden¹, O. K. Japalaghi¹, A. Willcock³, N. Miller⁴; ¹Ultragenyx Pharmaceutical, Novato, CA, ²Invitae, South Lyon, MI, ³Invitae Corp., San Francisco, CA, ⁴Ultragenyx, Brisbane, CA

Abstract Body:

Long-chain fatty acid oxidation disorders (LC-FAOD) are rare, life-threatening, autosomal recessive conditions that impair the utilization of fats for energy production. Undiagnosed LC-FAOD may present with hypoglycemia, cardiomyopathy, cardiac arrhythmias, and neuromuscular signs. **Methods:** Patients in the US, Canada, and Mexico of all ages who have either a clinical diagnosis or suspicion of LC-FAOD with a confirmatory acylcarnitine test ordered or performed are eligible for this no-charge genetic testing program. The next generation sequencing gene panel with copy number variant (CNV) detection includes the 6 genes associated with LC-FAOD (*ACADVL*, *CPT1A*, *CPT2*, *HADHA*, *HADHB*, *SLC25A20*) plus 19 additional genes associated with disorders that cause a similar acylcarnitine profile. **Results:** 561 patients were tested as of 30 MAR 2022 and 244 LC-FAOD gene variants were identified among 196 patients: 150 (61%) pathogenic/likely pathogenic (P/LP), 94 (39%) variant of uncertain significance (VUS). 4 patients had variants in 2 or more LC-FAOD genes. Additional evidence, including segregation, clinical/biochemical information, or functional modeling, led to the reclassification of 8 *ACADVL* VUS to P (3) or LP (5), impacting 11 individuals. 50 patients had a positive (n=30 P/P, LP/P, LP/LP) or potential positive (n=20 LP/VUS, P/VUS) LC-FAOD genetic diagnosis: 60% *ACADVL*, 16% *CPT2*, 8% *HADHA*, 4% *CPT1A*, 4% *HADHB*, 2% *SLC25A20*. Clinical signs reported for 21 of these patients include elevated creatine kinase (14), rhabdomyolysis (10), myopathy (8), myoglobinuria (4), cardiomyopathy (3), retinitis pigmentosa (3), hypoketotic hypoglycemia (1), and peripheral neuropathy (1). While most (56% of 561) patients tested were under 1 year (y) of age, the rate of LC-FAOD genetic diagnoses (50) varied with age: 9.9% under 1y, 4.2% 1y-12y, 15% 13y-20y, 9.7% 21y-40y, and 5% 40y or older. Among non-LC-FAOD panel genes there were 29 positive, 18 potential positive, and 6 uncertain (VUS only) genetic diagnoses. Of 76 patients with a positive confirmatory acylcarnitine test, 18 had a positive/potential positive LC-FAOD diagnosis; of 197 patients with an inconclusive confirmatory test, 12 had a positive/potential positive LC-FAOD diagnosis. **Conclusion:** These results demonstrate a diverse composition of gene variants in patients with suspected LC-FAOD and suggest the need for further approaches to resolve VUS and identify previously undetected variants. The higher LC-FAOD genetic diagnosis rates in adolescents/adults suggest these patients may have missed newborn screening, consistent with the timing of LC-FAOD addition to the Recommended Uniform Screening Panel in 2008.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2639. Mapping the effects of genomic deletions and duplications on cognitive ability across cortex

Authors:

S. Kazem¹, K. Kumar¹, G. HUGUET¹, J. Kopal¹, E. Douard², M. Jean-Louis¹, Z. Saci¹, L. Almasy³, D. Glahn⁴, G. Dumas², S. Jacquemont¹; ¹CHU Sainte-Justine, Montreal, QC, Canada, ²Université de Montréal, Montreal, QC, Canada, ³Children`s Hosp. of Philadelphia, Philadelphia, PA, ⁴IOL & Yale, Hartford, CT

Abstract Body:

Genomic deletions or duplications, copy number variants (CNVs), increase the risk for psychiatric disorders. Recent studies based on genetic constraint score (LOEUF) estimate that close to 50% of coding genes show measurable effects on cognitive ability when deleted or duplicated. However, functional prioritization is problematic because this broad spectrum of genes impacting cognition involves most annotated GO-term categories. In addition, cognition is not the direct product of these microscale functions; it emerges from large scale brain networks that structure the interaction of molecular and cellular functions. We hypothesize that spatial patterns of gene expression across large scale brain networks - that can be seen as macro-scale meta functions - will shed light on how such a broad group of genes impact cognitive ability when altered by CNVs. Our aim is to provide a brain map for the effect sizes of genes on cognitive ability when deleted or duplicated. First, we identified all CNVs larger than 50 kilobases in 265000 individuals with assessments of cognitive ability. Second, to assign genes to large scale brain networks, we partitioned coding genes into 180 sets based on whether they were highly expressed (data from Allen Human Brain Atlas) in one of the 180 cortical regions of the Glasser parcellation. Third, we fitted 180 linear models to compute the mean effect size on cognitive ability of genes highly expressed in each cortical region, for deletions and duplication separately. Finally we projected these effect sizes on the Glasser brain atlas and compared their cortical distribution with established cortical hierarchies. 155 and 138 out of 180 brain regions showed significant negative effects on cognitive ability with largest effect sizes observed in sensorimotor and association cortical regions, for deletions and duplications respectively. The cortical effect size maps for deletions and duplications were positively and negatively correlated to the gene-expression, anatomical, and functional cortical hierarchies. Stratifying genes using LOEUF and extensive sensitivity analyses did not change these results. Although all brain networks are involved, our results suggest that effect sizes of deletions and duplications have opposing distributions across the cortical gradient. For deletions, the largest effects on cognition are observed in genes highly expressed in the unimodal regions involved in action and perception. Duplications affect cognition most through integrative regions on the other end of the cortical gradient; key brain structures in human evolution that are involved in perceptually decoupled cognition and internal thought.

Molecular Effects of Genetic Variation Posters - Thursday

PB2640*. Massively parallel reporter assays with multi-layer annotations identified cell-type-specific functional variants and genes associated with melanoma

Authors:

E. Long¹, J. Yin², K. Funderburk³, M. Xu⁴, J. Feng¹, A. Kane¹, T. Zhang⁵, T. Myers⁶, A. Golden¹, R. Thakur⁷, H. KONG¹, L. Jessop⁸, E. Kim⁹, K. Jones¹, M. Machiela¹, K. Yu¹⁰, M. Iles¹¹, M. Landi⁵, M. Law¹², S. Chanock¹³, K. Brown¹, J. Choi¹; ¹Natl. Cancer Inst., Rockville, MD, ²NCI/NIH, Rockville, MD, ³Natl. Cancer Institute, Germantown, MD, ⁴Natl. Cancer Inst., Gaithersburg, MD, ⁵Natl. Cancer Inst., Bethesda, MD, ⁶NIH, Bethesda, MD, ⁷NCI/NIH, Bethesda, MD, ⁸NCI, Bethesda, MD, ⁹Yonsei Univ., Seoul, Korea, Republic of, ¹⁰NIH, Bethesda, MD, ¹¹Leeds Inst. of Data Analytics, Leeds, United Kingdom, ¹²QIMR Berghofer Med. Res. Inst., Brisbane, Australia, ¹³Natl. Cancer Inst, Rockville, MD

Abstract Body:

Melanoma is the deadliest form of skin cancer, with ~54 melanoma-associated loci identified by genome-wide association studies (GWAS). Most melanoma-associated loci contain multiple variants that are statistically indistinguishable due to linkage disequilibrium (LD); these are hypothesized to regulate gene expression in *cis* in a cell-type specific manner. Given these challenges, functional variants and their target genes for most melanoma-risk loci have not been characterized. Here, we performed massively parallel reporter assays (MPRA) of 1,992 variants selected from the most recent melanoma GWAS by LD ($R^2 > 0.8$) or GWAS statistics (log likelihood ratio $< 1:1000$) to test their potential as transcriptional enhancers in luciferase constructs via transfections into malignant melanoma ($n = 8$) and normal melanocyte cells ($n = 5$). Of 1,992 tested variants, we identified 285 from 42 loci (78% of the 54 loci) displaying significant allelic transcriptional activities in either cell type ($FDR < 1\%$). We further characterized MPRA-significant variants by motif prediction, epigenome annotation, and statistical/functional fine-mapping to create an integrative variant scoring system. This system efficiently prioritized a median of two plausible candidate variants per locus and nominated a single variant for 18 loci. Among them were well-characterized functional variants including two variants with the highest scores, which supported the validity of our system for variant prioritization. Overlaying the MPRA-significant variants with genome-wide significant expression or methylation quantitative trait loci (QTLs) from melanocytes ($n = 106$) or melanomas ($n = 444$) identified candidate susceptibility genes for 60% of them (172 of 285 variants). CRISPRi of top-scoring variants using the dCAS9-ZIM3 system in the melanoma cell line validated their effect on the eQTL target genes, *MAFF* (22q13.1) and *GPRC5A* (12p13.1). Finally, we identified 36 melanoma-specific and 45 melanocyte-specific MPRA-significant variants, a subset of which are linked to cell-type-specific target genes. Analyses of transcription factor availability in MPRA datasets and variant-transcription factor interaction in eQTL datasets highlighted the roles of transcription factors in cell-type-specific variant functionality. In conclusion, MPRA along with multi-layer annotations effectively prioritized plausible candidates from most melanoma GWAS loci and highlighted cellular contexts where the susceptibility variants and genes are functional; this approach is applicable to other complex diseases.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2641. Massively parallel saturation genome editing of an essential mitochondrial targeting sequence.

Authors:

M. Forrest¹, X. Jia², J. Kitzman³, A. Antonellis¹; ¹Univ. of Michigan, Ann Arbor, MI, ²Univ Michigan, Ann Arbor, MI, ³Univ MICHIGAN, Ann Arbor, MI

Abstract Body:

Aminoacyl-tRNA synthetases (ARSs) are ubiquitously expressed, essential genes that conjugate amino acids to cognate tRNAs for protein synthesis in the cytoplasm and mitochondria. Pathogenic variants in all loci encoding mitochondrial ARSs cause diverse mitochondrial disease phenotypes. Homozygous or compound heterozygous loss-of-function missense variants in the gene encoding the bifunctional lysyl-tRNA synthetase (*KARS1*) cause recessive sensorineural hearing loss, vision loss, developmental delay, and mitochondrial dysfunction. The mitochondrial isoform of KARS1 (mtKARS1) is encoded by *KARS1* transcripts that include exon 2, which encodes 49 distinct N-terminal amino-acids to allow mitochondrial localization. To date, no disease variants have been reported in the mtKARS1-exclusive *KARS1* exon 2 sequence; further, the critical amino-acid residues required for KARS1 mitochondrial localization are incompletely understood.

To assess the functional consequences of synonymous, missense, and nonsense variants across *KARS1* exon 2, we employed saturation genome editing (SGE), which combines CRISPR-Cas9 and homology repair plasmid template libraries to derive pools of knock-in human cell lines bearing all possible single-residue variants across *KARS1* exon 2 and flanking proximal introns. Variant frequency at two subsequent passages versus frequency in the template library was quantitated by deep DNA sequencing of fixed-amplicon libraries, with variants that are depleted by cell death across passages indicating KARS1 loss-of-function. Preliminary results showed recovery of 3596/3816 (94%) variants at passage 1, indicating efficient library knock-in. Nonsense variants were reduced overall by passage 2; however, nonsense variants in several codons adjacent to the cytoplasmic KARS1 termination codon at the 5'-end of *KARS1* exon 2 showed relatively neutral effects. Further, reduced tolerance for amino-acid substitution was noted for codons proximal to a predicted amphipathic mitochondrial localization motif. Here, we will present all of our unpublished functional data on the KARS1 MTS. The results of this study will define the amino-acid residues required for KARS1 mitochondrial localization and will serve as a database to aid in functional assessment of *KARS1* variants identified in patient populations.

Molecular Effects of Genetic Variation Posters - Thursday

PB2642. Maternally Inherited novel *SUMO2* variant associated with a complex phenotype

Authors:

D. Otohinoi¹, C. Hicks², R. Zambrano^{3,4}; ¹Louisiana State Univ. Hlth.Sci. Ctr., New Orleans, LA, ²Louisiana State Univ. Hlth.Sci. Ctr., New Orleans, LA, ³Louisiana State Univ Hlth.Sci Ctr, New Orleans, LA, ⁴Dept. of Pediatrics, Children's Hosp., New Orleans, LA

Abstract Body:

Background: Post-translational modifications (PTMs) remains a key player in nearly all aspects of biological processes by regulating protein functions. They also play a significant role in embryo development by participating in DNA damage response, chromosome condensation, and cytoskeletal organization. Among various PTMs involved in embryogenesis, SUMOylation on lysine residue, has a crucial role in gene expression, DNA damage responses, chromosomal stability, and DNA integrity. Amongst the isoforms of small ubiquitin-like modifier (SUMO) involved in SUMOylation, SUMO2, has been reported to be the most predominant and important. Here, we report a novel *SUMO2* variant, associated with a complex phenotype in both proband and his mother.

Case report: Proband is a 9-year-old male of African American ancestry delivered at 33 weeks gestation via emergency cesarean due to fetal bradycardia. Pregnancy was complicated by spotting and abnormal ultrasounds (lower extremity abnormalities). The proband spent 5 weeks in the neonatal intensive care unit and multiple congenital abnormalities were observed including a right femoral distal bifurcation, an absent tibia, syndactyly of 2-3-4th toes and an absent 1st toe, left metatarsus adductus, patent ductus arteriosus with hypoplastic arch, and dysmorphic facial features. His mother presented with similar phenotype including: partial tibial agenesis, clubfoot, and toe syndactyly. Whole exome sequencing identified a maternally inherited heterozygous variant in exon 1 of *SUMO2* (NM_006937.4; P61956) c.2 T>A: p.Met1?. This variant is not reported in population databases nor literature. In silico analysis including protein-protein interaction and impact prediction following ACMG guidelines suggests this variant is disease causing, hence, we propose a pathogenic classification.

Conclusion: We report a novel and likely pathogenic variant in *SUMO2*. In animal studies knockdown of *SUMO2* altered the expression of *CDX2*, *OCT4*, and *NANOG*; important genes in embryonic development, and result in embryonic lethality. We propose pathogenic variants in *SUMO2* are responsible for the phenotype in this family. Our findings set the stage to characterize the phenotype associated with *SUMO2* start codon pathogenic variants, a clinically heterogeneous presentation that well illustrates the importance of disruption of SUMOylation.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2643. Mechanisms of adaptation in high-altitude pregnancy: association of genotype with oxygen delivery and placental metabolism

Authors:

K. O'Brien¹, W. Gu², J. A. Houck³, L. M. W. Holzner⁴, J. L. Armstrong⁴, A. P. Sowton⁴, P. M. Darwin⁴, L. Toledo-Jaldin⁵, L. G. Moore⁶, A. J. Murray⁴, T. S. Simonson⁷, C. G. Julian³; ¹Univ. of California San Diego, San Diego, CA, ²Univ. of California, San Diego, La Jolla, CA, ³Univ. of Colorado, Denver, CO, ⁴Univ. of Cambridge, Cambridge, United Kingdom, ⁵Hosp. Materno-Infantil, Bolivia, Bolivia, Plurinational State of, ⁶Univ. of Colorado, Denver, CA, ⁷UC San Diego, San Diego, CA

Abstract Body:

The hypobaric hypoxia of high altitude (HA) residence challenges tissue oxygen homeostasis and metabolism. HA exposure during pregnancy reduces birth weight and alters placental metabolism. HA ancestry protects against altitude-associated reductions in birth weight, indicating hypoxia tolerance. Such protection appears to be genetic in nature, yet the underlying mechanisms are unknown. In a cohort of 69 pregnant Andeans (18-45y) living in La Paz, Bolivia (3600 - 4100m) and delivering by unlabored Cesarean section, we performed selection-nominated association studies to explore relationships between putatively adaptive variation and phenotypes related to oxygen delivery in pregnancy or placental metabolism. Maternal genotyping was performed using the 1.8 million SNP Multiethnic Genotyping Array (Illumina). Placental mitochondrial function was assessed in cryopreserved villous biopsies using high-resolution respirometry (Oxygraph-2k, Oroboros). Maternal and umbilical venous plasma was obtained for the measurement of circulating protein levels by ELISA. Using within-population selection tests (iHS) to detect signatures of natural selection, putatively adaptive haplotypes (iHS>3) were identified; those overlapping with an *a priori* cellular hypoxic signaling and metabolism gene list were prioritized for association analysis. Linear regression modeling revealed associations between prioritized haplotypes and key outcome measures at an FDR corrected level of $p < 0.05$. Haplotypes within 200kb of *CPT2* (iHS 5.38) and both *POMC* and *DNMT3* (iHS 3.28) associated with lower maternal plasma erythropoietin ($p=0.02$ and $p=0.01$, respectively). A haplotype within 200kb of *TBX5* associated with lower protein levels of the angiogenic factor VEGF (iHS 3.65, $p=0.04$) in umbilical venous blood. Finally, a haplotype within *PTPRD* (iHS 3.31) associated with lower placental respiratory capacity ($p=0.002$). Our results reveal novel associations between putatively adaptive gene regions and phenotypes linked to oxygen carriage and delivery, as well as placental mitochondrial respiratory capacity. Together, these findings provide new insights into mechanism of high-altitude adaptation at different points of the oxygen cascade in the context of reproduction.

Molecular Effects of Genetic Variation Posters - Thursday

PB2644. Mendelian randomization reveals the causal interaction of *MICA* transcription levels with the risk of Graves' disease

Authors:

Y. Sutoh¹, S. Komaki¹, T. Yamaji², S. Nakano², R. Katagiri², N. Sawada², K. Ono¹, H. Ohmomo¹, T. Hachiya¹, Y. Otsuka-Yamasaki¹, A. Takashima¹, S. Umekage¹, M. Iwasaki², A. Shimizu¹; ¹Iwate Med. Univ., Yahaba, Japan, ²Natl. Cancer Ctr. Inst. for Cancer Control, Tokyo, Japan

Abstract Body:

Exposure to environmental stress factors activates the cellular stress response. Stressed cells express specific molecules, so-called “danger signals”, which activate the immune response, leading to the elimination of these stressed cells. Natural killer group 2 member D (NKG2D) ligands (NKG2DLs) are expressed on the surface of stressed cells as a danger signal. NKG2DL⁺ cells are eliminated by cytotoxic cells to maintain tissue homeostasis. Interestingly, NKG2DL expression is also detected in activated immune cells, such as the macrophages infiltrating atherosclerotic plaques. This expression is thought to be associated with immune regulation; however, there are limited studies on humans. Here, we provide evidence for a phenotype associated with the NKG2DL expression level using an epidemiological approach based on the genotype data coupled with self-reported medical histories of 44,739 Japanese residents collected in the Tohoku Medical Megabank (TMM) project. First, we conducted a phenome-wide association study (PheWAS) of the expression quantitative-trait loci (eQTL) of NKG2DL transcripts. Following Bonferroni correction, we identified 10 or 13 significant outcomes for 58 available phenotypes associated with *MICA* or *MICB*, predominant NKG2DLs in various human tissues; 8 were common in both genes, including chronic hepatitis B (CHB), Graves' disease (GD), and allergic conjunctivitis. Brain tumors and rheumatoid arthritis were associated with only *MICA* eQTLs. Lung cancer, hypertension, and cavity were associated with only *MICB* eQTLs. Next, we performed Mendelian randomization (MR) with NKG2DL expression as exposure and identified the causal effect of the *MICA* expression level on the risk of GD ($p = 4.1 \times 10^{-3}$), allergic conjunctivitis ($p = 1.8 \times 10^{-2}$), and CHB ($p = 4.6 \times 10^{-2}$) using a weighted median estimator. Similarly, we observed the causal effect of *MICB* expression on the risk of CHB ($p = 2.9 \times 10^{-2}$) and cavity ($p = 3.4 \times 10^{-2}$). No significant pleiotropy was found in these associations ($p > 0.05$). A negative causal effect on the risk of GD (odds ratio (OR) 0.983; [95% confidence interval (CI) 0.971-0.995]) per standard deviation increase in *MICA* expression was observed. Finally, we performed replication analysis with different datasets and several sensitivity analyses with different estimators, such as the MR-Egger and inverse-variance weighted (IVW) method, and confirmed the robustness of the conclusion. These results suggest that low *MICA* transcription levels in immune cells are associated with a higher risk of Graves' disease. Our strategy might be useful for investigating a gene function based on a human dataset.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2645. Metabolomics to clarify the mechanism of *ALDH2* polymorphism-induced alcoholic liver injury.

Authors:

S. Harada^{1,2}, R. Toki¹, A. Hirata¹, N. Miyagawa¹, M. Iida¹, A. Hirayama², M. Sugimoto², T. Soga², M. Tomita², T. Okamura¹, T. Takebayashi^{1,2}; ¹Keio Univ. Sch. of Med., Tokyo, Japan, ²Inst. for Advanced BioSci.s, Keio Univ., Tsuruoka, Japan

Abstract Body:

Background: Alcoholic liver injury is associated with *ALDH2* (rs671) polymorphisms, particularly in Asians, but the pathogenic mechanism remains unclear. This study investigated how *ALDH2* polymorphisms and drinking habits are associated with liver function decline via metabolomic changes in a general Japanese population.

Methods: In the Tsuruoka Metabolomics Cohort Study conducted in Japan, 10,993 Japanese were genotyped, profiled for metabolites, and assessed for health status comprehensively. Absolute quantification of 94 plasma metabolites has been performed using the CE-MS method. This study included 3,200 participants who were genotyped for *ALDH2* (rs671) using Fluidigm SNP Type™ Assays (192.24 Dynamic Array™ integrated fluidic circuits) to examine the mechanisms underlying the development of alcoholic liver injury using mediation analysis. First, mediation analysis was conducted using *ALDH2* (rs671) polymorphism as an exposure, daily ethanol intake as a mediator, plasma metabolite level as an outcome, and age and sex as confounders to examine metabolites strongly associated with *ALDH2* polymorphism and alcohol consumption. Then, we conducted a mediation analysis with alcohol intake as an exposure, metabolite level as a mediator, and liver injury (serum AST level) as an outcome to determine how strongly a metabolite explained the pathogenesis of alcoholic liver injury.

Results: *ALDH2* (rs671) alleles were AA in 3.5%, AG in 29.5%, and GG in 67.0%. All but one of the AA carriers with inactive *ALDH2* were non-drinkers; therefore, AA carriers were excluded from the analysis. The 3,079 participants (62.9 ± 7.4 years old, 1,375 men and 1,704 women) with a complete dataset were included in the analysis. 1520 (49.3%) were daily drinkers. *ALDH2* (rs671) polymorphism was associated with plasma Gln level (-0.10 SD (95% CI: -0.17, -0.02) change for GG compared to AG). Of these, 76.5% were mediated by alcohol intake. Then, we conducted a mediation analysis with alcohol intake as an exposure, Gln as a mediator, and AST as an outcome. We found that AST increased by 0.05 (95%CI: 0.03, 0.07) per 1 g increase in daily alcohol intake, and 15% of this increase were mediated by plasma Gln level.

Conclusions: In the general Japanese population, *ALDH2* (rs671) polymorphism was strongly associated with plasma Gln level, and most of the associations were explained by alcohol intake. Gln level explained 15% of AST elevation due to alcohol, suggesting that Gln metabolism plays an essential role in the mechanism of *ALDH2* polymorphism-induced alcoholic liver injury. A follow-up study is needed to clarify the causal relationship.

Molecular Effects of Genetic Variation Posters - Thursday

PB2646. Mimicking NDD phenotypes and functional characterization of *PPP1R9A*^{+/-} mutation using iPSCs- derived neurons and single-cell transcriptomics

Authors:

M. Uddin^{1,2}, B. Zehra¹, N. Mohamed¹, N. Nassir¹, A. Ahmed¹, R. Khalil³, F. Ahmad³, N. Jezawi⁴, B. Berdiev¹; ¹Mohammed Bin Rashid Univ. of Med. and Hlth.Sci., Dubai, United Arab Emirates, ²GenomeArc Inc., Toronto, ON, Canada, ³American Univ. of Sharjah, Sharjah, United Arab Emirates, ⁴Princess Margaret Res. Ctr., Toronto, ON, Canada

Abstract Body:

PPP1R9A is an imprinted gene that codes Neurabin I and is located on chromosome 7q12. Neurabin I is a protein phosphatase-1 regulatory subunit that primarily interacts with F-actin, protein phosphatase 1 (PP1), neurabin-2 and p70-S6K; proteins that are directly involved in neurite formation and establishing synaptic connections. Genetic mutations impacting *PPP1R9A* are classified as a variant of uncertain significance in several neurodevelopmental problems and are recently reported as a candidate gene underlying the pathophysiological features of autism spectrum disorder (ASD). However, the functional and molecular role of *PPP1R9A* in NDD is still inconclusive. Therefore, this study aimed to functionally characterize the CRISPR/Cas9 mediated heterozygous knockout (KO) model for the *PPP1R9A*^{+/-} gene in hiPSCs to identify its role in NDD. These KO hiPSCs were then differentiated into neurons to recapitulate the condition *in vitro* and explore morphogenesis and differentiation patterns in the brain through morphometric analysis of dendritic spines, immunofluorescence, and protein expression of biomarkers. Furthermore, using an overexpression vector, a wild-type copy of the *PPP1R9A* gene was introduced in the KO *PPP1R9A*^{+/-} cells to rescue the mutation effect. The whole transcriptomics analysis of control, KO *PPP1R9A*^{+/-}, and over expressed *PPP1R9A* in iPSCs-derived neurons revealed the set of differentially expressed genes that were significantly enriched for functions of neural development, synapse signaling, and morphogenesis. Also, the expression for upregulated genes in KO *PPP1R9A*^{+/-} iPSCs-derived neurons was reverted to stabilized expression in *PPP1R9A* over expression neurons. Currently, we are conducting a single cell (SC) RNASeq experiment for the high-resolution detection of cell type-specific phenotypes through gene dysregulation that resulted in ASD-related neurodevelopmental phenotype in *PPP1R9A*^{+/-} iPSCs-derived neurons. Since we observed a dominant negative effect in the *PPP1R9A* overexpressed neurons, therefore, we are currently developing a gene therapy approach using antisense oligonucleotides (ASO) technology to reverse the KO effect and restore phenotypes comparable to the wild type. In summary, by integrating CRISPR/Cas9 technology in iPSCs, single-cell RNA seq, and other cutting-edge techniques, this study established the role of Neurabin I mutation in the pathogenesis of NDD.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2647. Misexpression of inactive genes is associated with nearby rare structural variants.

Authors:

T. Vanderstichele¹, K. L. Burnham¹, N. de Klein¹, B. Howell¹, K. Walter¹, K. Kundu^{1,2}, A. Nath^{2,3}, E. Persyn², J. Marten², INTERVAL Study, D. Roberts⁴, E. Di Angelantonio², J. Danesh², A. Berton⁵, A. Platt⁵, A. Butterworth², N. Soranzo¹, L. Parts¹, M. Inouye^{2,3}, D. Paul^{2,6}, E. E. Davenport¹; ¹Wellcome Sanger Inst., Hinxton, United Kingdom, ²Univ. of Cambridge, Cambridge, United Kingdom, ³Baker Heart and Diabetes Inst., Melbourne, Australia, ⁴Univ. of Oxford, Oxford, United Kingdom, ⁵Translational Sci. and Experimental Med., Res. and Early Dev., Respiratory and Immunology, BioPharmaceuticals R&D, AstraZeneca, Cambridge, United Kingdom, ⁶Ctr. for Genomics Res., Discovery Sci., BioPharmaceuticals R&D, AstraZeneca, Cambridge, United Kingdom

Abstract Body:

In human genetics, it remains challenging to identify rare genetic variants that influence human phenotypes and understand the underlying mechanism of their effect. In previous studies, gene expression outliers from population-scale RNA sequencing data have been used to identify functional rare variants with large effects. These analyses have focused on genes that are expressed across many individuals in the studied tissue. However, evidence from Mendelian diseases shows that genetic variants can cause misexpression of inactive genes in a specific tissue. It is currently unknown whether this phenomenon is widespread in human populations, by what mechanisms it occurs and the phenotypic impact it has. Using 4,542 whole blood RNA sequencing samples from a prospective cohort of apparently healthy European blood donors recruited to the INTERVAL study, we identified a set of genes that were not expressed in at least 95% of individuals, but were highly expressed in at least one other tissue according to the Genotype-Tissue Expression (GTEx) project (n = 6,401). We assessed whether rare variants in cis, identified for 2,804 samples with whole-genome sequencing data, were associated with misexpression of these normally inactive genes, and found that rare structural variants (MAF < 1%) were enriched within a +/- 200 kb window around the gene body. This enrichment increased with the magnitude of misexpression from a risk ratio of 1.61 for misexpression events greater than 1 TPM (p-value < 2.49x10⁻⁵) to 11.08 (p-value < 2.76x10⁻¹⁰) for events greater than 5 TPM. Common structural variants (MAF ≥ 1%) were not enriched among misexpression events. Rare duplications were most enriched among different structural variants types, while rare indels and single nucleotide variants were not enriched even within a +/- 10 kb window. Overall, we present an alternative approach for identifying rare genetic variants associated with disruption of normal gene expression in healthy human populations. Future analysis of the properties of the structural variants associated with misexpression will be useful for improving our understanding of the regulatory principles of gene expression and three-dimensional genome organisation.

Molecular Effects of Genetic Variation Posters - Thursday

PB2648. Mitochondrial Complex III (CIII) deficiency case study: Analysis of a likely pathogenic variant in *UQCRC2* gene as the etiology of intellectual disabilities and obesity.

Authors:

G. Arroyo Figueroa¹, A. Lebrón Ilarraza¹, G. Serrano Rodríguez², C. Velez Delgado³, F. Velez Bartolomei⁴, E. Albino⁵, S. Carlo⁶, A. Abstract Body:

Understanding the genetic factors that lead to rare diseases phenotypes is of critical importance, more so in genetically underrepresented populations such as Puerto Ricans. We are reporting a case involving *UQCRC2* gene, which encodes for protein 2, one of the 11 structural subunits of the mitochondrial complex III (CIII). CIII deficiency is a rare genetic condition caused by mitochondrial dysfunction. This multisystem disorder's phenotype includes; hypotonia, failure to thrive, encephalopathy, and delayed psychomotor development. Abnormalities of some nuclear genes that encode mitochondrial assembly factors are well established, but many CIII deficiency disorders remain ambiguous. In this case, we are presenting an exome analysis with a new heterozygous frameshift mutation, c.753delC(p.Asn252Thrfs*21), in *UQCRC2*. This deletion of a base pair results in reading frameshift at position 252 and the introduction of a premature termination codon 20 residues downstream. This is a 14-year-old female who's previous genetic evaluations at other mainland Children's Hospital suggested a possible clinical diagnosis of Prader-Willi syndrome. Genetic testing demonstrated a normal methylation 15q11 through 13 as well as no cytogenetic evidence of a microdeletion, rendering the diagnosis no longer valid. A whole exome sequencing documented the *UQCRC2* gene likely pathogenic variant. Phenotypical findings in this patient includes development delay, obesity, autism spectrum disorder (ASD), speech delay, behavioral problems, hypotonia, incontinence issues and fine motor deficits. Obesity has not been reported associated to mutations in *UQCRC2* gene. This patient does not have family history of obesity or other epigenetic factors that may be associated to obesity in her or her family. This case provides clinical evidence of an expansion of the phenotype associate to *UQCRC2* and/or Complex III phenotypes and should be consider a molecular etiology associate to obesity in the presence of developmental delay and ASD.

Molecular Effects of Genetic Variation Posters - Thursday

PB2649*. Mitotic recombination is a common mechanism of cellular mosaicism in Fanconi anemia.

Authors:

F. X. Donovan¹, R. Ramanagoudr-Bhojappa¹, F. P. Lach², D. C. Kimble¹, S. Soma¹, A-M. Gonzalez², R. O. Rosti², A. D. Auerbach³, A. Smogorzewska², S. C. Chandrasekharappa¹; ¹Cancer Genetics and Comparative Genomics Branch, NHGRI, NIH, Bethesda, MD, ²Lab. of Genome Maintenance, The Rockefeller Univ., New York, NY, ³Human Genetics and Hematology Program, The Rockefeller Univ., New York, NY

Abstract Body:

Objective: The aim of this study is to understand the mechanism of somatic mosaicism and its influence on patient phenotype among individuals with Fanconi anemia (FA).

Methods: We evaluated DNA from 742 individuals enrolled in the International Fanconi Anemia Registry (IFAR) by targeted sequencing with a custom capture kit designed for the entire length of a panel of 180 genes, including all known FA genes, and for 356 individuals we employed genome-wide SNP array (~1M SNPs). For variants that exhibited skewed allele frequency we performed deep sequencing using MiSeq. To confirm pathogenicity, we implemented targeted RNAseq or RT-PCR for splice variants, and cell cycle arrest, cell survival, and FANCD2 ubiquitination assays for missense variants.

Results: We identified evidence of somatic mosaicism in 32 individuals from 30 families. The advent of a *de novo* compensatory variant or the reversal of a pathogenic variant was observed in five and 13 individuals, respectively. Isodisomy of an FA gene resulting from mitotic recombination (MR) was exhibited by 14 individuals. In two families there were siblings that each exhibited mosaicism via different mechanisms. The isodisomy extended to the chromosome terminus in each case, influencing the allelic expression in two different ways: six cases exhibited the breakpoint junction within the FA gene, between two biallelic pathogenic variants, resulting in the replacement of the pathogenic variant by a wildtype sequence; eight cases exhibited isodisomy of the entire FA gene resulting in a loss of one variant and duplication of the second. Of the eight cases with isodisomy of the entire gene we performed functional analysis on 5/7 variants, as one variant occurred in two cases, and in each case the duplicated variant exhibited hypomorphic function. Neither isodisomy event appear to influence the age at onset of hematologic disease, but the cases with an intragenic isodisomy junction showed longer survival, indicating that the loss of variant and subsequent expansion of modified cells promoted a positive effect on the hematologic disease course.

Conclusion: We identified 30 families exhibiting somatic mosaicism via three distinct mechanisms: compensatory *de novo* variant, variant reversion, and isodisomy via MR. The MR group is further classified by whether the isodisomy includes the entire gene or its junction occurs within a gene. These natural corrections improved hematologic outcomes underscoring the importance of knowing how cells naturally revert pathogenic variants and how these reversions affect patient outcomes, which can influence the design of clinical interventions including gene therapy trials.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2650. Modeling single-cell activation states enhances power to identify ex vivo stimulation response eQTLs.

Authors:

C. Valencia^{1,2,3}, A. Nathan^{1,3,2}, J. Kang^{2,1,3}, I. Rumker^{1,2,3}, S. Raychaudhuri^{1,2,3}; ¹Brigham & Women's Hosp., Boston, MA, ²Harvard Med. Sch., Boston, MA, ³Broad Inst. of MIT and Harvard, Boston, MA

Abstract Body:

Genome-wide association studies (GWAS) of complex human traits such as susceptibility to infection implicate noncoding variation, where associations may be mediated through gene expression regulation. Studying expression quantitative trait loci (eQTL) aims to improve the interpretation of GWAS results by linking genetic variants to expression levels of specific genes. However, in most cases this aim remains elusive, in part because eQTLs are context-sensitive, and a complete characterization of eQTLs in the context of environmental stimuli and across cell types remains incomplete. Cell perturbations such as viral infection activate gene programs like interferon response. Previous studies used ex-vivo stimulation to identify “response” eQTLs, i.e. eQTLs that are specific to an infected cell state. However, these studies did not consider variation in cell response to the stimulus. Now single cell data reveal cell-cell heterogeneity in the stimulus response of individual cells. Effective modeling of per-cell activation state (and other cell-level variables) may enhance power to detect response eQTLs. Here, we used published data (Randolph, et al. 2022 Science) to study the effect of 12 hours of ex-vivo stimulation with either influenza virus (Flu) or mock (Control) in 208,223 peripheral blood mononuclear cells (PBMCs) of 45 African-American and 45 European men using single cell RNA-seq. First, we prioritized 1,955 eQTLs with robust effect across all stimuli and cell types. Then, we modeled the expression of these genes in single cells as a function of genotype and an interaction with cell state accounting for confounders and batch using the Poisson Mixed effects Model (PMM) described by Nathan et al 2022, Nature. Because the second expression principal component (PC-2) positioned cells along a stimulus gradient, and was enriched for interferon genes, PC-2 was used as a continuous activation state of stimulus response per cell. We found that around 10% of the 1955 eQTLs were heterogeneous along the continuous activation state based on the significance of the interaction term (response eQTL). In contrast, modeling activation state as binary in single cells or pseudobulk expression profiles found only 6.5% or 4.29% of the eQTLs to be response eQTLs, respectively. In addition, using the PMM with continuous single-cell activation state, we found that almost 66% of the response eQTLs showed heterogeneous effects across the 5 major cell types (Monocytes, NK, CD4-T, CD8-T, and B). In summary, our results demonstrated the benefit of studying response eQTLs at single cell resolution in heterogeneous samples.

Molecular Effects of Genetic Variation Posters - Thursday

PB2651. Modeling the effects of *KCNQ1* SNPs on type 2 diabetes risk in iPSC-derived pancreatic islets identifies an early role of methylation that alters islet composition and beta-cell mass.

Authors:

A. Nair, E. Grellinger, Y. Muller, M. Traurig, R. Nelson, C. Bogardus, L. Baier; NIDDK/NIH, Phoenix, AZ

Abstract Body:

The strongest association for type 2 diabetes (T2D) in Southwestern American Indians maps to intron 15 of *KCNQ1* where the lead SNP (rs2299620) is in a region of strong linkage disequilibrium (LD). We previously mapped a functional region in this intron to an ~400 bp fragment containing rs2299620 and 3 additional SNPs and demonstrated functionality of this fragment using American Indian iPSC-derived pancreatic islets. In the current study, we used CRISPR-CAS9 to generate iPSCs with targeted edits at these 4 SNPs, and 3 additional SNPs in strong LD, and used these isogenic iPSC-derived pancreatic islets as a model system to study the effect of the variants. Flow cytometry of these islets identified a lower percentage of beta-like cells (cells co-expressing *INS* and *NKX6-1*) in islets generated using iPSCs with the risk haplotype (35.6% vs 47.4%, n=3, P=0.03), suggesting an effect of these T2D associated SNPs on beta cell mass. Stage specific gene expression analyses identified a significant difference in the fold increase in *INS* gene expression during the endocrine progenitor (EPs) stage (755.5-fold increase in expression in risk vs 4403-fold increase in expression in non-risk, relative to pancreatic progenitors, n=3, P=0.0002). As endocrine cell type commitment occurs during EP stage and increase in *INS* expression correlates with beta cell commitment, the lower increase in insulin expression during this stage with the risk haplotype could in part explain the effect of the variants on mature islet composition. In EPs with the risk haplotype, we also identified increased expression (fold difference=1.7, n=3, P=0.06) of *H19* which maps upstream of the SNPs and is known to affect beta-cell mass.

Methylation at enhancers regulates gene expression. Therefore, we assessed stage specific methylation at all 13 CpG sites (*CpG-func*) that encompass the functional region (between rs2299620 and rs74046911) and 3 CpG sites (*CpG-ctrl*) immediately upstream of rs2299620. We identified dynamic methylation changes at *CpG-func* whereas no changes at *CpG-ctrl* (remained hypermethylated, average methylation >90%) during different stages of pancreatic islet differentiation. *CpG-func* were hypermethylated (86.71%) during the iPSC stage but became hypomethylated (46.2%) during the EP stage. Interestingly, a strong difference in methylation was seen in *CpG-func* only during the EP stage when compared between the risk (30.6%) and non-risk haplotypes (61.8%). In summary, the T2D SNPs at *KCNQ1* affect islet composition (beta-cell mass) and this effect is manifested early during development, likely via an effect on CpG methylation and gene regulation.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2652. Mosaicism of a *de novo* *TP53* mutation in a patient with breast cancer: value of two germ layers study

Authors:

D. Aguilar¹, A. Aranda-Gutierrez¹, L. Flores-Lagunes², C. Alaez-Verson²; ¹Hosp. Zambrano Hellion Tec Salud, San Pedro Garza García, Mexico, ²INMEGEN, CdMx, Mexico

Abstract Body:

Introduction: Li-Fraumeni syndrome (LFS) is associated with a high lifetime risk of developing breast cancer (BC). A subset of patients can present in the form of mosaicism with uncertain clinical implications. Whether hereditary or *de novo*, the presence of LFS has clinical implications. Our objective is to report a case of BC diagnosed in a patient with mosaicism of a *de novo* *TP53* likely pathogenic variant (LPV) and discuss the literature regarding this entity. **Case description:** 41-year-old woman with stage IA hormone-receptor negative and HER2-positive BC. She was treated with a simple mastectomy and adjuvant therapy. She did not undergo radiotherapy. Germline genetic testing identified a *TP53* LPV (NM_000546:c.523C>T (p.Arg175Cys)) in a saliva sample. Peripheral blood and formaldehyde fixed-paraffin embedded tumor tissue from her pre-adjuvant mastectomy were further studied at Genomic Diagnostic Laboratory of the National Institute of Genomic Medicine (INMEGEN), confirming *TP53* mosaicism. Biological relationship between the patient and her parents was confirmed, with neither being carriers of the *TP53* LPV. Therefore, the patient's LPV was confirmed to be *de novo*. The patient has remained asymptomatic and without evidence of BC recurrence or any other malignancy. **Discussion:** Mutations occurring at post-zygotic stage are responsible for mosaic *TP53*, which accounts for 5% of LFS phenotypes. Mosaicism should be suspected in any patient with allele frequencies that differ significantly from 50% in NGS-based genetic testing. In the present case, suspicions of mosaicism were raised from the identification of a LPV in *TP53* (NM_000546:c.523C>T (p.Arg175Cys)) at a variant fraction of 11.9% in an ectoderm-derived sample (saliva sample), at a variant fraction of 29% in blood sample and 40% in the tumor DNA. Of note, this was documented before the patient was started on adjuvant chemotherapy. In addition, the presence of the mosaic *TP53*, a second somatic *TP53* mutation were also demonstrated in the tumor, supporting the involvement of both variants in the development of the patient's BC. Currently, information concerning the optimal treatment and survival outcomes of BC patients with *TP53* mosaicism is lacking. Notwithstanding, recommendations do exist in literature for the management of BC in patients with LFS. **Conclusion:** This case highlights the importance of distinguishing between germline and somatic mosaic *TP53* mutations, as this knowledge can guide appropriate cancer surveillance protocols and genetic counseling. Future studies aimed at identifying the optimal cancer treatment and follow-up schemes in patients with *TP53* mosaicism are warranted.

Molecular Effects of Genetic Variation Posters - Thursday

PB2653. Multiomics identifies dysregulation of Wnt-signaling through epigenetic gene regulation across tissues in Bohring-Opitz Syndrome

Authors:

I. Lin; UCLA, Los Angeles, CA

Abstract Body:

ASXL1 (*Additional sex combs-like 1*) plays a key role in epigenetic regulation of early developmental processes and is ubiquitously expressed across tissues. *De novo* autosomal truncating mutations of *ASXL1* cause Bohring-Opitz Syndrome (BOS), a rare genetic disorder characterized by profound intellectual disability, developmental delay, seizures, heart defects, and 'BOS posture'. **We hypothesize that highly penetrant and high-effect mutations in *ASXL1* dysregulate common gene regulatory mechanisms across cell types.** To examine this, we collected blood and skin punch biopsies from 17 individuals with BOS and 27 controls. We generated RNAseq data and found that differentially expressed genes (DEGs) were more upregulated in both BOS fibroblasts (129/177 DEGs, 72.9%) and blood (590/1097 DEGs, 53.8%) compared to controls. DEGs were dysregulated in the same direction across tissue types and top DEGs included *GREM2*, *GRIK5*, and *VANGL2*. In addition, gene ontology enrichments were identified in Wnt signaling in blood, and neuron projection development in both tissue types, driven by key early morphogenesis genes. Since *ASXL1* mutations alter histone modifications, we performed ATACseq to examine whether transcriptional dysregulation acts through chromatin accessibility. ATACseq of fibroblasts with truncating *ASXL1* variants identified, globally, more open chromatin regions (3036/4336 differential peaks $p_{adj} < 0.05$, 70.0%) compared to controls. Intersection of ATAC- and RNAseq DEGs (37/177, 31.6%) revealed a strong positive correlation ($r(69) = 0.64$, $p = 2.39 \times 10^{-9}$) between increased chromatin accessibility and increased gene expression, suggesting that *ASXL1* mutations directly influence chromatin accessibility resulting in transcriptional dysregulation. To examine epigenomic changes that may drive this dysregulation, we performed CUT&RUN against H3K4me3 and H3K27me3 marks, known to be regulated by *ASXL1*, and genome-wide DNA methylation profiling. CUT&RUN showed differential histone methylation at transcriptional start sites of key genes of interest, such as *VANGL2*. Genome-wide DNA methylation data identified 5121 CpG sites (FDR < 0.05) associated with an ENSEMBL gene, with 609 sites mapping to blood RNAseq DEGs, including *GREM2*, *GRIK5*, and *VANGL2*. Across our datasets, genes such as *VANGL2*, a planar cell polarity pathway protein that acts through Wnt signaling to direct embryonic nervous system development, are consistently dysregulated. Collectively, our data further elucidates the impact of truncating *ASXL1* mutations on gene regulatory mechanisms and pathogenesis in Bohring-Opitz Syndrome using a multiomics approach across tissues.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2654. Mutant *Wac* mice exhibit phenotypes relevant to DeSanto-Shinawi Syndrome and provide initial insights into molecular and developmental mechanisms.

Authors:

N. Seban¹, A. M. Stafford², C. Canales¹, S. Lozano¹, J. Zhu¹, R. Ortiz¹, M. Corea¹, D. Rahbarian¹, A. Nord¹, D. Vogt²; ¹Univ. of California Davis, Davis, CA, ²Dept. of Pediatrics and Human Dev., Michigan State Univ., East Lansing, MI

Abstract Body:

Rare monogenic syndromes are emerging as a collectively common cause of neurodevelopmental disorders associated with cognitive, social, behavioral, and neurological impacts, including autism, attention deficit hyperactivity disorder (ADHD) and seizures. One such example, DeSanto-Shinawi Syndrome (DESSH), is caused by mutations in the *WAC* gene. Individuals diagnosed with DESSH present craniofacial alterations as well as cognitive symptoms that include autism, ADHD and seizures. *WAC* encodes a protein that contains WW and coiled coil domains, motifs important for protein/protein interactions. Previous reports have demonstrated a multitude of cellular roles for the *WAC* protein, including positive regulation of mammalian target of rapamycin (MTOR), mitosis, transcriptional initiation and autophagy. Comprehensive studies from a mammalian model to understand how these changes occur and whether the same interactions or unique events occur in the mammalian brain are needed. We generated a constitutive murine *Wac* mutant mice and assessed behavioral, anatomical, and cellular phenotypes that are relevant to humans diagnosed with DESSH, then evaluated transcriptional profiling at single cell level on postnatal day (PND) 2. *Wac* heterozygous (Het) mice exhibited dysmorphic craniofacial features, decreased expression of GABAergic interneuron proteins, susceptibility to seizures, and behaviors implicating decreased learning and memory. The phenotypes seen in the murine model indicate some relevance to the underlying biology that causes symptoms of DESSH. Single nuclei transcriptomic profiling of mutant and wild-type cerebral cortex at postnatal day (PND) 2 identified differential regulation across numerous cell populations, including evidence for perturbed GABAergic signaling in line with interneuron histological changes. Validation of these findings is ongoing. Overall, our data support that this new mouse model recapitulates core symptoms of DESSH, and our results provide novel insights regarding molecular and cellular pathologies and neuroanatomical impacts associated with *Wac* haploinsufficiency. Future work is needed to understand how cell-type specific perturbations might drive pathology and to understand the molecular mechanisms of *WAC* protein that are required in the brain. Our results suggest initial therapeutics for DESSH and will spark further exploration of the biological mechanisms underlying this rare syndrome.

Molecular Effects of Genetic Variation Posters - Thursday

PB2655*. Mutational scanning to determine pathogenicity of Variants of Uncertain Significance in genes in the Sonic Hedgehog Pathway

Authors:

D. Baldrige, J. Shepherdson, B. Cohen; Washington Univ. in St. Louis, St. Louis, MO

Abstract Body:

Sequencing of patients with suspected monogenic disorders is a powerful approach for identifying molecular diagnoses, although the expected diagnostic yield continues to be around 30-40%. One major limitation is the abundance of Variants of Uncertain Significance (VUS) due to insufficient evidence for determining if variants are pathogenic or benign. High-throughput functional assessment of variant effects offers a scalable solution to this critical problem in genomic medicine via mutational scanning. This approach involves the simultaneous assessment of thousands of variants in a protein of interest, using a reliable, carefully calibrated, cell-based assay. To demonstrate the feasibility of establishing mutational scans for transcription factors, we have established an assay for the gene, *GLI2*, part of the sonic hedgehog signaling pathway. Pathogenic variants in *GLI2* cause Culler-Jones syndrome, involving endocrine and skeletal patterning abnormalities. Using cells engineered with a GFP reporter and transduced with lentivirus expressing *GLI2* variants, we conducted a SortSeq experiment, coupling fluorescence-activated cell sorting (FACS) to sequencing, to demonstrate the functional effects of these variants. Our results show perfect discrimination of known pathogenic and benign variants in *GLI2*. We use this system to assay all 170 missense variants in *GLI2* that have been submitted to ClinVar, including about 100 VUS. The end result is a “look-up table” that gives clinicians and diagnostic laboratories high confidence functional evidence for reclassification of coding variants in *GLI2*. We also demonstrate that this same cell-based assay can be used to test variants in additional genes in the sonic hedgehog pathway, including *SMO*, suggesting a pathway-based approach for scaling mutational scanning to many genes in the genome.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2656. NASP contributes to autism via epigenetic dysregulation of neural and immune signaling pathways

Authors:

J. Li¹, S. Zhang², J. Yang², J. Glessner¹, H-Q. Qu¹, H. Hakonarson³; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Tianjin Med. Univ., Tianjin, China, ³Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

Epigenetics make substantial contribution to the etiology of autism spectrum disorder (ASD) and epigenetic regulators have been found to harbor causal mutations for ASD, but few studies have focused on the contribution of epigenetic regulators to the etiology of ASD and its immune comorbidity. Trio-based whole exome sequencing (WES) was conducted on a simplex family including one proband with autism and comorbidity of atopic disease. Genome editing technique was used to specifically knockout (KO) the tNASP (Nuclear Autoantigenic Sperm Protein) gene to understand the function of the potential causal gene tNASP. ATAC-seq, ChIP-seq and RNA-seq were performed to investigate impact of tNASP KO on chromatin accessibility, active chromatin state and gene expression profiling. Stable cell lines overexpressing wild type tNASP or the mutant tNASP at the tNASP KO background were constructed. ATAC-seq and RNA-seq were similarly conducted to examine the effect of tNASP mutation identified in the family. Screening in additional ASD subjects were carried out. Genetic analysis identified tNASP(Q289X) mutation as the potential causal variant for this family, which is a de novo likely gene disruptive (LGD) variant. Another ASD patient carrying copy number variant covering gene NASP was also identified. ATAC-seq and ChIP-seq showed that tNASP KO increases chromatin accessibility, promotes the active promoter state of genes enriched in synaptic signaling. RNA-seq further showed that tNASP KO leads to upregulated expression of genes functioning in the neural signaling and immune signaling pathways. The expression of tNASP(Q289X) is subjected to nonsense mediated decay. Comparing to WT tNASP, tNASP(Q289X) enhances chromatin accessibility of genes having enriched expression pattern in brain. RNA-seq revealed that genes involved in the neural signaling and the immune signaling are affected by the tNASP mutation. In summary, our study identifies a novel ASD gene tNASP, a histone binding protein with high expression in embryonic cells. Our data suggest that the de novo LGD variants of tNASP contribute to the pathogenesis of ASD and its immune comorbidity by regulating the chromatin accessibility, active promoter state of neural genes and further leading to the expression level change of immune genes.

Molecular Effects of Genetic Variation Posters - Thursday

PB2657*. Natural variants in *SEL1L* modify lethality, ERAD, and proteasome function in a model of NGLY1 deficiency.

Authors:

T. Tu'ifua, C. Y. Chow; Univ. of Utah, Salt Lake City, UT

Abstract Body:

N-glycanase 1 (NGLY1) deficiency is a rare disease caused by autosomal recessive loss of function mutations in the *NGLY1* gene. Patients suffer from movement disorder, developmental delay, liver dysfunction, and alacrima. NGLY1 removes N-linked glycans from glycoproteins in the cytoplasm and is thought to help clear misfolded glycoproteins from the endoplasmic reticulum (ER) through the ER associated degradation (ERAD) pathway. Despite this, the physiological significance of NGLY1 in ERAD is not understood. The best characterized substrate of NGLY1 is NRF1, a transcription factor that upregulates proteasome expression and the proteasome bounce back response. Our lab created a *Drosophila* model of NGLY1 deficiency that faithfully recapitulates several disease phenotypes observed in patients, including movement disorder, seizures, and lethality. We performed a *Drosophila* natural variation modifier screen using this model of NGLY1 deficiency and identified a number of modifiers that reduce the lethality of the model. In particular, we identified two putative loss of function variants in *SEL1L*: S780P and Δ 806-809. Both variants are localized in the SEL1L cytoplasmic tail, an uncharacterized domain of the protein. SEL1L is a known component of the ERAD complex that retrotranslocates misfolded proteins from the ER to the cytoplasm for degradation. To test the interaction between these *SEL1L* variants and *NGLY1*, we created CRISPR mutant fly lines that carry these *SEL1L* variants in a common genetic background and tested them with our model of NGLY1 deficiency. Validating our screen, the *SEL1L*^{P780} variant decreases the lethality observed in the NGLY1 deficiency model, as compared to the *SEL1L*^{S780} variant. Further, we found that, as compared to *SEL1L*^{S780}, *SEL1L*^{P780} reduces the NGLY1 model sensitivity to proteasome inhibition, a known defect in NGLY1 deficiency due to the misregulation of NRF1. We also find that these variants modify general ERAD function. We hypothesize that these *SEL1L* variants modify NGLY1 deficiency through NRF1 signaling and ERAD. These results will provide new insights into the role of NGLY1 in ERAD and the etiology of NGLY1 deficiency. *SEL1L* is a strong candidate modifier gene in patients, where variability in presentation is common.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2658. Novel actionable targets discovered by proteomic genome-wide association of 1715 unstudied proteins

Authors:

S. Kuliesius, L. Klaric, P. R. Timmers, P. Navarro, J. F. Wilson; Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract Body:

Genome-wide association study (GWAS) power lies in testing hundreds of thousands of single nucleotide polymorphisms (SNPs) across many genomes for associations with a trait. Recent technological developments in high-throughput proteomic assays allow simultaneous quantitative measurement of thousands of proteins in a single sample. Blood plasma proteins effectively provide a glimpse into multiple biological systems. Combining broad-capture proteomics with genomic variation across a population is a valuable resource with implications in elucidating complex traits and disease, drug development or repurposing, and precision medicine. Here, we investigated 6434 plasma proteins using the Somalogic aptamer-based technology in samples from the Viking Health Study - Shetland. 456 significant protein quantitative trait loci (pQTL) were found for 363 proteins in plasma (118 cis ($P < 5e-8$), 338 trans ($P < 6.6e-12$)). Of these, 73 pQTL were for previously unstudied proteins. We leveraged this new resource to perform causal inference using Mendelian randomization against complex traits of biomedical importance.

Molecular Effects of Genetic Variation Posters - Thursday

PB2660. Novel non-coding variant in *NMNAT1* reduces the transcription of *NMNAT1*, which leads to Leber Congenital amaurosis

Authors:

J. Han¹, J. Lee¹, S-T. Lee¹, J. Choi²; ¹Yonsei Univ. Coll. of Med., Seoul, Korea, Republic of, ²YONSEI Univ. Coll. OF MEDICINE, Seoul, Korea, Republic of

Abstract Body:

NMNAT1 defects lead to early-onset retinal degeneration characterized by macular coloboma-like degeneration in early infancy. This gene encodes nicotinamide mononucleotide adenylyl-transferase 1 that synthesize from NAD precursor to NAD⁺. Interestingly, the dysfunction in this ubiquitous enzyme usually affect eye without syndromic features. In our cohort with inherited retinal diseases, two unrelated patients with Leber congenital amaurosis had only one pathogenic c.709C>T:p.(Arg237Cys) variant in *NMNAT1*. These 2 patients had infantile onset nystagmus, macular coloboma like degeneration or diffuse ellipsoid zone degeneration since early childhood, which was compatible with *NMNAT1* Leber congenital amaurosis. Therefore, we conducted genome sequencing in 2 unrelated patients, and identified novel non-coding c.-57+21C>T variant in *NMNAT1* in 3 affected patients from 2 unrelated family. This non-coding variant was existed in trans with known pathogenic c.709C>T:p.(Arg237Cys) missense variant. No copy number variation, structural variant, or mobile element insertion was detected by cn.Mops, Manta, and MELT algorithms. The minor allele frequency of c.-57+21C>T variant (hg38: chr1:g.9943536C>T) was 1/152182 and 1/263690 in gnomAD and BRAVO, respectively. Although CADD score was considered as benign (Phred: 4.389), regulatory variant specific in silico predictions showed high impact in DeepSEA (2.26), Eigen-PC (1.880), ncBoost (0.990), ncER (94.579) and ReMM (0.794). Using NCBI open reading frame (ORF) finder, this non-coding variant does not create new uORF. In quadruplex forming G-Rich Sequences (QGRS) mapper, this variant did not alter the G-quadruplexes scores. Because the relevant retinal tissues could not be biopsied, blood RNA-sequencing was done. RNA-sequencing in affected families confirmed decreased expression of *NMNAT1* level compared to controls (DESeq2, 146.4±24.0 vs 253.4±18.0, *P* =0.05). Although its precise mechanism should be elucidated, c.-57+21C>T variant located in the 5' untranslated region may affect the expression of *NMNAT1* in the transcription level. Thus, we suggest that c.-57+21C>T regulatory variant may have potential role in *NMNAT1* expression.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2661. Novel plasma and brain proteins that are implicated in multiple sclerosis risk

Authors:

X. Lin; Menzies Inst. for Med. Res., Hobart, Australia

Abstract Body:

Understanding how variations in the plasma and brain proteome contribute to multiple sclerosis susceptibility can provide important insights to guide drug repurposing and therapeutic development for multiple sclerosis. However, the role of genetically predicted protein abundance in multiple sclerosis remains largely unknown. Integrating plasma proteomics (n=3,301) and brain proteomics (n=376 discovery; n=152 replication) into multiple sclerosis genome-wide association studies (n=14,802 cases and 26,703 controls), we employed summary-based methods to identify candidate proteins involved in multiple sclerosis susceptibility. Next, we evaluated associations of the corresponding genes with multiple sclerosis at tissue-level using large gene expression quantitative trait data from whole-blood (n=31,684) and brain (n=1,194) tissue. Further, to assess transcriptional profiles for candidate proteins at cell-level, we examined gene expression patterns in immune cell types (dataset 1: n=73 cases and 97 controls; dataset 2: n=31 cases and 31 controls) for identified plasma proteins, and in brain cell types (dataset 1: n=4 cases and 5 controls; dataset 2: n=5 cases and 3 controls) for identified brain proteins. We identified 39 novel proteins associated with multiple sclerosis risk. Based on five identified plasma proteins, four available corresponding gene candidates showed consistent associations with multiple sclerosis risk in whole-blood, and we found *TAPBPL* up-regulation in multiple sclerosis B cells, CD8+ T cells and natural killer cells compared to controls. Among the 34 candidate brain proteins, 18 were replicated in a smaller cohort and 14 of 21 available corresponding gene candidates showed consistent associations with multiple sclerosis risk in brain tissue. In cell-specific analysis, six identified brain candidates showed consistent differential gene expression in neuron and oligodendrocyte cell clusters. The associated proteins present a robust set of candidate biomarkers and potential therapeutic targets for multiple sclerosis, reinforced by high concordance in downstream transcriptomics findings at tissue-level. This study also highlighted the heterogeneity of cell-specific transcriptional profiles for the identified proteins. Together, these findings can serve as an important anchor for future studies of disease mechanisms and therapeutic development.

PB2662. Novel splice variant in *PRUNE1* leads to aberrant neurodevelopment and neurodegeneration.

Authors:

A. Srivastava¹, A. Katiyar¹, N. Ghali², A. Moccia³, M. Wheeler⁴, D. Nickerson⁵, M. Bamshad⁴, S. Phadke⁶, K. Srivastava⁷, S. Bielas³; ¹Sanjay Gandhi PostGraduate Inst. of Med. Sci., Lucknow, India, ²Univ. of Michigan Med. Sch., Ypsilanti, MI, ³Univ MICHIGAN, Ann Arbor, MI, ⁴Univ. of Washington, Seattle, WA, ⁵Univ Washington Sch Med, Seattle, WA, ⁶Sanjay Gandhi PGIMS, Lucknow, India, ⁷CSIR-Central Drug Res. Inst., Lucknow, India

Abstract Body:

Recessively inherited variants in *PRUNE1* are the genetic basis of early onset neurodevelopmental and neurodegenerative disease with a range of phenotypes termed NMIHBA (neurodevelopmental disorder with microcephaly, hypotonia and variable brain anomalies). *PRUNE1* is a member of the DHH phosphoesterase family that has exopolyphosphatase and phosphodiesterase activity predicted to alter cellular motility through interaction with GSK-3 β and Wnt/ β -catenin signaling pathway. This study presents two similarly affected siblings from a non-consanguineous Indian family as an additional case of NMIHBA. Both individuals present with severe developmental delay, primary microcephaly, and spastic quadriparesis. Quad - exome and Sanger sequencing identified a novel homozygous *PRUNE1* splice acceptor c.119-2A>G variant shared by both siblings. Exon 2 skipping and stable expression of mutant protein was confirmed by minigene reporter assay and Western blot. Consistent with this observation, *In silico* protein modelling reveals a mechanism for loss of exopolyphosphatase activity in the case, further confirming a critical role in NMIHBA. We present a possible mechanism for *PRUNE* neuropathology, acting on microtubule dynamics through its downstream effects on Wnt/ β -catenin signaling. This novel splice variant exhibits features of a founder variant within the Indian population, proposing future implications to the field of population genetics and highlighting the importance of functional studies.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2663. Nuclear abnormalities in novel LMNA variant segregating with LMNA-associated cardiocutaneous progeria syndrome

Authors:

M. Vernet Machado Bressan Wilke¹, T. Schwab¹, M. Wick^{2,3}, E. Klee^{1,3,4}; ¹Ctr. for Individualized Med., Mayo Clinic, Rochester, MN, ²Dept. of Obstetrics & Gynecology Mayo Clinic, Rochester, MN, ³Dept. of Clinical Genomics, Mayo Clinic, Rochester, MN, ⁴Dept. of Quantitative Hlth.Sci., Mayo Clinic, Rochester, MN

Abstract Body:

The *LMNA* gene encodes both the lamin A and lamin C structural components of the nuclear envelope, associated with progeria syndromes and with forms of cardiomyopathy, muscular dystrophy, lipodystrophy, and neuropathy. Pathogenic variants resulting in changes of the nuclear structure and chromatin architecture may lead to altered gene expression in affected tissues. A group of *LMNA*-linked progerias, has been classified as "atypical" for not altering lamin A processing and for having an older age of onset. One example is the LMNA-associated cardiocutaneous progeria syndrome (LCPS) described only in one family with prominent cardiovascular and cutaneous manifestations segregating with the p.Asp300Gly variant. **METHODS:** This is a case report describing a family with the LCPS phenotype. Informed consent for publication was obtained. Functional testing was performed to assess nuclear morphology by transfection and overexpression of LMNA expressing constructs tagged with RFP for both wild type LMNA and p.(Glu2Lys) LMNA. Cells were imaged on a confocal microscope four days post transfection to assess the effect of overexpression of LMNA on nuclear morphology. **RESULTS:** The proband is a 36-year-old female with personal and family history of severe calcific aortic stenosis along with a calcified mitral valve with insufficiency. The proband reported greying hair in her 20s. She presently has no evidence of lipodystrophy or solar keratoses. Exome sequencing reported a VUS in LMNA c. 4G>A p.(Glu2Lys) (NM_170707.2) located in a conserved amino acid and absent in the gnomAD database. The variant was upgraded to Likely Pathogenic after segregation studies demonstrated variant presence in three other affected relatives. Indirect immunofluorescence analysis of nuclei showed abnormal morphology including lobulation and occasional ringed nuclei as similarly previously described for p.Asp300Gly variant. **CONCLUSION:** Here we report a second family with a novel variant in *LMNA*, with a phenotype of prominent cardiovascular and cutaneous manifestations similar to what is described for LCPS. Preliminary findings show suggest this variant affects nuclear morphology in a manner comparable to what was described in the first LCPS family. Additional functional studies are planned after generation of stable cell lines expressing p.(Glu2Lys) *LMNA*; *it is anticipated that these future studies will help to elucidate* the effect of this variant on nuclear structure. Characterizing the atypical forms of LMNA-linked progerias is important to understand the clinical course of these patients.

Molecular Effects of Genetic Variation Posters - Thursday

PB2664*. Organ-specific prioritization of non-coding regulatory variants with stacking generalization.

Authors:

N. Zhao, S. Dong, A. Boyle; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Understanding the functional consequences of genetic variation in the non-coding regions of the human genome remains a challenge. Recently, we have introduced a computational tool, TURF, to prioritize regulatory variants with tissue-specific functions by leveraging evidence from functional genomics experiments, including over three thousand functional genomics datasets in Hg19 from the ENCODE project provided in our RegulomeDB database. However, TURF was optimized to predict well-studied cell lines/tissues, which lacks the power to generalize to unseen cell lines apart from the training cell lines or at a higher organ-specific level. In addition, new experimental and deep learning-predicted features are available through RegulomeDB in Hg38 which, for example, contains ~ 5X more TF ChIP-seq datasets than in Hg19. Here, we present T-Land, a flexible model architecture to predict non-coding regulatory variants in a tissue or organ-specific manner with the stacking generalization algorithm. New features in Hg38 were bagged into biological meaningful feature subspaces; stacking the classifiers which individually takes input as those feature subspaces prevents overfitting and makes robust predictions. Tissue-specific T-Land outperformed TURF and other top-performing models when evaluating in hold-on cell lines, and on independent MPRA datasets. We developed our organ-specific T-Land by integrating newly designed organ-specific features, which outperformed tissue-specific T-Land even on tissue-specific evaluation datasets. To our best knowledge, it is the first model to prioritize non-coding regulatory variants for 51 organs available on ENCODE. Organ-specific T-Land prioritized relevant organs of various GWAS traits by predicting higher enrichment scores for trait-related SNPs. Interpreting organ-specific T-Land through SHAP value analysis portrays the cross-prediction relationships among five histone marks across organs. An organ map integrated with the new organ-specific scores in RegulomeDB would provide a valuable source for the initial screen of variants of interest for future studies.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2665. Parallel functional screening of human duplicated genes in neurodevelopment at single-cell resolution using zebrafish

Authors:

J. Uribe-Salazar, G. Kaya, N. Mariano, C. Ingamells, M. Y. Dennis; Univ. of California, Davis, Davis, CA

Abstract Body:

Gene duplication is a fundamental source of innovation in the evolution of phenotypic features. In humans, while several notable human-specific duplicated (HSD) genes have been implicated in key neurodevelopmental processes, most genes remain uncharacterized. We evaluated ten HSD genes (including previously characterized *SRGAP2* and *ARHGAP11*) using zebrafish, a model that allows for robust parallel tests of function. Generating mosaic knockout or knockdown embryos for each zebrafish ortholog, we assayed morphometry at 3 days post-fertilization (dpf) and observed significant differences in measured features for numerous crispant mutants (*ptpn20*, *pdzk1*, *hydin*, *gpr89*, *srgap2*, and *fam72*) and a morphant (*arhgap11*) versus controls, including increased head width in *hydin* crispants matching results in knockout mice exhibiting hydrocephalus. We also performed single-cell (sc)RNA-Seq using combinatorial indexing of ~130,000 total cells prepared from dissociated heads of crispants/morphants at 3 dpf. For *srgap2* crispants, we observed significant differences in abundances of various cell types (~2,400 cells per biological replicate, n=3), including optic progenitors as well as excitatory (E; Glut+) and inhibitory (I; GABA+) neurons versus scrambled-injection controls; the latter results were subsequently validated as a shift in E:I ratio in transgenic fluorescent reporter lines and an increased incidence of high-speed motion events following drug-induced seizures. Interestingly, these same results were observed for larvae injected with human *SRGAP2C* mRNA, indicating that the HSD paralog antagonizes the conserved zebrafish ortholog, as also reported in mice. Work is ongoing to characterize the additional nine HSD crispant/morphant larvae, for which we have successfully generated scRNA-seq data, as well as “humanized” fish injected with mRNA of the human paralogs. Overall, this study represents the first to systematically test the functions of multiple HSD genes in parallel, with the ultimate aim to discover novel genes contributing to neurological traits and disorders in humans. Further, our combined use of gene editing coupled with scRNA-seq at scale to identify changes in the brain can be broadly applied to test functions of any gene important in neurodevelopment.

Molecular Effects of Genetic Variation Posters - Thursday

PB2666. Pathogenic mechanisms associated with a recurrent *CUX2* missense variant in epilepsy.

Authors:

J. Cheng, K-M. Lamar, A. Ramamurthy, J. Calhoun, G. Carvill; Northwestern Univ., Chicago, IL

Abstract Body:

Developmental and epileptic encephalopathies (DEEs) are a group of severe, pediatric epilepsies characterized by refractory seizures and associated intellectual disability. DEEs have a heterogeneous genetic etiology; pathogenic variants have been found in genes involved in chromatin remodeling, ion channel activity, and neurotransmitter release. However, the role of transcription factors (TFs) in epilepsy is less well understood. We focus on a recurrent missense variant (c.1768G>A, p.Glu590Lys) in the TF, *CUX2*, that we identified as a novel cause of DEE. *CUX2* has three CUT domains and a homeodomain which confer specificity for binding DNA to regulate gene expression during cortical neurodevelopment. The c.1768G>A variant is a heterozygous *de novo* variant that changes a glutamate in the first CUT domain to a lysine. This residue is highly conserved, and *in silico* analysis predicts the variant as damaging. Given that DNA is negatively charged, it is likely that the positively-charged lysine variant enhances *CUX2* binding to DNA in a gain-of-function manner, altering gene expression critical for proper neurodevelopment. To test this, we use a patient-specific induced pluripotent stem cell (iPSC) derived neuronal model, as well as an isogenic *CUX2* knockout and sex-matched, wild-type (WT) iPSC lines. We differentiated these lines to neural progenitor cells (NPCs). We assessed *CUX2* genome occupancy in the WT NPCs using CUT&RUN and determined that *CUX2* binds primarily to promoter regions related to genes involved in DNA and RNA maintenance processes. Additionally, we conducted RNA-seq on the variant, knockout, and WT NPC lines. Differential gene expression analysis between the variant and WT NPCs revealed the upregulation of genes significantly enriched in GABAergic interneuron development and neural morphogenesis. In the next few months, I will integrate the results of variant *CUX2* occupancy with the differentially expressed genes, thus identifying direct *CUX2* target genes and biological pathways. Given our preliminary results and the previously established role of *CUX2* in neurodevelopmental processes, we will assess the effects of the variant on neuronal differentiation, survival, and synapse abundance over the next year. Combined, these studies will reveal the pathogenic mechanism of this missense variant and lay the foundation for studying other TFs with missense variants in patients with neurodevelopmental disorders. Overall, our results will expand our knowledge of the biological mechanisms that underpin DEEs and may reveal pathways and genes that could provide novel targets for the development of therapeutics against these disorders.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2667*. Pathogenic variants in *PLEKHO2* predispose to heritable thoracic aortic disease

Authors:

X. Duan¹, D-C. Guo¹, A. Pinard¹, I. C. Marin¹, G. Zhu², H. Yang², L. Zhang³, E. M. Hostetler¹, M. J. Bamshad⁴, D. A. Nickerson⁴, Z. Zhou², D. Milewicz¹; ¹Dept. of Internal Med., The Univ. of Texas Hlth.Sci. Ctr., Houston, TX, ²Fuwai Hosp., Chinese Academy of Med. Sci. and Peking Union Med. Coll., Beijing, China, ³The Fifth Med. Ctr., Chinese PLA Gen. Hosp., Beijing, China, ⁴Dept. of Pediatrics and Dept. of Genome Sci., Univ. of Washington, Seattle, WA

Abstract Body:

While 11 genes have been identified for heritable thoracic aortic disease (HTAD), the majority of HTAD families have yet to be solved. A rare heterozygous variant, p.Gly392Glu, in *PLEKHO2* that was present in 1/125,000 anomAD v2.1.1 exomes and is predicted to be damaging, segregated with HTAD in a large family with an LOD score of 3.26. Analysis of exome sequencing data from affected probands of 392 unsolved HTAD families and from 545 unrelated individuals with early-onset sporadic thoracic aortic dissections \leq 60 years of age identified four additional rare and predicted damaging *PLEKHO2* missense variants. *PLEKHO2* encodes a protein with no established function. Smooth muscle cells (SMCs) explanted from the aorta of a person with *PLEKHO2* p.Gly392Glu showed significantly increased expression and protein levels of SMC contractile genes and reduced proliferation compared to that of wild type (WT) SMCs. Similar changes were observed in SMCs with *PLEKHO2* knockdown using shRNAs. *Plekho2*^{-/-} mouse aortas had increased expression and protein levels of SMC contractile genes and thickened medial layers than WT aortas. In *PLEKHO2* knockdown SMCs, there were no alterations in phosphorylation of SMAD2/3 with TGF- β 1 exposure. Instead, non-canonical TGF- β signaling was constitutively activated in the absence of TGF- β 1 exposure based on increased phosphorylation of TAK1 and p38 MAPK, but not JNK or p65. Inhibitors of TAK1 and p38 MAPK, along with knockdown of TRAF6 using shRNAs, decreased p21 and SMC contractile gene expression in *PLEKHO2* knockdown SMCs. Co-immunoprecipitation assays indicate that PLEKHO2 binds to TRAF6 and TAK1 and controls TAK1 activation. Our results indicate that loss of PLEKHO2 function leads to constitutive activation of TAK1-P38 MAPK signaling in SMCs, which ultimately predisposes to HTAD. Moreover, they emphasize the role of activation of TRAF6-TAK1-p38 MAPK in the molecular pathogenesis of thoracic aortic disease.

Molecular Effects of Genetic Variation Posters - Thursday

PB2668*. Patient-derived iPSC-CMs from TANGO2-deficient disorder revealed multi-channel defects, functional association between ERK1/2 and TANGO2, and folate as a potential therapeutic agent to mitigate arrhythmias in patients

Authors:

W. Xu¹, Y. Cao¹, A. Yu¹, S. Lalani², C. Miyake¹, L. Zhang¹; ¹Baylor Coll. of Med., Houston, TX, ²Baylor Coll. Med., Houston, TX

Abstract Body:

TANGO2-deficient disorder (TDD) is a rare recessive multiorgan genetic disease caused by biallelic loss-of-function (LOF) mutations in *TANGO2* (Transport and Golgi Organization protein 2) gene. The exons 3-9 deletion ($\Delta E3-9$) and G154R are two common mutations found in patients with European and Hispanic/Latino ancestry, resulting in no and reduced protein expression, respectively. Despite normal cardiac function at baseline, metabolic stresses such as fasting can cause cardiac arrhythmias, which is the leading cause of death in TDD due to poor response to standard antiarrhythmic medications. The molecular function of TANGO2 is poorly understood, and a cardiac model for studying cardiac crisis is lacking, which largely hinders the research for TDD. We generated multiple independent TDD patient-derived iPSC-CMs lines, along with WT isogenic controls by adenoviral expression or CRISPR editing. The TANGO2-deficient iPSC-CMs lines recapitulated key arrhythmic phenotypes typically seen in TANGO2 patients, which were fully reversed by ectopic expressing WT-TANGO2. First, a reduction in field potential (FP) spike amplitude that can be exacerbated by fasting, which resembles Brugada-like EKG indicating LOF in cardiac Na⁺ channel SCN5A. Second, prolonged FP duration which represents prolonged QT interval indicating LOF in K⁺ channel or gain of function in Na⁺ channel. Third, premature ventricular contractions (PVCs) caused by early afterdepolarization, which is primarily due to Ca²⁺ channel or Ca²⁺ handling defect. Collectively, our data suggest that TANGO2 deficiency leads to multi-channel defects in cardiomyocytes that results in lethal arrhythmias in TDD patients. Mechanistically, we detected reduced membrane fraction of SCN5A and KCNH2 in TANGO2-deficient iPSC-CMs, which explains the Brugada and prolonged QT EKG patterns, respectively. Moreover, ERK1/2 inhibition led to a TANGO2-dependent increase in FP spike amplitude which plateaued at 24hr, while causing PVCs in iPSC-CMs with $\Delta E3-9$ -TANGO2. These data suggest ERK1/2 signaling pathway is associated with TANGO2 function. Interestingly, ERK inhibition also increased FP spike amplitude in iPSC-CMs expressing G154R-TANGO2 but with a delayed rising time and plateaued at 36hr. We speculate that ERK inhibition may increase the stability of G154R-TANGO2 to restore its function. Therapeutically, we observed Vitamin B supplement dramatically reduced metabolic crises in TANGO2 patients. We show that folic acid (B9) abolished the PVCs and intermittent long pauses in TANGO2-deficient iPSC-CMs. Therefore, folate may be a potential therapeutic agent to mitigate cardiac arrhythmias for TDD patients.

Molecular Effects of Genetic Variation Posters - Thursday

PB2669*. Phenotypic and functional genomic impact of complex structural variation at the 17q21.31 locus.

Authors:

P. Zhang¹, R. Handsaker², L. Hernandez³, C. Wen¹, C. Jops¹, M. Kim⁴, M. Margolis¹, T. Werge⁵, W. Thompson⁶, S. McCarroll⁷, M. Gandal¹; ¹UCLA, Los Angeles, CA, ²Broad Inst., Charlemon, MA, ³Univ. of California, Los Angeles, Los Angeles, CA, ⁴David Geffen Sch. of Med. at UCLA, Los Angeles, CA, ⁵Lundbeck Fndn. Initiative for Integrative Psychiatric Res., Copenhagen, Denmark, ⁶Laureate Inst. for Brain Res., Tulsa, OK, ⁷Harvard Med. Sch., Boston, MA

Abstract Body:

Post-GWAS fine-mapping efforts mainly focused on prioritizing among multiple small variants, ignoring potential contributions from other forms of genetic variation, such as complex structural variants (SVs). Although SVs have well established contributions to complex traits, their contribution to GWAS results remains underexplored, due to the limitations in ascertainment and a lack of good methods for imputing these variants at large scale. As a result, some significant SNPs identified from GWAS may fail to be correctly fine mapped to nearby SVs, especially at complex genomic loci with extended linkage disequilibrium (LD). The 17q21.31 locus contains an inversion polymorphism, present in ~20% of Europeans, surrounded by several multiallelic copy number variation (mCNV) regions. SNPs within 17q21.31 locus have been found to be associated with a variety of traits and diseases, including neuroticism, body fat and height measures and blood cell counts, but whether these SNPs are tagging nearby SVs remains unknown. To evaluate the contribution of SVs at 17q21.31 locus to phenotypic associations, we imputed the inversion configuration and mCNV copy numbers into the UK Biobank (UKBB) and the Adolescent Brain Cognitive Development (ABCD) study, and performed phenome-wide association studies (PheWAS) taking into account of both SNPs and SVs at this locus. We found that SVs account for about half of the observed GWAS hits at this locus, with distinct SV-phenotype associations observed across a host of traits. The inversion captured the majority of trait associations - including neuroticism and blood cell counts. However, controlling for the inversion, mCNVs also served as lead variants for several traits including body fat and reaction time measurements. To further investigate the molecular mechanisms by which SVs regulates traits/diseases, we imputed SVs into several functional genomics reference panels, including PsychENCODE, GTEx and AMP-AD cohorts and analyzed the impact of SVs at this locus on chromatin accessibility, gene expression, local splicing and protein abundance across a host of tissues including the human brain. We found that 17q21.31 SVs had broad functional impact at different molecular levels, both *in-cis* and *in-trans*. Through colocalization and Mendelian randomization analyses, we pinpointed the potential molecular cascade through which 17q21.31 SVs regulate different phenotypes. Altogether, our results highlight the importance of accounting for complex structural variation when interpreting GWAS signals at a complex locus and identify new insights into the biological mechanisms underlying the pleiotropic effects at 17q21.31.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2670. PIEZO2 as a molecular candidate of respiratory phenotype induced by Congenital Central Hypoventilation Syndrome mutations in *PHOX2B*.

Authors:

T. Hedgecock¹, K. Victor¹, L. O. Romero¹, J. Cordero-Morales¹, C. M. Rand², D. E. Weese-Meyer², L. T. Reiter¹; ¹UTHSC, Memphis, TN, ²Ann and Robert H. Lurie Children's Hosp., Chicago, IL

Abstract Body:

Congenital central hypoventilation syndrome (CCHS) is an autosomal dominant disease that affects the autonomic nervous system (ANS). Individuals with CCHS present with a variety of clinical manifestations including impaired respiration, cardiac sinus pauses, neural crest tumors, gastrointestinal dysmotility, and in some cases, Hirschsprung disease. CCHS is caused by polyalanine repeat mutations (PARMs) and non-PARMs (NPARMs) in the gene *PHOX2B*. PARMs can range in alanine repeat number from less severe (20/24 genotype) to the need for continuous ventilation for 27-33 alanines on the affected allele (20/27-20/33 genotype). The *PHOX2B* gene encodes a transcription factor that regulates ANS neural development. To date, there are no direct molecular ties between *PHOX2B* mutations and the clinical ventilatory slope. CCHS respiratory defects observed in humans and in animal models are reminiscent of the respiratory phenotype found in mice with a knockout (KO) for the *Piezo2* gene. PIEZO2, a mechanosensitive cation channel, plays a known role in maintaining baroreflex and respiratory homeostasis. Using neurons differentiated from neurotypical and CCHS dental pulp stem cells (DPSC), *PIEZO2* and *PHOX2B* mRNA transcripts were analyzed using qPCR to determine if there is a relationship between *PHOX2B* and *PIEZO2* transcription, as well as whether PARM number influences *PHOX2B* and *PIEZO2* transcription. Additionally, PIEZO2 currents were examined to determine if PARM number impacts PIEZO2 activity in CCHS patients compared to neurotypical individuals. We found that PIEZO2 levels are significantly decreased in CCHS neurons versus neurotypical neurons. These findings will provide new possibilities for the treatment of CCHS by restoring PIEZO2 function.

Molecular Effects of Genetic Variation Posters - Thursday

PB2671. Pooled RNA-IP approach to investigate variant effects on RBP binding and splicing.

Authors:

M. Schertzer^{1,2}, P. Halmos¹, K. Dobrindt³, K. Brennand³, D. Knowles^{1,2}; ¹New York Genome Ctr., New York, NY, ²Columbia Univ., New York, NY, ³Yale Univ., New Haven, CT

Abstract Body:

Alternative splicing is a fundamental cellular process that regulates 95% of multi-exon genes to diversify protein output and define cell-type specific functions. Both constitutive and alternative splicing are controlled by combinations of cis-acting pre-messenger RNA sequences and trans-acting RNA-binding proteins (RBPs), including splice factors. Therefore, variation in splicing regulatory elements or RBPs can be highly disruptive to basic cellular activities and often lead to disease, including neurological and muscular disorders as well as various cancers. We and others have identified thousands of genetic variants that are associated with splicing changes: splicing quantitative trait loci (sQTLs). For many complex traits, sQTLs appear as enriched as expression QTLs. The causal variants for most sQTLs and their intermediate molecular effects are largely unclear. Although it is expected that many sQTLs function by altering binding of one or more RBPs, there is very limited experimental data on how genetic variants alter RBP binding to assess this hypothesis. The goal of this project was to identify binding QTLs for a subset of RBPs and, then, to mechanistically link genetic variants with splicing outcome by overlapping binding and splicing QTLs. To identify sites of allele-specific binding (ASB), where a variant increases or decreases RBP binding, in a high throughput manner, we generated data using a pooled cell line approach and developed a corresponding analysis pipeline. First, we pooled 9 induced pluripotent stem cell lines (iPSCs) and performed RNA immunoprecipitations (RNA-IPs) for three splicing factors, HNRNPK, RBFOX2, and HNRNPA1. Next, to estimate cell line proportions in the pooled data, we imputed genotypes for the 9 cell lines and used constrained linear regression to estimate cell line proportions. Finally, we developed a Bayesian probabilistic model to distinguish sites of allele-specific binding from allele-specific expression via analysis of pre-IP and post-IP RNA allelic counts. At a 10% false discovery rate, we identified thousands of variants that exhibit ASB (binding QTLs). In support of a mechanistic link between these binding QTLs and splicing, we detected a strong overlap with fine-mapped sQTLs from 1,367 iPSC lines. Collectively, our work provides a novel high-throughput method for identifying binding QTLs which will significantly improve interpretation of splicing QTLs and disease-associated variants.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2672. Population genetic study for 16 autosomal STR loci in unrelated 15,546 Korean individuals

Authors:

H. Park, Y-H. Sohn; Seegene Med. Fndn., Seoul, Korea, Republic of

Abstract Body:

Genotyping of autosomal short tandem repeat (STR) markers is widely used for the genetic identification of individuals in paternity disputes, acquirement of nationality of refugees, forensic DNA analyses in Korea. Our institute has performed genetic identification of individuals over than 15 years. Hereupon we analyze allele frequencies of STR of large Korean population. DNA typing was performed on 31,092 Koreans submitted to our institute during 2009-2022. Every one sample from submitted pairs was excluded for avoid any selection bias, so 15,546 results were used for analysis. Allele frequencies of 16 autosomal STR loci (*D8S1179*, *D21S11*, *D7S820*, *CSF1PO*, *D3S1358*, *TH01*, *D13S317*, *D16S539*, *D2S1338*, *AMEL*, *D5S818*, *FGA*, *D19S433*, *vWA*, *TPOX*, *D18S51*) were obtained using the AmpF/STR Identifier PCR Amplification kit. For all 16 autosomal STR markers, no deviations from the Hardy-Weinberg equilibrium were observed. In addition, power of discrimination, mean exclusion chance, polymorphism information content of each locus were calculated using Arlequin 3.5 software (Excoffier & Lischer, 2010). This is the largest STR profile dataset will be a useful tool for forensic identification & parental testing in Korea.

Molecular Effects of Genetic Variation Posters - Thursday

PB2673. Population-specific non-coding and coding putative causal variants shape quantitative traits

Authors:

X. Liu¹, S. Koyama^{1,2,3}, Y. Koike^{1,4}, K. Tomizuka¹, K. Hikino¹, M. Koido⁵, S. Ito^{1,6}, N. Otomo¹, H. Suetsugu^{1,7}, S. Yoshino^{1,7}, M. Akiyama⁸, C. Benner⁹, P. Natarajan^{2,3}, P. Ellinor^{2,3}, T. Mushiroda¹, M. Horikoshi¹⁰, M. Ikeda¹¹, N. Iwata¹¹, The Biobank Japan Project, S. Niida¹², K. Ozaki¹², Y. Kamatani¹³, Y. Momozawa¹, S. Ikegawa¹, K. Ito¹, C. Hosp., Boston, MA, ³Broad Inst., Boston, MA, ⁴Hokkaido Univ., Sapporo, Japan, ⁵The Univ. of Tokyo, Tokyo, Japan, ⁶Shimane Univ., Izumo, Japan, ⁷Kyushu Univ., Fukuoka, Japan, ⁸Kyushu Univ., Fukuoka, Japan, ⁹Univ. of Helsinki, Helsinki, Finland, ¹⁰RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, ¹¹Fujita Hlth.Univ., Toyoake, Japan, ¹²Natl. Ctr. for Geriatrics and Gerontology, Obu, Japan, ¹³The Univ. of Tokyo, Minato-ku, Japan, ¹⁴Shizuoka Gen. Hosp., Shizuoka, Japan, ¹⁵Univ. of Shizuoka, Shizuoka, Japan

Abstract Body:

Human genetic variants associate with numerous human traits through alterations in gene function and regulation. Determining these functional variants in a large-scale genetic study may help elucidate the causes of disease or traits. In this study, combining Japanese-specific genotype imputation with a novel reference panel and statistical fine-mapping methods, we identified 826 and 9,406 putatively causal genetic associations (posterior probability of inclusion >90% and >10%) in 3,309 loci across 63 quantitative traits among 203,216 Japanese individuals. These putative causal variants are not always the lead variants of the loci, but tend to be rare, functional coding or non-coding variants in medically relevant genes/tissues and specific to the Japanese population. These variants include known and unrevealed pathogenic variants in monogenic disorders shaping the relevant quantitative traits. A series of putative causal non-coding variants were supported by state-of-art in-silico functional assays and had comparable effect sizes to coding variants. Namely, a Japanese-specific cryptic splicing variant in the intron of *FLT3* had a large impact on various immunological traits. Our study provides a list of fine-mapped causal variants to be tested for functionality and provides insights into the strategy to detect causal variants in the associated loci. Further, our approach underscores the importance of sequencing/genotyping and associating efforts in diverse populations to discover causal variants for diseases/traits, which can be a point of intervention in global populations.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2674. Population-specific RNA-seq data empowers the functional follow-up of disease-associations from FinnGen

Authors:

C. Benoit-Pilven¹, E. Vartiainen¹, S. F. Qadri², K. M. Donner³, K. Tuomainen³, M. Daly¹, H. Yki-Järvinen², T. Tukiainen¹; ¹Inst. for Molecular Med. Finland (FIMM), Helsinki, Finland, ²Dept. of Internal Med., Helsinki Univ., Helsinki, Finland, ³FIMM genotyping services, Inst. for Molecular Med. Finland, Helsinki, Finland

Abstract Body:

The Finnish population is unique in its genetic characteristics compared to other European populations. This property, together with the longitudinal health records available in Finland, are utilized in the FinnGen project to discover disease-associated genetic variation that can point to new therapeutic avenues. As expected, many FinnGen findings indicate highly Finnish-enriched variants which are typically absent or present in very low frequencies in datasets of broader European origin. To facilitate the functional interpretation of FinnGen discoveries, we generated a dataset combining liver RNA-seq and genotypes from 127 Finnish individuals. To allow for the examination of coding variant effects on the gene transcripts, we carried out an allele-specific expression (ASE) analysis on this high-quality data and found on average, 12200 informative heterozygous sites per sample (with a minimum coverage of 20 reads). Out of the 14876 coding variants associated ($p < 1e-5$) to a FinnGen (release 9) health registry endpoint, 2760 single-nucleotide variants had reliable ASE data from at least two samples. In aggregate, stop-gain variants ($N=18$) showed most pronounced allelic imbalance (AI) with an average of 63% bias for the reference allele ($p=0.02$), in line with these variants inducing nonsense mediated decay. As an example, our data confirms the loss of function impact of a low frequency variant (rs2270416) in CDH15 associated with varicose veins ($AI=0.34$). However, some variants predicted as stop-gain variant did not show the expected allelic imbalance (e.g. stop-gain variant (rs41257904) in CFHR2 associated to Age-related macular degeneration with $AI=0.03$), pointing to potential tissue-specific mechanisms. Focusing on the low frequency ($AF < 10\%$) Finnish-enriched (>2 -fold enrichment) missense variants ($N=425$), 77 show significant (proportion test $qvalue < 0.01$) allelic imbalance (>0.15), indicating impacts on the transcript abundance. Further, some of these missense variants show only expression from the reference allele, suggesting that they are partial loss-of-function variants. For example, a low frequency missense variant (rs142351376) in STAB2 gene associated with venous thromboembolism has an AI of 0.38 and another rare missense variant (rs150414818) in ALDH16A1 gene associated with gout has an AI of 0.34. Overall, we show that a Finnish RNA-seq dataset empowers us to define and confirm the functional consequences of disease-associated Finnish-enriched variants, that are too rare to be studied in datasets of broader European origin. By refining the variant consequences, these results can help to inform therapeutic development.

PB2675. Possible complex Di-Genetic inheritance in Primary Congenital Glaucoma

Authors:

D. Bercovich; Tel Hai Academic Coll., Tel Hai, Israel

Abstract Body:

Primary Congenital Glaucoma (PCG) generally have strong genetic contributions and many disease-causing mutations that lead to pathogenesis have been identified like the CYP11B1, LTBP2, MYOC, FOXC1, GPATCH3, and TEK genes and in patients with early-onset secondary glaucoma PAX6, PITX2, PITX3, FOXC1, FOXE3, EYA1, LMX1B, and MAF. To between 10-20% of patients, no mutations are found in these genes. Because glaucoma is a complex, heterogeneous disease likely to be the consequence of the interaction of multiple genes. This underlying complexity may hinder efforts to identify glaucoma-associated genes (or related mutations) and to uncover their pathogenic mechanisms. Identification of new glaucoma inheritance models, may assist in addressing both of these issues. To this end, screening the full Exom of PCG patients and family members can help to identified a glaucoma models caused by a mutation's new genes. Whole Exom sequencing on 26 PCG patients and family members (a total of 72 participants), with no mutations in the genes list above, reviled possible complex Di-Genetic inheritance in 9 families. Of the 18 pathogenic heterozygous mutations, 9 are nonsense mutations, 3 mutations are Indel (small deletions), 3 are splicing mutations & 3 are rare missense mutations. These genes can be found in the literature or data bases as been related to the possible development of glaucoma like the progressive death of retinal ganglion cells and atrophic excavation of the optic nerve, Elevated intraocular pressure, defects in outflow of aqueous humor aqueous humor secretion, by the ciliary body, and drainage through the trabecular meshwork, a porous tissue located in the iridocorneal angle. Finding new genes and inheritance models in PCG may contributed to our knowledge of glaucoma and can help clinicians to preform prenatal screening.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2676. Predicted nasal epithelial transcriptome-wide association study in African-ancestry populations

Authors:

R. K. Johnson¹, E. Esquinca¹, M. Boorgula¹, B. Szczesny², A. Romero¹, M. Campbell¹, S. Chavan¹, N. Rafaels¹, I. Ruczinski², K. Kammers³, H. Watson⁴, R. C. Landis⁴, M. A. Taub⁵, M. Daya¹, N. Hansel⁶, C. N. Rotimi⁷, C. O. Olopade⁸, C. A. Figueiredo⁹, C. Ober⁸, A. H. Liu¹⁰, E. Kenny¹¹, R. A. Mathias¹², K. C. Barnes¹, Barbados Asthma Genetics Study (BAGS), Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA); ¹Univ. of Colorado Anschutz Med. Campus, Aurora, CO, ²Johns Hopkins Univ., Baltimore, MD, ³Johns Hopkins Univ Sch. of Med., Baltimore, MD, ⁴Faculty of Med. Sci., The Univ. of the West Indies, Queen Elizabeth Hosp., St. Michael, Barbados, ⁵Johns Hopkins, Baltimore, MD, ⁶Johns Hopkins Med., Baltimore, MD, ⁷NIH, Woodstock, MD, ⁸Univ. of Chicago, Chicago, IL, ⁹Federal Univ. of Bahia and Fundação Program for Control of Asthma in Bahia (ProAR), Salvador, Brazil, ¹⁰Children's Hosp. Colorado, Aurora, CO, ¹¹Icahn Sch. of Med. at Mt Sinai, New York, NY, ¹²Johns Hopkins Univ, Baltimore, MD

Abstract Body:

The nasal epithelium plays a central role in modulating asthma, but this tissue is poorly represented in repositories such as GTEx, particularly for African-ancestry populations that are disproportionately affected by asthma. Using African-ancestry populations, we built and applied predictive models to estimate genetically driven gene expression in the nasal epithelium, and identified associations between predicted gene expression and asthma. We trained gene expression prediction models using RNA-seq data generated from nasal epithelial samples and MEGA genotypes from 536 participants (253 asthma cases, 283 controls) of phase 2 of the *Consortium on Asthma among African-ancestry Populations in the Americas* (CAAPA). Using cross-validated elastic nets, we predicted gene expression from SNPs within a 1Mb window of each gene's start and stop position, adjusting for sex, asthma, ancestry PC1, and 60 PEER factors. We used these models to predict nasal epithelial gene expression from TOPMed WGS available among 920 participants (426 asthma cases, 494 controls) of the Barbados Asthma Genetics Study (BAGS) and discovered transcriptome-wide associations (TWAS) with asthma using linear mixed models adjusted for sex, age, PC1, and kinship. Out of 21,144 autosomal genes, 9,407 were significantly predicted from cis-SNPs (model $R^2 > 0.01$ and $P < 0.05$). From TWAS in BAGS, six genes were associated with asthma (q -value < 0.1). Asthma cases had lower nasal epithelial expression of *SCG3* ($P = 6E-5$), *UGGT1* ($P = 4E-5$), *TRIO* ($P = 1E-5$), and *KPNA5* ($P = 2E-5$), and higher expression of *SORBS1* ($P = 5E-5$) and *UFD1* ($P = 2E-5$). *SCG3* is located in the 15q21 locus near asthma candidate genes *RORA* and *SMAD3*. None of the other five genes were identified in prior asthma GWAS; *KPNA5* and *SORBS1* were implicated in prior asthma expression studies. While *SORBS1* encodes an adaptor protein primarily involved in insulin signaling, *SORBS1* transcript usage has been shown to be higher in lung tissue of COPD cases compared to controls. The *UGGT1*-encoded protein glucosyltransferase 1 performs quality control of misfolded proteins in the endoplasmic reticulum (ER); its increased expression in the nasal airway may reflect ongoing ER stress characteristic of asthma. Identification of expression signatures associated with asthma in the nasal epithelium recapitulated candidate asthma genes and identified novel candidate genes with biologically plausible mechanisms of action, providing new insight into the molecular mechanisms driving dysfunction in asthma.

Molecular Effects of Genetic Variation Posters - Thursday

PB2677. Predicting functional and fitness effect of missense variants

Authors:

Y. Zhao, Y. Shen; Columbia Univ., New York, NY

Abstract Body:

Missense variants are the most common type of single nucleotide variants in protein coding regions, but most of them have uncertain functional effect. Accurate prediction of functional effect of missense variants is critically important to improving statistical power in new risk genes discovery of human diseases and diagnosis in clinical testing. Most of existing computational methods rely on pathogenicity labels from curated databases in supervised training. This leads to bias in performance since curated databases are noisy and over-represented with well-studied genes. Moreover, pathogenicity is dependent on implicated diseases and conditions. It is conceptually ambiguous as a generic score in the absence of disease or conditions. Here, we propose a probabilistic method which jointly and explicitly estimates the effects on protein function (damageness, d) and the fitness effect in human population (selection coefficient, s). We argue that d and s have more direct damaging variant in a protein that is implicated in a disease is pathogenic to the disease, and the aggregated fitness effect of all diseases or conditions determine the selection coefficient in human population. We show that in each gene, pairs of variants with strong coevolution strength are more likely to have similar selection coefficient, and such information could be used to aggregate similar variants for estimating their selection coefficients s . We encoded the distribution of damageness d by a dense neural network given the gMVP latent embedding vectors. Further, we modeled the selection coefficient s is a sigmoid function over d , while scaled by gene-specific parameters. We selected C-to-T variants in 943 highly constrained genes and trained this model by maximizing the probability of observed allele counts in UKBB (2e5 samples). Prior to training, the probability of allele counts was already approximated as Inverse Gaussian distribution with parameters optimized to simulated European population as functions of mutation rate and heterozygous selection coefficient s . We found in genes TP53, BRCA1 and PTEN, the estimated mean of d given the protein context embedding, correlates better with the functional scores derived from deep mutation scanning experiments than most existing methods. The distribution of d for benign variants is also more consistent across genes. Finally, the estimated selection coefficient s predicts allele frequency in a second population better than the baseline models without information on damageness.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2678*. Profiling Local Ancestry Effects on Gene Regulation in An Admixed Population

Authors:

H-H. Chen¹, W. Zhu², H. Polikowsky², L. Petty², S. Fisher-Hoch³, J. McCormick³, K. North⁴, E. Gamazon¹, J. Below¹; ¹Vanderbilt Univ. Med. Ctr., Nashville, TN, ²Vanderbilt Univ., Nashville, TN, ³The Univ. Of Texas Hlth.Sci. Ctr. at Houston, Brownsville, TX, ⁴Univ North Carolina, Chapel Hill, NC

Abstract Body:

Background: Although transcriptome regulation in humans has been investigated and used successfully to interpret genetic findings and map disease genes, most expression quantitative trait loci (eQTL) were estimated in European populations. While ancestry-specific effects on gene expression have been reported, environmental differences among populations confound efforts to identify the ancestry-specific eQTL effects. In this study, we leveraged haplotypic patterns resulting from recent admixture in Hispanics to identify eQTL and estimate their local-ancestry effect.

Methods: We sequenced 645 whole blood RNA samples from the Cameron County Hispanic Cohort. These individuals were genotyped by Illumina MEGA array and imputation was performed to the TOPMed reference. Global genetic ancestry analysis identified an average of 49.0% Amerindian (AMR), 45.7% European (EUR), and 4.6% West African in our samples, estimated by Admixture with 1000 Genomes enriched with 248 participants from the Hispanic Community Health Study / Study of Latinos as a reference panel. Local ancestry was detected by RFMix2 with the same reference. Haplotype-specific expression was estimated by Phaser. Then, both total aligned read counts and haplotype-specific aligned reads were used to identify ancestry-specific cis-eQTL (within ± 1 Mb of transcription start site) and estimate their effects. DAP-G was performed for cis-eQTL fine-mapping.

Results: Among the 16,093 genes that passed quality control, 2,565 genes are significantly differentially expressed between EUR haplotypes and AMR haplotypes after Bonferroni correction (p -value $< 3.1 \times 10^{-6}$) and covariate adjustment, including sex, age, five genetic principal components, RNA-seq batch, and 60 transcriptome PEER factors. We identified over 5.6 significant variants for 9,916 genes (FDR-adjusted p -value < 0.05), of which 7,463 have at least one local ancestry-specific eQTL. Among 78,169 ancestry-specific causal eQTL which passed fine-mapping (posterior inclusion probabilities > 0.1), 32,541 variants are only significant in AMR haplotypes (p -value in EUR > 0.1 and FDR-adjusted p -value in AMR < 0.05). In addition, 9,964 eQTL have opposite effects on gene expression in two ancestral haplotypes (both FDR-adjusted p -value < 0.05).

Conclusions: We generated the first profile of an ancestry-specific regulatory landscape in Hispanic/Latinos, a recently admixed population. These effects may contribute to inconsistent GWAS and TWAS findings across populations and emphasize the importance of diversity in genetic research.

Molecular Effects of Genetic Variation Posters - Thursday

PB2679*. Quantifying negative selection in human 3'UTRs uncovers deleterious non-coding genetic variation.

Authors:

S. Findlay¹, L. Romo², C. Burge³; ¹MIT, Cambridge, MA, ²Boston Children's Hosp., Boston, MA, ³Massachusetts Inst. of Technology, Cambridge, MA

Abstract Body:

Interpretation of non-coding genetic variants is a fundamental challenge in contemporary human genetics. In processed mRNA transcripts, the majority of non-coding variants are found in 3'untranslated regions (3'UTRs), which play integral roles in post-transcriptional regulation of gene expression. Most of this regulation is mediated by interactions between RNA-binding proteins (RBPs) and regulatory elements in the mRNAs they bind.

We used allele frequency data from gnomAD to identify classes of genetic variants in 3'UTRs under negative selection in humans. Since mutability also influences allele frequency spectra, estimates of negative selection have typically been calibrated using a set of "neutral" synonymous coding variants matched for dinucleotide context. However, synonymous variants are: 1) not truly neutral, and 2) routinely found within the regulatory elements we sought to examine. Thus, we developed intergenic MAPS (iMAPS), an enhanced version of the previously described mutability-adjusted proportion singleton (MAPS) metric used to quantify negative selection. By calibrating to a much larger set of intergenic variants, iMAPS captures the impact of extended nucleotide contexts known to affect mutability. This resulted in improved calibration for the majority (54%) of 3'UTR variants. This is especially important for regulatory elements in 3'UTRs which are known to converge on similar motifs of low sequence complexity.

We derived a set of high-confidence RBP binding sites across a diverse set of RBPs in 3'UTRs by intersecting RBP binding data obtained from cells (eCLIP) and in vitro (Bind-n-Seq). Variants in our high-confidence sites were enriched for: 1) variants altering steady state transcript levels in a 3'UTR MPRA, and 2) high-PIP eQTLs.

Variants that disrupted these high-confidence RBP binding sites in 3'UTRs were under levels of negative selection similar to (or even exceeding) missense coding variation. In contrast, variants preserving RBP-RNA interactions at the same sites experienced lower negative selection similar to synonymous variants. Variants disrupting a set of affinity-matched sites within the same 3'UTRs were under minimal selection, suggesting that sequence motifs alone are insufficient to identify RBP binding sites where disruption is likely to be deleterious and thus pathogenic.

We then tested variants from the high-confidence sites for their ability to modulate transcript levels in a 3'UTR MPRA in cells, directly identifying variants with regulatory activity.

Collectively, this work has nominated thousands of likely deleterious genetic variants that act by disrupting RBP-RNA interactions in human 3'UTRs.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2680. Rare protein-coding variants in the insulin receptor gene (*INSR*) identified in women with polycystic ovary syndrome (PCOS).

Authors:

R. Bauer¹, L. Gorsic^{2,1}, R. Legro³, G. Hayes¹, M. Urbanek¹; ¹Northwestern Univ., Chicago, IL, ²GeneDx, Gaithersburg, MD, ³MS Hershey Med. Ctr, Hershey, PA

Abstract Body:

Polycystic ovary syndrome (PCOS) is the most common form of anovulatory infertility among reproductive age women. In addition to reproductive symptoms, women with PCOS are at elevated risk of developing obesity, insulin resistance (IR), and type 2 diabetes. Severe Mendelian diseases of IR include Donohue Syndrome and Rabson-Mendenhall Syndrome, two disorders caused by recessive missense alleles in the insulin receptor gene (*INSR*). Women with these disorders of IR also experience symptoms of PCOS such as amenorrhea and hyperandrogenism. We therefore hypothesize that genetic variation in *INSR* also contributes to PCOS, which is a common form of IR. To test this hypothesis, we comprehensively screened 602 women with PCOS and 125 reproductively normal women for genetic variation in *INSR*. We identified 11 missense variants in *INSR* in 22 cases and 1 control subject. One of these variants, A119V, has previously been identified in Donohue Syndrome subjects. Another variant, V1012M, found in 9 PCOS subjects and zero controls, has been identified in insulin resistant diabetes mellitus with acanthosis nigricans. 10 out of 11 *INSR* variants are likely to be deleterious (CADD score \geq 15). There was no significant evidence for association between the set of all 11 *INSR* variants in the PCOS cohort relative to our phenotyped controls ($X^2 = 2.7$; p-value = 0.10; odds ratio (OR) = 4.61) or relative to the gnomAD non-Finnish European cohort ($X^2 = 1.03$; p-value = 0.31; OR = 1.25). In order to determine which of these variants are rare polymorphisms and which truly impact protein function and thus likely have a role in the development of PCOS, we have pursued cell-based studies to assess the effect of these variants on the insulin receptor's ability to achieve insulin-dependent signaling. Here we show preliminary investigation into the effects of the identified variants on the insulin signaling cascade in response to insulin stimulation.

Molecular Effects of Genetic Variation Posters - Thursday

PB2681. Regulation of stress granules by VCP in health and genetic degenerative diseases

Authors:

N. Helton, B. Dodd, S. Moon; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

The integrated stress response (ISR) is an evolutionarily conserved mechanism in eukaryotes that induces transcriptional and translational reprogramming in response to various stressors. These stressors can include nutrient deprivation, oxidative stress, buildup of unfolded proteins, or viral infection. During the ISR, global canonical translation is inhibited and RNAs are sequestered in mRNP condensates known as stress granules. Chronic ISR activation and aberrant stress granule-like aggregates are prevalent in tissues of patients with degenerative diseases of the muscular, skeletal, and nervous systems including amyotrophic lateral sclerosis and frontotemporal dementia. Valosin-containing protein (VCP), a hexameric AAA+ ATPase that plays many roles in proteostasis, is an important stress granule regulator. Mutant alleles of VCP associated with neurodegeneration impair stress granule composition and disassembly. These alleles correspond to progressive autosomal dominant adult late-onset multisystem diseases that are ultimately lethal after degeneration of muscle, bone, and brain. Therefore, understanding the molecular mechanism by which VCP regulates stress granules is critical for understanding its role in disease. We discovered that VCP indirectly regulates stress granules by mediating translation in a co-translational quality control pathway. We are using live cell fluorescence microscopy and ribosome profiling to elucidate the molecular mechanisms behind VCP-mediated stress granule regulation. Given that VCP is involved in many cellular processes, defining the mechanisms by which it regulates stress granules will advance our understanding of how stress granule behavior becomes impaired in common and devastating degenerative conditions.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2682. Regulatory rare variant trait associations in 127,724 UK Biobank genomes

Authors:

D. Ribeiro^{1,2}, D. Avalos^{3,2}, C. Ziyani¹, R. Hofmeister^{1,2}, O. Delaneau^{1,2}; ¹Univ. of Lausanne, Lausanne, Switzerland, ²Swiss Inst. of Bioinformatics, Lausanne, Switzerland, ³Univ. of Geneva, Geneva, Switzerland

Abstract Body:

A central goal of genetics is to shed light on the **genetic basis of polygenic human diseases and traits**. Genome-wide association studies (GWAS) have associated tens of thousands of common variants with traits, but these fail to account for the entire trait heritability. Due to their predicted stronger effects on phenotypes, the study of rare variation promises to be complementary to GWAS in linking genotype to phenotype. Indeed, the study of rare variation in exonic regions has proved instrumental in associating hundreds of genes to human traits. Yet, the impact of **rare variation in gene regulatory regions** - where most GWAS hits are found - has not been fully explored. The recent availability of the **UK Biobank whole genome sequences** for >125,000 individuals thus offers an unprecedented opportunity to assess the impact of rare genetic variation, particularly in the regulatory regions of the genome.

Here, we present a **novel approach to determine the effect of rare variation in gene regulatory regions** in multiple complex traits using 125,363 UK Biobank British genomes. To evaluate the use of different regulatory region annotations, we performed association testing between several **blood cell count and biomarker phenotypes** and rare variation (MAF<1%) present in three state-of-the-art gene regulatory annotations in blood cell types: (1) regulatory regions from **promoter capture Hi-C data**, (2) cis-regulatory domain predictions based on **ChIP-seq data** and (3) gene-enhancer associations from **multimodal single-cell data**. Applying association testing methods specialised for rare variation - including burden tests and SAIGE-GENE - on these three regulatory annotations, **we identified 251 gene-trait associations** (189 distinct genes, 125 loci) across the 12 blood traits tested. The three regulatory annotations shown to be complementary in finding associations. Importantly, **~40% of the gene-trait associations were replicated** in rare variant exome studies or GWAS studies. Moreover, >80% of the associations were kept when conditioning for known fine-mapped common variants, indicating that rare variants reveal **independent signals**. The discovery of hundreds of gene-trait associations - including many novel ones - at a level similar to what we found in exonic regions demonstrate that **gene regulatory regions can be highly informative of genotype-to-phenotype signals**.

Our results warrant further exploration of regulatory regions **across human cell types** as well as across the **thousands of phenotypes** available in biobanks. We expect these analyses to improve our understanding of complex human traits and ultimately aid the development of pertinent therapeutic agents.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2683. Role of SNPs of Leptin gene in Etiology of Venous Thromboembolism among Females contraceptive users in Pakistan Population

Authors:

Z. Agha, M. azam, A. Hashmi, K. Khalil; COMSATS Univ. ISLAMABAD, ISLAMABAD, Pakistan

Abstract Body:

Venous thromboembolism (VTE) is critical multifactorial disorder caused by various acquired and genetic factors. Combined hormonal contraceptives (CHCs) including estrogen and progestin, are one of the highly recommended methods of contraception for women and play critical role in increasing the risk for the females already susceptible to VTE genetically. It has been suggested that raised leptin levels may increase the risk of venous thromboembolism (VTE) in animal studies. However, clinical studies in this field are still largely unexplored. Thus the following case control study was aimed to analyze single nucleotide polymorphisms (SNPs) in leptin gene in elevating the risk of VTE in females contraceptive users. It has been hypothesized that the SNP in LEPR (Gln223Arg) gene was associated with susceptibility to increase the risk for developing VTE in female contraceptive users. Genotyping of SNP were done by restriction fragment length polymorphism assay and the data was analyzed using various statistical tools. It has been observed that the SNP in LEPR rs1137101 G>A is significantly associated with VTE in accordance with both genetic models (DM; OR=9.270, CI (4.977-17.264), p=0.0000, RM; OR=19.70, CI (2.658-146.11), p=0.000). The frequency of risk allele G (52%) also shows significant association with the disease phenotype (OR=6.63, CI (3.910-0.1345), p=0.0001). Other risk factors including body mass index (BMI), body weight and ABO blood types were also analyzed for their association with VTE. Pearson correlation and regression analysis was done to further analyze the data. The correlation between body weight and duration of contraceptives usage was found to be 0.152 (p=0.020). Regression analysis was done to find the relationship between body weight (dependent variable) and duration of contraceptive usage (independent variable). The results show significant relationship (p=0.000) where 1 fold increase in duration (time in years) results in 0.4 folds increase in body weight (Kg) of females using contraceptives. Here, the current study concluded that CHCs could be one of the critical risk factor which increase the chances of developing VTE in genetically susceptible females in Pakistani population.

Molecular Effects of Genetic Variation Posters - Thursday

PB2684. Scalable mQTL analysis of biochemical pathways with the UK Biobank using REVEAL:Biobank

Authors:

Z. Pitluk, M. Peterson, U. Mudgal, A. Poliakov, S. Sarangi; Paradigm4, Waltham, MA

Abstract Body:

Metabolite levels in different bodily fluids such as blood, serum, and urine offer an invaluable window into understanding the physiological state of the body. As precursors, intermediates, and end products in biochemical pathways, linking metabolite analysis to underlying genetic variations can be crucial in developing systems-wide models of complex diseases and disorders by highlighting variants with metabolic consequences. Metabolite quantitative trait loci (mQTL) analysis can be used to identify variants across multiple genes that are potentially involved in regulation of metabolite concentrations. Due to the multifactorial dependence between metabolites and genetic variants in a pathway, mQTL studies are challenging and involve testing millions of associations. Metabolomics-focused resources such as the KEGG PATHWAY and Human Metabolome Databases, and biobank-scale multiomics datasets such as the UK Biobank are valuable tools to build and test hypotheses and identify biomarkers of interest. However, performing such studies at scale present major challenges such as computational cost and efficiency, and ease of use. REVEAL: Biobank presents a scalable, cost-effective, and user-friendly solution to conduct multiomic data analyses. In this study, we created an example workflow in REVEAL: Biobank querying the KEGG and the Human Metabolome Databases for genes involved in the Bile Biosynthesis pathway. Following that we did a GWAS analysis between variants of the identified genes from the 200K Whole Exome Sequence data and the NMR Metabolomics dataset (data category ID - 220; 169 phenotypes plus metabolite ratios) from the UK Biobank (Application ID: 51518) using PLINK and SAIGE algorithms. We also performed a linkage disequilibrium (LD) analysis combined with a regression burden test between pairs of the gene variants and the metabolomic phenotypes. Finally, we explored clinical data from the UK Biobank for cohorts differentiated by the genotype and metabolite values from the associations identified in the GWAS and LD analyses. Our goals in this study were to create a workflow for conducting cost-effective and efficient mQTL analysis of biochemical networks at scale using external databases and biobank-scale datasets to improve understanding of the complex associations between genetic variations and metabolomics.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2685. Seamless integrative pipeline for QTL datasets enhance the discovery of putative causal variants for Alzheimer's Disease.

Authors:

J. Cifello, P. P. Kuksa, L-S. Wang, Y. Leung; Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Colocalization of significant loci between genome-wide association studies (GWAS) and quantitative trait loci (QTLs) have demonstrated tissue-specific associations. Such signals have been useful in understanding the mechanisms of Alzheimer's Disease (AD), utilizing recent data from multiple authors and brain regions. However, transforming these datasets into analysis-ready files is not straight-forward due to differences in files formats, variant nomenclature, how alleles are represented, and variations in provided statistics. For example, some datasets are published with effect sizes reported with respect to the minor alleles while other datasets use the alternative alleles. Here, to facilitate the use of QTL datasets in understanding the regulatory potential of non-coding variants, we developed a scalable, automated pipeline (bitbucket.org/wanlab-upenn/filer-xqtl-pipeline) for expedited harmonization and ingestion of QTL data into the FILER repository (Kuksa et al, 2022), which contains over 60,000 functional genomic and annotation datasets available for query. Using this pipeline, we have integrated over 25 billion QTL records representing 84 different tissues and cell types. We illustrated use of these harmonized QTL data by analyzing 11,449,726 variants (241 linkage-disequilibrium blocks) from an AD GWAS (Kunkle et al. 2019). These were compared to AMP-AD QTL data (Sieberts et al, 2020) from three brain regions (cerebellum (CER), dorsolateral prefrontal cortex (DLPFC), and temporal cortex (TCX)). We used our scalable colocalization pipeline (based on coloc (Giambartolomei et al, 2014)) and found a total of 173 significantly colocalized variants, associated with 24 expression-QTL target genes and 116 GWAS loci. Then, after restricting our search to significant loci by excluding HLA and APOE regions, four GWAS loci remained. We queried these loci using FILER and found they have all been previously reported as significant loci in GTEx splicing-QTLs (Zhang et al, 2020). Three chr8 variants (rs6987305, rs2322599, and rs17057043), colocalizing in CER and TCX, have been shown to be positively correlated with PTK2B in whole blood, but negatively correlated in adipose tissue. These variants, all within 12kb on chr8, may add additional insights into how PTK2B plays a role in AD. Using a scalable pipeline for harmonization and analysis of QTL and GWAS data can help to systematically profile GWAS results for functional effects and identify their tissue and cell type context.

Molecular Effects of Genetic Variation Posters - Thursday

PB2686. SEPT-GD: a decision tree to prioritise potential RNA splice variants in cardiomyopathy genes for functional splicing assays in diagnostics.

Authors:

M. Alimohamed¹, L. Boven², K. van Dijk², Y. Vos³, Y. Hoedemaekers⁴, P. van der Zwaag², R. Sijmons⁵, J. Jongbloed⁶, B. Raddatz², H. Westers⁷; ¹Muhimbili Univ. of Hlth.and Allied Sci., Dar es salaam, Tanzania, United Republic of, ²Univ. Med. Ctr. Groningen, Groningen, Netherlands, ³Univ Med Ctr Groningen, Groningen, Netherlands, ⁴Erasmus Med Ctr, Rotterdam, Netherlands, ⁵Univ. Med. Ctr. Groningen, Groningen, Groningen, Netherlands, ⁶Univ Med Ctr, Groningen, Netherlands, ⁷Univ Med Ctr. Groningen, Groningen, Netherlands

Abstract Body:

Background: Splice prediction algorithms currently used in routine DNA diagnostics have limited sensitivity and specificity, therefore many potential splice variants are classified as variants of uncertain significance (VUSs). However, functional assessment of VUSs to test splicing is labour-intensive and time-consuming. We developed a decision tree to prioritise potential splice variants for functional studies and functionally verified the outcome. **Materials and methods:** We built the decision tree, SEPT-GD, by setting thresholds for the splice prediction programs implemented in Alamut. A set of 343 variants with known effects on splicing was used as control for sensitivity and specificity. We tested SEPT-GD using variants from a Dutch cardiomyopathy cohort of 2002 patients that were previously classified as VUS and predicted to have a splice effect according to diagnostic rules. We then selected 12 VUSs ranked by SEPT-GD to functionally verify the predicted effect on splicing using a minigene assay: 10 variants predicted to have a strong effect and 2 with a weak effect. RT-PCR was performed for nine variants. Variant classification was re-evaluated based on the functional test outcome. **Results:** Compared to similar individually tested algorithms, SEPT-GD shows higher sensitivity (91%) and comparable specificity (88%) for both consensus and non-consensus splice-site variants. Using clinical diagnostic criteria, 1295 unique variants in our cardiomyopathy cohort had originally been classified as VUSs, with 57 predicted by Alamut to have an effect on splicing. Using SEPT-GD, we prioritised 31 variants in 40 patients. In the minigene assay, 12 variants showed results concordant with SEPT-GD predictions. RT-PCR confirmed the minigene results for two variants, *TMEM43* c.1000+5G>T and *TTN* c.25922-6T>G. Based on these outcomes, the *SGCD* c.4-1G>A and *CSRP3* c.282-5_285del variants were reclassified as likely pathogenic. **Conclusion:** SEPT-GD outperforms the tools commonly used for RNA splicing prediction and improves prioritisation of variants in cardiomyopathy genes for functional splicing analysis in a diagnostic setting.

PB2687. Sex differences in gene expression affect host response to influenza A infection

Authors:

A. Jones, B. Schott, L. Wang, D. Ko; Duke Univ., Durham, NC

Abstract Body:

Every year, approximately 30 million people are infected with influenza A virus (IAV) in the United States alone. However, there are diverse outcomes in IAV susceptibility and severity, with some cases presenting as entirely asymptomatic, and others resulting in death. An integral variable in IAV infection is host biological sex. Female individuals of reproductive age have greater morbidity and mortality from IAV infection, while male individuals, particularly children and those >65, are more susceptible to infection. However, despite well-established evidence for sex differences in IAV infection, common genetic variants that contribute to this difference have not been identified. We hypothesize that human genetic variation drives sex differences in gene expression that impact IAV infection susceptibility and severity. To elucidate mechanisms that underly sex differences in IAV infection, we utilized a single-cell RNA-seq model of IAV infection in lymphoblastoid cell lines (48 females, 48 males) to **1**) investigate genes with sex-biased expression associated with IAV phenotypes and **2**) determine human genetic variants that affect sex-biased gene expression and IAV infection. Transcriptomic data revealed widespread sex biases in gene expression during IAV infection with 192 genes showing significant differential expression by sex (FDR < 0.1). In addition, we identified genomic variants that significantly affect gene expression in a sex-dependent manner during infection (n = 40, FDR < 0.05) and are associated with IAV infection phenotypes in human cells. Our study, the first to identify common genetic variants affecting sex-biased response to IAV infection, confirms that biological sex is a critical variable in IAV pathogenesis while identifying targets for future development of diagnostic and therapeutic approaches.

PB2688. Short chain fatty acid abnormalities: Genotype-Phenotype correlation in thirteen Puerto Rican patients.

Authors:

J. R. Pascual¹, O. Quincoces¹, C. Hernandez², S. Carlo³, A. Cornier⁴; ¹Ponce Hlth.Sci. Univ., Ponce, PR, ²Natl. Children's Hosp. Pediatrics, Washington, DC, DC, ³Ponce Hlth.Sci. Univ., Cabo Rojo, PR, ⁴San Jorge Children s Hosp./ Ponce Hlth.Sci. Univ., San Juan, PR

Abstract Body:

We are presenting thirteen patients of Puerto Rican Descent that were diagnosed with mitochondrial fatty acid oxidation disorder (mFAO). Two patients are brother and sister while the rest are unrelated. The patients were referred to the genetics clinic at different ages ranging from seven months to nine years. The reasons for the referral included the broad phenotype of hypotonia, behavioral problems, speech, and global developmental delay, and sensory disorder. Microarray studies were unremarkable. Metabolic laboratory workup showed one or various elevated metabolites. These include lactate, ethylmalonic acid (EMA), methylmalonic acid (MA), dicarboxylic acids (DA), butyryl glycine and C3-C5 acylcarnitine species by-products. Due to these results, a Fatty Acid Oxidation Defects gene panel was ordered. Results showed all patients had genetic within the fatty acid oxidation disorders genes. The patients were identified to be heterozygous, compound heterozygous or homozygous for the genetic changes. The most prevalent genetic change was c. 625G>A or the c. 511 C >7 variant in the ACADS gene. These variants have been identified to cause enzyme susceptibility in previous in vivo and cell culture studies. Other identified variants in genes associated with mFAO include ACADVL, ACADM, *SLC22A5* and *HADHB*. The laboratory and clinical findings, and identified variants are suggestive of short chain fatty acid abnormalities as the genetic etiology of these patients' phenotype. We believe there is a strong genotype-phenotype correlation in this patient cohort.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2689*. Single-cell caQTL reveals cell-state-dependent regulation in immune cells in rheumatoid arthritis.

Authors:

Z. Mu¹, W. Wei², P. Zhu², Y. Li¹; ¹Univ. of Chicago, Chicago, IL, ²Dept. of Clinical Immunology, Xijing Hosp., Xi'an, China

Abstract Body:

For many complex diseases such as rheumatoid arthritis (RA), genome-wide association studies (GWAS) have identified hundreds of independent susceptibility loci (**Ishigaki et al., medRxiv, 2022**). However, mechanistic understanding of these loci remains fundamentally challenging, as the majority of associated variants map to non-coding sequences. Previous studies have shown that only an average of 40% of GWAS loci colocalize with molecular quantitative trait loci (molQTL) in healthy donors (**Mu et al., Genom. Biol., 2021**), suggesting that the remaining 60% of susceptibility loci may affect disease- and context-specific gene regulation. Here, we applied scATAC-seq to 41,813 peripheral blood mononuclear cells (PBMC) from 5 RA patients and 13 healthy donors, and identified 268,112 accessible peaks. We applied topic modeling based on Poisson Non-negative Matrix Factorization (NMF) to peak count data (**Dey et al., PLoS Genet., 2017**), revealing a continuum of cell states in multiple immune cell lineages. Using these continuous cell states, we identified 62,413 state-specific peaks, 27,207 (43.6%) of which were not captured in cluster-level differential analysis. We developed a framework to integrate fine-mapped disease GWAS with the topic model to nominate causal SNPs and genes in a cell-state-specific fashion. In general, we show that topic modeling is a powerful alternative to cluster analysis for scATAC-seq data. Finally, we performed chromatin QTL (caQTL) mapping in our dataset followed by meta-analysis with two additional published datasets. In total, we discovered ~8,000 caQTLs at 10% FDR across various cell types. By modeling continuous cell states from the topic model in caQTL mapping, we identified a continuous relationship between caQTL effect sizes and cell states, further refining the definition of cell-type-specific caQTLs. We estimated that about 5%-20% of peaks with significant caQTL show evidence of genotype-by-cell-state interaction. Finally, we highlighted several examples where caQTLs could help explain previously uncolocalized GWAS loci. To summarize, our study provides an atlas of chromatin accessibility within RA and healthy PBMCs, establishes a framework for studying dynamic gene regulation in disease contexts, and offers novel insight in the genetic architecture of RA.

Molecular Effects of Genetic Variation Posters - Thursday

PB2690. Single-nucleus transcriptome analysis of 424 aging brains identifies cell type and subtype specific *cis*-eQTL and their relation to neurodegenerative disease susceptibility.

Authors:

M. Fujita¹, Z. Gao¹, L. Zeng¹, C. McCabe², C. White¹, B. Ng³, G. Green⁴, B. Vardarajan¹, H-U. Klein¹, G. Wang¹, N. Habib⁴, J. A. Schneider⁵, T. Young-Pearse⁶, S. Mostafavi⁷, D. A. Bennett⁵, V. Menon¹, P. L. De Jager¹; ¹Columbia Univ., New York, NY, ²The Broad Inst., Cambridge, MA, ³Univ. of British Columbia, Vancouver, BC, Canada, ⁴The Hebrew Univ. of Jerusalem, Jerusalem, Israel, ⁵Rush Univ., Chicago, IL, ⁶Harvard Med. Sch., Boston, MA, ⁷Univ. of Washington, Seattle, WA

Abstract Body:

Genome-wide association studies have identified genetic variation associated with complex traits of human brains, such as susceptibility to Alzheimer's disease. However, the functional consequences of these variants remain largely unclear, particularly at the level of cell type specificity. Recent advances in single-cell technology opened new opportunities to explore genotype-expression relationship at cellular resolution. In this study, we performed single-nucleus RNAseq of dorsolateral prefrontal cortex material from 424 individuals of the ROS/MAP cohorts of cognitive aging. More than 1.7 million cells were analyzed and classified into seven cell types and further subclassified into 81 cell subtypes. Cell-level expression data were aggregated into individual-level "pseudobulk" expression data. This pseudobulk expression was used to map cell type-specific *cis*-eQTL by correlating it with genotype of matched individuals. In total, 10,004 unique eGenes were detected at the cell type level, and 8,138 unique eGenes were detected at the cell subtype level. Statistical power to detect eGenes was strongly correlated with the frequency of cell types. Subtype analysis boosted eQTL discovery by identifying eGenes that were not detected at the cell type analysis. Most eGenes were expressed in more than one cell types but had eQTL association only in one cell type, demonstrating context specificity of brain eQTL. As an example, we detected a SNP that is a microglia-specific eQTL of *APOE* expression level. The SNPs had significant association with risk of Alzheimer's disease and cerebral amyloid angiopathy, independently from *APOE* ϵ 4 haplotype. To explore association with disease susceptibility, we performed colocalization analysis between GWAS risk SNPs and cell type-specific eQTL. Risk SNPs of Alzheimer's disease, Parkinson's disease, and schizophrenia colocalized with eQTL, revealing potential cell types responsible for the altered susceptibility. Similar analyses were performed for brain-related traits, including educational attainment and regional brain volumes based on MRI. We further utilized our data to perform cell type-specific transcriptome wide association study, which revealed additional novel candidates of causal genes of neurodegenerative diseases. Overall, this large dataset of single nucleus data is a valuable resource to explore cell type-specificity of the genetic architecture of gene expression in the aging human brains and to prioritize the gene(s) and cell subtype(s) involved in the propagation of functional consequences of susceptibility variants for neuropsychiatric diseases.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2691*. SMN modulates adverse effects associated with GEMIN5-mediated neurodevelopmental syndrome

Authors:

U. Pandey¹, S. Kour¹, A. Chimata², E. Anderson¹, C. Ward¹, O. Chauhan¹, C. O'Brian¹, D. Rajasundaram¹, D. Rajan¹, A. Singh², T. Fortuna¹; ¹Univ. of Pittsburgh Med. Ctr., Pittsburgh, PA, ²Univ. of Dayton, Dayton, OH

Abstract Body:

GEMIN5, an RNA-binding protein, plays an important role in the core assembly of small nuclear Ribonucleoproteins (snRNPs), the building blocks of spliceosome formation. We identified novel autosomal recessive variants among 35 patients presenting with developmental delay, ataxia, motor dysfunction, and cerebellar atrophy using whole-exome sequencing approach. GEMIN5 variants perturb the subcellular distribution, stability, and expression of GEMIN5 protein and its interacting partners in iPSC neurons, indicating a potential loss-of-function mechanism. Interestingly, GEMIN5 mutations disrupt snRNP complex assembly formation in patient iPSC neurons. Molecular determinants of GEMIN5-mediated disease are yet not known. While doing a genetic screen, we identified SMN, a component of the snRNP complex, as a genetic modifier of GEMIN5 phenotypes in vivo. We found that GEMIN5 levels are upregulated in response to genetic expression of SMN in iPSC neurons and in vivo. Interestingly, treatment of the SMN2 therapeutic antisense oligonucleotide, ISS-N1 (nusinersen), significantly upregulated GEMIN5 protein levels in iPSC neurons, suggesting a functional interaction between both proteins. SMN expression restored the defective snRNP components of the SMN complex in GEMIN5 patient neurons. In addition, we show that SMN expression increases the number of nuclear bodies which are otherwise lost in GEMIN5 patient neurons. Our findings indicate that SMN is a novel regulator of GEMIN5 expression and neuropathologies.

Molecular Effects of Genetic Variation Posters - Thursday

PB2692. Spectrum of pathogenic ATM variants in Indian ataxia telangiectasia patients.

Authors:

R. Shukla¹, A. Sankar¹, R. Gatti²; ¹All India Inst. of Med. Sci., New Delhi, India, ²UCLA Sch. of Med., Los Angeles, CA

Abstract Body:

Pathogenic variants in the *ATM* gene are responsible for the autosomal recessive neurodegenerative disorder, ataxia telangiectasia (A-T). Mutations in various ethnic groups have been described and there seem to be no hotspots. In the present study, A-T patients from 41 Indian families were assessed for their clinical phenotypes and *ATM* haplotype analysis, and screened for *ATM* mutations. Thirty seven distinct haplotypes were observed in 41 unrelated families comprising of 21 homozygous and 16 heterozygous haplotypes. Pathogenic *ATM* variants were identified in all 41 families, Eleven of these were aberrant splicing, 5 truncations, 13 frameshifts, 2 missense, and one large genomic deletion spanning exon 17-63 and the other a deletion of 193nt of exon 11. Recurring haplotype and associated variant c.5631_5635delinsA was observed in 7 families of North Indian origin, suggestive of a possible founder effect in Indian A-T patients. Of the 42 *ATM* variants identified in the present study, 29 were novel unreported variants, thereby suggesting that the profile of mutations in the India subcontinent is unique. The present data adds to the multitude of unique *ATM* mutations identified worldwide.

Molecular Effects of Genetic Variation Posters - Thursday

PB2693. Structural and functional characterization of missense variants in *NPR2* augments genetic associations, phenotypic prediction, and mechanistic understanding of skeletal development.

Authors:

S. Covarrubias, C. Bauer, D. Shanghavi, Y-S. Tseng, A. Luu, K. Estrada, S. Froelich; Biomarin Pharmaceuticals, San Rafael, CA

Abstract Body:

Associations between rare coding variants and the human phenome can provide a rough draft of the biological mechanisms underlying disease, but these efforts are currently limited by our inability to classify the effects of novel missense variants. We have conducted cell-based functional screens on hundreds of missense variants in the human Natriuretic peptide receptor B (*NPR2*) derived from patients and the general population. Our data not only allows us to classify dozens of variants as loss of function as well as several as gain of function, but we can quantitatively score variants with intermediate activity levels. These variant scores enhance prediction of adult height when combined with polygenic scores, augment statistical power to detect phenotypic associations, and provide insights into the biological mechanisms of C-Type Natriuretic Peptide (CNP) signaling through *NPR2* in skeletal development. *NPR2* is a key regulator of skeletal growth. Biallelic loss of function (LoF) mutations in *NPR2* can cause severe disproportionate dwarfism while some rare missense variants have been linked to overgrowth and extremely tall stature. Our results demonstrate that variants implicated in overgrowth are often substitutions of basic residues near the kinase homology domain that increase cellular cGMP production. Non-neutral variants in the guanylyl cyclase domain are exclusively linked to reduced signaling while we observe a range of effects caused by mutations in the ligand binding domain. We also show that incorporation of the functional activity score for each variant predicts human phenotype. Across all carriers of a single LoF allele, we can explain 34% of the residual variance in height after adjusting for their polygenic scores. Using variant activity scores in association tests improves power in association tests for height and allows us to detect other disease associations involving cardiovascular and mental health traits. Finally, we compare our results to computationally predicted variant effects as well as predicted protein folding changes induced by these substitutions providing a path toward missense variant scoring for other genes where cell-based screening is less tractable. The classification of missense variants in *NPR2* more than doubles the number of LoF variants for this gene, indicating an overall frequency of more than 1 in 1500. A CNP analog, vosoritide, has recently been demonstrated to enhance growth velocity in children with achondroplasia. Our data suggests that some of these individuals may benefit from this therapeutic targeted to the causal mutations of their growth deficits.

Molecular Effects of Genetic Variation Posters - Thursday

PB2694. Systematic analysis of the impact of short tandem repeats on gene expression

Authors:

S. Benton, L. Zhang, M. Maksimov, S. Shleizer-Burko, Q. Gong, C. Wang, M. Lamkin, M. Gymrek, A. Goren; Univ. of California San Diego, La Jolla, CA

Abstract Body:

Short tandem repeats (STRs) represent an intriguing type of genetic variation given the high level of complexity they can provide as well as their high rate of mutability. The repeat units of STRs vary in properties such as repeat unit length (ranging from 1-6 base pairs), composition (e.g., (A)_n, (AC)_n or (CCG)_n), and sequence variations within the STR (i.e., a mix of perfect and non-perfect repeat units). We previously identified ~28,000 STRs that show an association between the number of repeat units and expression of nearby genes and proposed that they can impact gene expression via multiple mechanisms. Here, to systematically evaluate the involvement of STRs in proximal regulation of gene expression, we established a massively parallel reporter assay (MPRA) built on existing MPRA frameworks but optimized to handle complex and error-prone repetitive sequences. For each STR of interest, we test 230bp fragments including the STR and surrounding genomic context, and test for three separate repeat lengths. In total, our array includes 100,000 different STR sequences spanning approximately 33,000 unique STRs found in promoter regions of human genes. Our system employs random barcodes, enabling up to dozens of measurements per sequence in a single experiment.

In our initial evaluation, we generated libraries capturing >44% of the sequences in our pool. Notably, longer STR sequences and those with high GC content are more likely to drop out of our pool, and thus, incomplete library coverage is expected. Following transfection of these libraries to the HEK293 human cell line, we observed a strong correlation of normalized expression levels between replicates (R=0.60). Further, an STR nearby the POMC gene, a previously identified STR associated with transcription regulation, was among the STRs in our MPRA that showed a positive impact on the expression of the reporter gene, and a linear trend with increased repeat number.

Together, our study provides a system for high-throughput interrogation of the involvement of STRs in modulating gene expression by directly perturbing repeat length and sequence. This system is likely to provide new insights into causal mechanisms by which STRs influence gene regulation. It will also serve as valuable resource for evaluating STR associations with expression identified in large population-based cohorts. While our initial experiment has focused on promoter STRs, future extensions of our approach to study STRs in other genomic regions (e.g., intergenic or intragenic) that potentially may be impacting transcription by other mechanisms.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2695. Targeted-NGS across the β -globin gene cluster identifies multiple linkage disequilibrium patterns in north Indian non-transfusion dependent β -thalassemia patients

Authors:

N. Singh, P. Sharma, M. Jamwal, R. Sharma, R. Das, A. Khadwal, A. Trehan; Post Graduate Inst. of Med. Ed. & Res., Chandigarh, India

Abstract Body:

Introduction: Non-transfusion-dependent β -thalassemia (NTD β T) is an enigmatic disorder influenced by *HBB* and α -globin genotypes and fetal hemoglobin (HbF) levels. Haplotyping of the β -globin gene cluster's (β -LCR's) Locus Control Region is often attempted in order to discover single nucleotide polymorphisms (SNPs) with high linkage disequilibrium (LD) that may modulate the HbF-to-HbA switch and thereby, the severity of thalassemia. Tag-SNPs are representative polymorphisms that "tag" a particular haplotype. They are useful to test associations of a marker locus with qualitative/quantitative traits, without having to genotype all of its SNPs. **Objective:** To identify different haplotypes and their associated Tag-SNPs across the β -globin gene cluster including the β -LCR in genetically similar north Indian NTD β T patients. **Methods:** NTD β T patients (n=51) harboring *HBB:c.92+5G>C* and β^0/β^+ variant underwent targeted NGS of the β -globin gene cluster using Agilent's HaloPlexHS™ target-enrichment kit, with variant calling using Agilent's SureCall™ pipeline. Haplotypes were constructed using HaploView™ v4.2 (Broad Institute). The patients were divided into mild (n=28) and moderate (n=23) severity using the Mahidol scoring system. **Results:** 135 SNPs were delineated spanning an over 95 kbp region. Haplotypes were constructed using common SNPs (MAF >0.05, Hardy-Weinberg p-value >0.01). Among mild NTD β T, 94 qualifying polymorphisms meeting the above criteria were segregated by HaploView™ into 8 LD-blocks. HaploView's Tagger function used with LD-threshold $r^2 > 0.8$ and with aggressive tagging with 2- and 3-marker haplotype and an LD cut-off 3.0 yielded 30 Tag-SNPs. The same approach applied among moderate NTD β T generated five LD blocks containing 62 SNPs and 27 tag-SNPs. In the mild NTD β T group LD block 2 was the largest (an over 22 kbp region with 14 tag SNPs) while in the moderate group LD block 1 represented a 21 kbp region with 13 tag SNPs. These two largest blocks covered the ϵ , $\zeta\gamma$, $A\gamma$, δ , and β globin genes. This region had 5 tag SNPs that were common to both the severity groups. The *HBG1-HBD* ($A\gamma$ - δ) intergenic region contains the non-coding gene *BGLT3*. This region contained two tag-SNPs: rs7483789 in mild and rs7480197 in moderate NTD β T. **Conclusion:** Haploview™ analysis using targeted-NGS of the β -globin cluster identifies multiple LD patterns in genetically similar north Indian NTD β T patients with varying degree of severity. This suggests a diversified genomic structure in this group and should aid future comparisons of NTD β T patients with divergent phenotypes across various regions.

Molecular Effects of Genetic Variation Posters - Thursday

PB2696. Testing the association of Grantham score with functional impact for clinical variant interpretation

Authors:

K. Owens, G. A. Maston; Quest Diagnostics, Seacaucus, NJ

Abstract Body:

Background: The Grantham score (GS) is a calculation that compares the different properties of any 2 amino acids to predict the impact of a substitution on protein function. Previous research has explored the use of GS in the clinical interpretation of missense variants; however, no systematic testing has been done to confirm the accuracy of GS for predicting pathogenicity for all types of amino acid changes. The present study takes advantage of previously published high-throughput *BRCA1* functional data (Findlay GM, Daza RM, Martin B, et al. *Nature*. 2018;562[7726]:217-222) to address how well GS correlates with loss of function (LOF) for different types of amino acid changes. We hypothesized that greater GS would be associated with a higher percentage of loss of function results (% LOF) for any given amino acid substitution. **Methods:** Data from Findlay, et al regarding the functional impact of *BRCA1* variants in the RING and BRCT domains were stratified by reference amino acid and tallied to determine how many times each specific amino acid substitution resulted in a loss of protein function based on the functional assay performed by Findlay, et al. These results were converted to a percentage (% LOF) and plotted against the GS for each amino acid substitution on a graph with a best-of-fit line. These values were also compared to Align GVGD scores for each given amino acid position. **Results:** A polynomial equation provided the best-of-fit line for each reference amino acid chart, although most of the reference amino acids did not reflect a strong correlation between % LOF and GS. Five amino acids exhibited a correlation (R^2) of greater than 0.70: cysteine (Cys), isoleucine (Ile), methionine (Met), tyrosine (Tyr), and valine (Val). Cys, Ile, and Val substitutions displayed a positive correlation between % LOF and GS, as anticipated. Met substitutions appeared to have a threshold for GS, where the % LOF was stable until after a score of 80, at which point the % LOF increased dramatically. Tyr substitutions displayed a parabolic inverse correlation between % LOF and GS. **Limitations:** This analysis only examines codons in known functional domains of *BRCA1*; additional testing is needed to determine if these correlations hold true for amino acid changes in different protein domains or in different genes. **Conclusions:** The results of this study suggest that GS for amino acid substitutions do not always correlate with functional evidence and should not be used in isolation to interpret missense variants. It may be necessary to develop gene- or domain-specific rules on the proper use of GS in clinical variant interpretation.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2697. The contribution of mitochondrial DNA variation to disease risk in a diverse cohort

Authors:

A. Zaidi, C. Morse, A. Verma, M. Ritchie, Regeneron Genetics Center, Penn Medicine Biobank, I. Mathieson; Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Little is known about how variation in mitochondrial DNA or mtDNA copy number (mtCN) contributes to phenotypic variation. There is extensive interaction between proteins encoded by the mitochondrial and nuclear genomes, but the degree to which these interactions contribute to disease risk is unknown. To address these questions, we analyzed data from the Penn Medicine Biobank, a large (N = 43,000) diverse cohort with genetic and electronic health record data. We estimated mtCN from exome sequence data and replicated associations between mtCN and predictors such as sex, age, and blood cell counts. We also carried out a genome-wide association study for mtCN, replicating previously discovered genetic variants with consistent effects across individuals of European and African ancestry. Mitochondrial copy number was associated with 14 out of 1,131 health-related phenotypes at a false discovery rate of 0.05. These included diabetes, hypertension, epilepsy, liver and pulmonary disease, prostate cancer, and chronic kidney disease (CKD). The association with CKD was supported by consistent associations with related biomarkers such as serum creatinine and serum albumin levels and was significant in both European ($P = 1.2 \times 10^{-5}$) and African ancestry ($P = 5.7 \times 10^{-5}$) individuals.

Disease associations for specific mitochondrial haplogroups have been reported but are hard to confirm because geographic variation in haplogroups is confounded with environmental variation and nuclear ancestry. To overcome this, we analyzed data from individuals with mixed African and European ancestry (N = 9,037) where we can correct for the effects of nuclear ancestry. We show that mitochondrial haplogroups are not significantly associated with any phenotype, suggesting that haplogroup-specific variants do not contribute substantially to disease risk variation across ancestries. In admixed individuals, the interaction between mitochondrial and nuclear ancestry is also not significantly associated with mtCN or any other phenotype, despite sufficient power to detect moderate to large effects. This suggests that mito-nuclear incompatibility does not contribute substantially to health-related variation. Our study confirms the utility of mtCN as a biomarker of disease and shows that mitochondrial variation has limited or no contribution to ancestry-related differences in disease risk.

Molecular Effects of Genetic Variation Posters - Thursday

PB2698. The contribution of short tandem repeats to splicing variation in humans

Authors:

Y. Li, J. Margoliash, Y. Dong, Z. Zhang, A. Goren, M. Gymrek; Univ. of California, San Diego, San Diego, CA

Abstract Body:

Alternative splicing (AS) is a fundamental step that plays a critical role in the regulation of gene expression and protein diversity in eukaryotes. Emerging studies have identified thousands of genetic variants associated with variation in AS of nearby genes. Most of those studies have focused on single nucleotide polymorphisms (SNPs). Short tandem repeats (STRs), consisting of repeated sequences of 1-6bp, have been implicated in multiple splicing-related processes, including forming binding sites for splicing factors such as hnRNP-L and modulating RNA secondary structure. However, their contribution to splicing variation in humans has not been explored on a genome-wide scale.

Here, we use whole-genome sequencing and expression data from 41 tissues in the Genotype-Tissue Expression Project to systematically evaluate the contribution of STRs to AS in humans. We applied HipSTR to perform multi-sample STR genotyping of 1.6 million STRs across 652 individuals. We then tested for associations between the mean repeat length of STRs and the percent spliced in (PSI) of exons within 10kb of those STRs while controlling for population structure and PEER factors.

In total, we identified 7,467 unique associations (spliceSTRs). Cross-tissue analysis suggests the 48.5% of these spliceSTRs are shared across two or more tissues. We applied the FINEMAP algorithm to perform fine-mapping of spliceSTR associations against nearby SNPs. We identified 1,921 unique spliceSTRs with at least 50% posterior inclusion probability and recapitulated multiple previously known spliceSTRs, including the myotonic dystrophies (*DMPK*), suggesting those spliceSTRs are strong candidate causal variants. Overall, our study reveals the regulatory associations of STRs with AS, identifies a set of high confidence spliceSTRs candidates and provides a valuable resource for future studies of complex traits.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2699. The effect of rare protein-coding sequence variants on the human plasma proteome

Authors:

B. Prins, O. Burren, Q. Wang, R. Dhindsa, K. Carss, K. Smith, S. Petrovski; Ctr. for Genomics Res., Discovery Sci., BioPharmaceuticals R&D, AstraZeneca, Cambridge, United Kingdom

Abstract Body:

Combining human genomics with proteomics can facilitate therapeutic target identification and validation and shed light on pathogenic processes and associated biomarkers. We integrated the plasma abundances of 1,472 proteins measured on the Olink™ platform with exome sequences from 37,124K UK Biobank participants to assess the influence of rare coding sequence variation on the human plasma proteome. We identified 1,248 significant ($p < 2e-9$) gene-protein associations through a gene-level collapsing analysis of rare variants that included 706 *cis* and 539 *trans* signals. A complementary rare variant (MAF < 0.1%) exome-wide association analysis identified 1,192 non-synonymous variants associated with the plasma levels of 850 proteins, of which 723 were in *cis* and 469 were in *trans*. Phenome-wide analysis identified 24 genes harbouring rare genetic variants that were associated with both plasma protein abundance and a binary clinical endpoint. Variants within the gene *TNFRSF13B*, encoding the transmembrane activator and CAML interactor (TACI), are associated with low immunoglobulin levels and combined variable immune deficiency (CVID)¹. In *cis*, known CVID pathogenic missense variants in *TNFRSF13B* were associated with decreased TACI plasma protein abundance (e.g., 17-16940415-G-T, $P = 2.4 \times 10^{-46}$, $\beta = -0.70$ [95%CI -0.80 — -0.60]). In *trans*, we observed significant associations with increased plasma abundance for 13 proteins including BAFF, the B cell survival factor that signals through TACI (17-16940415-G-T, $P = 1.8 \times 10^{-17}$, $\beta = 0.42$ [95%CI 0.32 — 0.52]). Such associations highlight the complex role of TACI in B-cell regulation and antibody response and suggest additional proteins that may be involved in CVID pathogenesis. Our study shows that rare, non-synonymous variants can modulate the plasma proteome and can be used to explore disease mechanisms and therefore inform therapeutic development. Future work will integrate these results with other clinical and molecular phenotypes available for UK Biobank participants and will be made available through our online PheWAS portal (<https://azpewas.com/>).

Vacic¹; ¹23andMe Therapeutics, South San Francisco, CA, ²GlaxoSmithKline, Stevenage, United Kingdom, ³23andMe, Sunnyvale, CA, ⁴GSK, Stevenage, United Kingdom, ⁵GSK, Cambridge, MA, ⁶GlaxoSmithKline, Stevenage, United Kingdom, ⁷GlaxoSmithKline, Upper Providence, PA

Abstract Body:

Underrepresentation of individuals of African ancestry in biomedical studies is an established fact in need of remediation. This is particularly true in the case of genetics and genomics, where nearly all studies are performed in individuals of European descent. To help address this inequity, we have conducted whole genome sequencing (WGS) of DNA from saliva and RNA-sequencing (RNA-seq) of venous blood samples of 1,012 23andMe, Inc consented research participants of African ancestry as part of the Black Representation in Genomic Research (BRGR) study. Additionally, we did RNA-seq of lymphoblastoid cell lines (LCL) from 665 individuals belonging to the African Ancestry superpopulation (AFR) from the 1000 Genomes Project. All biological sample collection was performed in accordance with the terms of informed consents and under an IRB approved protocol. These data were used to conduct expression quantitative trait loci (eQTL) studies in the BRGR cohort (N = 737), and together with published WGS, in the AFR LCL cohort (N = 659). We find 26,877 eQTLs affecting expression of protein coding genes in the BRGR study, and 20,371 in the AFR LCL study. We compare these numbers to previously published eQTL studies in European individuals -- the venous blood study from the Parkinson Progression Marker Initiative (PPMI), and the European cohort of GEUVADIS LCLs -- and discover twice as many or more eQTLs per person in BRGR and AFR LCL as compared to PPMI (N = 1,251; 20,525 eQTLs) and GEUVADIS Europeans (N = 358; 7,171 eQTLs). We show that increased heterozygosity in individuals of African as compared to European ancestry strongly impacts eQTL discovery. Using these African and European datasets, we further (a) show that comparisons of heritability of gene expression are confounded by population substructure; (b) show that local ancestry does not largely affect eQTL discovery; (c) explore strategies for eQTL calling in a multi-ancestry setting; (d) investigate the relationship between genes differentially expressed between cohorts and eQTLs unique to a cohort; and (e) using both African American GWAS from the Million Veterans Project and a GWAS of height in 23andMe research participants of African ancestry, examine results of GWAS variant-to-gene mapping when ancestries are or are not aligned between GWAS and eQTL studies. Consistent with consent provided, we will make these data publicly available by 2023 to all qualified researchers -- academic or industry -- in the hopes that they will accelerate research that reduces health disparities and improves outcomes for individuals of African ancestry.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2701. The human myocardial transcriptomic response to the interaction effect of genetic variants and ischemic stimulus identified by a novel approach.

Authors:

A. Yazdani¹, L. Luigi Pesce², M. Oliva², J. gorham³, C. Seidman³, J. Seidman⁴, S. Body⁵, S. Aranki³, B. Stranger⁶, J. Muehlschlegel¹; ¹Brigham & Women's Hosp. / Harvard Med. Sch., Boston, MA, ²Northwestern Univ., Evanston, IL, ³Harvard Med. Sch., Boston, MA, ⁴Harvard Med Sch, Boston, MA, ⁵Boston Univ., Dover, MA, ⁶Northwestern Univ., Chicago, IL

Abstract Body:

Interindividual gene expression variation is impacted by both genetic variation and environmental exposures. We investigated genetic-transcriptomic relationships in response to myocardial ischemia as an environmental factor to understand mechanisms that underlie the pathological processes of myocardial ischemia in humans. Left ventricular biopsies from 118 patients undergoing aortic valve replacement surgery were obtained at baseline and after an average of 79 minutes of cold cardioplegic arrest/ischemia. In this study, we explored the genetic basis of gene expression through mapping expression quantitative trait loci (eQTL), with a focus on response eQTL (reQTL), defined as the effect of genetic variants on the gene expression response to stimulus, in this case, ischemia. Since genetic variants affect expression level regardless of stimuli, we need to account for baseline expression while estimating the reQTL. While conventional reQTL approaches subtract/divide expression values, we instead proposed to adjust for the “effect” of baseline expression on post expression as a complementary approach. Focusing on cis-QTLs, where gene expression levels are affected by variants in the gene body and 1 megabase up and 1 megabase down the gene, the conventional approaches identified at most 11 reQTL at a false discovery rate (FDR) ≤ 0.25 . The conditional model introduced above identified 530 reQTL at FDR ≤ 0.05 , where 64 were among the post-ischemia-specific eQTL, 35 among baseline-specific eQTL, and 5 were neither baseline nor post-ischemia eQTL, and 426 were eQTL at baseline and post-ischemia. To assess the role of post-ischemia eQTL and reQTL in myocardial ischemic injury, we integrated the summary statistics of the eQTLs with a separate set of 1751 patients undergoing a coronary artery bypass graft surgery and estimated the causal effect of eQTLs on troponin using Mendelian randomization after assessing the lack of pleiotropic action of eQTLs utilized as instrumental variables. Troponin is a complex protein integral to cardiac muscle contraction and elevated levels in the blood after cardiac surgery. In addition, we carried out a colocalization analysis between cis-eQTLs and variants associated with heart diseases and other enrichment analyses including replication in GTEx and in a mouse model. We identified 19 cis-regulatory genes acting as mediators of myocardial infarction effects, such as MRAS (Ras family GTPase), NBR2 (long non-coding RNA), and MED15 (subunit of a transcription co-activator).

Molecular Effects of Genetic Variation Posters - Thursday

PB2702. The importance of the use of genomics in early diagnosis of tuberous sclerosis: case report.

Authors:

A. Lambraño^{1,2}, L. Moreno Giraldo³; ¹1045701331, cali, Colombia, ²Univ. Libre, Cali , Valle del Cauca, Colombia, ³Orphan Diseases Program, New Clinic of Cali., cali, Colombia

Abstract Body:

INTRODUCTION: tuberous sclerosis is a rare disorder with multisystemic clinical manifestations that can compromise vital organs such as the kidney, lung and heart, which requires early diagnosis to provide timely and targeted treatment, improving the prognosis and reducing the morbidity and mortality attributed to these pathologies. **OBJECTIVE:** To establish the importance of the use of genomics and the phenotype-genotype correlation for the diagnosis, treatment, follow-up, prognosis, genetic counseling of tuberous sclerosis **MATERIALS AND METHODS** case report with clinical suspicion of tuberous sclerosis with genetic confirmation by having a Pathogenic heterozygous variant in the TSC2 gene **RESULTS:** A pathogenic heterozygous deletion was found that changes a cytosine at position 2539 of the TSC2 gene cDNA (c.2539delC), leading to a premature stop codon at amino acid 893 (p.Leu847Cysfs*47) into a protein of 1,807 amino acids with pathogenic clinical significance **CONCLUSIONS:** Tuberous sclerosis complex is an orphan disease for Colombia given its low population prevalence, with a high morbidity and mortality burden due to multisystem involvement. Its confirmation is carried out through molecular-genomic methods that allow establishing a phenotype-genotype correlation and searching for possible affected organs or systems in individuals, bringing us closer to personalized and precision medicine

Molecular Effects of Genetic Variation Posters - Wednesday

PB2703. The Multiple *de novo* Copy Number Variant (*MdnCNV*) phenomenon: peri-zygotic DNA mutational signatures and multilocus pathogenic variations

Authors:

H. Du¹, A. Jolly¹, C. Grochowski¹, B. Yuan¹, M. Dawood¹, S. Jhangiani¹, D. Muzny¹, J. Fatih¹, Z. Coban-Akdemir^{1,2}, A. Scheuerle³, K. Witzl⁴, J. Posey¹, M. Pendleton⁵, S. Juul⁵, P. Hastings¹, W. Bi¹, J. Lupski¹, F. Sedlazeck¹, R. Gibbs¹, C. Carvalho⁶, P. Liu¹; ¹Baylor Coll. of Med., Houston, TX, ²The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, ³Univ. of Texas, Southwestern Med. Ctr., Dallas, TX, ⁴Univ. of Ljubljana, Ljubljana, Slovenia, ⁵Oxford Nanopore Technologies, New York, NY, ⁶Pacific Northwest Res. Inst., Seattle, WA

Abstract Body:

Background: The multiple *de novo* copy number variant (*MdnCNV*) phenomenon is a rare peri-zygotic mutational event observed once in at least every 12,000 individuals referred for clinical Chromosome Microarray Analysis (CMA). Variable congenital abnormalities have been observed in individuals with the *MdnCNV* phenomenon. We investigated genetic variation-causing genome instability and the underlying phenotypic rare disease trait manifestations in families with *MdnCNV*. **Methods:** Using several genomic analysis techniques, including CMA and short and long-read DNA sequencing, we characterized the *de novo* mutation signatures of a newly identified *MdnCNV* case. Trio-based rare variant analysis and single-based substitutions (SBS) signatures analysis on *dnSNV* was performed on this family and four previously published *MdnCNV* families to infer potential genetic etiologies. Lin semantic similarity scores informed quantitative human phenotype ontology analysis on three *MdnCNV* families to identify gene(s) driving or contributing to the clinical phenotype. **Results:** The newly identified *MdnCNV* family presents with eight non-mosaic *de novo* tandem direct duplications, each ~1 Mb long with microhomology present at 6/8 breakpoint junctions. CNV phasing reveals a 1:1 ratio of *dnCNV* parental origin. Enrichment of *de novo* single nucleotide variants (SNV: 6/79) and *de novo* indels (1/12) was found at and within 4 Mb of the *dnCNV* genomic regions. Characterization of *dnSNV* suggests an elevated post-zygotic SNV mutation rate in *MdnCNV* families. The rare variant analysis identified multiple maternally inherited high-impact variants affecting the DNA replication repair pathway. SBS Mutational signature analysis suggests one *MdnCNV* family shows a potential mutation signature associated with DNA polymerase epsilon. Phenotype analysis suggests that gene(s) within *dnCNV* regions contribute to the observed proband phenotype in 3/3 of cases. CNVs in two cases, one with a contiguous gene duplication of *PMP22* and *RAI1* and another with *NSD1* and *SMARCC2* at separate loci, contribute to phenotype manifestation. **Conclusions:** The characteristics of *dnCNVs* in the newly described case were consistent with a microhomology-mediated break-induced replication (MMBIR) driven mechanism generating multiple *dnCNVs* during the peri-zygotic period. Maternal genetic variants in DNA repair genes could increase peri-zygotic genomic instability, increasing the post-zygotic SNV and CNV mutation rate. The variable phenotypic features observed across *MdnCNV* probands reflect the contribution of more than one locus, supporting *de novo* multilocus pathogenic variation (MPV).

Molecular Effects of Genetic Variation Posters - Thursday

PB2704*. The role of introgressed archaic DNA in the human genome.

Authors:

R. Young¹, J. Kang², A. S. Ramgolam¹; ¹Univ. of Edinburgh, Edinburgh, United Kingdom, ²Zhejiang Univ. - Univ. of Edinburgh Inst., Haining, China

Abstract Body:

Modern humans harbour a substantial component of DNA which has been introduced from archaic hominid species through historical introgression events. Neanderthal DNA is more common within the European population, while the highest percentage of Denisovan DNA is found within Asian genomes. However, we do not yet have a comprehensive understanding of the biological contribution this introgressed, archaic DNA makes to contemporary human population variation. Here, we focus on gene expression regulation as a molecular phenotype to address this question genome-wide across tissues and populations.

We first integrated publicly available data on the locations in the human genome of (1) Neanderthal and Denisovan DNA and (2) various expression quantitative trait loci (eQTLs) datasets from the GTEx project and others. We found that all tissues for which we had eQTL data were enriched for archaic eQTLs (relative to non-regulatory polymorphisms, Fisher's exact tests, $p < 0.05$). These enrichments were particularly prominent for Neanderthals when compared to European polymorphisms and when compared to Asian polymorphisms, i.e. in the populations where each archaic genomic is more commonly found. The effect sizes of Neanderthal and Denisovan eQTLs were less than for tissue-matched eQTLs from the same population (Mann-Whitney tests, $p < 0.01$). We reconstructed the evolutionary trajectory of eQTL alleles across Neanderthal and modern humans where we observed a bias towards down-regulation of gene expression by the Neanderthal allele (0.95-fold, Mann-Whitney test, $p < 2.2 \times 10^{-16}$). We are currently working to replicate this analysis for Denisovan eQTLs.

We next investigated whether those genes whose expression was regulated by archaic DNA have previously been associated with human disease. Using the OMIM database, we found 3,641 unique disease-associated genes which are regulated, in at least one tissue, by Neanderthal or Denisovan DNA. Neanderthal eQTLs are more likely to regulate genes associated with disease (1.08-fold, Fisher's exact test $p = 5.01 \times 10^{-52}$) while Denisovan eQTLs are less likely (0.96-fold, Fisher's exact test $p = 1.10 \times 10^{-8}$). Ongoing work is investigating whether these archaic alleles are protective or drive susceptibility to disease.

Our work suggests that regulatory archaic DNA has preferentially retained its regulatory potential and that this contribution varies across global populations. Regulatory Neanderthal DNA is more commonly associated with disease than Denisovan. These results have important consequences for interpreting the biological significance of evolutionary recent additions to the human genome.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2705. The Unmasking Of 'Mitochondrial Adam' And Structural Variants Larger Than Point Mutations As Stronger Candidates For Traits, Disease Phenotype And Sex Determination

Authors:

A. Singh^{1,2}; ¹Schiller Intl. Univ., Heidelberg, Germany, ²ABioTeQ, Delhi, India

Abstract Body:

Structural Variations, SVs, in a genome can be linked to a disease or characteristic phenotype. The variations come in many types and it is a challenge, not only determining the variations accurately, but also conducting the downstream statistical and analytical procedure. Structural variations, SVs, with size 1 base-pair to 1000s of base-pairs with their precise breakpoints and single-nucleotide polymorphisms, SNPs, were determined for members of a family. The genome was assembled using optimal metrics of ABySS and SOAPdenovo assembly tools using paired-end DNA sequence. An interesting discovery was the mitochondrial DNA could have paternal leakage of inheritance or that the mutations could be high from maternal inheritance. It is also discovered that the mitochondrial DNA is less prone to SVs rearrangements than SNPs, which propose better standards for determining ancestry and divergence between races and species over a long-time frame. Sex determination of an individual is found to be strongly confirmed using calls of nucleotide bases of SVs to the Y chromosome, more strongly determined than SNPs. We note that in general there is a larger variance (and thus the standard deviation) in the sum of SVs nucleotide compared to sum of SNPs of an individual when compared to reference sequence, and thus SVs serve as a stronger means to characterize an individual for a given trait or phenotype or to determine sex. The SVs and SNPs in HLA loci would also serve as a medical transformational method for determining the success of an organ transplant for a patient, and predisposition to diseases a priori. The sample anonymous dataset shows how the de-novo mutation can lead to non-inherited disease risk apart from those which are known to have a disease to mutation association. It is also observed that mtDNA is highly subjected to mutation and thus the factor for a lot of associated maternally inherited diseases. 'mitochondrial Adam' can be a fair reality as certainly the biparental mode of mtDNA puts in question the theory of 'mitochondrial Eve'. SVs would serve as a stronger fingerprint of an individual contributing to his traits, sex determination, and drug responses than SNPs.

Molecular Effects of Genetic Variation Posters - Thursday

PB2706. *TP53* codon 72 polymorphism modulates macrophage polarization through altered PI3K/Akt signaling pathways

Authors:

A. Silwal, B. Reese, N. Lodhi, M. Karbowniczek, M. Markiewski; Texas Tech Univ. Hlth.Sci. Ctr., Abilene, TX

Abstract Body:

The purpose of this study is to determine the role of the most common p53 single nucleotide polymorphism (SNP) at codon 72, which encodes proline (P72) or arginine (R72), in the regulation of macrophage polarization. Bone marrow-derived macrophages (BMDMs) from human p53 knock-in (Hupki) mice, in which exons 4-9 of the endogenous mouse p53 allele were replaced with the homologous human p53 gene sequence, carrying P72 and R72 variants were treated with lipopolysaccharide (LPS) to activate macrophages. Signaling pathways involved in macrophage activation were analyzed by RT-PCR, Western blotting, and immunofluorescence. A highly selective Akt inhibitor MK-2206 was used to determine the effect of Akt blockade in R72 macrophage polarization and signaling. Volumes of tumors generated by subcutaneous injections of tumor cells (TC1), mixtures of tumor cells, and LPS-stimulated P72 (TC1+P72^{LPS}) and R72 (TC1+R72^{LPS}) macrophages were measured. LPS stimulation of BMDMs led to a greater upregulation of M1 genes (*Socs1* & *Nos2*) in P72 compared to R72 macrophages. Further, we examined the activation of PI3K/Akt as this pathway is essential for restricting proinflammatory (M1) and promoting anti-inflammatory (M2) responses in toll-like receptor (TLR4)-stimulated macrophages. The expression of p-Akt (S473) was increased to a greater extent in R72 vs. P72 macrophages upon LPS treatment. Consistent with increased Akt activity in R72 macrophages, the p-FOXO3a (S253) residue was greater in these cells. This phosphorylation inhibits FOXO3a transcriptional activity via nucleus to cytoplasm shuttle. NF-κB activation, nuclear translocation, and subsequent transcriptional regulation is a key to the induction of several proinflammatory genes. Cytoplasmic FOXO3a was demonstrated to inhibit NF-κB via direct binding to NF-κB in the cytoplasm and prevent its nuclear translocation. We observed increased cytoplasmic colocalization of FOXO3a and NF-κB upon LPS stimulation by Immunofluorescence. Western blotting further corroborated these data showing impairment of NF-κB nuclear translocation. Following treatment with MK2206, we observed reduced p-FOXO3a (S253), enhanced NF-κB nuclear translocation, and increased expression of M1 genes in R72 (*Socs1* & *Nos2*) cell. The addition of LPS-stimulated P72 macrophages to tumor cells reduced tumor growth, in contrast to R72 macrophages in a syngeneic model of HPV-induced cancer. Here, we report that macrophages carrying R72 variant are biased toward M2 phenotype through altered NF-κB nuclear translocation which also impacts in vivo macrophage function as R72-LPS stimulated macrophages lose ability to reduce tumor growth.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2707. Two types of variants pointing out a crucial role for RNF216 in healthy and diseased brain.

Authors:

L. Versluys¹, A. Sieben², P. Ervilha Pereira¹, N. Schuermans¹, E. Mondragon Rezola³, P. LeBlanc¹, M. Galas⁴, P. Santens⁵, E. Bogaert¹, B. Dermaut¹; ¹Ghent Univ., Ghent, Belgium, ²Antwerp Univ., Antwerp, Belgium, ³Univ. Hosp. Donostia, Gipuzkoa, Spain, ⁴Univ. Lille, Inserm, CHU Lille, CNRS, Lille NeuroSci. & Cognition, Lille, France, ⁵Ghent Univ. Hosp., Ghent, Belgium

Abstract Body:

Mutations in RNF216, an E3-ubiquitin ligase, have been identified as the genetic cause of Gordon Holmes syndrome (GHS), a rare recessive neurodegenerative disease. RNF216 mutations can be roughly classified into two groups based on their location within the protein. The first group of mutations cluster within the catalytic domain and lead to a loss of ubiquitin ligase activity. In the brain of one patient with a homozygous R751C variant in the catalytic domain, intranuclear ubiquitin-positive inclusions were found (Margolin et al, 2013). The second group of mutations reside in the N-terminal region, outside the catalytic domain with preserved ligase activity. Still, the mechanism by which this second group of mutations is leading to loss-of-function is elusive. Interestingly, in a previously reported patient with a homozygous N-terminal G456E mutation outside the catalytic domain (Santens et al, 2015) we replicated the neuropathological findings observed in the R751C patient, pointing towards a similar loss-of-function mechanism at play. Immunohistochemical analysis shows ubiquitin and p62 immunoreactive intranuclear inclusions which are negative for hyperphosphorylated tau, β -amyloid and TDP-43. Intriguingly, we identified a patient combining variants from both groups: one variant, C752Y, in the catalytic domain and one, W449R, in the N-terminus, suggesting that indeed both variants convergence into a loss-of-function pathway. As the endogenous function of RNF216 is crucial to understand RNF216-mediated neurodegeneration, we want to investigate beyond the catalytic activity, a novel and additional nuclear function for RNF216. This will be enabled by in-vitro experiments and proteomics on human GHS-patient brain tissue and fibroblasts, hiPSC-derived neuronal cultures expressing RNF216 disease-variants, and BioID. The physiological and pathological mechanisms explored in this project hold the potential to greatly improve our understandings of GHS, shed light on novel key players in neurodegeneration, and open new avenues for a novel therapeutic target for this rare neurodegenerative disease.

Molecular Effects of Genetic Variation Posters - Thursday

PB2708. TxEWAS identifies genetic modifiers of drug response and side effects through retrospective gene-environment association studies.

Authors:

M. Sadowski, M. Thompson, J. Mefford, R. Border, S. Sankararaman, N. Zaitlen; Univ. of California, Los Angeles, Los Angeles, CA

Abstract Body:

The impact of environmental exposures on complex traits can be modulated by genetic variation. Such gene-environment interactions (GxE) may underlie population variability in drug response, susceptibility to carcinogens, and resilience in aging. However, interaction effects at individual genetic variants are typically small, and few examples have been discovered to date. Moreover, when identified, associations at individual variants are difficult to interpret functionally.

To address these concerns, we develop a new framework to test for GxE effects in an imputed expression-trait association model—TxEWAS, which extends the TWAS model. TxEWAS trains a linear predictor of the *cis* genetic component of expression in a cohort of unrelated individuals with both genotypes and gene expression measured. It then uses this predictor to impute expression levels and scan for expression-environment interactions in a cohort of phenotyped individuals (without directly measured expression).

Importantly, TxEWAS accounts for the heterogeneity of phenotype variance—a continuously underappreciated source of bias in conventional GxE methods. Realistic biobank scale simulations showed that failing to account for this bias can cause a threefold increase in the false positive rate.

We applied TxEWAS to eight drug exposure-response pairs in the UK Biobank, where responses were measures of target effects or side effects of the tested drugs (statins, warfarin and methotrexate). We identified 191 significant interacting genes, potentially involved in response to those drugs. In particular, our analysis revealed *PCSK9* and *GIPR* as one of the potential modulators of the effect of statin use on LDL cholesterol and HbA1c (a clinical marker of glycemic control) levels respectively. *PCSK9* was previously postulated to modulate efficacy of the statin therapy. *GIPR* was demonstrated by mouse model studies to be involved in regulation of insulin levels in the presence of elevated glucose, and shown to be associated with increased risk of developing hyperinsulinemia under antipsychotic drug treatment of schizophrenia. Together, these results demonstrate the power of the TxEWAS approach, and in particular, its potential to offer an insight into genetic determinants of individual drug response.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2709. Types of cis- and trans-gene regulation of expression quantitative trait loci across human tissues.

Authors:

A. Fu¹, J. Kvamme¹, M. Badsha², E. Martin¹, J. Wu³, M. Megheib¹, X. Wang³; ¹Univ. of Idaho, Moscow, ID, ²St Jude Children's Res. Hosp., Collierville, TN, ³Inst. of Basic Med. Sci., Chinese Academy of Med. Sci., Beijing, China

Abstract Body:

Expression quantitative trait loci (eQTLs) have been identified for most genes in the human genome across tissues and cell types. While most of the eQTLs are near the associated genes, some can be far away or on different chromosomes, with the regulatory mechanisms largely unknown. Although the canonical model is cis-gene mediation (eQTL → cis-gene → trans-gene), other modes of relationships have been observed, although only in a couple of cell lines. There is also experimental evidence supporting functionally important inter-chromosomal interactions.

Here, we study cis- and trans-regulation of eQTLs across nearly 50 tissues and cell types. Specifically, we constructed trios consisting of an eQTL, its cis-gene and trans-gene and inferred the regulatory relationships with causal network inference. Similar to the GTEx consortium, we focus on protein-coding genes and long noncoding RNAs (lncRNAs). Across tissues, the number of trios selected for this analysis ranges from 627 to 4668 (median: 2279), mainly due to the varying sample sizes (median: 235). We performed PEER normalization on the gene expression data for each tissue and identified the principal components (PrCs) that are significantly associated with each trio; these PrCs are potential confounding variables. We then applied our MRPC method (Badsha and Fu, 2019; Badsha et al., 2021) to perform causal network inference on each trio and its associated PrCs, treating each variable as a node in the network. Our extensive simulation studies had demonstrated that MRPC tends to be conservative and achieves better recall, precision and stability across many scenarios on networks of small to moderate sizes.

We identify multiple types of regulatory networks for trios: across all the tissues, above 50% of the tested trios are inferred to be conditionally independent, where the two genes are conditionally independent given the genotype of the eQTL (cis-gene ← eQTL → trans-gene). Around 1.8% of the trios are inferred to be mediation (eQTL → mediator → target), around 0.3% fully connected among the three nodes, and just a handful v-structures (eQTL → gene 1 ← gene 2). The remaining trios are inferred to have just one edge. Unexpectedly, across the tissues, on average over 70% of the mediation trios have the trans-gene as the mediator. Most of the cis- and trans-gene mediators are also tissue specific. To verify the results, we further applied to these trios other methods, such as a less conservative version of MRPC, and the GMAC method (Yang et al., 2017) that detects only mediation. These analyses provided consistent results.

Molecular Effects of Genetic Variation Posters - Thursday

PB2710*. UBA5-related Epilepsy: From Cellular Models to Novel Therapies

Authors:

H. Chen¹, E. Almanza Fuerte¹, H. Mefford²; ¹St Jude Children's Res. Hosp., Memphis, TN, ²St. Jude Children's Res. Hosp., Memphis, TN

Abstract Body:

UBA5 encodes an E1 activating enzyme involved in the ubiquitin-fold modifier 1 (UFM1) pathway, known as ufmylation. Biallelic mutations in *UBA5* cause a neurodevelopmental disorder characterized by epilepsy, severe developmental delay, and growth failure. In ~70% of affected individuals, one of the pathogenic alleles is a missense variant, p.A371T, that produces a hypomorphic protein while the other is either a nonsense or missense variant that encodes a nonfunctional protein. The p.A371T variant is present in the general population at a frequency of 0.19% (gnomAD). Interestingly, at least three healthy adults with homozygous p.A371T variants have been reported. Thus, despite the decreased enzymatic activity of the p.A371T allele, the combination of two hypoactive alleles provides enough enzyme activity to prevent disease outcome. This suggests that augmenting the amount of the p.A371T allele may be an effective therapy. SINEUPs are long noncoding antisense RNA that can increase translation of sense mRNAs of target genes. Synthetic SINEUPs have been used to restore motor deficits in a murine model of Parkinson disease. Thus, we propose that increasing the level of the p.A371T protein using SINEUP to restore UBA5-mediated ufmylation pathway can alleviate symptoms in UBA5 patients. We generated cell lines with pathogenic alleles representing those identified in patients, specifically, UBA5^{A371T/F292X}. We observed an increase of ufmylation pathway proteins by immunoblotting and qRT-PCR analysis. UBA5-mediated ufmylation pathway is involved in ER stress response and apoptosis, thus our analysis will focus on the ER stress, unfolded protein response (UPR) pathways and cell death. We then noted that UBA5^{A371T/F292X} showed increased abundance of ER stress proteins and ER volume, suggesting elevated base-level ER stress compared to UBA5^{Wt/Wt}, UBA5^{Wt/A371T} and UBA5^{Wt/Q303X}. It is unknown whether UBA5^{A371T/A371T} phenocopies UBA5^{Wt/Wt} at the cellular level. We generated a cell line with homozygous p.A371T allele and demonstrated that UBA5^{A371T/A371T} behaves similar to UBA5^{Wt/Wt}, showing no elevated base-level ER stress, unlike UBA5^{A371T/F292X} cells. We designed various UBA5-specific SINEUPs and showed they elevate the levels of p.A371T allele in UBA5^{A371T/F292X} cells. We are now testing whether this increase can rescue UBA5 mutant cellular phenotypes. We demonstrated that UBA5^{A371T/A371T} phenocopies UBA5^{Wt/Wt} at the cellular level, and SINEUPs can be utilized to augment the levels of p.A371T protein in UBA5^{A371T/F292X} cells. These findings further support that restoration of the hypomorphic p.A371T by SINEUP may be a novel therapeutic outlet.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2711. UK Biobank whole genome sequencing and large-scale proteomics identifies novel protein quantitative trait loci (pQTLs) contributing to human disease.

Authors:

L. Hou¹, A. H. Li¹, E. H. Baugh¹, A. Doostparast Torshizi¹, H. A. Hejase¹, T. Sato², H. Bell-Temin³, A. Hart⁴, S. Guo¹, B. A. J. Sarver¹, S. Li¹, M. Black¹; ¹Population Analytics, Data Sci. Analytics & Insights (DSAI), Janssen R&D, Spring House, PA, ²Early Detection & Data Sci., World Without Disease Accelerator, Janssen R&D, Spring House, PA, ³Discovery Proteomics Platforms, Discovery Technologies and Molecular Pharmacology, Janssen R&D, Cambridge, MA, ⁴Immunology Translational Sci., Immunomics, Janssen R&D, Spring House, PA

Abstract Body:

Background: Previous large-scale protein quantitative trait loci (pQTLs) studies focused primarily on common variants based on genotype arrays. The contribution of rare variants to protein levels genome-wide remains largely unknown. Here, we utilized proteomics and whole genome sequencing (WGS) data from the UK Biobank to comprehensively map plasma pQTLs. **Methods:** We identified pQTLs for 1,463 proteins assayed by Olink™ from plasma samples collected from 13,227 UK Biobank European participants with WGS data. We performed variant-level genetic association analyses for ~23M variants with minor allele count ≥ 5 (lowest MAF=0.026%). We also performed gene and exon-level association analyses by collapsing rare functional variants (i.e., clinically classified pathogenic/likely pathogenic, and in silico predicted deleterious and loss of function variants). **Results:** Single-variant analyses identified 2,374 significant sentinel pQTLs for 1,088 proteins ($p < 1.46 \times 10^{-12}$), including 940 cis-pQTLs and 1,434 trans-pQTLs. Of these, 18 loci were not previously identified by the UK Biobank Pharma Proteomics Project (UKB-PPP) consortium-led analysis of SNP array data. Gene-based analyses revealed 258 significant sentinel pQTLs (207 cis-pQTLs and 51 trans-pQTLs, $p < 2.97 \times 10^{-10}$), of which seven loci are novel. Exon-based analysis identified 152 significant sentinel pQTLs (132 cis-pQTLs and 20 trans-pQTLs, $p < 1.69 \times 10^{-10}$), including one novel trans-pQTL. For example, gene-level collapsing analyses yielded significant association between rare (MAF<0.1%) functional variants in *STAB1* and higher levels of NOTCH3 ($p = 3.89 \times 10^{-12}$, $\beta = 0.53$), as well as higher levels of MYOC and LTBP2, all of which constitute novel pQTL signals in trans. Aberrant NOTCH3 signaling and overexpression is known to be oncogenic and associated with resistance to chemotherapy and decreased survival. NOTCH3-targeted antibody drug conjugates have recently been investigated for treatment of solid tumors, and an understanding of the role of STAB1 in upregulating NOTCH3 may inform therapeutic efficacy, safety, and patient stratification. **Conclusion:** Our findings provide a comprehensive genetic atlas of the human plasma proteome, including rare/ultra-rare pQTLs not previously described. Such results may be used to finemap pQTLs and refine our understanding of causal variants toward the goal of improved identification of targets for safe and effective therapies.

PB2712. Unbiased linkage of SNV to expression in single cells for regulatory variant discovery influencing cancer drug resistance

Authors:

I. Salas-Gonzalez, T. Morozova, D. Arvapalli, S. Velivela, J. West, G. Harton, J. Zawistowski, V. Weigman; BioSkryb Genomics, Durham, NC

Abstract Body:

Single-cell RNAseq methodologies have revolutionized the ability to define cell type identity and transcriptional phenotypic diversity within a tumor sample, yet in most studies DNA-level variation contributing to driving this diversity of gene expression remains uncharacterized. We employed ResolveOME chemistry to bridge this gap within an individual cell, by taking inventory of genome-wide single nucleotide variation (SNV) and cross referencing it with full-transcript RNAseq data in an acute myeloid leukemia (AML) cell line model of drug resistance. The catalog of genome-wide SNV in conjunction with transcriptomic data in this model powered an association screening to identify regulatory SNVs with biased prevalence in single cells resistant to the FLT3 inhibitor quizartinib vs treatment-naïve single cells, which then were correlated with differential expression of genes proximal to the variant in the same cell. Initially, we focused on nucleotide variation within core promoter regions and within gene bodies. Fitting a zero-inflated linear model to a matrix of expression and genotype across all single cells revealed an intronic heterozygous variant in *MYC* in parental single cells, while, in contrast, the alternate allele was absent in quizartinib-resistant cells. Upregulation of *MYC* transcript was correlated with the absence of this variant in resistant single cells, suggesting that the single nucleotide change may have intronic enhancer activity as opposed to intronic regulation of splicing. Additionally, the screen uncovered a heterozygous single nucleotide change within 5kb 5' of the transcriptional start site of the mRNA binding factor *PABPC4* as a candidate promoter variant not present in parental single cells yet harbored by 50% of the quizartinib resistant single cells displaying *PABPC4* expression relative to parental cells. Differential expression analysis uncovered the enhancer factor *CEBPA* as upregulated in the resistant single cells, and the genomic component of ResolveOME identified two SNVs 20 kb upstream of the locus representing putative *CEBPA* enhancer variants influencing the differential gene expression. The co-identification of *CEBPA* and *PABPC4* through this multi-omic approach suggest that quizartinib resistance in this model is mediated in part by global gene regulation through enhancer modulation and through mRNA stability/translational regulation, respectively. We are furthering enhancer variant detection in intergenic space by overlaying ChIP-seq, chromatin accessibility, and transcription factor binding site data to prioritize candidates contributing to resistance in this AML drug resistance model.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2713. Uncovering sources of human gene expression variation in a globally diverse cohort.

Authors:

D. Taylor, M. Tassia, R. McCoy; Johns Hopkins Univ., Baltimore, MD

Abstract Body:

Genetic variation influencing gene expression accounts for a large proportion of phenotypic variation within and between species, including humans. While previous large-scale studies of human gene expression have been invaluable for revealing mechanisms of genome function, they have largely focused on individuals of European ancestries. This bias may diminish the generalizability of results, while limiting broader understanding of the diversity and evolution of gene expression across human populations. To address these challenges, we performed RNA sequencing of lymphoblastoid cell lines derived from 731 globally-diverse individuals from the 1000 Genomes Project, evenly drawn from each of the 5 superpopulations and 26 subpopulations. We quantified gene expression in this dataset, and characterized patterns of gene expression across populations. On average, we observed that the vast majority (92%) of gene expression variation is partitioned within as opposed to between populations, mirroring patterns of human diversity at the level of DNA sequence. Moreover, gene expression variation is greatest among African populations and declines as a reflection of the serial founder effects during historical eastward expansions across the globe. By combining the expression data with existing high-coverage whole-genome sequencing data from the same individuals, we mapped associations between genetic variants and the expression of nearby genes (i.e., cis expression quantitative trait loci or "eQTLs"). We identified over 15,000 eGenes (genes with at least 1 eQTL) and over 1.9 million eQTL variants across the entire sample. In addition to replicating the results of previous large-scale eQTL studies (e.g. Geuvadis), we identified over 1.7 million novel eQTL variants not reported by Geuvadis. This includes many variants that are specific to Asian or Admixed American samples, which were absent or under-represented in previous molecular association studies. Such eQTL data could be particularly useful for interpreting the results of past and future GWAS that include individuals of diverse ancestries. Additionally, the diverse history of recombination events in sample breaks up linkage disequilibrium and allows us to narrow in on smaller sets of candidate causal variants to isolate the genetic and epigenetic mechanisms that modulate transcription, RNA stability, and/or degradation. Together, our study expands understanding of gene expression diversity across human populations and offers an inclusive resource for studying the evolution and function of human genomes.

PB2714. Unsupervised Density Estimation for Noncoding Variant Effect Prediction

Authors:

R. Rastogi, R. Chung, A. Reddy, N. Ioannidis; Univ. of California, Berkeley, Berkeley, CA

Abstract Body:

Cross-species conservation is an integral feature in most previous computational methods that predict the pathogenicity of human noncoding variants. However, the utility of these conservation metrics, which are computed over multiple sequence alignments (MSAs), is hindered by the limited number of species that are closely related to humans and by the sparsity in whole-genome alignments. However, buoyed by the recent 241-way alignment of eutherian mammals produced by the Zoonomia Project, we develop new unsupervised density estimation models to predict noncoding variant effects and learn meaningful representations of regulatory regions using only MSAs, and no other functional annotations, as input. Specifically, we train Potts models, which learn pairwise interactions, and variational autoencoders, which learn higher-order interactions, on noncoding regions of interest. We will also train a single large language model, similar to the MSA Transformer, using masked autoencoding to learn from alignments throughout the genome. Aside from comparing each of these models to existing methods on noncoding pathogenicity prediction, we will also finetune the language model on downstream tasks, such as cell-type specific accessibility prediction, to validate that the model learns meaningful representations of regulatory regions.

Molecular Effects of Genetic Variation Posters - Thursday

PB2715. Use of reference population data for resolving variants of uncertain significance in hematopoietic genes.

Authors:

V. Avramovic, C. Diao, T. Maroilley, M. Tarailo-Graovac; Univ. of Calgary, Calgary, AB, Canada

Abstract Body:

Limited ability to interpret variant effects is one of the major bottlenecks in genome-wide diagnostic approaches. The interpretation of certain variant types, including deep intronic, 5'UTR and deep exonic synonymous variants, is especially difficult.

Here we explore a strategy to improve variant interpretation in hematopoietic genes. Germline variants in many hematopoietic genes have been associated with rare diseases. It has been suggested that somatic variants in dozens of hematopoietic genes implicated in human rare diseases may be present in the blood-based reference population datasets. These variants often drive the process of clonal expansion, by which their carrier cells become more abundant in the blood tissue. Consequently, these variants appear in reference population datasets, where they are often misclassified as germline variants. We proposed that the presence of these somatic variants in reference population databases, such as TOPMed and gnomAD, can be used as an important feature for prediction of their functionality in rare diseases, in germline. To test this, we assessed the variants from one of the hematopoietic genes with known rare disease association, *ASXL1*. The results we obtained with *ASXL1* nonsense variants (severe pediatric rare disease, Bohring-Opitz syndrome is due to *ASXL1* haploinsufficiency) confirmed our basic hypothesis. The majority of the *ASXL1* nonsense variants observed in "healthy" individuals in the TOPMed database show signs of somatic origin, while their assessment with a selected combination of *in silico* pathogenicity predictors returned very high pathogenicity scores. Next, we expanded the assessments to include deep intronic, 5'UTR and deep exonic synonymous variants of uncertain significance (VUS) in the *ASXL1*. We reasoned that similar to nonsense variants, the transcript altering ones will present mosaic effects in population databases. Our analyses revealed a number of variants with driver potential, which we are experimentally validating for their transcript effects. The experimental validations will help support our hypothesis that evidence of somatic mosaicism in blood-derived population databases suggests driver/pathogenic effect of variants affecting hematopoietic genes, yet currently considered as VUS.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2716. Using massively parallel reporter assays to dissect context-specific regulatory grammars in type 2 diabetes

Authors:

A. Tovar, Y. Kyono, M. Bose, A. Varshney, J. Kitzman, S. Parker; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Genome-wide association studies have revealed that ~90% of disease-associated genetic variants are found in non-coding regions, including in type 2 diabetes (T2D), where they are expected to modify gene regulation and downstream disease mechanisms. The framework to translate the impact of non-coding variants on specific transcriptional processes is ill-defined, underscoring the need for a set of regulatory grammars to accelerate efforts to link genetic associations with specific pathogenic consequences. Here, we used a massively parallel reporter assay (MPRA) to screen enhancer activity across a panel of 197-bp fragments spanning >10k T2D- and metabolic trait-associated variants. To measure enhancer activity across several promoter and enhancer contexts in a diabetes-relevant cell model, we cloned these fragments up- or downstream of a reporter gene driven by a synthetic housekeeping promoter (SCP1) or the cell-specific human insulin (INS) promoter, and delivered the library to a pancreatic beta cell line (832/13 rat insulinoma). Next, we examined enhancer activity bias across this library (FDR < 0.05) based on position and linked promoter. Two unique subsets of fragments emerged: one with positional bias (n = 702/11,656) and one with promoter bias (n = 698/11,656). The former set was evenly distributed across up- and downstream activity bias, while a majority of fragments in the latter set had higher enhancer activity when paired with the cell-specific INS promoter (n = 512/698). To identify sequence features associated with promoter preference, we used Lasso regression with 562 genomic annotations and discovered that fragments with INS promoter-biased activity are enriched for HNF1 motifs. HNF1 family members HNF1A and HNF1B are key regulators of glucose metabolism and exonic mutations cause maturity onset diabetes of the young (MODY), suggesting genetic convergence between rare coding variants that cause MODY and common T2D-associated regulatory variants. We designed a follow-up MPRA containing HNF1 motif-enriched fragments to observe consequences of mutating or deleting these motifs on promoter-biased activity, and results from this library will be presented. Together, our study suggests that cell-specific regulatory activity is partially influenced by enhancer-promoter compatibility, and indicates that MPRA design is critical to capture context-specific regulatory processes at disease-associated genetic signals.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2718. Variant-to-gene mapping at the insomnia *WDR90* locus and subsequent luciferase assay analyses implicates *PIGQ* as an effector gene in sleep dysregulation

Authors:

S. Sonti¹, J. Palermo², A. Zimmerman^{3,1}, A. Chesi^{3,1}, C. Lasconi⁴, E. Brown², J. A. Pippin⁵, A. D. Wells^{3,1}, F. Doldur-Balli³, D. R. Mazzotti⁶, A. Pack³, P. Gehrman³, A. C. Keene², S. F. A. Grant^{1,3}; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Texas A&M Univ., College Station, TX, ³Univ. of Pennsylvania, Philadelphia, PA, ⁴CHOP, Philadelphia, PA, ⁵Children's Hosp. of Philadelphia, Philadelphia, PA, ⁶Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract Body:

Sleep disturbances in humans are associated with several physiological complications and diseases. However, the pathophysiology and pathways involved in sleep disturbances are not fully understood. While initial studies in twins identified genetic contributions to variability in sleep patterns, GWAS have greatly assisted in identifying novel genetic variants associated with sleep traits and disturbances such as insomnia. To date, the largest GWAS of insomnia was performed in 1,331,010 individuals and identified 202 novel associated loci (Jansen et al, Nature Genetics 2019). Leveraging the 202 GWAS loci, our ATAC-seq/promoter focused Capture C approach in neural progenitor cells implicated proxy SNPs at 36 insomnia loci that both resided in a region of open chromatin region and contacted one or more open gene promoters. At the *WDR90* locus, our 3D genomic constraints shortlisted three insomnia-associated intronic proxy SNPs (rs3752495, rs8062685 and rs9932282; r^2 with sentinel SNP rs3184470 = ~ 1), all of which contacted the open promoters of Phosphatidylinositol N-acetylglucosaminyltransferase subunit Q (*PIGQ*) and NHL-Repeat-Containing Protein 4 (*NHLRC4*). The involvement of *PIGQ* in sleep was previously unknown; however, our group has reported that *PIGQ* deficient fruit-flies (*Drosophila melanogaster*) and zebra fish (*Danio rerio*) present with longer sleep phenotypes (Palermo, Chesi, Zimmerman et al, bioRxiv 2021). This warranted further validation of this variant-to-gene contact in a human cell model. Using a luciferase reporter assay, we sought to determine *in vitro* if these proxy SNPs influence promoter activity in SH-SY5Y cells (a *PIGQ* expressing neuronal cell line). One of the three proxy SNPs, rs3752495, revealed a 4-fold increase in luciferase reporter expression ($N=4$), indicating that this variant resides in an enhancer element influencing the expression of *PIGQ*. Our variant-to-gene approach therefore implicates *PIGQ* in the pathogenesis of human insomnia.

Molecular Effects of Genetic Variation Posters - Thursday

PB2719. Variation of 5'untranslated regions by dosage sensitivity reveals differences in post-transcriptional regulation important for interpreting variant effect

Authors:

N. Wieder, A. C. Martin-Geary, F. Lassen, E. N. D'Souza, M. Fernandes, R. Davies, N. Whiffin; Univ. of Oxford, Oxford, United Kingdom

Abstract Body:

Background: Untranslated regions (UTRs) are the regions flanking the protein-coding sequence of genes that form part of the mRNA, but are not translated into protein. UTRs are important mediators of post-transcriptional regulation, controlling mRNA stability, cellular localisation and the rate of translation into protein. UTRs are known to vary substantially across genes, both in terms of length, and the composition of regulatory elements within them, including linear and structural elements which mediate their effects through binding to various proteins and RNA. **Aims:** We investigated the differences in 5'UTR composition across deciles of tolerance to loss-of-function (LoF; LOEUF scores) and between different sets of disease genes (developmental disorder (DD) and cancer (C) genes sets). We investigated 5'UTR length, whether the 5'UTRs undergo splicing (intron number) and the number and type of upstream open reading frames (uORFs) within the 5'UTRs, using both uORF predictions and high-confidence uORFs from ribosome profiling data.

Results: Genes that are more sensitive to changes in dosage or that are linked to dominant disease have more complex 5'UTRs. Whilst 5'UTRs average 193bps in length, with 35% containing uORFs, LoF intolerant and disease gene 5'UTRs are significantly longer (DD: 368bp, $P=1.1 \times 10^{-41}$; C: 251bp, $P=1.8 \times 10^{-5}$; most intolerant LOEUF decile: 273bp, $P=1.1 \times 10^{-98}$) and more often contain uORFs (DD:60%, $P=2.6 \times 10^{-23}$; C:50%, $P=0.0002$; most intolerant LOEUF decile:46%, $P=2.4 \times 10^{-56}$). This is despite an overall depletion of upstream start codons (uAUGs). The uORFs of LoF intolerant genes also have stronger Kozak consensus than LoF tolerant gene uORFs (18.2% vs 14.2% "strong" kozaks) but weaker stop-codons (54.5% vs 48.9% weak stop codon (TGA codon).

Conclusion: Genes that are intolerant to LoF have more complex 5'UTRs and are enriched for cis-acting regulatory elements. The properties of uORFs in LoF intolerant genes point to them being efficiently translated and optimised for downstream re-initiation. These results confirm the important role of 5'UTRs in tight regulation of mRNA and protein levels, particularly for genes where changes in dosage are deleterious and lead to disease. A better understanding of the differences in UTR composition across genes will help us interpret how alterations to regulatory elements within them cause disease.

Molecular Effects of Genetic Variation Posters - Wednesday

PB2720. x-QTL: A mixture-model for identification and characterization of trans-eQTLs

Authors:

C. Wu¹, T. Xu¹, D. Munro^{1,2}, P. Mohammadi², A. Palmer¹, A. Goren¹, M. Gymrek¹; ¹Univ. of California, San Diego, La Jolla, CA, ²Scripps Res., La Jolla, CA

Abstract Body:

Studies of expression quantitative trait loci (eQTLs) aim to discover genetic variants that explain variation in gene expression levels, and may in turn drive associations with complex traits and diseases. While thousands of cis-eQTLs have been reliably identified, consistently replicating trans-eQTL effects proved to be challenging due to insufficient statistical power, and lack of comparable tissues and cohorts. In particular, technical covariates lead to substantial variation in expression datasets and result in false positive eQTL calls. As a result, biological mechanisms and characteristics of trans-eQTLs remain largely unknown.

Here, we introduce x-QTL, a novel trans-eQTL detection method that improves statistical power over methods that test gene-by-variant pairs separately by jointly modeling effects of an individual variant across all genes. The x-QTL package also implements previous trans-eQTL detection methods for comparison. x-QTL's model is similar to that of CPMA, an existing trans-eQTL detection technique, but uses a more biologically plausible mixture model of effect sizes. Importantly, our use of the mixture model infers the total number of target genes of a variant and demonstrates improved power over other tools. Additionally we developed a novel open-source simulation framework to benchmark performance of x-QTL. The simulation framework allows us to evaluate the suitability of datasets and the effects of trans-eQTLs that we can hope to detect.

We test x-QTL by applying it to a publicly available yeast expression dataset with 1,012 meiotic segregants. We identify 367 unique variants acting as trans-eQTLs at FDR 5% and replicate 3 hotspots of trans-eQTLs which x-QTL predicted to affect over half of the expressed genes. Next, we applied x-QTL to a dataset from RatGTEx that consists of five brain regions from 88 outbred rats for which a variety of behavioral and physiological traits have been measured. We identify novel trans-eQTLs across different tissues and observe an interesting trans-eQTL in NR3C1, a transcription factor that regulates genes controlling development, metabolism, and immune response. Finally, we applied x-QTL to expression data for 52 tissues in humans from the GTEx cohort. While this analysis did not return strong novel trans-eQTL candidates, our power analyses suggest existing human datasets are still substantially underpowered to detect even moderately strong trans-eQTLs. Overall, our framework provides important resources for future trans-eQTL studies involving humans and other complex organisms.

The x-QTL package and simulation framework can be found here:

<https://github.com/cynthiaewu/trans-eQTL>

Pharmacogenomics Posters - Wednesday

PB2721. A Pharmacogenetic Integration Solution for Clinical Decision Support Software

Authors:

H. Katzov-Eckert¹, M. Dawes^{1,2}, C. Verzosa¹, B. Esquivel^{1,3}; ¹GenXys Hlth.Care Systems, Vancouver, BC, Canada, ²Univ. of British Columbia, Vancouver, BC, Canada, ³Personalized Med. Latin American Association, Mexico City, Mexico

Abstract Body:

Pharmacogenetics has the potential to improve the effectiveness of medications and reduce the incidence of adverse drug events. One of the main barriers to implementing pharmacogenetics into practice is the lack of tools that simplify the use of pharmacogenetic results into the clinical workflow. In addition, providers are required to interpret the genotype data into phenotypes and clinically actionable information, something that many clinicians find challenging. Clinical decision support systems (CDSS) consolidate complex drug-gene interactions with biophysical patient data and provide safe and effective medication therapy options. We present a novel tool that facilitates the integration of pharmacogenetics to a CDSS. The web-based tool, LabGx offers a comprehensive solution for translating pharmacogenetic test results and embedding those results into a CDSS. The use of CDSS provides clinicians with real-time, multi-factorial medication optimization and personalization options for patients. LabGx was designed for clinical laboratories, irrespective of genotyping testing technology and supports SNP, SNV, CNV, and haplotype data. LabGx incorporates this information into a CDSS and interprets the content using evidence-based guidelines. Due to the complexity of genomic data, a Unified Lab Result (ULR) JSON file was developed as a standard for genotype data input. The genetic data converted into the ULR format streamlines the process of translation into the CDSS for laboratories. LabGx enables the use of pharmacogenetic information at point of care, potentially increasing adoption by healthcare providers, leading to a significant improvement in the population's quality of care and quality of life.

Pharmacogenomics Posters - Thursday

PB2722. A systematic review and comparison of statistical methods for testing genotype-treatment interaction effects in trans-ethnic pharmacogenomics GWAS.

Authors:

W. Zhong, J. Shen; Merck & Co., Inc., Rahway, NJ

Abstract Body:

Pharmacogenomics (PGx) genome-wide association studies (GWAS) aim to discover prognostic and predictive genetic biomarkers associated with drug responses. The typical approach of detecting predictive biomarkers in PGx GWAS analysis is to test the significance of a genotype-treatment interaction (GTI) term in a statistical model. Many statistical methods have been proposed to detect genotype-environment interaction (GEI) effects in disease genetics space, which can be directly applied to testing GTI effects in PGx GWAS. However, it is unclear whether these existing methods can accurately control type I error (or genome inflation) and achieve detecting power for GTI test in *trans-ethnic* PGx GWAS. We systematically reviewed and compared multiple statistical methods for testing GTI effects to find optimal tests and methods for *trans-ethnic* PGx GWAS analysis. Extensive simulations were conducted under various genetic architectures and scenarios to evaluate the genome inflation and power performance of the statistical methods including pooled-analysis approaches (i.e., linear regression-based methods and linear mixed model-based methods) and meta-analysis approaches (i.e., fixed effects, random effects, and meta-regression methods). We simulated different scenarios of distribution of variants' effect sizes, different strengths of genetic main and GTI effects, and different sample sizes across multiple ancestries. These simulation studies showed that meta-analysis-based methods controlled the genomic inflation better and had larger power than alternative methods in most scenarios. Mixed model-based methods demonstrated advantage over meta-analysis-based methods, if the sample size is limited in a subset of ancestries for GWAS analysis. Our systematic review and simulation-based comparison of existing statistical methods provide a clear guidance for predictive biomarker discovery in *trans-ethnic* PGx GWAS.

Pharmacogenomics Posters - Wednesday

PB2723. Accurate CYP2D6 star (*) allele diplotyping for long-read PacBio HiFi sequencing

Authors:

J. Harting¹, N. Gonzaludo¹, L. Zhu¹, X. Chen¹, A. Gaedigk², S. Scott³, P. Baybayan¹; ¹PacBio, Menlo Park, CA, ²Children s Mercy Kansas City, Washington, MO, ³Stanford Univ., Stanford, CA

Abstract Body:

The CYP2D6 gene is widely studied in the field of pharmacogenomics as it is directly involved in the metabolism of ~25% of the most commonly prescribed medications, including antidepressants, opioids, and cancer drugs. However, CYP2D6 is challenging to interrogate by short-read sequencing due to its highly homologous neighboring pseudogenes, and the presence of common structural variation, including complete gene deletions/duplications, tandem alleles, and gene conversions. Given these challenges, it is common to employ multiple technologies to comprehensively characterize the CYP2D6 locus; however, phasing variants and alleles still relies on inference and/or computational predictions. Recently, long-read HiFi amplicon sequencing has demonstrated that CYP2D6 can be fully captured, with direct phasing of haplotypes and characterization of specific duplicated alleles. However, a remaining challenge is the translation of identified variants and haplotypes into star (*) allele diplotypes, as the majority of bioinformatic translation tools were developed for short-read sequencing. Here we present a novel long-read CYP2D6 typer that accurately and unambiguously assigns star (*) allele diplotypes from PacBio HiFi reads. Briefly, long reads are sorted into unique alleles and variants from each are matched to star (*) allele definitions, as defined by PharmVar. Structural breakpoints are identified to characterize tandem duplications, deletions, and hybrid alleles. Phased alleles are then sorted into haplotypes for fully characterized diplotypes.

We demonstrate the use of this caller on Coriell reference samples that had undergone long-read PacBio HiFi amplicon, probe-based targeted enrichment, and/or genome sequencing. Taken together, these results support the use of this method for accurate and unambiguous star (*) allele assignment, enabling an end-to-end solution for CYP2D6 phenotype prediction and the implementation of long-read sequencing for comprehensive CYP2D6 characterization.

Pharmacogenomics Posters - Thursday

PB2724. Allelic diversity of the pharmacogene *CYP2D6* in New Zealand Māori and Pacific peoples.

Authors:

M. Kennedy¹, L. Hitchman¹, A. Faatoese¹, T. Merriman², A. L. Miller¹, Y. Liao¹, O. Graham¹, K. Ping Sui¹, J. F. Pearson¹, T. Fakahau³, V. A. Cameron¹, S. D. S. Maggo¹; ¹Univ. of Otago, Christchurch, New Zealand, ²Univ. of Otago, Dunedin, New Zealand, ³Pacific Trust Canterbury, Christchurch, New Zealand

Abstract Body:

The enzyme cytochrome P450 2D6 (*CYP2D6*) metabolises approximately 25% of commonly prescribed drugs, including analgesics, anti-hypertensives, and anti-depressants, among many others. Genetic variation in drug metabolising genes can alter how an individual responds to prescribed drugs, including predisposing to adverse drug reactions. The majority of research on the *CYP2D6* gene has been carried out in European and East Asian populations, with indigenous and minority populations greatly underrepresented. However, genetic variation is often population specific and analysis of diverse ethnic groups can reveal differences in alleles that may be of clinical significance. For this reason, we set out to examine the range and frequency of *CYP2D6* variants in a sample of 202 Māori and Pacific people living in Aotearoa (New Zealand). We carried out long PCR to isolate the *CYP2D6* region, and then carried out nanopore sequencing to identify all variants and alleles in these samples. We identified 11 novel variants, one of which was an exonic missense mutation. Six of these occurred in single samples (<0.5% each) and one was found in 11 samples (5.4%). In addition, five new suballeles of *CYP2D6* were identified. One striking finding was that *CYP2D6**71, an allele of unknown functional status which has been rarely observed in previous studies, occurs at a relatively high frequency (9.2%) within this cohort. These data will help to ensure that *CYP2D6* genetic analysis for pharmacogenetic purposes can be carried out accurately and effectively in this population group.

Pharmacogenomics Posters - Wednesday

PB2725. An NGS approach to detecting novel LOF variants in *DPYD* across >69,000 individuals

Authors:

G-h. Kim, A. T. Chande, H. E. Williams, J. Van Den Akker, C. L. Neben, A. Y. Zhou; Color Hlth., Burlingame, CA

Abstract Body:

Background: The metabolism of chemotherapeutic drugs such as 5-fluorouracil (5FU), capecitabine, and tegafur are known to be affected by variants within *DPYD*. With improper dosing, these medications can lead to decreased treatment efficacy and potentially life-threatening toxicity, such as bone marrow suppression. As such, pharmacogenomic (PGx) testing in these patients is a crucial step to determine the correct dosing regimen.

Genotyping arrays are a common approach to clinical PGx testing, but use of this technology limits analysis to common, known variants and leaves rare, novel variants undetected. Furthermore, variants in *DPYD* have been shown to vary across genetic ancestry groups. In contrast, NGS allows for the detection of both known and novel variants and is not subject to the inherent ascertainment bias of genotyping arrays developed from individuals of European descent. Here, we analyzed NGS data from 69,226 individuals who had clinical PGx and identified novel potential loss of function (pLOF) variants in *DPYD*.

Methods: All individuals consented to have their de-identified information and sample used in anonymized studies. Variant data was interrogated for variants within *DPYD* and unique variants were normalized and subsequently annotated using Variant Effect Predictor. pLOF variants were defined as variants predicted to be deleterious with consequences labeled missense, start loss, stop gain, frameshift, or splice donor/acceptor variants.

Results: Approximately 1.6 million variants (2,765 unique variants) were detected among 69,226 individuals within the *DPYD* expanded genomic region, the majority of individuals were white (n=55,456, 79.4%, self-reported race/ethnicity). Of the 2,765 unique variants detected, 385 (13.9%) variants were classified as pLOF in 9,075 (13.1%) individuals. The vast majority of individuals (n=8794, 97.0%) were found to have one pLOF variant while one individual showed 10 pLOF variants. Across the entire cohort, we observed start loss (n=9, 2.33%), stop gain (n=4, 1.04%), splice donor/acceptor (n=33, 8.57%) and missense (n=321, 83.4%) variants, as well as variants with multiple predicted consequences (n=28, 7.27%). Self-reported ethnicity showed the majority of pLOF variants were found in white individuals, and a small number (n=17, 4.4%) were enriched in Asian and African individuals.

Conclusion: These data demonstrate that NGS is a useful tool to detect novel variants across a diverse population of individuals. Further investigation is needed to determine the functional consequences of these *DPYD* pLOF variants to avoid potentially life-threatening adverse effects and improve efficacy of treatment.

Pharmacogenomics Posters - Thursday

PB2726. Clinical genetic testing and reporting of homoplasmy or low-level heteroplasmy for *MT-RNR1* m.1555A>G conferring an increased risk for aminoglycoside induced ototoxicity and irreversible hearing loss.

Authors:

N. Cody¹, R. Zimmerman¹, J. Shaw¹, R. Rigobello¹, D. Ilg¹, S. Schnakenberg¹, M. Ghoname¹, R. Kadakia¹, F. Chaabani², C. Neiss², B. Ramey¹, C. Buchovecky¹, R. Kornrieck¹, S. A. Scott³, L. Edelmann¹; ¹Sema4, Stamford, CT, ²Illumina, San Diego, CA, ³Stanford Univ., Stanford, CA

Abstract Body:

Aminoglycoside antibiotic exposure may result in ototoxicity and irreversible hearing loss for patients harboring pathogenic variants in the mitochondrial *MT-RNR1* gene. Clinical Pharmacogenetics Implementation Consortium guidelines provide evidence and therapeutic recommendations for avoidance of aminoglycosides for *MT-RNR1* m.1095T>C, m.1494C>T, and m.1555A>G. Sema4 offers molecular supplemental newborn screening panels that include a pharmacogenetics (PGx) test containing 13 PGx gene/variants including *MT-RNR1* m.1555A>G. These panels are available for asymptomatic/presymptomatic children under the age of 10. Testing was performed on DNA extracted from buccal swab specimens. The m.1555A>G region was sequenced with >15000X coverage using Agilent SureSelect capture-based sequencing on the Illumina NovaSeq 6000 platform. Heteroplasmy was estimated as a percentage of reads harboring the m.1555A>G alteration over the total. Targeted genotyping was performed using PCR and single-base extension with Agena SpectroCHIP on a MassArray Analyzer, which was verified for performance of detecting homoplasmy and heteroplasmy >50%. Two of 1440 patients tested from 2019 to 2022 from two independent families were positive for m.1555A>G. One patient was considered homoplasmic (100%, 15000X) and the other patient had an estimated heteroplasmy of ~12% (2238/20651X). Reports for NGS results contained recommendations to avoid aminoglycosides, obtain genetic testing to confirm maternal inheritance, and perform additional testing for at-risk maternal relatives. A supplemental report using third-party software provided statements on impacted medications and avoidance of aminoglycosides. Impacted medication statements were not available on the PGx report if heteroplasmy was below 50%. In this instance, comments were included to clarify heteroplasmy may be variable across different tissues, and recommended avoidance of aminoglycosides. Report distribution followed with critical alert notifications to the healthcare provider and recommendations for genetic counselling support. Heteroplasmy, tissue specificity, and temporal changes in mutation burden create challenges for clinical testing of *MT-RNR1* m.1555A>G. Parallel testing and reporting positive findings was crucial when encountering low levels of heteroplasmy. Future validation of an Illumina microarray platform enhanced for PGx will enable the integration of two additional *MT-RNR1* variants to improve the clinical utility of this test. Supplementing clinical reports with discrete data and clinical decision support tools to assist healthcare providers is warranted.

Pharmacogenomics Posters - Wednesday

PB2727. Convergence of bipolar disorder treatments and gene knockdown on the transcriptome

Authors:

V. Vuokila^{1,2}, C-E. Castonguay^{1,2}, N. Farhangdoost¹, A. Khayachi¹, C. Liao^{3,4}, P. Dion¹, G. Rouleau^{1,2}; ¹Montreal Neurological Inst., McGill Univ., Montreal, QC, Canada, ²Dept. of Human Genetics, McGill Univ., Montreal, QC, Canada, ³Stanley Ctr. for Psychiatric Res., Broad Inst. of MIT and Harvard, Cambridge, MA, ⁴Analytic and Translational Genetics Unit, Dept. of Med., Massachusetts Gen. Hosp., Boston, MA

Abstract Body:

Common medications used for the acute treatment of bipolar disorder (BD) include mood stabilizers and antipsychotics, though how the drug mechanisms relate to BD disease etiology is poorly understood. We have conducted an analysis into the convergent transcriptomic effects of seven drugs commonly used to treat BD (Lamotrigine, carbamazepine, sodium valproate, chlorpromazine, clozapine, risperidone, and ziprasidone) with publicly available data from the LINCS L1000 perturbation database. Using Stouffer's Z-score method for convergent transcriptomic drug targets ($pval < 0.05$) and the gProfiler2 R package for pathway enrichment analysis, we found that pathways related to extracellular exosomes ($qval = 4.19 \times 10^{-8}$), extracellular vesicles ($qval = 6.12 \times 10^{-8}$) and extracellular organelles ($qval = 6.23 \times 10^{-8}$) were among the most significantly upregulated pathways by these drugs in wild-type neurons. Exosomes are small extracellular vesicles that carry molecular signals and are able to cross the blood-brain barrier, making them relevant in the context of psychiatric disorders. Although this transcriptomic screen has shed light on potential mechanisms through which drugs might reduce symptoms, it does not take into account the disease contexts in which pharmacological agents act. Therefore, we sought to model the effects of these BD drugs in a system that approximates BD biology. Genes that have a downregulatory association with BD include FURIN and MMD (Mullins et al. 2021). We aim to characterize the convergent transcriptomic signature of FURIN and MMD downregulation through CRISPRi in iPSC-derived excitatory cortical neurons. We demonstrate the knockdown effect of FURIN and MMD in their corresponding iPSC lines through TaqMan RT-qPCR ($RQ = 0.526$ and $RQ = 0.266$, respectively). We will differentiate our knockdown cell lines into neurons and assay the transcriptome through bulk RNA-sequencing in untreated and BD drug-treated knockdown neurons. We hypothesize that the knockdown of the FURIN and MMD will have common, convergent downregulatory effects in extracellular exosome, vesicle, and organelle pathways. Further, we hypothesize that treatment with BD drugs will ameliorate this downregulation. These results would highlight the importance of extracellular pathways in BD and further elucidate the genetic etiology of BD.

Pharmacogenomics Posters - Thursday

PB2728. CRISPR enrichment of complex *CYP2D6-D7-D8* loci allows for accurate detection of *CYP2D6* structural variation and phased haplotyping.

Authors:

A. Turner¹, A. D. Dereziński¹, A. Gaedigk², M. E. Berres³, D. Gregornik⁴, U. Broeckel¹, G. Scharer¹; ¹RPRD Diagnostics, Milwaukee, WI, ²Children's Mercy Kansas City, Washington, MO, ³Univ. of Wisconsin, Madison, WI, ⁴Children's Minnesota, Minneapolis, MN

Abstract Body:

The highly polymorphic *CYP2D6* gene is one of the most clinically tested pharmacogenetic genes contributing to the metabolism of >20% of common clinical drugs. A large portion of enzyme variability can be explained by single nucleotide polymorphisms (SNPs), as well as structural variants (SVs) such as copy number variation (CNV) and hybrid rearrangements with the highly similar *CYP2D7* pseudogene. CNVs/SVs are known to occur in different configurations and frequencies across populations. Simple SVs can be reliably detected using current methods, however clinically relevant complex SVs, especially those harboring *CYP2D6* and *CYP2D7*-derived hybrid sequences and/or multiple gene copies, are notoriously difficult to detect and characterize accurately. This can lead to incorrect enzyme activity assignment and impact drug dosing recommendations, particularly in underrepresented populations. To overcome *CYP2D6* genotyping limitations we developed a method utilizing *CYP2D6-CYP2D7-CYP2D8* locus targeted guide RNAs (gRNAs) along with CRISPR-Cas9 technology and PCR-free single molecule long-read sequencing to accurately determine diplotypes (phased haplotypes) regardless of SV complexity. This novel methodology was evaluated using previously characterized samples with a variety of SVs including complex *CYP2D6* CNVs and *CYP2D6/CYP2D7* hybrids, and further tested with high-molecular weight DNA obtained from multiple sample types including lymphoblastoid cell lines and blood (n=10). PCR-free single molecule libraries were prepared using targeted gRNAs and Cas9 Sequencing Kit, then sequenced using Oxford Nanopore MinION flow cells. Using standard and custom-build data analysis programs, data was base-called, filtered, aligned, sorted, indexed and coverage assessed and visualized over a ~38Kb region covering *CYP2D6*, *CYP2D7*, and *CYP2D8*. Samples with *CYP2D6* or hybrid copy number gains were enriched for reads up to 52kb. Analysis of reads >25kb with PHRED-scaled Qscores averaging >14 showed significant sequence enrichment of the targeted region (average read depth >150x). Our novel methodology accurately determined SNP level genotypes and complex diplotypes with SVs such as *CYP2D6**2/*36+*10 and *1/*13+*2, unconstrained by amplicon size or sample structural complexity. For the first time we enriched and analyzed the entire *CYP2D6-2D7-2D8* locus using PCR-free single molecule long-read sequencing. This allows fully phased dissection of the locus haplotype structure, including breakpoints, which offers unique advantages for clinical genotyping and phenotype prediction, overcoming the limitations of current testing platforms.

Pharmacogenomics Posters - Wednesday

PB2729. DEEPCT(Deep-learning-based Clinical Trial) simulates a drug clinical trial by exploiting germline variants as random assignment of drug.

Authors:

J. Kim^{1,2}, S. Lee^{1,3}, H. Kim¹, Y. SANGHYCK^{1,4}, E. Lee¹, D. KIM¹, N. Kim^{1,4}, E. Kim¹, J-H. Lee¹, S. Ko¹, S. Lee¹, S. Lee¹, W. Chung²; ¹Basgenbio, Seoul, Korea, Republic of, ²Dept. of Statistics and Actuarial Sci. Soongsil Univ., Seoul, Korea, Republic of, ³Dept. of Hlth.Policy, Korea Univ. Graduate Sch., Seoul, Korea, Republic of, ⁴Dept. of Epidemiology and Hlth.Promotion, Inst. for Hlth.Promotion, Graduate Sch. of Publ. Hlth., Yonsei Univ., Seoul, Korea, Republic of

Abstract Body:

Clinical trials are essential for evaluating the efficacy and safety of novel drugs and medical devices. However, clinical trials are costly, time-consuming, inappropriate for interventions with ethical issues, and have potential to pose unknown risks to the participants. In silico simulations of clinical trials prior to actual clinical trials may address the aforementioned challenges and improve the success rate of the actual trials. Using the data of 488,221 participants from the UK Biobank, including 20,437 participants who had gout events, we simulated the drug effect of xanthine dehydrogenase (XDH) inhibitors (e.g., allupurinol, febuxostat), which lowers serum uric acid and treat gout. The simulation algorithm consisted of deep learning approaches to a genome-wise association study (GWAS) and a genetic score calculation, followed by a mendelian randomization analysis. We refer to the series of the in silico methods as DEEPCT (Deep learning Clinical Trial).

We identified urate-level-lowering 10 variants within the XDH gene using a deep reinforcement learning algorithm. To calculate of the genetic score, the number of selected alleles was weighted by the GWAS effect of each variant on urate levels.

The XDH genetic score for lowering serum urate level by 0.1 mg was associated with a decrease of 14% in the risk of gout events (OR [95% CI] = 0.86 [0.77, 0.91]; $p < 0.001$). In addition, the XDH score for lowering serum urate level by 1 mg was associated with a reduced incidence rate of cardiovascular disease by 31% (OR [95% CI] = 0.69 [0.49, 0.96]; $p = 0.029$).

The drug effect estimated using the DEEPCT were in parallel with the drug effect of commercial XDH inhibitor drugs, which have been confirmed by actual clinical trials. The DEEPCT may be utilized prior to actual clinical trials to predict the effects of novel drugs and therapies.

Pharmacogenomics Posters - Thursday

PB2730*. Dynamics in blood transcriptomic networks responding to TNF inhibitors in patients with rheumatoid arthritis

Authors:

C-Y. Yu¹, H-S. Lee², Y. Joo², S-K. Cho², C-B. Choi², Y-K. Sung², T-H. Kim², J-B. Jun², D. Yoo², S-C. Bae², K. Kim¹, S. BANG²; ¹Kyung Hee Univ., Dondaemungu, Korea, Republic of, ²Hanyang Univ. Hosp. for Rheumatic Diseases, Seoul, Korea, Republic of

Abstract Body:

Although TNF inhibitors have widely been used for the effective treatment for rheumatoid arthritis (RA), one-third of patients do not respond well, subsequently showing poor prognosis. Our study aimed to uncover the main transcriptomic dynamics under anti-TNF treatments and identify biomarkers to stratify potentially well-responding patients. RNA-seq data from peripheral blood cells and clinical disease activity indices of patients with RA in a Korean cohort (n=62) and a Caucasian cohort dataset (Corrona CERTAIN, GSE129705; n=20) were obtained before and after treatment of TNF inhibitors. Response-associated genes were defined by estimating the differential expression changes after treatment between good and null responders. We found 458 response-associated genes that were significantly enriched in innate immunity and interferon response-related signaling pathways in the gene-level gene set enrichment analysis (GSEA). All longitudinal expression data from the two cohorts were used to build coexpression networks of which response-associated modules were subjected to a Bayesian key driver analysis to identify driver genes responsible in regulation of network-level expression changes upon treatment. A coexpression network analysis followed by a network-level GSEA identified 16 coexpression modules in the blood transcriptome. Of them, two modules were associated with innate immunity and interferon response-related signaling pathways, including significantly more response-associated genes, consistent with the gene-level GSEA. In the two response-associated coexpression modules, we identified 37 module-specific response-associated key drivers whose down-regulations were correlated with the improvement of response upon treatment in both the cohorts. Furthermore, the treatment-induced expression changes of key drivers in the interferon signaling networks were significantly associated with the change of erythrocyte sedimentation rate in moderate responders. In summary, this study provides the landscape of response-associated transcriptomic changes in peripheral blood cells from RA patients emphasizing the importance of innate immunity-related signatures in response prediction of anti-TNF biologics.

Pharmacogenomics Posters - Wednesday

PB2731. Elucidating the multi-omic drivers of hepatic drug metabolism in African Americans

Authors:

C. Clark, T. De, G. Yang, C. Alarcon, J. M. Avitia, M. Perera; Northwestern Univ., Chicago, IL

Abstract Body:

Background: Prediction of drug response in African Americans (AAs) using genetic variants discovered in other populations has been poor. Drug metabolizing enzymes (DMEs), located primarily in hepatocytes, metabolize most currently prescribed drugs. Phase I (i.e., cytochrome P450s, CYP450s) and Phase II (i.e., glucuronosyltransferases, UGTs) DMEs catalyze reactions that make drugs easier to excrete. Variations within these DME genes, their regulatory regions, or within regulatory proteins can contribute to interindividual variability of drug response and adverse drug events. This study aims to identify genetic variation and genes that associate with differences in drug metabolism using an AA cohort. **Method:** Hepatocytes were extracted from 75 AA cadaveric livers and subjected to a panel of validated probe substrates for DMEs (Midazolam, Bupropion, Mephenytoin, Diclofenac, Phenacetin, Acetaminophen) to measure metabolite formation rate (MFR). Hepatocytes underwent genome-wide genotyping, mRNA sequencing, and DNA methylation profiling. MFR was collected via LC-MS/MS, thus linking the donor's genetic, transcriptomic, and epigenetic data. A genome-wide association and differential gene expression study were conducted for the MFR of each probe substrate with age, sex, and principal components as covariates. **Results:** Wide variability in all MFRs were seen between individuals, reflecting the known variation in AA drug metabolism. Genome-wide significant associations were identified at the ANGPT2 locus ($p=1.8 \times 10^{-8}$). The top ANGPT2 SNP (rs2515447) was associated with decreased MFR. Loci reaching suggested level were also identified, including CYP2C (Mephenytoin, $p=4.1 \times 10^{-7}$), CYP4X1 (Bupropion, $p=7.5 \times 10^{-6}$), SEPT9 (Midazolam, $p=9.7 \times 10^{-7}$). Transcriptomic, epigenetic and fine-mapping analyses are ongoing. **Conclusion:** This first-of-its-kind study of MFR found genes previously linked to liver function or DMEs specific to African ancestry populations. ANGPT2 is a growth factor implicated in liver cancer prognosis and inflammatory pathways linked to CYP regulation. Both CYP2C and CYP4X1 enzymes have known roles in the metabolism of probe substrates. Importantly, CYP2C genetic variation has repeatedly been associated with clopidogrel (antiplatelet drug) and warfarin (anticoagulant) response. SEPT9 methylation is a clinical biomarker of hepatocellular carcinoma and is associated with liver fibrogenesis. These results provide needed African-ancestry pharmacogenomic data that will be critical for individualizing drug dosing and drug-type selection in AAs and in understanding the regulation of these important enzymes.

Pharmacogenomics Posters - Thursday

PB2732*. Estimating UK Biobank population-specific PGx allele and phenotype frequencies using PharmCAT

Authors:

B. Li¹, K. Sangkuhl¹, R. Whaley¹, M. Woon¹, K. Keat², R. Altman³, M. Carrillo¹, M. Ritchie⁴, T. Klein¹; ¹Stanford Univ., Stanford, CA, ²Univ. of Pennsylvania, Philadelphia, PA, ³Stanford Univ., Menlo Park, CA, ⁴Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Pharmacogenomics (PGx) investigates the genetic influence on drug response. It is an integral part of precision medicine and contributes to maximization of drug efficacy and reduction of adverse drug event risk. From a research perspective, it is important to understand PGx allele and phenotype distributions in different biogeographic groups. This knowledge provides guidance for future PGx studies and clinical genetic test panel design to serve individuals of wider biogeographic or genetic backgrounds. Nonetheless, to date, for many genes with published PGx-informed clinical drug prescribing guidelines, frequency information for some alleles is still missing, rarely reported, or seldomly tested due to various reasons. To address the issue, we applied the Pharmacogenomics Clinical Annotation Tool (PharmCAT) on an integrated UK Biobank genetic data set (N = 200,044), which incorporated quality-controlled whole exome sequencing, imputed, and microarray-based genotypes data to achieve a high-quality, comprehensive coverage of PGx positions. We mapped the self-reported ethnicities to five of the nine PharmGKB biogeographic groups: European (N = 187,660, 93.81%), Central/South Asian (N = 3,460, 1.73%), East Asian (N = 637, 0.32%), African American/Afro-Caribbean (N = 637, 0.32%), and Sub-Saharan African (N = 1,235, 0.62%); and an “other” group (N = 5,126, 2.56%) with participants who could not be classified into a single biogeographic group. For over 200K UK Biobank participants, PharmCAT reported alleles and phenotypes for 16 pharmacogenes (*ABCG2*, *CACNA1S*, *CFTR*, *CYP2B6*, *CYP2C19*, *CYP2C9*, *CYP3A5*, *CYP4F2*, *DPYD*, *IFNL3*, *NUDT15*, *RYR1*, *SLCO1B1*, *TPMT*, *UGT1A1*, and *VKORC1*) in five biogeographic groups. We observed frequency differences among biogeographic groups. E.g., for *CYP219*, which has guidelines for clopidogrel, proton pump inhibitors, antidepressants, etc., the percentage of poor metabolizers with clinical actionable recommendation was five-fold higher in the Central/South Asians and East Asians (10.98% and 11.77%, respectively) than in the Europeans (2.47%). We reported frequencies for no-function alleles that were rare or seldom tested in certain groups by previous studies. E.g., 19 (0.27%) and 570 (0.15%) *CYP2C19**35 in the Central/South Asians and Europeans, respectively, and 146 (3.79%) *SLCO1B1**31 in the African American/Afro-Caribbeans. This systematic estimate of PGx frequencies, which will be shared on the Pharmacogenomics Knowledge Base (PharmGKB), aims to bring awareness and crucial information to improve future PGx studies and clinical genetic test panels, particularly for underrepresented populations in genomics.

Pharmacogenomics Posters - Wednesday

PB2733. Evaluating the frequency and the impact of pharmacogenetic variants in an ancestrally diverse Biobank population

Authors:

K. Keat¹, S. Verma², B. Li³, G. Hoffecker⁴, M. Risman⁵, Regeneron Genetics Center, K. Sankuhl³, M. Whirl-Carrillo³, S. Dudek⁵, A. Verma⁴, T. E. Klein⁶, M. D. Ritchie⁵, S. Tuteja⁴; ¹Genomics and Computational Biology PhD Program, Univ. of Pennsylvania, Philadelphia, PA, ²Dept. of Pathology & Lab. Med., Univ. of Pennsylvania, Philadelphia, PA, ³Dept. of BioMed. Data Sci., Stanford Univ., Stanford, CA, ⁴Dept. of Med., Univ. of Pennsylvania, Philadelphia, PA, ⁵Dept. of Genetics, Univ. of Pennsylvania, Philadelphia, PA, ⁶Dept. of BioMed. Data Sci. and Med. (BMIR), Stanford Univ., Stanford, CA

Abstract Body:

Pharmacogenetics (PGx) aims to utilize a patient's genetic data to enable safer and more effective prescribing of medication. The Clinical Pharmacogenetics Implementation Consortium (CPIC) provides guidelines for 24 genes that affect 72 medications. Despite strong evidence linking PGx variants to drug response, there is a large gap in the actual implementation and return of actionable pharmacogenomic findings to patients in standard clinical practice. In this study, **we evaluated opportunities for genetically guided medication prescribing in a diverse health system** and determined the frequencies of actionable PGx alleles in an ancestrally diverse biobank population. A retrospective data mining of Penn Medicine electronic health record (EHR) data, which includes ~3.3 million patients between 2012-2020 provides a snapshot of the distribution of highly ranked CPIC drugs in the Penn Medicine health system. Additionally, the Penn Medicine BioBank (PMBB) consists of a diverse group of 43,359 participants whose EHR data is linked to genome-wide genotype data and whole exome sequencing. We used the Pharmacogenomics Clinical Annotation Tool (PharmCAT), which annotates pharmacogenetic alleles in a variant call format (VCF) file to identify samples with actionable PGx phenotypes. We identified ~316,000 unique patients that were prescribed at least 2 CPIC Level A or B drugs. Genetic analysis of samples from PMBB was used to measure PGx phenotype frequencies and clinical burden. All genotyped participants had at least one non-reference allele in a CPIC gene. PharmCAT annotation also identified that **98% of participants are carriers of one or more PGx actionable phenotypes**, indicating a modification in drug therapy would be recommended. We linked genetic data with prescription data in the EHR and identified that **13.3% of participants (n=5785) were prescribed medications impacted by their PGx alleles**. We found 849 participants who received clopidogrel with CYP2C19 intermediate or poor metabolizer phenotypes who were at increased risk for major adverse cardiovascular events. When we stratified by genetic ancestry, we found disparities in PGx allele frequencies and clinical burden. Notably, **clopidogrel users of Asian ancestry in PMBB had significantly higher rates of CYP2C19 intermediate or poor metabolizer phenotypes than European ancestry users** ($p < 0.0001$, $OR = 3.72$). This analysis provides an overview of the distribution of PGx associated genetic alleles and the prescription rates of medications impacted by PGx variants, illustrating the potential utility of pre-emptive genotyping for PGx and implementation in clinical care.

Pharmacogenomics Posters - Thursday

PB2734. Exploring polygenic risk scores as a biomarker of treatment response in systemic lupus erythematosus

Authors:

J. Esparza Gordillo¹, E. Arciero², D. Fraser³, L. McCarthy², S. Gowrisankar³, M. Chiano², C. Cox²; ¹GlaxoSmithKline, Genomic Sci., Tres Cantos, Madrid, Spain, ²GlaxoSmithKline, Genomic Sci., Stevenage, United Kingdom, ³Parexel, Durham, NC

Abstract Body:

Polygenic risk scores (PRS) enable the identification of individuals who are at high risk of disease and may help to improve clinical decision-making. We tested the utility of a PRS biomarker for predicting treatment response in patients with systemic lupus erythematosus (SLE). First, we selected 117 instruments from a published genome-wide association study for SLE and constructed a “SLE risk PRS” on the UK Biobank, where we observed a 30-fold higher SLE prevalence in individuals within the top versus the bottom percentile of the PRS distribution. Next, we tested for correlation between SLE PRS and response to belimumab in Phase 3 SLE clinical trials (N=755 individuals). Given that belimumab provides clinical benefit by blocking the B-cell activating factor (BAFF; also known as B-lymphocyte stimulator, BLyS), we hypothesized that individuals with “B-cell driven disease” are more likely to show clinical benefit. Thus, we implemented an additional “B-cell specific PRS” that used bioinformatic approaches, such as eQTL, gene expression, and overlap of credible set single nucleotide polymorphisms with B-cell enhancer marks, to select SLE risk variants potentially affected through impact on B cells. Both the “SLE PRS” and “B-cell specific SLE PRS” correlated with SLE severity at baseline (based on SELENA-SLEDAI scores) but did not independently predict treatment response (positive correlation between PRS quartile and “high dose” prednisone use at baseline OR [95% confidence interval (CI)] 1.19 [1.05, 1.35], p=0.005 and no correlation with SRI4 medicine response OR [95% CI] 1.00 [0.86, 1.18], p=0.96). Based on these results and on previous experience in the field we will discuss potential challenges and opportunities for the use of PRS on clinical decision-making.

Pharmacogenomics Posters - Wednesday

PB2735. Genetic associations of iron absorption among individuals of East Asian and European descent.

Authors:

A. Barad¹, Y. Wang¹, Y. Xu¹, E. Bender¹, S. Bird², Z. Gu¹, A. G. Clark^{3,4}, K. O. O'Brien¹; ¹Div. of Nutritional Sci., Cornell Univ., Ithaca, NY, ²Univ. of Rochester Med. Ctr., Rochester, NY, ³Dept. of Molecular Biology and Genetics, Cornell Univ., Ithaca, NY, ⁴Dept. of Computational Biology, Cornell Univ., Ithaca, NY

Abstract Body:

Iron (Fe) balance in humans is maintained by tight regulation of dietary non-heme Fe absorption. Although several genetic variants have been shown to be associated with biomarkers of Fe status, the associations between these genetic variants and non-heme Fe absorption remain unknown. Previously we showed an Asian-prevalent haplotype had a suggestive association with increased Fe absorption, which may help explain the higher body Fe stores in East Asians compared to Europeans. Our aim is to assess the genetic contribution of a functional measure of Fe homeostasis (*i.e.*, Fe absorption) to observed variability in Fe status in East Asian and European adults. We are conducting a nutrigenomic study (FeGenes; ClinicalTrials.gov ID: NCT04198545) in adults (18-50 y) of genetically confirmed East Asian (N=252) or European (N=252) ancestry. We are collecting data on Fe biomarkers and regulatory hormones, quantifying Fe absorption using a stable Fe isotope, and measuring genome-wide genetic variants with Illumina's Global Diversity Array. We carried out a preliminary association study of all previously reported Fe-associated SNPs and polygenic risk scores of enhanced Fe status (PRS-Fe) in Europeans and related this to Fe absorption in FeGenes participants. Consistent with published data, serum ferritin levels were higher in East Asian (N=87) compared to European (N=97) adults ($P=0.003$), and East Asian adults (N=30) absorbed more Fe ($P=0.008$) compared to European adults (N=27) for a fixed amount of storage Fe (ferritin). We replicated published results showing an association between *TMPRSS6*-rs855791 and Fe absorption with consistent effects in both ancestry groups (meta: $\beta=0.37$, $P=0.04$, N= 57); the Asian-prevalent haplotype in *HFE* was only associated with Fe absorption in East Asian adults ($\beta=0.70$, $P=0.03$, N=30). With the current sample size (N=57), we did not observe significant associations between the low-frequency *HFE* variants (H63D and C282Y) and Fe absorption. Of the variants tested, we found three additional SNPs in *VANGL1* (meta: $\beta=-0.53$, $P=0.03$), *NAT2* (meta: $\beta=0.47$, $P=0.03$), and *ARNTL* (meta: $\beta=-0.50$, $P=0.04$), respectively, to be associated with Fe absorption. Moreover, we computed PRS-Fe based on results from GWAS in Europeans and found significant positive associations between PRS-Fe and Fe absorption (meta: $P=0.03$). In sum, we found that known Fe-associated SNPs are associated with non-heme Fe absorption. On-going genetic association studies of Fe absorption in FeGenes may reveal new genes involved in the regulation of Fe homeostasis in humans and may provide an explanation to the observed population differences in risk of Fe overload or deficiency.

Pharmacogenomics Posters - Wednesday

PB2736. Genomic analysis of hydroxychloroquine-associated retinal toxicity in a large cohort

Authors:

E. Ullah¹, M. Ramachandran², D. M. McGaughey¹, A. E. Turriff³, P. A. Sieving⁴, R. B. Hufnagel¹, C. A. Cukras¹; ¹Natl. Eye Inst., NIH, Bethesda, MD, ²Univ. of Missouri-Columbia, Columbia, Columbia, MO, ³Natl. Human Genome Res. Inst., NIH, Bethesda, MD, ⁴UC Davis Eye Ctr., Sacramento, CA

Abstract Body:

Hydroxychloroquine (HCQ) is used as a first-line agent to treat autoimmune diseases including rheumatoid arthritis, systemic lupus erythematosus, juvenile idiopathic arthritis and Sjogren's syndrome. Chronic long-term use of HCQ has been associated with a risk of irreversible damage to photosensitive retinal layers leading to vision loss. DNA sequence variants in *ABCA4* gene has been investigated in multiple studies with varying results finding an association with risk of toxicity in some studies and protective effects in others. To better understand the potential association of genetic elements in a cohort of cases with HCQ-associated retinal toxicity, 50 cases and 81 controls with and without retinopathy following 5 years of hydroxychloroquine use were enrolled following comprehensive battery of clinical tests. Participant DNA was genotyped by using Illumina Infinium OmniExpressExome SNP microarray (960,919 SNPs), followed by data processing on GenomeStudio v2.0 and genome-wide association analysis (GWAS) by PLINK 1.9. NGS-based panel (*ABCA4*, *BEST1*, *CDH3*, *DRAM2*, *EFEMP1*, *ELOVL4*, *IMPG1*, *IMPG2*, *PROM1*, *RDS*, *RP111*, *TIMP3*, *TLL5*), exome and genome sequencing were also performed on genomic DNA samples. Sequence data was processed by in-house developed customized pipeline for alignment, quality control, variant calling and variant annotation. Rare variant association testing was done by c-alpha test, Fisher's exact test, and GWAS was performed by PLINK 1.9. In this multimodal genomic analysis, *ABCA4* variants were not observed to increase or decrease risk for HCQ-associated retinal toxicity following correction for variants with different frequency by ancestry. NGS-based panel of maculopathy genes and exome sequence also did not reveal any significant association. Using ancestrally-neutral SNPs from genome data, genome-wide association analysis of common variants did reveal a locus on chromosome 1, nearby loci for systemic lupus erythematosus and age-related macular degeneration, which may be associated with conferring risk towards HCQ-associated retinal toxicity. Further analyses are underway. This is the largest cohort reported for HCQ-based retinal toxicity, in which the genomic analysis noted no associated effect of *ABCA4* variants on affected status as previously reported. Furthermore, Genome sequencing followed by association analysis identified a locus on chromosome 1 which is being further investigated for its association with HCQ-based retinal toxicity.

Pharmacogenomics Posters - Thursday

PB2737. Impact of global and local ancestry on pharmacogenetics in African American persons with multiple sclerosis.

Authors:

M. Davis¹, L. C. Silva¹, S. W. Brugger²; ¹Brigham Young Univ., Provo, UT, ²Brigham Young Univ., Orem, UT

Abstract Body:

Multiple sclerosis (MS) is a disease of the central nervous system treated with disease-modifying therapies, including the biologic, interferon- β (IFN- β). Up to 60% of IFN- β -exposed MS patients develop abnormal biochemical liver test results, and 1 in 50 experiences drug-induced liver injury. SNP rs2205986, linked to differential expression of *IRF6*, has demonstrated a statistical association with drug-induced liver injury in patients of European ancestry. Studies have revealed a differential risk for MS development among African American individuals compared to those of primarily European ancestry. Additionally, the penetrance of a given MS risk allele near the centromere on chromosome 1 can differ significantly depending on whether the allele is European or African in origin. We aim to evaluate the association of rs2205986 with IFN- β -induced liver injury in African American MS patients in the context of both global and local ancestry. We acquired de-identified electronic health records (EHRs) for 70 African American MS patients from Vanderbilt University Medical Center BioVU. Patient genomes were genotyped on the Illumina MEGAex platform. Utilizing the ADMIXTURE software with a k value of 2, we ran a supervised ADMIXTURE analysis using the CEPH and YRI datasets from the 1KGP as European and African controls, respectively. The majority of samples had less than 50% African ancestry, with a wide distribution. Using RFMix, we will evaluate local ancestry across the genomes of our African American samples. We will analyze which regions of the genome have a local ancestry that differs significantly from the genome average. Significant signals will be analyzed for risk according to ancestry. By studying the genetic admixture of these patients, we aim to identify if differential risk of IFN- β -induced liver injury can be attributed to local ancestry deviations.

Pharmacogenomics Posters - Wednesday

PB2738. Implementation of clinical pharmacogenomics: How NCBI's Medical Genetics Summaries and MedGen can help educate and support clinicians.

Authors:

A. Malheiro, M. S. Kane, M. A. Hoepfner, T. Venkatapathi, B. Kattman; NCBI | NLM | NIH, Bethesda, MD

Abstract Body:

Pharmacogenomics (PGx) implementation depends upon specialized knowledge spread across many clinical disciplines and stages of clinical care. There is a need for a common foundation for PGx practice that enables information sharing for all stakeholders and a centralized resource to guide clinicians for optimized clinical care. The National Center for Biotechnology Information (NCBI) at the National Library of Medicine supports these efforts with the NIH Genetic Testing Registry (GTR), Medical Genetics Summaries (MGS), and MedGen which are all freely available. Approximately 335 US Food and Drug Administration (FDA)-approved drugs contain PGx information on the drug label; about 110 of which the FDA has deemed have sufficient evidence to suggest that genotype can affect drug metabolism and therapeutic effects. As the field of PGx expands so does the availability of clinical testing for PGx variants. Currently, GTR has information on over 880 tests for more than 200 PGx phenotypes from 112 laboratories—66 US and 46 international labs from 23 countries. MGS is a resource that aims to provide support to clinicians in need of PGx information by summarizing the latest research on the genetic factors that influence an individual's response to a drug, discussing available testing strategies, and providing access to practice guidelines from authoritative groups. The MGS articles compile practical information about PGx from authoritative sources for use in clinical settings in an unbiased approach and are extensively reviewed by experts. Currently, MGS covers 54 drugs with more in development. MedGen provides access to relevant clinical information on one page that is available for clinicians, laboratories, and researchers. MedGen aggregates and standardizes drug names, genes and gene products involved in drug metabolism and response, and pharmacogenetic phenotype names. Using automation and curated approaches, MedGen data is collected from authoritative sources: professional societies like CPIC and PharmGKB, and submitters to GTR and ClinVar. Data in MedGen is available for automated processing and can be integrated into products such as electronic health records. These clinical products at NCBI are cross-referenced to aid findability, linked to external authoritative groups, and offer targeted searches of the medical literature in PubMed and NCBI Bookshelf. Standardized terminology for drug-response clinical phenotypes in MedGen allows a clinician to search a specific drug name and discover information through this interconnectivity. By consolidating the expertise of the community, NCBI provides a common foundation for clinical PGx implementation.

Pharmacogenomics Posters - Thursday

PB2739. Investigating pharmacogenetics of dupilumab in the treatment of atopic dermatitis in an Asian clinical cohort

Authors:

Y. Yew^{1,2}, V. Koh³, F. Tai², M. Loh^{4,5,1}; ¹Natl. Skin Ctr., Singapore, Singapore, ²Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore, ³Sch. of Biological Sci., Nanyang Technological Univ., Singapore, Singapore, ⁴Nanyang Technological Univ., Singapore, Singapore, ⁵Imperial Coll. London, London, United Kingdom

Abstract Body:

Background: Dupilumab is an approved targeted biologic therapy for moderate to severe atopic dermatitis (AD). While it is effective in many AD patients, its efficacy and adverse effects are variable. It can also be costly. Pharmacogenetics may allow us to better predict responders and episodes of adverse effects.

Aim: To better predict responders and adverse effects among AD patients treated with dupilumab by studying the variability in drug response due to genetic factors.

Method: Patients with atopic dermatitis (AD), treated with dupilumab from July 2020 to January 2021 at a tertiary skin centre were recruited and genotyped with the Infinium® Global Screen Array (GSA). Standard genotyping QC (quality control) procedures were performed using PLINK version 1.09. SNPs were excluded should they have a call rate < 98% and any possible gender swap after sex check. Genetic variants associated with treatment response, responders vs non-responders as a binary outcome were examined. Patients who achieved an Investigator Global Assessment (IGA) score of 0 and/or 1 at week 16 were considered as treatment responders. Those who have failed these treatment targets were deemed as non-responders. The Fisher's Exact Test was performed to compare allelic frequencies between responders and non-responders. A P-value of less than 0.05 was considered statistically significant. Statistical analyses and functional annotation were performed, and pathway analyses was conducted to understand the biological implications.

Results: A total of 15 patients were recruited with a total of 11 responders and 4 non-responders. Majority (86.7%) of patients were Chinese with 26.7% female. 160 variants with a minor allele frequency (MAF) > 50% were present in responders. These variants were significantly associated ($p < 0.05$) with responders to dupilumab. SNPs with the highest frequency include rs8110935, rs12154459, rs133434495, rs183693, rs2117655, rs3753931 and rs680930 with a MAF of 68.2%. Minor alleles from these 160 variants were not present in non-responders, strongly suggesting that patients who are heterozygous or homozygous for these minor alleles may be better suited for dupilumab treatment. Genetic variants significantly associated with dupilumab response were mostly involved in the immune system directly or indirectly. Other significantly associated pathways included those involving neurogenic inflammation.

Conclusion: These genetic variants could potentially be used as predictors, and provide better understanding of the underlying mechanisms involved in dupilumab treatment response. Future, larger sample size studies would be required to validate these findings.

Pharmacogenomics Posters - Wednesday

PB2740. LOF *CYP2C19* allele evaluation identifies significant number of Indian CAD patients are low responders to Clopidogrel

Authors:

G. Rastogi, V. Sharma, A. Sharma, L. GUPTA; NMC GENETICS INDIA PRIVATE LIMITED, GURUGRAM, India

Abstract Body:

Clopidogrel is used as an antiplatelet drug and is frequently prescribed to individuals with acute coronary syndrome and ischemic stroke. Despite the drug being effective in majority of the patients, some still experience ischemic events which might be due to poor platelet aggregation inhibition. *CYP2C19* plays an important role by converting Clopidogrel into its active form. Individuals with LoF alleles combinations are intermediate or poor metabolizers. An alternative antiplatelet therapy is recommended by Clinical Pharmacogenetics Implementation Consortium CPIC for poor and intermediate metabolizers. Genotyping tests are available to check the alleles of *CYP2C19* gene and the phenotypes are then interpreted as ultra, extensive, intermediate or poor metabolizer. Clopidogrel prescription in coronary artery disease patients is frequently given in South Asians especially in Asian Indians where the risk of CAD is almost double than Europeans. The goal of this study is to check the prevalence of cytochrome P450 2C19 *CYP2C19* loss-of-function SNPs or haplotypes in Indian CAD patients. In order to have accurate estimate of prevalence, the genotyping of 416 established CAD patients belonging to different states of India was performed. Perturbing results were observed with 50 % approximately of CAD patients were low responder to clopidogrel genetically; signifying evaluation of these LoF variations in CAD patients prescribed with clopidogrel in order to reduce recurrent ischemic event.

Pharmacogenomics Posters - Thursday

PB2741. Meta-analyses of genome wide association studies of toxicity to oxaliplatin and fluoropyrimidine chemotherapy in 1800 patients with advanced colorectal cancer

Authors:

K. Watts¹, C. Wills¹, A. Madi², C. Palles³, T. Maughan⁴, R. Kaplan⁵, N. Al-Tassan⁶, R. Kerr⁷, D. Kerr⁷, R. Houlston⁸, V. Escott-Price⁹, J. Cheadle¹; ¹Cardiff Univ., Cardiff, United Kingdom, ²The Clatterbridge Cancer Ctr. NHS Fndn. Trust, Wirral, United Kingdom, ³Univ. of Birmingham, Birmingham, United Kingdom, ⁴CRUK/MRC Oxford Inst. for Radiation Oncology, Oxford Univ., Oxford, United Kingdom, ⁵Univ. Coll. of London, London, United Kingdom, ⁶King Faisal Specialist Hosp. and Res. Ctr., Riyadh, Saudi Arabia, ⁷Oxford Univ., Oxford, United Kingdom, ⁸The Inst. of Cancer Res., Sutton, United Kingdom, ⁹Dementia Res. Inst., Cardiff, United Kingdom

Abstract Body:

Background

Chemotherapies administered at normal therapeutic dosages can cause significant side-effects. Inter-individual variation in toxicity highlights the need for biomarkers to personalise treatment. We sought to identify such biomarkers by conducting meta-analyses of genome-wide association studies for ten toxicities in patients with advanced colorectal cancer treated with oxaliplatin and fluoropyrimidine chemotherapy ± cetuximab from the MRC COIN and COIN-B trials.

Methods

Association analyses were performed on 1,055 patients treated with capecitabine and oxaliplatin (XELOX) ± cetuximab and 745 with folinic acid, fluorouracil and oxaliplatin (FOLFOX) ± cetuximab. We also analysed rs6783836 in *ST6GALI* with hand-foot syndrome (HFS) in CRC patients from QUASAR2. Since genetic variation in *ST6GALI* is a risk factor for type-2 diabetes (T2D), a disease also associated with HFS, we sought to confirm an association between *ST6GALI* and T2D (17,384 cases, 317,887 controls) and analysed rs6783836 against markers of diabetes and inflammation using UK Biobank data.

Results

rs6783836 at *ST6GALI* was associated with HFS in patients treated with XELOX (OR=3.1, 95%CI=2.1-4.6, P=4.3x10⁻⁸) and was borderline significant in patients receiving capecitabine from QUASAR2, but with an opposite allele effect (OR=0.66, 95% CI=0.42-1.03, P=0.05). *ST6GALI* was associated with T2D (lead SNP rs3887925, OR=0.94, 95%CI=0.92-0.96, P=1.2x10⁻⁸) and the rs6783836-T allele was associated with lowered HbA1c levels (P=5.9x10⁻³) and lymphocyte count (P=2.7x10⁻³) beyond thresholds for multiple testing. We identified eight other loci associated with toxicities at suggestive significance levels (in XELOX treated patients: rs12433034 [*LOC105370399*] and rs143685874 [*LINC02504*] with stomatitis, and rs11295266 with diarrhoea; in FOLFOX treated patients: rs12029003 [*TMIGD3*], rs141748690 [*LOC105379133*] and rs1233378 with stomatitis; rs825249 [*CDH13*] with neutropenia and rs79848933 with nausea; all P<1.0x10⁻⁶).

Conclusion

rs6783836 in *ST6GALI* is a potential biomarker for HFS with links to T2D and inflammation. This and eight other putative biomarkers warrant further investigation for their potential clinical utility.

Pharmacogenomics Posters - Wednesday

PB2742*. Novel genetic signals identified for angiotensin-converting enzyme inhibitor-induced cough

Authors:

K. Coley¹, D. J. Shepherd¹, C. John¹, R. Packer¹, R. C. Free^{2,3}, E. J. Hollox⁴, L. V. Wain^{1,2}, M. D. Tobin^{1,2}, C. Batini¹; ¹Dept. of Hlth.Sci., Univ. of Leicester, Leicester, United Kingdom, ²NIHR Leicester BioMed. Res. Ctr., Univ. of Leicester, Leicester, United Kingdom, ³Dept. of Respiratory Sci., Univ. of Leicester, Leicester, United Kingdom, ⁴Dept. of Genetics and Genome Biology, Univ. of Leicester, Leicester, United Kingdom

Abstract Body:

Background: Angiotensin-converting enzyme inhibitors (ACEIs) are a class of antihypertensive drugs which are largely well tolerated. However, the most common adverse drug reaction (ADR) to their use is a persistent dry cough which affects 5-35% of users. In response to this ADR, clinical guidelines indicate a switch to an angiotensin-II receptor blocker (ARB). We have utilised such drug switches recorded in electronic health records (EHRs) as a proxy to study genetic determinants of ACEI-induced cough.

Methods: We have harnessed primary care EHRs linked to UK Biobank and the EXCEED study to identify cases who switched from ACEIs to ARBs within 12 months of initiating ACEIs, and controls who were continuous users of ACEIs. Utilising imputed genomic data in a meta-analysis of both cohorts, we identified ten independent sentinel variants (p -value $< 5 \times 10^{-8}$) in Stage 1, which were followed up in genome-wide association study (GWAS) summary statistics of ACEI-induced cough from the eMERGE Network (Stage 2), and meta-analysed. Functionally-informed fine-mapping was used to identify putative causal variants for variant-to-gene mapping.

Results: A total of 5,435 cases and 34,436 controls from four ancestral groups (African, East Asian, European and South Asian) were included in the Stage 1 meta-analysis of ~ 17 M variants. Of the 10 independent sentinel variants, 5 were also genome-wide significant (p -value $< 5 \times 10^{-8}$) in the Stage 1 and Stage 2 joint meta-analysis and 3 did not have available Stage 2 data. Variant-to-gene mapping identified *KCNIP4* which has been previously associated with ACEI-induced cough, as well as novel genes including *NTSR1* and *PREP* which are both involved in the mediation of neuropeptide activity. Further, PheWAS of rs6062847 (*NTSR1*) and genetic correlation analysis showed genetic overlap with chronic dry cough phenotypes.

Conclusion: We have utilised a proxy phenotype to perform the largest GWAS of ACEI-induced cough to date, identified putative causal variants and genes, and provided evidence for shared genetic determinants with chronic cough. In line with existing hypotheses, these findings highlight the role of proinflammatory mediators in sensory airway sensitivity and cough reflex modulation.

Pharmacogenomics Posters - Thursday

PB2743. Pharmacogenetics of tenofovir clearance among Southern Africans living with HIV.

Authors:

Z. Cindi¹, A. N. Kawuma¹, G. Maartens¹, P. Denti¹, R. Wasmann¹, Y. Bradford², M. Ritchie², L. Wiesner¹, S. Sokhela³, N. Chandiwana³, F. Venter³, D. W. Haas⁴, P. Sinxadi¹; ¹Univ. of Cape Town, Cape Town, South Africa, ²Univ. of Pennsylvania, Philadelphia, PA, ³Univ. of the Witwatersrand, Johannesburg, South Africa, ⁴Vanderbilt Univ, Nashville, TN

Abstract Body:

Background: Tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF), prodrugs of the nucleotide analogue tenofovir, are prescribed in antiretroviral regimens to people with HIV (PWH). Plasma tenofovir exposure is higher when given as TDF and causes renal and bone toxicity in some patients. TAF yields lower plasma but higher intracellular tenofovir concentrations, and a more favorable safety profile. We characterized the pharmacogenetics of tenofovir clearance in Southern African PWH. **Methods:** Adults randomised to initiate TAF or TDF in dolutegravir-containing arms of the ADVANCE trial were studied. Plasma tenofovir clearance was estimated with non-linear mixed-effects models. Associations between pharmacogenetic polymorphisms, genome-wide polymorphisms, and unexplained variability in tenofovir clearance were examined using linear regression models stratified by study arm, with adjustment for 2 principal components. **Results:** 340 participants consented for genetic testing and associations were evaluable in 138 and 130 in the TAF and TDF arm, respectively. We found no significant associations with tenofovir clearance for either TAF or TDF among 5 polymorphisms previously associated with tenofovir pharmacokinetics (lowest P-value > 0.3 for each drug). Among 11 polymorphisms selected based on both prior strong association with any drug phenotype in PharmGKB and any genome-wide association with any trait in the GWAS catalog, the lowest P-value in both arms was for *IFNL4* rs12979860 (TAF: $P = 2.9 \times 10^{-3}$; TDF: $P = 3.0 \times 10^{-3}$), with the C allele associated with increased tenofovir clearance. This withstood correction for multiple testing. In genome-wide analyses, the lowest P-values for tenofovir clearance in the TAF and TDF arms were with *LINC01684* rs9305223 ($P = 3.0 \times 10^{-8}$) and intergenic rs142693425 ($P = 1.4 \times 10^{-8}$), respectively. Several additional polymorphisms were genome-wide significant [TAF: *LINC01684* rs4816969 ($P = 3.7 \times 10^{-8}$) and intergenic rs2829163 in chromosome 21 ($P = 4.5 \times 10^{-8}$); TDF: intergenic rs112914324 in chromosome 11 ($P = 1.6 \times 10^{-8}$) and intergenic rs11995962 in chromosome 8 ($P = 2.3 \times 10^{-8}$)]. **Conclusion:** Among Southern African PWH randomized to TAF or TDF, increased unexplained variability in tenofovir clearance was associated with an *IFNL4* polymorphism previously associated with resolution of hepatitis C virus infection. It is unclear how this gene would affect tenofovir disposition.

Pharmacogenomics Posters - Wednesday

PB2744. Pharmacogenomic analysis of drug metabolizing enzymes associated with plasma clozapine/N-desmethylclozapine ratio.

Authors:

S-I. Park^{1,2}, S. Kim³, K. Park⁴, J. Lee⁴, E. Kim^{3,5}; ¹Kangwon Natl. Univ., Chuncheon, Korea, Republic of, ²Kangwon Natl. Univ. Hosp., Chuncheon, Korea, Republic of, ³Seoul Natl. Univ. Bundang Hosp., Seongnam, Korea, Republic of, ⁴Kyung Hee Univ., Seoul, Korea, Republic of, ⁵Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract Body:

Background: Clozapine is a drug of choice for the treatment of resistant schizophrenia; however, inter-individual variations in the pharmacokinetics and pharmacodynamics limit its clinical benefits. N-desmethylclozapine, an active metabolite of clozapine, partially contributes to the clinical effect of clozapine. Clozapine is metabolized into N-desmethylclozapine by hepatic cytochrome P450 (CYP450) enzymes, with a major role in CYP1A2. Evaluation of genetic polymorphisms associated with the pharmacokinetic variability of clozapine can facilitate personalized pharmacotherapy.

Methods: Forty-five patients with flexible-dose escalation according to the clinician's instructions were included in the study. Genomic DNA was extracted from blood samples, and plasma metabolic ratio (clozapine/N-desmethylclozapine) was measured after eight (visit 2) and 18 weeks (visit 4) of the first dose of clozapine. Previously reported genes and SNPs related to the pharmacokinetics of clozapine were selected for targeted next-generation sequencing analysis. The genes included only the coding DNA sequence (CDS) region. For SNPs outside the CDS region, additional target probes were designed. This was followed by hybridization capture-based next-generation sequencing and data collection using a genome analysis tool kit. Statistical analysis was performed by using SPSS v 26.0. All *P*-values were based on two-sided comparisons, and *P* < 0.05 was considered statistically significant.

Results: Among the 81 variations identified by targeted capture sequencing, only 7 SNPs (2 for CYP1A2, 1 for UGT1A4, 1 for UGT1A1, and 3 for CYP2C19) showed nominal significance (*P* < 0.05) in metabolic ratio according to the genotype or phenotype of each gene. Phenotypes of CYP1A2 were determined by a combination of two SNPs, rs2069514 (c.-3860G > A) and rs762551 (c.-9-154C > A), showed significant associations with metabolic ratio (*P* = 0.020, t-test) at visit 4. In addition, phenotypes of CYP2C19 determined by three linked SNPs, rs12769205 (c.332-23A > G), rs4244285 (c.681G > A), and rs3758580 (c.990C > T), showed significant associations with metabolic ratio (*P* = 0.033, Kruskal Wallis test) at visit 2. The homozygous mutant group (N = 6) showed significantly higher metabolic ratio than the wild type + heterozygous mutant group (N = 39) at visit 2 (*P* = 0.010, Mann-Whitney test).

Conclusions: We found that the phenotypes of CYP1A2 and CYP2C19 were significantly associated with mid-term and earlier metabolic ratios of clozapine, respectively. These findings may provide a better understanding of the inter-individual variations in pharmacokinetics and pharmacodynamics of clozapine.

Pharmacogenomics Posters - Thursday

PB2745. Pharmacogenomics for All of Us: Approach to testing and return of results in 1M participants

Authors:

P. Empey¹, A. Radhakrishnan², J. D. Smith², S. McGee², E. Venner³, A. Haddad⁴, C. L. Neben⁵, A. Y. Zhou⁵, G-h. Kim⁵, H. Hoban⁵, K. Walker³, D. Kalra³, D. Murdock³, K. Doheny⁶, N. J. Lennon⁷, B. Shirts⁸, A. Wise⁹, A. Musick⁹, B. Ozenberger⁹, H. L. Rehm⁷, G. Jarvik², R. A. Gibbs³, J. C. Denny⁹, S. E. Topper⁵; ¹Univ. of Pittsburgh, Pittsburgh, PA, ²Dept. of Genome Sci., Univ. of Washington, Seattle, WA, ³Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX, ⁴Dept. of Pharmaceutical Sci., Univ. of Pittsburgh Sch. of Pharmacy, Pittsburgh, PA, ⁵Color Hlth., Burlingame, CA, ⁶Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ⁷Broad Inst. of MIT and Harvard, Cambridge, MA, ⁸Univ of Washington, Seattle, WA, ⁹All of Us Res. Program, NIH, Bethesda, MD

Abstract Body:

Pharmacogenomic (PGx) information is valued by patients and healthcare practitioners because genetic variation impacts drug pharmacokinetics and response. The All of Us Research Program (AoURP) is committed to return PGx reports along with other medically-actionable information to a diverse cohort of 1M participants. We designed an AoURP PGx return of results strategy to deliver value while mitigating potential risks within US regulatory frameworks.

In the AoURP, DNA derived from blood/saliva undergoes whole genome sequencing and participants provide secondary consent to elect to receive PGx results. Pharmacogenes, variants, phenotype translations, and medication associations to be reported were selected based on scientific evidence of actionability [Clinical Pharmacogenetics Implementation Consortium Level A gene-drug pairs, FDA PGx data and drug product labeling, professional society recommendations, and variants having a known altered function], the existence of validation controls, and the ability to support complex haplotyping. A priori analytical validation of PGx alleles was conducted using 221 clinical samples and cell lines. A participant-directed PGx report underwent multiple rounds of qualitative (n=21) and quantitative (n=205) user comprehension testing to ensure understanding and to minimize potential risks. The entire process was reviewed by the FDA for an Investigational Device Exemption (IDE). Finally, the value of returned PGx results was estimated by evaluating the prevalence of medication exposures among participants who provided electronic health record (EHR) data as of Jan. 2021.

Seven genes (CYP2C19, DPYD, G6PD, NUDT15, TPMT, SLCO1B1, and UGT1A1) and 46 variants were chosen for initial return. Validation results yielded >99% concordance with the truth set and between labs. User testing of the PGx report showed high comprehension for genetics knowledge (98.0%) and self-efficacy (98.3%). An IDE was awarded after 2 years of FDA engagement and importantly, included a reporting rubric for inclusion of 57 medications based on predicted phenotype associations. Among 194,418 AoURP participants with EHR medication data, 5.02% (2,618,872/52,158,718) of medication exposures were for PGx drugs included in the IDE and 60.0% (116,687/194,418) of participants had an exposure to at least one drug that had a potential PGx interaction.

The AoURP return of results strategy represents a path forward for returning PGx results to research participants. Information provided in the “Medicine and Your DNA” report is likely to be of interest to the majority of AoURP participants based on their common exposures to impacted medications.

Pharmacogenomics Posters - Wednesday

PB2746. Predicted expression of enzymes in the thiopurine metabolic pathway and risk of side effects in patients with inflammatory conditions treated with azathioprine

Authors:

L. Daniel, A. Dickson, P. Nepal, J. Zanussi, T. Miller-Fleming, P. Staub, W-Q. Wei, A. Davis, A. Hung, N. Cox, Q. Feng, M. Stein, C. Chung; Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract Body:

Introduction: Thiopurines are immunosuppressants with numerous side effects. We recently described that a higher risk score generated from the predicted liver expression of *AOXI* and *NME1* (enzymes in the thiopurine metabolic pathway) was associated with azathioprine discontinuation attributed to hematopoietic toxicity. Little is known about the association between this score and other known azathioprine side effects. We examined the association between the score and known azathioprine side effects. **Methods:** This was a retrospective cohort study of new azathioprine users with inflammatory conditions (e.g., systemic lupus erythematosus, rheumatoid arthritis); we limited the cohort to White TPMT/NUDT15 normal metabolizers and used MEGAchip genotyping with quality control and imputation. The risk score used PrediXcan (GTEx version 8) estimates of the genetically regulated expression of *NME1* and *AOXI* for each patient. Phecodes group phenotypes into clinically meaningful categories using ICD codes. We prespecified nine groups of phecodes (infections, hematologic, dermatologic, skin malignancies, other malignancies, hepatotoxicity, other gastrointestinal, constitutional, and other) corresponding to known azathioprine adverse effects. We tested the association between the score and the candidate phenotypes (n=99) using PheWAS. For outcomes that were significant ($p < 0.05$) in the PheWAS, we reviewed electronic health records to confirm the presence or absence of the side effects and performed logistic regression to assess the associations between the score and confirmed cases. **Results:** The cohort included 1259 patients (mean age 44.6 ± 17.6 years, 66% female) followed over a median of 1.6 years. The gene expression score (range 0.51 to 9.87 units) was significantly associated with the phecode for leukopenia (288.1); record review confirmed all 23 potential cases. Higher risk scores were associated with leukopenia [OR=1.19, (95% C.I. 1.02-1.39), $p=0.026$]. Results remained significant after adjustment for azathioprine daily. The score was not significantly associated with rash [OR 1.01, p-value 0.94], nausea and vomiting [OR 0.98, p-value = 0.75], thrombocytopenia [OR 0.97, p-value 0.75], or other known azathioprine adverse reactions. **Conclusion:** There was an association between a score including the predicted expression of *AOXI* and *NME1* with leukopenia. We found no associations between the score and other side effects, suggesting that these side effects are independent of *AOXI* and *NME1*.

Pharmacogenomics Posters - Thursday

PB2747. *PTPN2* and Discontinuation of Azathioprine Attributed to Myelotoxicity.

Authors:

A. Dickson, J. T. Zanussi, P. Nepal, L. L. Daniel, P. Straub, T. W. Miller-Fleming, W-Q. Wei, A. M. Hung, N. J. Cox, C. Stein, J. D. Mosley, Q. FENG, C. P. Chung; Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract Body:

Background: Azathioprine is an affordable immunosuppressant used globally to treat wide-ranging conditions, including multiple rheumatic conditions. Despite its broad application, dose-dependent side effects (e.g., myelotoxicity) frequently limit azathioprine use. Variants in genes within the thiopurine metabolic pathway—*TPMT* and *NUDT15*—predict some cases of myelotoxicity; however, most people who discontinue azathioprine for myelotoxicity are normal *TPMT* and *NUDT15* metabolizers. We hypothesized that a variant in *PTPN2*—rs11664064—that reached significance in a GWAS of azathioprine-associated leukopenia (defined as white blood cell count < 3.0 K/ μ L during azathioprine exposure) among these patients may predict discontinuation for myelotoxicity in a real-world clinical setting.

Methods: We conducted a retrospective cohort study among new users of azathioprine without an indication of organ transplant at a tertiary care center. We restricted the cohort to patients with EHR-reported White race and normal *TPMT* and *NUDT15* metabolizer status. The outcome was azathioprine discontinuation attributed to myelotoxicity in the clinical record. We used Cox hazard regression with competing risk (i.e., discontinuation attributed to other side effects) to examine the association between this variant and the clinical decision to discontinue azathioprine attributed to myelotoxicity. Given the small number of patients with the homozygous variant (n=4), we grouped patients as carriers or non-carriers of this variant for analysis.

Results: In the cohort of 1,184 patients, there were 39 outcomes among 1,063 non-carriers followed for a median of 21 [4-59] months; there were 10 outcomes among 121 among carriers followed for a median of 26 [5-75] months. In unadjusted competing risk analysis, carriers were at higher risk to discontinue azathioprine for attributed myelotoxicity: HR=2.28 (95%CI: 1.13-4.61, p=0.02). Results were similar without competing risk or when adjusted for 1) age and sex, and 2) age, sex, indication, initial dose-weight ratio, and prior testing for *TPMT*.

Conclusion: The rs11664064 variant in *PTPN2* was associated with a higher risk of azathioprine discontinuation attributed to myelotoxicity among White patients with indications other than organ transplants.

Pharmacogenomics Posters - Thursday

PB2748. Testing for common pharmacogenomic predictors of vigabatrin-associated visual field loss, under univariate & polygenic models.

Abstract Body:

Background: The anti-seizure drug vigabatrin (VGB) is an effective drug for controlling seizures, especially infantile spasms. However, use is limited by VGB-associated visual field loss (VAVFL). Approximately 33% of VGB-exposed adult patients experience this adverse reaction (Maguire, 2010) although the mechanisms by which VGB causes VAVFL remains unknown. Average peripapillary retinal nerve fiber layer (ppRNFL) thickness is correlated with the degree of visual field loss (measured by mean radial degrees) (Clayton, Dévilé et al. 2011). Duration of VGB exposure, maximum daily VGB dose, & male sex are associated with peripapillary retinal nerve fiber thinning. We hypothesize that common genetic variation is a predictor of VAVFL. Identifying pharmacogenomic predictors of VAVFL could potentially enable safe prescribing of VGB and broader use of a highly effective drug. Methods: Optical coherence topography (OCT) data were produced on VGB-exposed individuals (n=99) from the EpiPGX consortium. We conducted quantitative GWAS analyses for the following OCT thickness measurements: 1) Average ppRNFL, 2) inferior quadrant, 3) nasal quadrant, 4) superior quadrant, 5) temporal quadrant, 6) inferior nasal sector, 7) nasal inferior sector, 8) superior nasal sector, 9) nasal superior sector. We included sex, cumulative dose, maximum daily dose, duration of prescription of VGB (years) and 4 principal components as covariates. Using the summary statistics from the GWAS analyses we conducted gene-based testing using VEGAS2. To determine if VGB exposed patients were predisposed to having a thinner RNFL, we calculated their polygenic burden for retinal thickness. We conducted nine different PRS analyses using the OCT measurements. PRS alleles for retinal thickness were calculated using the summary statistics from a large-scale GWAS of inner retinal morphology using the OCT images of 31,434 UK Biobank participants (Currant, Hysi et al. 2021). Results: The GWAS analyses did not identify a significant association after correction for multiple testing. Similarly, the gene-based and PRS analyses did not reveal a significant association that survived multiple testing. Conclusion: We set out to

ASHG 2022 Annual Meeting Poster Abstracts

identify common genetic predictors for VGB-induced ppRNFL thinning (as a marker of VAVFL), under univariate & polygenic models. Results suggest that large-effect common genetic predictors are unlikely to exist for VGB-induced VAVFL. Sample size was a limitation of this study; but recruitment is a challenge as VGB is rarely used today because of this adverse reaction. Rare variants may be predictors of this ADR and were not studied here.

Pharmacogenomics Posters - Wednesday

PB2749. The Alabama Genomic Health Initiative Integrating Genomics into Primary Care

Authors:

N. Limdi¹, D. Absher², I. Asif¹, G. Barsh², L. Bateman¹, K. Bowling³, G. Cooper², B. Davis¹, K. East², C. Finnila², B. Goff¹, M. Kelly², S. Hiatt², W. Kelley², B. Korf¹, D. Latner², J. Lawlor², T. May⁴, M. Might¹, I. Moss¹, M. Nakano-Okuno¹, T. Osborne¹, S. Sodeke⁵, A. Stout², M. Thompson²; ¹Univ. of Alabama at Birmingham, Birmingham, AL, ²Hudson Alpha Inst. for Biotechnology, Huntsville, AL, ³Washington Univ. Sch. of Med., Saint Louis, MO, ⁴Washington State Univ., Spokane, WA, ⁵Tuskegee Univ., Tuskegee, AL

Abstract Body:

Introduction The Alabama Genomic Health Initiative (AGHI) is a state-supported, IRB-approved research study launched in 2017 to evaluate the impact of population-based genomic screening. In 2021, AGHI adopted a new clinic-based model, partnering with UAB Family Medicine providers with a primary goal of integrating genomic medicine into primary care. Participants and providers receive results about variation in medically actionable genes and pharmacogenetics (PGx). **Methods** Participants are enrolled in UAB clinics (Birmingham, Hoover, and Selma, AL), and a blood sample, personal/family history, and medications are collected. DNA is analyzed using the Illumina Global Diversity Array and Taqman assays (*CYP2D6* copy number changes). Sanger sequencing is used to confirm variation in medically actionable genes. Sanger sequencing and PGx analyses are performed in CLIA-certified labs. Genetic counselors and pharmacists review results in the context of the participant's personal/family history and medications, respectively, and highlight potential risks in return-of-results (ROR) reports. Provider reports are returned via the electronic medical record (EMR), and patient reports are mailed approximately two weeks later. Providers are notified when a high impact result is identified. Genetic counselors and pharmacists are available to provide education and guidance to providers and patients. Provider feedback is used to identify and refine processes.

Results From July 2021-June 2022, 485 individuals (62% non-white; 75% female) have enrolled in AGHI, and 286 have completed analysis and ROR. Of these, 31.1% (n=89) had a result affecting a current medication, and 1% (n=4) had a medically actionable result (*KCNQ1*, *TTN*, *BTDR*, and *CACNA1S*). To enable the incorporation of genomic information into the EMR, we worked with UAB Health System Information Services, to develop 1) automated transfer of reports into the EMR, 2) Genetics and Pharmacogenetics Reports folders and 3) a Genomic Medicine MPage in Cerner, which allows providers to view genetic reports in one location.

Conclusion There has been substantial interest on the part of family medicine providers in being involved in AGHI, and we have obtained important feedback. Many of their patients are from disadvantaged socioeconomic backgrounds, and much of the feedback has entailed refinement of messaging about participation and return of results. Additionally, embedding genetic results in the EMR allows this information to be available and inform future care and prescribing.

Pharmacogenomics Posters - Wednesday

PB2750. Vaccinations against pneumonia and the flu may protect carriers of particular genotypes against Alzheimer's disease

Authors:

S. Ukraintseva¹, K. Arbeev¹, H. Duan¹, A. Yashkin¹, A. Tropsha², I. Akushevich¹, A. Yashin¹; ¹Duke Univ., Durham, NC, ²UNC, Chapel Hill, NC

Abstract Body:

Background: Vaccines with beneficial off-target effects could be promising candidates for repurposing for Alzheimer's disease (AD) prevention. Earlier we found that the association of pneumococcal vaccine with AD can be modified by rs2075650 polymorphism in *TOMM40*, a known genetic risk factor for AD. Here we further explore the modulating effects of genetic risk factors for AD on the associations between vaccinations and AD risk. In this analysis we focus on the SNP rs6859 in *NECTIN2* gene that was linked to *both* AD and vulnerability to infections in prior research, including our own. **Method:** We evaluated associations between vaccinations against pneumonia and the flu received between ages 65 and 75 and the risk of AD later in life (a binary variable defined as 0 = "no AD, and lived longer than 75 years", and 1 = "AD onset after age 75") in the sample of 5,146 participants of the Cardiovascular Health Study, taking into account the rs6859 polymorphism. Logistic model with covariates including sex, race, birth cohort, education, smoking status, and number of A alleles of rs6859 (AD risk factor) was used. We also performed stratified analysis by genotype (carriers vs. non-carriers of A alleles of the rs6859). **Results:** The total count of vaccinations against pneumonia and the flu received between ages 65-75 was associated with the lower risk of AD later in life in the model with all covariates (OR=0.87; p=0.01). In the stratified analysis, the total count of vaccinations was associated with the lower risk of AD only in carriers of A allele of the rs6859 (OR = 0.84; p=0.04), but not in the non-carriers. Number of flu shots, separately, didn't show a significant association with AD. Pneumococcal polysaccharide vaccine received between ages 65 and 75 (with or without an accompanying flu shot) was associated with 33% lower risk of AD onset later in life in carriers of A allele (OR=0.67; p=0.05), but not in the non-carriers. All odds ratios were close to 1 in the non-carriers of A allele group. **Conclusion:** In this study, pneumococcal polysaccharide vaccine, as well as the total count of vaccinations against pneumonia and the flu received between ages 65-75, had genotype-specific associations with the risk of AD, with protective effects of vaccinations seen only in carriers of A allele of the rs6859, but not in the non-carriers. These results support the repurposing of pneumococcal and flu vaccines for personalized, genotype-tailored, AD prevention.

Pharmacogenomics Posters - Thursday

PB2751. Variant Calling and Orthogonal Verification of 20 Pharmacogenomics (PGx) Clinical Pharmacogenetics Implementation Consortium (CPIC) Level A Genes including 4 Challenging Genes Using Illumina DRAGEN Bio-IT Platform.

Authors:

S. Catreux¹, K. Mukherjee¹, E. Roller¹, V. Onuchic¹, I. Filip¹, S. Tzur¹, J. Han¹, M. Axford², M. Curtis², L. Lau²; ¹Illumina, San Diego, CA, ²The Hosp. for Sick Children, Toronto, ON, Canada

Abstract Body:

Pharmacogenomics (PGx) is a field of research that studies how a person's genes affect how he or she responds to medications. Information from PGx testing is used by healthcare providers to tailor drug dose, predict side effects, and measure effectiveness of drugs for individuals with defined genotypes.

The Clinical Pharmacogenetics Implementation Consortium (CPIC) curates and posts freely available, peer-reviewed gene/drug clinical practice guidelines. Out of the list of PGx-related genes, there is a set of 20 genes classified as "Level A" by CPIC (as of March 2022), with moderate to high levels of evidence in favor of changing drug prescribing.

Variants from 16 of 20 genes can be called with high accuracy using standard whole genome sequencing (WGS) or panel-based workflows. However, 4 genes have been difficult to interrogate with next-gen sequencing (NGS): HLA-A/B genes due to high levels of polymorphism and CYP2B6/CYP2D6 due to paralogous regions in the genome. CYP2B6 has one pseudogene (CYP2B7), with ~ 93% shared sequence homology. CYP2D6 has two pseudogenes CYP2D7 (~97% homology) and CYP2D8P (~91% homology). Here, we introduce the application of 3 gene specific targeted callers (HLA-A/B, CYP2D6, CYP2B6) as well as describe the integrated star allele caller which genotypes the following remaining 16 genes: CACNA1S, CFTR, CYP2C19, CYP2C9, CYP3A5, CYP4F2, IFNL3, RYR1, NUDT15, SLCO1B1, TPMT, UGT1A1, VKORC1, DPYD, G6PD and MT-RNR1. The PGX calling function in DRAGEN provides an easy-to-use workflow that can genotype these CPIC Level A genes in a single streamlined process starting from sequence read data (FASTQ or BAM) to final star allele calls.

The performance of the DRAGEN PGx calling function was assessed through two independent studies. The first study showed that DRAGEN's PGx star allele caller achieved 100% concordance with external PGx callers such as PharmCAT and Aldy when tested on around 3300 samples from Coriell and the 1k Genome project. The CYP2D6 and CYP2B6 callers were tested against GeT-RM PGx calls and found to have 99.3% and 92% concordance respectively. The HLA-A/B caller has an accuracy of 99.6% when compared against a reference truth set generated via Sanger sequencing.

The second study was executed by the Hospital for Sick Children (SickKids). They examined 20 samples using orthogonal PGx testing via MassArray, the external PGx caller PharmCAT (using DRAGEN 3.10.8 variant calls), and the DRAGEN integrated star allele caller in v4.0 and found close to 100% concordance between the calls.

Variant calling for all 20 genes including 4 gene specific targeted callers will be available in DRAGEN v4.0.

Pharmacogenomics Posters - Wednesday

PB2752. Variation in *CYP2A6*, a nicotine metabolism gene, associates with lung diseases: A Phenome-wide Association and Mendelian Randomization study.

Authors:

H. Giratallah^{1,2}, M. J. Chenoweth^{1,2}, J. Pouget^{1,2,3}, A. El-Boraie^{1,2}, C. Lerman⁴, J. Knight⁵, R. F. Tyndale^{1,2,3}; ¹Dept. of Pharmacology & Toxicology, Univ. of Toronto, Toronto, ON, Canada, ²Campbell Family Mental Hlth.Res. Inst., CAMH, Toronto, ON, Canada, ³Dept. of Psychiatry, Univ. of Toronto, Toronto, ON, Canada, ⁴Norris Comprehensive Cancer Ctr., Univ. of Southern California, Los Angeles, CA, ⁵Data Sci. Inst., Lancaster Univ. Med. Sch., Bailrigg, United Kingdom

Abstract Body:

Background: *CYP2A6* is a genetically variable enzyme that inactivates nicotine, activates carcinogens (e.g. nitrosamines), and metabolizes many pharmaceuticals. Genetic variation in *CYP2A6* changes smoking behaviours and the risk for tobacco-related diseases. This Phenome-Wide Association Study (PheWAS) examined associations between our previously developed *CYP2A6* weighted genetic risk score (wGRS), a robust genotypic marker of *CYP2A6* activity, with diseases in the UK Biobank (N~400,000). The top associations were then evaluated using Mendelian Randomization (MR) to estimate the potential causal effects of *CYP2A6* activity on these diseases. **Methods:** The wGRS was computed for participants in the UK Biobank after extracting raw or imputed genotypes for each of the *CYP2A6* wGRS variants or their proxy variants ($r^2 > 0.8$). The reconstructed wGRS using proxy variants, was validated in an independent sample (N=922). The phenome consisted of mapped UK Biobank diagnosis codes (ICD-9 and ICD-10) to PheCodes. PheCodes-wGRS associations were tested in linear models adjusting for and/or stratifying on relevant covariates. Two-sample MR used the independent sample as *CYP2A6* exposure and the phenome-wide significant (PWS) signals in the UK biobank as outcomes in current smokers. **Results:** In the total sample and current smokers, six PWS signals were identified: two lung cancers and four obstructive respiratory diseases, where higher wGRS (i.e. faster *CYP2A6* activity) was associated with higher disease risk ($P < 1 \times 10^{-6}$). No PWS signals were detected in former or never smokers. In current smokers, the top lung cancer signal had a higher estimate in females versus males. However, when restricted to lighter smokers (≤ 20 cigarettes/day), females and males estimates were similar. MR effects of *CYP2A6* activity on the six PWS signals in current smokers were significant (OR=1.168-1.442; $P < 0.001$), providing evidence supporting causation. MR sensitivity analyses by Egger and leave-one-out methods indicated no evidence of horizontal pleiotropy. Whether the *CYP2A6* effect is via nitrosamine activation or mediated by increased smoking is now being investigated using mediation and mediation MR analyses. **Conclusions:** This is the first study showing, in a hypothesis-free approach in a large biobank, an association of *CYP2A6* wGRS with lung cancers and obstructive respiratory diseases and providing evidence supporting causation. Our findings support a role for *CYP2A6* variation as a risk factor for lung cancer and obstructive respiratory diseases, with potential utility in early lung cancer screening programs that currently only rely on smoking history and age.

Pharmacogenomics Posters - Thursday

PB2753*. Whole Exome Sequencing adds power to prioritize drug targets when combined with other genetic data types

Authors:

S. Ranganathan¹, J. Flannick²; ¹Broad Inst. of Harvard and MIT, Boston, MA, ²Boston Children's Hosp., Boston, MA

Abstract Body:

90% of drugs that enter clinical trials do not get approved, increasing the cost of drug development. This high attrition rate is partly due to the inability of preclinical models to accurately predict efficacy. Human genetic evidence can address these limitations by providing 'experiments of nature' that inform on the effects of drug target perturbation in vivo. Existing studies have presented the odds ratio (OR) of drugs supported by genetic evidence being approved over drugs without genetic evidence getting approved, focusing on common variant associations from GWAS (OR=1.5) and Mendelian disease associations from OMIM (OR=2.6). Whole exome sequencing (WES) studies present a third-class of associations that balance the benefits of GWAS associations and Mendelian disease associations. We sought to evaluate (a) the ability of WES associations to predict drug success rate; (b) the extent to which various ways of analyzing WES data impact this ability; and (c) the extent to which WES data complements the other classes of genetic associations in providing genetic support for drug targets. For our analysis, we used WES gene-trait associations in the UK Biobank and previously published drug target-indication data. We compared drug approval ORs and the number of drugs with genetic support across GWAS, OMIM, and WES data, and evaluated the effects of various parameters (p-value thresholds to consider an association significant, variant mask and statistical used to compute a gene-trait association) on these values for WES data. Comparing the gene-trait associations identified by the different databases, though WES prioritized fewer associations than OMIM and GWAS, it identified new gene-trait associations (7) even with the strictest significance thresholds of $p < 1e-05$. WES gene-trait associations under different classes of diseases revealed a significant difference in the approval ORs for the different classes of diseases (OR = 1.5 for cardiovascular diseases, OR = 2.5 for neoplasms). For all parameter choices, WES data showed significant drug approval ORs, with the highest OR produced by a significance threshold of $p < 1e-04$ for a burden test of pLoF variants and SKAT test of missense variants ((OR = 2.61). Integrating this with GWAS and OMIM by taking the union of the gene-trait associations in the three databases, OR = 1.71 with 131862 gene-trait associations fulfilling the different parameters. Overall, these results demonstrate that incorporating WES data into a pipeline for drug target validation can add substantial information. Investigating the optimal way to integrate WES, OMIM and GWAS into a genetic support pipeline could be a valuable research direction.

Evolutionary and Population Genetics Posters - Wednesday

PB2754. A Bayesian framework to capture the probability of polymorphism with sequence context across the human genome.

Authors:

C. Adams, M. Conery, B. Auerbach, S. T. Jensen, I. Mathieson, B. F. Voight; Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Germline mutations are the primary vehicle by which genetic variation is created and maintained in species, with inferences derived from mutation rate models fundamental to many population genetics inference methods. Previous models have demonstrated that nucleotides flanking polymorphic sites - local sequence context - explain variation in the probability that a site is polymorphic in the genome. However, limits to these models exist as the size of the local sequence context window expands, which includes the lack of robustness to data sparsity for practical applications, lack of regularization to generate parsimonious models, and finally a lack of quantified uncertainty in estimated rates to facilitate comparison of rates between models. To address these limitations, we present Baymer, a regularized Bayesian hierarchical tree model to capture the heterogeneous effect of sequence contexts on polymorphism probabilities. Baymer implements an adaptive Metropolis-within-Gibbs Markov Chain Monte Carlo sampling scheme to estimate the posterior distributions of sequence-context based probabilities that a site is polymorphic. We show that Baymer accurately infers polymorphism probabilities and emits well-calibrated uncertainty estimates based on the posterior distributions, is robust to circumstances of data sparsity, appropriately regularizes to return parsimonious models, and is computationally scalable at least up to 9-mer sized context windows. We demonstrate application of Baymer in two ways -- first, in identifying differences in polymorphism probabilities between continental populations in the 1000 Genomes Phase III dataset, and secondly in a sparse-data setting to demonstrate the portability of polymorphism models as a proxy for de novo mutation probabilities as a function of variant age, sequence context window size, and demographic history. Altogether, we demonstrate Baymer is a dynamic polymorphism probability estimation algorithm that is well suited to handling the sparsity of existing datasets, varying information content in sequence context window sizes, and accounts for uncertainty in these parameters, thus providing a novel tool for population genetics inference problems.

Evolutionary and Population Genetics Posters - Thursday

PB2755. A likelihood-based framework for demographic inference from genealogical trees

Authors:

C. Fan¹, N. Mancuso², C. Chiang²; ¹Univ. of Southern California, Los Angeles, CA, ²Univ. OF SOUTHERN CALIFORNIA, Los Angeles, CA

Abstract Body:

Demographic inference of a population not only sheds light on its population size and migration histories, but also serves as a null model for patterns of genetic variation, from which one can further construct non-neutral evolutionary models. However, traditional methods to reconstruct demographies from genetic data rely heavily on simplifying assumptions or summary statistics of the underlying genealogy, thereby undermining accuracy and/or flexibility of the results. For instance, populations are often assumed to be homogeneous with little or no migration, or that the genealogical tree is trimmed, losing subtle information contributed by ancient population histories. Here we propose a genealogical likelihood framework, gLike, to derive the likelihood of an ancestral recombination graph (ARG) given a proposed demography. Intuitively, we use a continuous time Markov process to describe the migration of lineages among populations, and the coalescence of lineages within the same population. A given genealogical tree may result from different traveling histories of the lineages (called paths), and the total probability of the tree is the summation over all possible paths. Implemented with maximum likelihood methods, gLike gives the most plausible demography to explain the observed ARG. The fact that our method is directly based on the ARG — rather than genetic data as in previous methods — lessens the assumptions and dependence about the mutation process, and naturally connects the flexibility of the ARG structure with the variety of demographic models, especially those with complex admixtures. Through extensive simulations on hundreds of samples, we show that demographic parameters estimated by gLike are unbiased and more accurate compared with existing non-ARG-based methods. Our work sheds light on the stochastic process of the formation of a genealogy under an arbitrary population history, which may facilitate investigations into genetic questions such as the areas including population structure analysis and history of genetic disease alleles. To our knowledge, gLike is the first full likelihood demographic model inference method based on the ARG, and because our framework requires only few light assumptions, we expect it to be a firm foundation on which other applicable theories or methods about the ARG could be built.

Evolutionary and Population Genetics Posters - Wednesday

PB2756. A robust kinship inference approach based on machine learning method for missing person identification

Authors:

M. Huang; Univ. of North Texas Hlth.Sci. Ctr., Fort worth, TX

Abstract Body:

Estimating the relationships between individuals is the fundamental component of missing person identification. Recent advances in whole genome sequencing (WGS) and genotyping microarray technology have enabled rapid profiling of millions of single nucleotide polymorphisms (SNPs), which provides much higher cumulative discrimination power than that of the traditional Short Tandem Repeats (STRs) analysis. However, for missing persons cases, the samples (e.g., bones) are usually highly degraded, and ancestry information of these samples are usually unknown. Thus, the genotyping error of these samples could be high (e.g., ~5% or higher depending on the quality filtering of the data). The Identity-by-Descent (IBD) segment measures can be easily interrupted by genotyping errors, but the genome-wide relatedness measures (e.g., King-robust) that are based on individual markers may be more robust to errors. In this study, we describe a machine learning approach that combines 17 genome-wide relatedness measures to train classification models aiming to reduce the effect of genotyping error and improve the accuracy of relationship estimation. A hierarchical classification strategy was implemented, in which a top-level classifier was to determine the relationship degrees (e.g., 1st, 2nd, 3rd, and unrelated) and three second-level classifiers were for determining the specific relationships within each degree. (e.g., parent-child or full-sibling for 1st degree). Both simulated and real datasets with various error rates (from 1% to 10%) were used to train and test the classifiers. The results showed that this approach outperformed the individual measures (e.g., KING-robust). In addition, higher accuracies could be obtained using the training sets with the correct error rates (i.e., training and test datasets share the same error rate). This new approach also had a robust performance with lower density SNPs (e.g., as low as 50K).

Evolutionary and Population Genetics Posters - Thursday

PB2757. Addressing population stratification in GWAS with variational autoencoders.

Authors:

D. Yang, J. Bartlett, W. Bush; Case Western Reserve Univ., Cleveland, OH

Abstract Body:

Variational autoencoders (VAEs) are generative deep learning models in which a mirrored pair of neural networks seek to first compress a set of input variables into a low-dimensional latent space and then recreate the input data to provide a measure of information loss due to the compression. Unlike the more standard principal components analysis (PCA), they can incorporate non-linear relationships that allow a low dimensionality representation within a latent space with better preservation of global geometry. Recently, VAEs have been adopted for single-cell sequencing and transcriptome and methylome data analysis because of their high capacity to manage large-scale datasets. Population stratification acts as an omnipresent threat to the validity of genome-wide association studies (GWAS) that could cause spurious associations of risk factors to diseases. Traditionally, PCA has been used for visualization and inference of population structure in genotype data but often results in multiple dimensions capturing linear patterns only. Here, we explored the utility of VAEs for addressing population stratification in GWAS using popvae (Batty *et al.* 2020) that took unphased genotypes from unrelated individuals from the Alzheimer's Disease Sequencing Project dataset (n = 14,604) to train the popvae algorithm and obtained sampled coordinates in a two-dimensional latent space that captures subtle aspects of individuals' ancestral information. We compared the results from popvae, PCA, and K-means methods to the self-reported ancestry via visualization. Then we conducted GWAS of common variants using the latent coordinates as ancestry estimation and contrasted performance to adjustments for PCs. We used the genomic inflation factor (λ) and identified risk factors for quality assessment. Popvae classified all samples into five distinct clusters with only two dimensions compared to ten PCs with PCA. Between our classifications and self-reported ancestry, we found higher rates of agreement for non-Hispanic Black and Hispanic groups than the non-Hispanic White, non-Hispanic Asian, and other non-Hispanic populations. We identified a similar λ value (VAEs: 1.28; PCA: 1.14) and significant risk factors near the *APOE* gene and the *APP* gene. Overall, VAEs are a promising new approach that may allow an equivalent or better identification of genetic ancestry components and subgroups for genetic association analyses that expend fewer degrees of freedom than PCA, especially in the setting of large-scale data with multi-ancestry samples. They could also be integrated into many other multi-omics analyses to improve the performance of dimensionality reduction tasks.

Evolutionary and Population Genetics Posters - Wednesday

PB2758. Analysis of evolutionary pressure on gene expression identifies patterns of selection in tissues and disease

Authors:

A. Sartori¹, T. Dupuis², E. T. Dermitzakis¹, A. A. Brown²; ¹Université de Genève, Dept. of Genetic Med. and Dev., Genève, Switzerland, ²Univ. of Dundee Sch. of Med., Dundee, United Kingdom

Abstract Body:

As our collections of populations and species with DNA sequence expands, across multiple species, geographical regions and time-frames with ancient DNA, so does our ability to identify regions of the genome either conserved due to negative selection or under more recent selection specific to the environment. In parallel, molecular studies and disease genetics studies provide information on how the genome functions: taken together, these can help us understand the mechanisms by which natural selection has shaped human populations. Using expression data from 48 GTEx tissues, we defined sets of specifically expressed genes (2560 genes per tissue, Wilcoxon p value $< 4E-22$) and looked for evidence that molecular processes in those tissues were more likely to be under selection. We found significant evidence that genes specific to esophagus (p value = $4.9E-05$), stomach (p value = 0.001) and colon sigmoid (p value = 0.03), part of the digestive system, were more likely to be under recent selection than genes specific to our chosen baseline tissue whole blood, consistent with different dietary pressures, as well as genes specific to the cerebellum (p value = 0.003) and cerebellum hemisphere (p value = 0.04) regions of the brain. These regions are central to physical movement, underpinning our development into *Homo erectus*. In contrast, genes specific to the amygdala (p value = $7.5E-24$) and hippocampus (p value = $8.4E-33$) are significantly more likely to be conserved across primates; the amygdala is central to vigilance and threat detection, crucial to survival across species. Both regions are part of the limbic system, hippocampus controls sexual behavior and the ovary's reproductive functions. Our results also allow us to re-evaluate known findings of positive selection: investigating the *LCT* gene which allows Northern Europeans to digest milk and the *EPAS1* gene which aids survival at high altitude, we see the former is specific to the small intestine and the latter to whole blood, artery tissue and lungs. Finally, we used the PhenomeXcan database to identify genes associated to 21 diseases. We found that genes associated with three autoimmune diseases, T1D, Lupus and IBD, were more likely to be under recent positive selection in Europeans than East Asians. Such diseases have also higher incidence in Europeans, explaining their larger effect on survival and reproduction there. This result also suggests that risk alleles for these diseases may be being purged from European populations, highlighting the need for genetic studies to use a wide and diverse range of populations.

Evolutionary and Population Genetics Posters - Thursday

PB2759. Analysis of human disease variants from ancestrally diverse Asian genomes

Authors:

S. Chan¹, Y. Bylstra², P. Tan^{2,3,4}, S. S. Jamuar⁵, J. NGEOW^{1,6}, W. Lim², SG10K_Health Consortium; ¹Natl. Cancer Ctr. Singapore, Singapore, Singapore, ²SingHlth.Duke-NUS Inst. of Precision Med., Singapore, Singapore, ³Genome Inst. of Singapore, Agency for Sci., Technology and Res., Singapore, Singapore, ⁴Precision Hlth.Res. Singapore (PRECISE), Singapore, Singapore, ⁵KK Women's and Children's Hosp., Singapore, Singapore, ⁶Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore

Abstract Body:

Despite comprising most of the global population, Asian populations remain poorly characterized in terms of genetic epidemiology of disease given their under-representation in human genomics research. In this study, we characterized clinically significant genetic variation for monogenic disorders and pharmacogenomics from 9,051 human genomes representing populations of East Asian, South Asian and severely under-represented Austronesian-speaking Southeast Asian ancestries. Of the sequenced individuals, 3.4% (309/9,051) harbored a medically actionable pathogenic variant in at least one of the 73 genes in the American College of Medical Genetics and Genomics (ACMG) list for reporting secondary findings (SF v3.0), and an additional 1.6% (148/9,051) of individuals carrying variants of uncertain significance with potential for pathogenic classification upon further clinical or experimental evidence. Twenty-seven percent (10/37) of genes linked to severe recessive disorders with appreciable carrier frequencies in Asians are currently missed by carrier screening panels, and we conservatively estimated 0.5% Asian couples at risk of having an affected child. At the population level, disparate burden of genetic risks attributable to ancestry-specific recurrent variants were observed, however, we also detected individuals harboring pathogenic variants highly specific to ancestries discordant to their self-reported ethnicity, mostly due to cryptic admixture. Beyond genetic disease risk, examination of the pharmacogenomic landscape revealed that 99.7% of sequenced individuals carried at least one actionable pharmacogenetic finding in 23 pharmacogenes with high confidence gene-drug associations; predominantly driven by the high frequency of the Asian-prevalent *VKORC1* rs9923231 allele affecting sensitivity to warfarin. Combining pharmacogenomics with genetic risk assessment revealed that 22.5% (32/142) of Asians predisposed to Centers for Disease Control and Prevention (CDC) Tier 1 genetic conditions would benefit from pre-emptive pharmacogenomics for therapy optimization. Our findings illustrate the genetic variability related to human disease in Asians, providing insights towards understanding genetic epidemiology of disease and improving delivery of precision medicine in a large, diverse and substantially under-represented population.

Evolutionary and Population Genetics Posters - Wednesday

PB2760. Analysis of Latvian genome diversity combining the whole-genome sequencing with genome-wide genotyping data.

Authors:

J. Klovins, R. Rescenko, M. Briviba; Latvian BioMed. Res. and Study Ctr., Riga, Latvia

Abstract Body:

Establishing a population-specific genome variation reference is an obvious step needed to implement genome-based applicability into personalized medicine. As a pilot, to achieve this goal, we have performed whole-genome sequencing of 600 individuals from a population-based cohort included in the Genome Database of Latvian Population (LGDB). We provide the first information on the quality and composition of variants obtained from this experiment. The resulting data were cross-validated with genotypes obtained by an Illumina GWAS chip from the same individuals with high concordance between both platforms. We also included 4500 genotyped samples from the LGDB to evaluate the Latvian population's genetic structure and ancestry admixture. We observed a distinct population stratification of the Latvian sample based on ethnic and regional origin. Self-reported ethnicity correlated to a high degree with the composition of ancestral populations in admixture analysis compared with data from neighboring countries. The group of people with Latvian ethnicity displayed an unusually high proportion of Western Hunter-gatherer ancestry compared to other populations. We also demonstrate significantly improved imputation of low-frequency variants using a haplotype reference panel specific to the Latvian population. This study provides the most extensive to-date analysis of genetic variation in Latvia, providing a background for a public reference resource. Our results show that the genetic composition of the Latvian population is uniquely formed and should be considered an essential factor in future genetic and biomedical studies.

Evolutionary and Population Genetics Posters - Thursday

PB2761. Ancestral genetic tracing defies socio-cultural structure in the north western human populations of India

Authors:

A. Singh^{1,2}, M. Thakur², V. Sahajpal³, S. Kumar¹; ¹Natl. forensic Sci.s Univ., Gandhinagar, India, ²Zoological Survey of India, Kolkata, India, ³State Forensic Sci. Lab., Shimla, India

Abstract Body:

The Himalayas, a mountainous home of varied ethnic populations is one of the most undisturbed regions considering the tough terrain and climatic conditions. Several populations of the north-western Himalayas followed strict social barriers for thousands of years culminating in the present caste endogamy. With this preserved genetic pool based on the caste system, genetic differentiation among the Himalayan populations must follow social division. However, prior migrations and demographic changes may have impacted the genetic makeup of the populations, which must be analyzed on a bigger scale. Based on 20 STRs, we obtained the genetic data of 1005 unrelated individuals from 12 groups from the high elevational locations of India's north-western Himalayas. Most of these populations adhere to stringent marriage traditions within their caste, which reduces the likelihood of shared genetic components leading to population sub-structure. Both Bayesian and non-Bayesian studies, however, indicated a paucity of population substructure, indicating extensive ancestral mixing and panmixia. Regardless of caste or socioeconomic structure, majority of the populations demonstrated close genetic connections. However, when compared to the other groups of the central and eastern Himalayas, the inhabitants of the western Himalayas grouped indicating geographical boundaries of the Himalayan regions. These findings show that the genetic structure of western Himalayan populations is panmictic, defying the ancestral gradient associated with the caste system.

Evolutionary and Population Genetics Posters - Wednesday

PB2762. Ancestral haplotype prediction using neural networks

Authors:

S. Belsare, A. D. Kern; Univ. of Oregon, Eugene, OR

Abstract Body:

Reconstructing the genealogy of a sample of DNA sequences in the form of an Ancestral Recombination Graph (ARG) can give access to the history of that sample, and help gain insights into the biological processes that gives rise to that set of sequences or individuals. Indeed recently, approaches aimed at ARG reconstruction have matured to the point of application in studying the genetics of related individuals and understanding evolutionary events.

A key step in inferring genealogies is generating the ancestral haplotypes at internal nodes in the tree which gives rise to the sample of interest. Existing methods for inferring ancestral haplotypes use heuristic approaches, e.g. generating consensus haplotypes from extant sequences. We present here a deep learning based method to improve ancestral haplotype inference. This method trains neural networks on simulated data of extant and ancestral sequences to predict ancestral haplotype segments. We show that our predicted ancestral haplotype segments from the neural network are more accurate than existing heuristic approaches. Full length ancestral haplotypes are then generated by algorithmic concatenation of the predicted segments. We incorporate our neural network haplotype predictions into existing genealogy inference methods and demonstrate better performance of our predictions by comparing reconstructed trees resulting from these methods with tree comparison metrics.

Evolutionary and Population Genetics Posters - Thursday

PB2763. Ancient trans-species polymorphism at the Major Histocompatibility Complex in primates

Authors:

A. Fortier, J. Pritchard; Stanford Univ., Stanford, CA

Abstract Body:

Genes within the Major Histocompatibility Complex (MHC) are responsible for peptide presentation to T cells, thus playing a central role in immune defense against pathogens. These genes are subject to strong selective pressures including both balancing and directional selection, resulting in exceptional genetic diversity---thousands of alleles per gene! Moreover, some alleles appear to be shared between primate species, a phenomenon known as Trans-Species Polymorphism (TSP) or Incomplete Lineage Sorting, which is rare in the genome overall. However, despite the clinical and evolutionary importance of *MHC* diversity, we currently lack a full picture of primate *MHC* evolution. To start addressing this gap, we used Bayesian phylogenetic methods to determine the extent of TSP at six classical *MHC* genes. We find strong support for TSP in all six genes, including between humans and old-world monkeys in *HLA-DRB1* and even, remarkably, between humans and new-world monkeys in *HLA-DQB1*. Despite the long-term persistence of ancient lineages, we observe rapid evolution at amino acids within the peptide-binding domain. The most rapidly evolving positions are also strongly enriched for autoimmune and infection disease associations. Together, these results suggest complex selective forces arising from differential binding of pathogen peptides, which drive short-term allelic turnover within lineages while also maintaining deeply divergent lineages for at least 40 million years.

PB2764. Ancient virome analyses of ancient individuals who lived in the Japanese archipelago

Authors:

L. Nishimura^{1,2}, R. Sugimoto³, H. Kanzawa-Kiriyama⁴, K. Shinoda⁴, I. Inoue^{3,2}; ¹Natl. Inst. of Genetics, Mishima, Japan, ²The Graduate Univ. for Advanced Studies (SOKENDAI), Mishima, Japan, ³Natl. Inst. of Genetics, Mishima, Japan, ⁴Natl. Museum of Nature and Sci., Tsukuba, Japan

Abstract Body:

Ancient viral sequences have been discovered in historical samples such as bones, teeth, and mummified tissues. Various ancient human pathogenic viruses have been discovered since the RNA of ancient influenza viral was analyzed in 1997. Those ancient viruses help elucidate past pandemic events and long-term viral evolution. However, the number of discovered ancient viruses has been limited. Here, we analyzed whole genomic sequencing (WGS) data derived from ancient individuals who lived in the Japanese archipelago for more than thousands of years to discover ancient viruses. We conducted several bioinformatic analyses to detect the ancient viruses from WGS data: de novo assembly to obtain longer sequences, contigs and reads alignment to known viral reference sequences, metagenomic profiling, and non-homologous viral detection using CRISPR immunological memories of host bacteria. Firstly, we recovered an almost complete sequence of Siphovirus contig89 (CT89) by assembling and characterized its genomic features. Based on its genomic characteristic, we compared the ancient CT89 genomes and modern ones to comprehend the long-term evolution of the CT89 virus. The result indicated that the most recent common ancestor of CT89 was around 7,900 years ago. We also detected five ancient viral sequences that did not show homology with modern viral sequences. It might reflect highly diverged or extinct ancient viral genomes. Then, we characterized ancient viromes of each ancient individual based on the reads alignment results and metagenomic profiling. It revealed the differences between ancient and modern Japanese viromes, and it might reflect the different dietary behavior of ancient people. Overall, our results suggested that the ancient viral analyses might be useful for understanding the existence of viruses in the past and long-term viral evolution.

Evolutionary and Population Genetics Posters - Wednesday

PB2765. Between-population genetic differences for human complex traits

Authors:

V. Hivert¹, J. A. Revez¹, M. E. Goddard^{2,3}, N. R. Wray^{1,4}, L. Yengo¹, P. M. Visscher¹; ¹Inst. for Molecular BioSci., The Univ. of Queensland, Brisbane, QLD 4072, Australia, ²Agriculture Victoria Res., Agribio, 5 Ring Road, Bundoora, VIC 3083, Australia, ³Faculty of Vet. & Agricultural Sci., Univ. of Melbourne, Parkville, VIC 3010, Australia, ⁴Queensland Brain Inst., The Univ. of Queensland, Brisbane, QLD 4072, Australia, Australia

Abstract Body:

It is notoriously difficult to draw inference about between-population phenotypic differences using genetic data, because there are many reasons why genetic differences between populations do not lead to phenotypic differences and, conversely, why phenotypic differences are not caused by genetic factors, especially in human populations. Environmental or cultural effects, gene-by-environment and gene-by-gene interactions, and natural selection can all cause observed phenotypic mean differences to deviate from genetic differences. Here, we ask what between-population differences are expected for human complex traits, assuming a simple neutral and additive model of population divergence, in the absence of genotype-by-environment interaction or covariance. Under such a model, the expected mean genetic difference is zero but the variance of the difference is not. When estimating genetic means from Genome-Wide Association Study (GWAS) data, the expected variance of the mean difference in polygenic scores between any pair of populations equal twice the among-population additive genetic variance explained by the markers used in the score. We perform a simulation study to validate theoretical expectations of between-population differences that we derive as a function of parameters we can observe from genetic data, such as the fixation index (F_{ST}) and the within-population heritability of a trait (h^2_w). Under this demo-genetic model, meaningful between-population genetic and, given our assumptions, phenotypic differences are possible. For example, for European and African populations with $F_{ST}=0.14$, and the traits height and schizophrenia (both $h^2_w=0.7$), we would expect the standard deviation of the between-population phenotypic difference for height to be 2.8cm, and the expected range in lifetime prevalence of schizophrenia to differ by more than 100-fold. Finally, we show that our results still hold when simulating a more realistic model of human evolution including different demographic events.

Evolutionary and Population Genetics Posters - Thursday

PB2766. Biological functions and spatial distribution of rapidly evolving brain-expressed genes in the human lineage

Authors:

T. Ajumobi¹, A. DeCasien¹, K. Wagstyl², A. Raznahan¹; ¹NIMH Intramural Res. Program, NIH, Bethesda, MD, ²Wellcome Ctr. for Human Neuroimaging, Univ. Coll. London, London, UK, London, United Kingdom

Abstract Body:

Distinct features of the human brain are likely to reflect evolutionary modifications of human genome structure (e.g. DNA sequence) and function (e.g. gene expression) in the human lineage. However, it remains unclear how these two modes of evolution are related at the gene-level and whether genes that differ in these signatures also differ in their neurobiology. Here, we estimated sequence divergence (SD) and expression divergence (ED) for N=7108 genes with 1:1 homologs between humans and chimpanzees and human and rhesus macaques (Aim 1); compared the functions of genes with high SD or high ED (Aim 2); identified genes that may have been particularly critical to human brain evolution as those exhibiting simultaneously high SD and ED (Aim 3); and provided functional and spatial annotations for these genes (Aim 4). We estimated: i) sequence divergence as the rate of nonsynonymous to synonymous changes (dN/dS) in the human lineage (since our last common ancestor with chimpanzees); and ii) expression divergence as the average difference in expression level between human vs. chimpanzee and human vs. macaque brain tissues. We found that genes tend to exhibit either high SD or high ED ($\rho < 0.2$, Aim 1), genes exhibiting brain-specific expression patterns exhibit lower SD but higher ED than non-brain-specific genes, high ED genes are associated with brain development while high SD genes are associated with general biological processes (Aim 2). We then identified N=99 genes with simultaneously high SD and ED (Aim 3) and found that these genes are collectively most highly expressed in cortical areas that have undergone most marked expansion during human evolution ($\rho = 0.432$; $p_{\text{spin}} = 0.027$) (Aim 4). Furthermore, these high ED and high SD genes are enriched within spatially derived co-expression networks that are associated with radial glial cells and autism. These findings indicate that changes in gene sequence and gene expression represent two largely dissociable evolutionary signals in the human lineage and intersect with different neurobiological processes. The few genes that show both these evolutionary signatures are highly expressed in cortical regions that have undergone marked evolutionary expansion and are associated with early brain development and genetic risks for neurodevelopmental disorders.

Evolutionary and Population Genetics Posters - Wednesday

PB2767. CAFE: Ancestry and genotype calling uncertainty-adjusted ancestry-specific allele frequency estimation from admixed samples.

Authors:

J. Wang¹, S. Zöllner^{1,2}; ¹Dept. of Biostatistics, Univ. of Michigan, Ann Arbor, MI, ²Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Estimates of allele frequency distributions across different populations provide important insights into the transferability of GWAS results, population-specific drivers of disease etiologies, and interpopulation demographic histories. Allele frequencies from recently admixed groups are often more difficult to interpret in this context due to heterogeneous ancestry background of each allele. Existing methods proposed to deconstruct the allele frequencies of the underlying ancestral groups from admixed samples are typically based on “best-guess” local ancestries and genotypes. These methods ignore uncertainty in local ancestry and genotype calling, which can bias the allele frequency estimates especially for rare variants and can overestimate the differentiation among ancestral groups.

Here, we present CAFE, a novel local ancestry based method for estimating ancestry-specific allele frequency, which adjusts for ancestry and genotype calling uncertainty. CAFE is an Expectation-Maximization (EM) algorithm and it informs allele frequency estimates by averaging individual genotype dosages characterized by probabilistic local ancestry calls, genotype calling uncertainties and estimated allele frequency distributions. CAFE is capable of interpreting large-scale ($N > 10,000$) phased or unphased data generated from array-based or sequence-based genotyping techniques and of multi-way admixture patterns. In simulation studies, we evaluated the impact of allele frequency distribution, population structure, genotyping error rate, sequencing error rate and depth, and sample size on the estimates obtained from CAFE and from methods not adjusting for the uncertainty. The results demonstrate high estimation accuracy of CAFE in both array-based and sequence-based genotyping data (Pearson’s R with true values > 0.999). The simulation studies also demonstrate that ignoring the uncertainty inflates bias in estimating allele frequencies 16-fold and 9-fold on average from array-based genotyping or low-depth sequencing data respectively, even with corresponding low error rates ($\sim 0.1\%$) and large sample size ($\sim 10K$). We further applied CAFE to 1000 Genomes sequencing data to estimate African allele frequencies and European allele frequencies from admixed African samples. The resulting allele frequency estimates are highly correlated with allele frequencies for their corresponding superpopulations (Pearson’s R, AFR = 0.995; EUR = 0.965). Thus, we provide a new, computationally efficient method that provides precise estimates of ancestral allele frequencies and can thus support the analysis of samples from recently admixed populations.

Evolutionary and Population Genetics Posters - Thursday

PB2768. Cardiovascular associations and signals of selection at the *Adrenergic Receptor Alpha-1A* gene (*ADRA1A*) in high-altitude Andeans.

Authors:

E. Moya, J. Reeves, W. Gu, E. Lawrence, J. Hall, T. Simonson; Univ. of California San Diego, La Jolla, CA

Abstract Body:

People living at high-altitude exhibit respiratory and cardiovascular adaptations to the stressful environment produced by hypoxic conditions that may be associated with genetic adaptations. Mechanisms involving adrenergic pathways are especially relevant, since adrenergic receptors have been involved in regulation of cardiovascular consequences observed in animal models exposed to hypoxia. We hypothesize that variants in the *Adrenergic Receptor Alpha-1A* gene (*ADRA1A*) underlie cardiovascular phenotypes in a high-altitude Andean population. We localized adaptive signals based on the composite of multiple selection scan, which demonstrated selection at the *ADRA1A* locus in both Andean and Tibetan populations. We identified a missense, non-synonymous variant (rs1048101, A>G, p.[Arg347Cys]) within the second exon of *ADRA1A* and examined its associations with cardiovascular phenotypes in an Andean population (N = 194). We found that the putatively adaptive A allele of rs1048101 is enriched in Peruvians compared to the rest of the world (both Andeans and Peruvian A allele frequency = 55%) and is associated with a lower chronic mountain sickness score ($p < 0.045$) and a higher heart rate in male participants when breathing room air ($p < 0.021$). We conclude that additional copies of the putatively adaptive allele A at rs1048101 are linked to beneficial physiological traits, such as lower prevalence of chronic mountain disease and increased heart rate, suggesting a potential adaptive role involving the *Adrenergic Receptor Alpha-1A* gene. Future studies in controlled models are necessary to establish the direct cellular and physiological consequences of this variant under hypoxic conditions.

Evolutionary and Population Genetics Posters - Wednesday

PB2769. Challenging continental groupings of humans using a data-driven approach.

Authors:

M. Palma Martínez¹, Y. Posadas García², C. Quiroz López³, T. Lasisi⁴, K. A. Bird⁵, A. Zaidi⁶, M. Sohail¹; ¹UNAM, Cuernavaca, Mexico, ²UASLP, San Luis Potosí, Mexico, ³ENAH, Ciudad de México, Mexico, ⁴Univ. of Southern California, Los Angeles, CA, ⁵Michigan State Univ., East Lansing, MI, ⁶Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Over the last decades, population geneticists have explicitly pushed back against the claim that humans can be grouped into commonly defined racial categories on the basis of genetic variation. Current approaches have used genetic ancestry as a grouping alternative. However, reliance on genetic ancestry as defined by continental groupings can lead to approaches that recapitulate racial thinking (Lewis et al., 2022). Here we use a data-driven approach to challenge the validity of continental groupings.

We reanalyze 1000G project and HGDP data using previously reported genetic metrics by the 1000G consortium. We show that many genomic signatures of interest are not structured by continental groupings. For example, the number of singletons found in 1000 Genomes populations showed patterns that superseded continental groupings (e.g. Finnish vs. British, Luhya vs. Yoruba, etc.).

The idea of continental groups is sometimes justified with ADMIXTURE-type analyses, where the inferred ancestry components are thought to represent ‘pure’ ancestral groups. We push against this framing by first showing that ADMIXTURE components do not represent ‘true’ underlying groups but are rather a function of the sample being analyzed. For example, we show that in the 1000G, ADMIXTURE detects within-continent substructure even before the emergence of all major continental labels. We also show that some components are shared across continents as exemplified by populations from Europe, South, and Central Asia (K=7). To further illustrate how sampling scheme affects ADMIXTURE inference, we show if only one or a few individuals from the JPT subpopulation are included in the analysis, the ADMIXTURE component corresponding to the JPT populations is no longer detected. Furthermore, inclusion of samples from underrepresented regions such as Africa and Asia leads to the emergence of new clusters, representing substructure inside continental groups. This also changes the order at which other pre-existing components are detected. This highlights the fact that ADMIXTURE results, although useful to understand population structure, represent statistical properties of the data rather than some ground truth about continental ancestry.

Our results emphasize the fact that population genetic variation tracks differences in demographic history rather than arbitrarily defined continental groups and that such groups are often not useful for applications in human genetics. We also caution against the use of typological thinking whereby reference populations within a continent are treated as “type specimens” that accurately represent all other populations within that continent.

Evolutionary and Population Genetics Posters - Thursday

PB2770. Characterizing the origin of African ancestral tracts in admixed individuals of the UK Biobank

Authors:

N. N. Shah, T. Tan, G. E. Tietz, E. G. Atkinson; Baylor Coll. of Med., Houston, TX

Abstract Body:

High-throughput genome sequencing has allowed for fine characterization of genetic ancestry leading to better understanding of the complex demographic and migratory history of diverse human populations. Recent genetic studies have elucidated and confirmed the historical records of major demographic events and the timeline of when admixture occurred for multiple admixed American populations. However, limited work has thus far investigated the ancestral origins of African ancestry in admixed European populations.

Here, we characterize the geographic origin and demographic history of the African components of modern admixed individuals of the UK Biobank (UKB) to sub-continental resolution. Using a subset of ~4,500 two-way admixed African-European UKB individuals, we explore the population structure of these individuals using both allele frequency and local ancestry informed methods, and construct a demographic model for this population. We performed PCA and ADMIXTURE analyses, followed by ancestry-specific PCA (ASPCA) to identify the fine-scale geographic areas within the African continent from which African local ancestry tracts in our admixed sample derive. We conducted ASPCA in two steps - first, PCAdmix was used for local ancestry estimations, and then each ancestry was independently masked to be projected against a reference population of continental African and European populations from the 1000 Genomes Project and African Genome Variation Project. We observed highly variable proportions of African ancestry, with an average of ~56% of West-Central and West African ancestry. To characterize the demographic history of these admixed African descent UKB participants, we analyzed the length of African ancestry tract segments to understand how recently in the past pulses of admixture occurred. We did this by testing different demographic models fitting a variety of potential migration histories using the Tracts software program, which utilizes local ancestry inference calls.

In sum, we quantified and investigated that African haplotypes in a subset of admixed UKB individuals, tracing the bulk of tracts in this cohort back to the West-Central African ancestral origins, and identified the optimal demographic model for two-way admixed African-European individuals in the UKB. This knowledge sheds light on the fine-scale ancestral history of modern European individuals of the African diaspora. Further it will help inform the anticipated patterns of genetic variation in diverse admixed cohorts which is vital for optimal benchmarking and calibration of statistical methods.

Evolutionary and Population Genetics Posters - Wednesday

PB2771. *Cis*-regulatory genetic variants influence distinct expression profiles of adipose and muscle tissue transcripts between African and European ancestry individuals.

Authors:

C. Langefeld, M. Comeau, S. Das; Wake Forest Univ. Sch. of Med., Winston-Salem, NC

Abstract Body:

Genetic regulation of transcription plays a key role in the etiology of many diseases. Genetic regulatory variants may contribute to the ethnic disparities in disease predisposition by generating variability in transcript expression among different populations. Here we utilized adipose and muscle tissue expression data to identify differences in gene expression between individuals of African and European ancestry. European Americans (EA, N=99) and African Americans (AA, N=36) from the Arkansas metabolic study cohort were simultaneously metabolically phenotyped, molecularly profiled (transcript expression by Illumina HT12-V4 chip and RNA-seq), and genotyped (Illumina Infinium Omni5Exome-4 Chip) using the same methods. Self-identified race and genotype-defined admixture were used as predictors in two different linear regression models adjusting for age, sex, and BMI. We identified 505 and 297 genes in adipose and muscle tissue, respectively; exhibiting differential expression between AAs and EAs or associated with African admixture (FDR<0.05). Increased expression of nine genes (e.g., GSTM3, GSTT2B, CRYBB2) and lower expression of 20 genes (e.g., NARS2, DHRS4, SLC25A26) was observed in both adipose and muscle tissue of AAs compared to EAs. Pathway enrichment analysis suggested decreased expression of mitochondrial genes and higher xenobiotics metabolism genes in AAs. Expression quantitative trait analysis identified *cis*-regulatory SNPs (*cis*-eSNPs) for a subset of these transcripts (FDR<0.05) in the EA cohort or AAs from AAGMEx (N=256). To test the effect of genetic variants on differential expression of transcripts between African and European ancestry individuals, we recomputed linear regression by including the top *cis*-eSNP genotypes for each transcript as covariates in the model. Adjustment for *cis*-eSNPs removed statistical significance of differential expression >2 log-scale for 144 (64.9%) and 65 (46.4%) transcripts in adipose and muscle, respectively. Current work is exploring the impact of both allele frequency and linkage disequilibrium on the observed patterns. In summary, this study suggests a significant contribution of *cis*-eSNPs in determining the differential expression of transcripts between population groups.

Evolutionary and Population Genetics Posters - Thursday

PB2772. Coding variants associated with healthy aging: Findings from the Long Life Family Study (LLFS)

Authors:

T. Gunasekaran¹, R. Cheng^{1,2}, B. Thyagarajan³, A. I. Yashin⁴, T. T. Perls⁵, J. M. Zmuda⁶, M. A. Province⁷, S. Cosentino^{1,2}, N. Schupf^{1,2}, J. H. Lee^{1,2}, B. Vardarajan^{1,2,8}; ¹The Gertrude H. Sergievsky Ctr., Columbia Univ., New York, NY, ²Taub Inst. for Res. on Alzheimer's Disease and the Aging Brain, Columbia Univ., New York, NY, ³Dept. of Lab. Med. and Pathology, Univ. of Minnesota, Minneapolis, MN, ⁴Duke Univ., Durham, NC, ⁵Boston Univ. Sch. of Med., Boston, MA, ⁶Dept. of Epidemiology, Univ. of Pittsburgh, Pittsburgh, PA, ⁷Washington Univ. Sch. of Med., St. Louis, MO, ⁸Dept. of Neurology, Columbia Univ., New York, NY

Abstract Body:

Background: Exceptional longevity (EL) is a complex trait that is likely the result of an interaction between environmental, behavioral, genetic and stochastic factors. Over 20 genetic loci have been associated with healthy aging and several were implicated in aging-related diseases. Identifying the genetic determinants of EL could also lead to the discovery of genes that affect the rate of aging and predisposition for or against age-related diseases. Such discoveries would be helpful in the prediction, prevention and treatment of age-related diseases as well as predictors of and strategies for healthy aging. **Methods:** We selected 420 unrelated individuals of European ancestry from the Long Life Family Study (LLFS) families (one per family). Individuals were selected with the least summary disease score (SDS) defined as the sum of the presence (1) or absence (0) of phenotypes in eight health domains - heart disease, stroke, lung disease, hypertension, diabetes, peripheral artery disease, cancer and dementia. Elderly individuals of the same genetic background were selected from Washington Heights and Inwood Community Ageing Project (WHICAP) as controls. Whole exome sequencing (WES) was conducted followed by joint variant calling, QC and annotation. We conducted single marker and gene-burden analysis to identify variants enriched for EL in LLFS cohort and compared minor allele frequencies (MAF) with variants in gnomAD. **Results:** Single marker analysis identified rs28357075 in *C4A* ($p=2.95E-06$, MAF=0.13), rs201667800 in *FAM185A* ($p=5.35E-06$, MAF=0.19), rs1809279 in *NPEPPS* ($p=3.69E-04$, MAF=0.07) and rs140030732 ($p=3.75E-04$, MAF=0.009) in *TET1* associated with EL. In gene-based rare variant analyses, *HLA-DRB1* was the strongest association (nvariants=11, $p=3.89E-13$) detected with EL phenotype. In addition, associations in *PABPC1* (nvariants=4, $p=6.47E-13$) and *PRKRA* (nvariants=8, $p=6.25E-12$) genes were detected at genome-wide significance threshold. Genes with variants enriched in the LLFS samples were involved in exonuclease activity and galactose metabolism pathways. Genes depleted in EL were involved in disease risk pathways including auto-immune diseases, diabetes, peptidase activity and response to stress. **Conclusion:** WES in individuals with EL identified multiple genetic loci that have been previously associated with longevity, cancer and aging related phenotypes such as Alzheimer's Disease. This suggests that the genes identified in EL are likely to confer protection against the common diseases and eventually promoting longer life span.

Evolutionary and Population Genetics Posters - Wednesday

PB2773. Comparing human centromeres with TandemAligner

Authors:

A. Bzikadze, P. A. Pevzner; UC San Diego, La Jolla, CA

Abstract Body:

Recent advances in long-read sequencing technologies led to rapid progress in centromere assembly. We previously presented *centroFlye* — the first tool for centromere assembly from long error-prone reads. In 2019, we joined efforts with the Telomere-to-Telomere Consortium that, in Apr 2022, published a landmark achievement — the complete sequence of a human genome that includes sequences of all centromeres. This progress opens a possibility to address the long-standing questions about the centromere architecture. Centromeres are formed by *extra-long tandem repeats* (ETRs) representing some of the most rapidly evolving regions of the human genome. Since variations in centromeres are linked to cancer and infertility, comparison of centromeres is an important task for understanding their evolution and genomic diversity. A common approach to variant calling is based on mapping reads that originated from the query genome to the target sequence. Provided assembled sequences of centromeres, the difficult problem of calling variants in centromeres is substituted by a seemingly simpler problem of alignment of their sequences. Surprisingly, there are no algorithms that approach that problem. At first glance, it appears that similarities between centromeres can be revealed by the standard sequence alignment based on dynamic programming. However, we show that it is an inadequate computational model for centromeres analysis since the highest-scoring pairwise alignment does not reveal the evolutionary events that made two centromeres different.

We propose the TandemAligner algorithm to address the ETR comparison problem and illustrate its performance using the centromere on chromosome X from a haploid cell line CHM13 (CHM13X) and from a male individual HG002 (HG002X). We define the *count* of a substring P in a string S as the number of occurrences of P in S and say that P is *rare* if its count in S does not exceed a defined threshold, and *frequent*, otherwise. Since ETRs are rich with frequent substrings, selecting a correct match between these substrings in two ETRs is challenging. Indeed, if the count of a substring P in string S (in string T) is N (M), the total number of matches is $N*M$. Instead, TandemAligner introduces a novel alignment scoring that prioritizes matches of rare substrings since they are more likely to be relevant to the evolutionary relationship between ETRs. It further finds the optimal alignment with respect to this scoring and attempts to reconstruct the evolutionary scenario that led to generation of CHM13X and HG002X from their common ancestor. We show that the mutation rate across centromeres substantially exceeds the average rate across the human genome.

Evolutionary and Population Genetics Posters - Thursday

PB2774. ConsensuSV - HPC-ready, ML-enhanced automated pipeline for Illumina-based variant detection.

Authors:

M. Chilinski^{1,2}, D. Plewczynski^{2,1}; ¹Warsaw Univ. of Technology, Warsaw, Poland, ²Univ. of Warsaw, Warsaw, Poland

Abstract Body:

We have developed two bioinformatics pipelines: ConsensuSV-core, and ConsensuSV-pipeline for the identification of several types of mutations in human DNA sequences of the whole genomes. The first algorithm serves the purpose of merging the calls from multiple, independent Structural Variant (SV) callers using consensus approach. For that purpose, we are using deep neural network, that we pretrained on New York Genome Center (NYGC) high-quality Illumina data. The algorithm itself is flexible, and can be easily retrained for any other sequencing method (for example Oxford Nanopore Sequencing, or PacBio), and other Structural Variant callers can be easily added. The second algorithm serves as a wrapper for the first one - it is high performance computing (HPC) ready pipeline for variant detection developed using luigi framework. It is completely automated, and incorporates using raw Illumina fastq data and aligning it accordingly to the Human Genome Structural Variation Consortium (HGVS) alignment recommendations. After the alignment step, 8 gold-standard SV callers are utilised, along with SNP and Indel caller. Finally, it merges the all sets of SVs using our ConsensuSV-core, that was pre-trained on two trios, and tested on third one from 1000 Genomes project (CHS, PUR, YRI). ConsensuSV-pipeline is open source software, and comes with Docker image (as well as Dockerfile), and complete documentation allowing super easy setup on personal computers and HPC centres. Availability: <https://github.com/SFGLab/ConsensuSV-pipeline> <https://github.com/SFGLab/ConsensuSV-core>

PB2775. Conservation and function of the *NXF2* palindrome in male fertility.

Authors:

A. Lawson, J. Mueller; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Large (>10kb), nearly identical (>99% nucleotide identity) palindromes harbor genes with testis-biased expression and are enriched on the mammalian X and Y chromosomes. Previous studies have identified the independent acquisition of large X- and Y-linked palindromes; however, whether some X-palindromes are deeply conserved across mammals remains unclear. We hypothesize some mammalian X-palindromes are as old as the origin of the sex chromosomes and persisted to benefit male fertility. To determine the extent of X-palindrome conservation across mammals, we are sequencing and assembling putative palindromic regions across seven mammalian species based upon their known conservation across primates. To study the function of ancient palindrome-associated genes, we selected nuclear export factor 2 gene *Nxf2*, a gene family harbored in a X-palindrome conserved across mammals. Mouse *Nxf2* is necessary for male fertility, demonstrated by a previous study of *Nxf2*^{-Y} mice exhibiting age- and strain-dependent male germ cell depletion due to an unknown mechanism. We hypothesize mouse *Nxf2*-related sub/infertility is caused by failure to silence transposable elements (TE). This hypothesis is based on the observation that fly *nxf2* is necessary for TE silencing and mouse *Nxf1* suppresses transcripts harboring TEs. To study the role of mouse *Nxf2* in TE regulation we re-created the previously characterized *Nxf2*^{-Y} mice to assess TE activity and generated NXF2-3X-FLAG mice to assess the molecular mechanism by which *Nxf2* disruption results in spermatogenic defects. Understanding the extent of X-palindrome conservation throughout mammals will inform us to how large palindromes have shaped sex chromosome evolution and acquired roles in spermatogenesis.

Evolutionary and Population Genetics Posters - Thursday

PB2776. Continuous measures of genetic diversity in biomedical research.

Authors:

A. Dixit, A. Mañas, L. Seninge; Coral Genomics, San Francisco, CA

Abstract Body:

The use of discrete race or ethnicity categories in biomedicine and, more specifically, genetics research has a long and complex history. Their use risks reinforcing the false notion that there are a set of discrete biological types that map directly onto historical race categories. A possible alternative, would be to ignore such categories altogether. Such an approach risks exacerbating health disparities by leading to biomedical advances with poor applicability of predictions or interventions in diverse patient populations. The preceding points lead to a dilemma for researchers who want to advance biomedical research in an equitable, socially aware manner. A metric is presented for characterizing the representation of human diversity in clinical research without relying on categorial variables. A related metric is proposed for evaluating the performance of biological advances. Both metrics apply in the specific context that genetic data is available on the study population.

Our derivation of continuous metrics is based on a reference population that is as representative of global human diversity as possible (ex: panels incorporating 1000 Genomes, the All of Us initiative, UK Biobank, and H3Africa). The genetic diversity of the reference panel is encapsulated in a minimal set of orthogonal axes. These axes are constructed to be robust to genotyping platform. For each axis, the representation of diversity is compared to the study population and a continuous measure of the difference is derived based on information theory.

We apply this algorithm to both synthetic datasets and hundreds of previous genetic studies to quantify representation and diversity on a continuous basis for the first time at scale. Finally, we apply these diversity axes towards evaluating the performance of polygenic risk scores without resorting to categorical race or ethnicity labels.

Evolutionary and Population Genetics Posters - Wednesday

PB2777*. Contrasting patterns of positive selection at *Plasmodium falciparum* and *Plasmodium vivax* associated loci in Oman.

Authors:

P. Haffener¹, A. Z. Al-Riyami², S. Zadjali³, G. B. J. Busby⁴, M. Al-Rawahi⁵, S. Al Hosni², A. Al Marhoobi⁵, A. Al Sheriyani⁶, E. M. Leffler¹; ¹Univ. of Utah, Salt Lake City, UT, ²Sultan Qaboos Univ. Hosp., Muscat, Oman, ³Sultan Qaboos Comprehensive Cancer Ctr., Muscat, Oman, ⁴Allelica, New York, NY, ⁵Sultan Qaboos Univ., Muscat, Oman, ⁶Royal Oman Police Hosp., Muscat, Oman

Abstract Body:

Plasmodium falciparum and *P. vivax*, the two most common causes of malaria in humans, utilize distinct molecular strategies and have driven different human adaptations. *P. falciparum* tends to cause higher parasitemia resulting in more severe disease and is suggested to be a stronger selective pressure than *P. vivax*. Nevertheless, the Duffy null allele that removes an essential receptor for *P. vivax* invasion from red blood cells has strong evidence for natural selection in African and admixed African populations. Other variants have been associated with susceptibility to severe *P. falciparum* malaria. Like the Duffy null allele, these are more common in African populations and in populations with African admixture. Oman has had a long history of contact with African populations, in part due to East African settlements and trade of the Omani Empire. In addition, Oman has recently struggled with endemic *P. falciparum* and imported *P. vivax* malaria. To learn about the relative impact of the two parasite species in human populations, we aimed to contrast evidence for selection on loci associated with either *P. falciparum* or *P. vivax* malaria in Oman after their introduction through genetic admixture with African populations. We conducted whole genome sequencing of DNA collected from 100 healthy Omani blood donors and merged the resulting variant calls with the 1000 Genomes Phase 3 variant call set. We first assessed global ancestry proportions and found that, combined across all Omani genomes, about 1/5 of genetic ancestry was derived from African populations. To determine whether malaria-associated loci were introduced via admixture, we inferred local genetic ancestry and searched for significant deviations from genome-wide expectations. Although we did observe African ancestry on some haplotypes carrying alleles associated with protection from *P. falciparum* malaria, none displayed a significant excess of African ancestry relative to the genome-wide average. In contrast, we found that the Duffy null allele was at high frequency in Omanis (86%) and that this locus harbored the greatest excess of African ancestry across the entire genome. Interestingly, other tests for selection also did not reveal any signal at *P. falciparum*-associated loci, indicating that *P. falciparum* was likely not a strong selective pressure following historical admixture. We conclude that the excess of African ancestry at the Duffy null allele is the result of positive selection in response to pressure from *P. vivax* malaria and that the historical prevalence of *P. falciparum* may have been too low to provide sufficient protection to overcome the fitness costs of *P. falciparum*-associated alleles.

Evolutionary and Population Genetics Posters - Thursday

PB2778. *De novo* assembled and phased human genomes from Persian Arab trios show divergent and novel sequence versus CHM13 and GRCh38, providing valuable population specific reference genomes for middle eastern region.

Authors:

M. Ghorbani¹, I. Alazwani¹, S. Moosa¹, R. Razali², Z. Siddig¹, R. Mathew¹, M. Al Hashmi¹, A. El Khouly¹, S. Poolat¹, S. Tomei¹, K. Fakhro^{1,3,4}, E. Eichler⁵, Y. Mokrab^{1,3}; ¹Human Genetics Dept., Sidra Med., Doha, Qatar, ²Dept. of BioMed. Sci., Coll. of Hlth.Sci., Qatar Univ., Doha, Qatar, ³Dept. of Genetic Med., Weill Cornell Med., New York, NY, ⁴Coll. of Hlth.and Life Sci., Hamad Bin Khalifa Univ., Doha, Qatar, ⁵Washington Univ., Dept. of Genomic Sci., Seattle, WA

Abstract Body:

The genetic diversity of the Middle Eastern region is poorly captured in GRCh38 and the various reference genomes published to date. Genomic analysis of SNV and SV calls for both disease association studies and rare gene discovery were shown to be improved significantly using population-specific genomic references and annotations. Based on three family trios with Persian Arab ancestry from Qatar, we built *de novo* reference genomes using a combination of PacBio long-read sequencing (50-70X), Bionano optical mapping (70X), and Illumina short-read sequencing (30-60X). For four individuals from these trios, we generated high quality draft assemblies for both collapsed (N50 = 59.5-79.2 Mb) and haplotype-resolved using trio-based phasing (N50 = 10.3-22.7 Mb). Haplotypes were resolved accurately using independent assessment of assemblies by parental inherited short reads k-mers, showing 95~99% of k-mers being correctly placed in each haplotype. Also, high QV (quality value) values were achieved for the assemblies' haplotypes (range 34-38) which is equivalent to >99.9% accuracy. In terms of essential gene completeness, these assemblies contain >98% of essential genes from BUSCO analysis. In addition, our collapsed genome results scaffolds contiguity is comparable to that of GRCh38. Relative to the latest CHM13 T2T and GRCh38 references, our assemblies show novel sequence up to 15.2 Mb. Up to 24K SV calls were made versus GRCh38 and 22K SVs versus CHM13 T2T highlighting divergence relative to these references. This highlights the need for such references as population-specific tools to advance the understanding of genetic variants implicated in disease in the Middle Eastern region and beyond.

Evolutionary and Population Genetics Posters - Wednesday

PB2779. Detection of Genomic Regions undergoing Selection in post-Neolithic Transition

Authors:

C. Bhattacharyya¹, P. Ghosh¹, S. K. Paine¹, A. Basu²; ¹Natl. Inst. of BioMed. Genomics, Kalyani, India, ²Natl. Inst. of BioMed. Genomics, Kalyani, India

Abstract Body:

From early domestication of plants to a full-fledged settled agriculturist society, human populations have undergone several environmental and demographic changes. Altogether those changes might have put evolutionary pressure on the people who have adapted to the complex and sedentary agricultural lifestyle. Here, we hypothesize that people who adopted the practice of farming and formed large complex societies; manifest a footprint of recent positive selection in their genomes that has been advantageous in the changing environment. From the data generated in GenomeAsia100k Consortium, we selected 171 individuals from 15 large populations which are sedentary, complex in social relationships, dependent on an agrarian economy. We consider these populations as ones who were early to transform to an agrarian lifestyle. In contrast to these populations, we selected 166 individuals from 17 extant tribal populations who do not exhibit any of the above features of agrarian lifestyle, even today. To explore the signatures of selection in the trait(s) pertinent in transition to farming cultures, we have employed two types of test: 1) Population Branch Statistic (PBS), that identifies variants whose frequency has significantly altered in 'agriculturist' compared to 'non-agriculturist' when compared against an outgroup population 2) cross-population Extended Haplotype Homozygosity (XP-EHH), which identifies recently selected long-haplotypes among 'agriculturists'. After stringent filtering, we identified 347 variants with PBS scores above 99th percentile, clustering into 29 unique 1MB regions of the genome and 1603 variants with significantly high post-adjustment XP-EHH score (more than 4) clustering into 7 genomic regions. Significant genes from the regions identified through PBS are COL12A1, CALCR, KITLG, ANO5, NELL1; which are associated with mineralization of bones and protection from osteoporosis. Our top hit region identified through XP-EHH contains 894 variants (mean adjusted score 5.9, SD 1.5), is chr15:48416360-48891965, spanning the genes SLC12A1, DUT, FBN1 which strongly impacts kidney function. SLC12A1 is a major sodium potassium chloride cotransporter, mostly expressed in the thick ascending limb of the loop of Henle. We propose that changes in genes involved in mineralization of bones and reabsorption of salt can be in response to sedentary agrarian life and salt-rich diet.

Evolutionary and Population Genetics Posters - Thursday

PB2780. Did Neanderthals have different 3D genome folding from modern humans?

Authors:

E. McArthur¹, D. Rinker¹, E. Gilbertson², G. Fudenberg³, M. Pittman², K. Keough⁴, K. Pollard⁵, J. Capra²; ¹Vanderbilt Univ., Nashville, TN, ²Univ. of California San Francisco, San Francisco, CA, ³Univ. of Southern California, Los Angeles, CA, ⁴Gladstone Inst.s, San Francisco, CA, ⁵Gladstone Inst.s / UCSF, San Francisco, CA

Abstract Body:

Introduction: Changes in gene regulation were a major driver in the divergence of archaic hominins--Neanderthals and Denisovans--and modern humans. The three-dimensional (3D) folding of the genome is critical for regulating gene expression; however, its role in recent human evolution has not been explored because the degradation of ancient samples does not permit experimental determination of archaic 3D genome folding.

Hypothesis: We hypothesize that the 3D genome differed between modern and archaic hominins and that these differences can be revealed by reconstructing the genome folding via machine learning methods and experimental Hi-C. Furthermore, we hypothesize that these 3D differences contributed to phenotypic divergence in the evolution of modern humans.

Results: We apply novel deep learning methods to infer 3D genome organization from DNA sequence to Neanderthal, Denisovan, and 20 diverse modern human genomes. Comparing the resulting 3D contact maps across the genome, we identify 167 distinct regions with diverged 3D genome organization between archaic and modern humans. We show that these 3D-diverged loci are enriched for genes related to immune response, cognition, and morphology of the eye, supra-orbital ridges, hair, and lungs. Despite these specific diverged loci, the 3D genome of archaic and modern humans are more similar than expected based on sequence divergence. This suggests that the pressure to maintain 3D genome organization constrained hominin sequence evolution. Finally, we identify loci where modern Eurasians inherited novel 3D genome folding patterns via introgression from archaic ancestors that associate with traits including height, fat distribution, and blood pressure. Our results provide a putative molecular mechanism for the phenotypes associated with these introgressed haplotypes. To validate modern human loci with hypothesized archaic 3D genome folding patterns, we conduct experimental HiChIP on diverse lymphoblastoid cell lines with and without Neanderthal ancestry.

Conclusion: Using deep learning to predict archaic 3D genome organization, we illustrate the potential of inferring molecular phenotypes from ancient DNA to reveal previously unobservable biological differences contributing to human evolution and disease.

Evolutionary and Population Genetics Posters - Wednesday

PB2781. Discovering determinants of short tandem repeat stability in local sequence context using gradient-based attribution scores.

Authors:

R. DeVito, M. Gymrek; Univ. of California San Diego, La Jolla, CA

Abstract Body:

Short tandem repeats (STRs), tracts in DNA where a short motif is repeated, are among the most polymorphic and mutation prone loci in the human genome. Only around 19% of STRs are stable, meaning they have a fixed copy number, while the remaining unstable STRs vary in copy number or have base substitutions in the population. This variation has been shown to affect a variety of traits, including gene expression, monogenic disorders such as Huntington's Disease, and complex traits. Multiple studies have identified total repeat copy number as the primary determinant of STR stability. While other determinants of STR stability have been identified, including GC content and recombination rates, these explain relatively little variation in mutation rates across loci and have shown inconsistent associations across studies.

In this work we explored whether local sequence around an STR may help explain differences in STR stability across loci. Using sequence data from the reference genome and stability labels from 2,504 unrelated 1000 Genomes samples, we trained a 1-D convolutional neural network to predict STR stability from local sequence context with a balanced set of 37,198 dinucleotide STRs of lengths 12 and 13 bp. Our best model achieved auROC 0.82 on an orthogonal test set of STRs. We then used integrated gradients, a gradient-based attribution score, to identify sequence features contributing to our model's performance.

Through analysis of these gradient-based scores, we identified three repetitive patterns in the sequences directly flanking an STR that are significantly correlated with stability (rank-biserial correlations of 0.24, 0.20, and 0.11). All of these determinant patterns involve the base at the boundary of the STR and maintaining a pattern with a periodicity of 2 or 1. For example, an AC repeat followed by a sequence that continues the "C" at every other base pair is more likely to be unstable. Overall, our study highlights a strong and previously unreported impact of the local sequence immediately adjacent to STRs as an important contributor to STR stability. These findings will help develop improved models of STR mutation properties and can give new insights into STR mutation mechanisms.

Evolutionary and Population Genetics Posters - Thursday

PB2782. Disease-associated STR loci in diverse populations

Authors:

C. Steely¹, N. Russell², W. Watkins², L. B. Jorde²; ¹Univ. of Utah, Sch. of Med., Salt Lake City, UT, ²Univ. of Utah, Salt Lake City, UT

Abstract Body:

Short tandem repeats (STRs) are tandemly repeated sequences of 1-6 bp motifs. STRs compose only 3% of the genome, but they have been frequently used in studies of population genetics and evolution, as well as in forensic analyses due to their high heterozygosity. Normal population variation at some of these loci has also been associated with variation in gene expression. Expansion of STRs in certain loci (both intronic and exonic) has been linked to over 50 human diseases, including Friedreich ataxia, Huntington disease, amyotrophic lateral sclerosis (ALS), and fragile X syndrome. Using publicly available data from gnomAD and the genomes of 300 individuals included in the Simons Genome Diversity Project, we analyzed 57 STRs that have been associated with disease. The genomes included in gnomAD and the Simons Genome Diversity Project include individuals from understudied and underrepresented groups. Similar to the analysis performed on the gnomAD data, we used ExpansionHunter to genotype 57 STRs in disease-associated genes in the Simons Genome Diversity Project. Of the 57 loci analyzed in this study, 39 (~68%) had significantly different average STR lengths among the populations analyzed. Because longer STRs mutate more readily, we also analyzed the relationship between the average length of these loci in each population and the prevalence of the associated disease. Huntington disease is more prevalent in non-Finnish European individuals, and the STR in *HTT* had the highest mean allele length in the non-Finnish European individuals. This study highlights the importance of including diverse populations to better understand the genetics of disease.

Evolutionary and Population Genetics Posters - Wednesday

PB2783. Evaluation of imputation performance of different reference panels in a Pakistani population.

Authors:

J. Xu^{1,2}, A. Arsalan³, G. Genovese⁴, D. Liu¹, B. Fennessy¹, E. Cheng¹, A. W. Charney¹, J. A. Knowles⁵, M. Ayub⁶, R. E. Peterson⁷, T. B. Bigdeli⁸, L. M. Huckins^{1,2}; ¹Pamela Sklar Div. of Psychiatric Genomics, Icahn Sch. of Med. at Mount Sinai, New York, NY, ²Dept. of Psychiatry, Yale Sch. of Med., New Haven, CT, ³Univ. of Peshawar, Peshawar, Pakistan, ⁴Stanley Ctr. for Psychiatric Res., Broad Inst., Cambridge, MA, ⁵The Human Genetics Inst. of New Jersey, Rutgers Univ., Piscataway, NJ, ⁶Univ. Coll. London, London, United Kingdom, ⁷The Virginia Inst. for Psychiatric and Behavioral Genetics, Virginia Commonwealth Univ., Richmond, VA, ⁸SUNY Downstate Hlth.Sci. Univ., Brooklyn, NY

Abstract Body:

Despite calls for increasing diversity, GWAS studies are almost exclusively performed in European individuals, impeding the discovery of biologically important loci. Powerful imputation reference panels allow us to include rare variants in GWAS; however, performance of these panels is uneven across ancestries. Here, we compare for the first time the performance of three imputation panels in a large Pakistani population. We genotyped 2,219 Pakistani individuals using the Illumina Infinium™ Global Screening Array (v3.0). Genotypes were called following the MoChA pipeline using Google Cloud. Imputation was carried out using three reference panels: TOPMed, 1000 Genomes [1000G], and Genome Asia Pilot [GAsP]. First or second-degree relatives were removed. Among genotyped SNPs, the average mask R^2 (correlation between true genotyped values and imputed dosages) for common SNPs ($MAF > 0.05$) was 0.87, 0.87, and 0.86, respectively, for TOPMed, 1000G and GAsP; the average R^2 for rare SNPs ($MAF < 0.01$) was 0.57, 0.56, and 0.53. Among imputed SNPs, the average R^2 for common SNPs was 0.88, 0.84, and 0.84, whereas average R^2 for rare SNPs was 0.06, 0.18, and 0.20. TOPMed imputed 7.7-fold more rare SNPs than 1000G, and 20.6-fold more than GAsP. If we restrict to only SNPs shared across all 3 panels, the average R^2 for common SNPs was 0.89 for TOPMed, 0.87 for 1000G, and 0.85 for GAsP, and the average R^2 for rare SNPs was 0.37, 0.28, and 0.23. In terms of SNP counts, TOPMed, 1000G and GAsP imputed 5,281,437, 5,266,802, and 3,822,999 common SNPs with $R^2 \geq 0.8$. For rare SNPs, these 3 panels imputed 4,349,982, 1,415,749 and 646,301 SNPs with $R^2 \geq 0.8$. In addition, 648,080 multi-allelic SNPs and 812,111 indels with $R^2 \geq 0.8$ were imputed using TOPMed, compared to 189,677 multi-allelic SNPs and 820,967 indels using 1000G. No multi-allelic or indels was imputed using GAsP. We found 4 major categories of imputed SNPs: downstream, intergenic, intron and upstream. Among these, TOPMed has more SNPs with $R^2 \geq 0.8$ in each category. Our findings suggest that TOPMed with its much greater sample size ($n=97,256$) was able to impute more high-quality SNPs, especially the rare ones, with the caveat that it also imputes more low-quality rare SNPs that need to be filtered out prior to GWAS. For next step, we will examine R^2 between imputed SNPs and SNPs from targeted sequencing in the same set of individuals for evaluation of imputation accuracy. Overall, this work will contribute to more inclusive genetic studies of global populations.

Evolutionary and Population Genetics Posters - Wednesday

PB2784. Evidence of potential natural selection in African American individuals post admixture.

Authors:

J. Jaworski¹, J. Bartlett², R. Durodoye², H. Diaz-Zabala¹, S. Williams³, M. Aldrich⁴; ¹VUMC, Nashville, TN, ²Case Western Reserve Univ., Cleveland, OH, ³Case Western Reserve Univ, Cleveland, OH, ⁴Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract Body:

Introduction. Admixed populations are formed by the mixing of genetically differentiated ancestral populations. Alleles that are highly differentiated, after an admixture event, can be present in frequencies locally that deviate from the global genome-wide admixture average. This can be due to natural selection post admixture. The extent of such recent selection in African American individuals is an unresolved question with prior work giving conflicting evidence with respect to directional selection since admixture in African American individuals. We looked for evidence of non-random patterns of local ancestry, perhaps due to natural selection, in a subset of the Southern Community Cohort Study. **Methods.** The sample consisted of 1,375 unrelated African American participants that were previously genotyped on a set of Illumina arrays (1M to 2.5). After merging and applying standard quality control metrics to the dataset, a total of 604,224 markers were available for analysis. The software, Efficient Local Ancestry Inference (ELAI) was used to measure African (AFR) and European (EUR) ancestry on an overlapping set of ~583K markers. We performed pairwise comparisons to search for regions for evidence of genome-wide selection. Tests were done using multiple reference AFR and EUR populations from the 1000 Genome reference dataset. We subsequently ran the same comparisons using the program RFMix (v1.5.4) to verify the results. **Results.** The average genome-wide AFR ancestry among was 84.4% (standard deviation = 0.835). A region on chromosome 2 (74.37 Mb to 75.10 Mb) showed an excess EUR ancestry over 5 standard deviations above the genome-wide mean ancestry and was observed in all reference comparisons. In addition, regions on chromosome 11 (57.41 Mb to 57.97 Mb) and chromosome 14 (45.26 Mb to 46.74 Mb) had excesses EUR ancestry in most of the AFR/EUR comparisons. Findings were replicated in the RFmix analysis. None of these regions have been previously reported. Within the chromosome 2 region, a nearby gene of interest is *HK2*, which catalyzes the phosphorylation of hexose and is associated with Type 2 Diabetes Mellitus, Thyroid Dysmorphogenesis 1, and Chondroblastoma. **Conclusion.** Our analysis shows three potential chromosomal regions of selection since admixture in an African American population. Future analyses will estimate the selection coefficient to explain the observed excess in EUR ancestry.

Evolutionary and Population Genetics Posters - Thursday

PB2785. Examining polygenic adaptation in time-stratified genome samples

Authors:

X. Cheng, M. Steinruecken; Univ. of Chicago, Chicago, IL

Abstract Body:

With the rapid accumulation of ancient DNA (aDNA) genomes and evolve-and-resequence (E&R) data, more time-stratified population genomic datasets are emerging. Such time-series data allow us to examine the temporal dynamics of natural selection and can lend power to detecting its footprints. Few selection-detecting methods, however, are tailored to jointly consider multiple samples of the same population at different times, especially when more than one locus is involved. Meanwhile, increasing evidence is supporting the polygenic nature of most traits under selection, underscoring the need for approaches that account for multiple loci. Here, we constructed a hidden-Markov model (HMM) framework based on the Wright-Fisher diffusion model explicitly for directional or stabilizing selection on polygenic traits. To reduce the computational load, we use a normal approximation for the step-wise transition between generations in the underlying diffusion model. We implemented this framework as a Python package with its command-line-interacting script, and benchmarked its performance with both forward and backward simulations. Further, for each major complex trait in the UKBioBank, we extract variation records of their significant loci in historical British populations during the past ~4500 years from the Allen aDNA Resources dataset, and assign these loci their respective effect size estimates in UKBioBank. With the composite likelihood incorporating independent loci across the genome, we were able to obtain estimates of the predominant mode of selection, i.e., directional or stabilizing, and its intensity, for each trait, gaining insights into recent human adaptation.

Evolutionary and Population Genetics Posters - Wednesday

PB2786. Exploring population health disparities through identity by descent genetic communities in The Biobank at The Colorado Center for Personalized Medicine

Authors:

J. Shortt¹, M. Lin¹, N. Rafaels², C. Caggiano³, R. Shemirani⁴, G. Belbin⁵, N. Zaitlen⁶, E. Kenny⁷, K. Crooks⁸, C. Gignoux¹; ¹Univ. of Colorado Anschutz Med. Campus, Aurora, CO, ²Univ. of Colorado Sch. of Med., AURORA, CO, ³UCLA, Marina del Rey, CA, ⁴Icahn Sch. of Med. at Mount Sinai, Palo Alto, CA, ⁵Gencove Inc., New York, NY, ⁶UCLA, Los Angeles, CA, ⁷Icahn Sch. of Med. at Mt Sinai, New York, NY, ⁸Univ Colorado, Aurora, CO

Abstract Body:

Human demographic history and selection have shaped the genetic variation found within human populations for tens of thousands of years, and thus play a profound role in the risk of disease during an individual's life. However, understanding an individual's risk of disease is complicated by interacting environmental exposures that vary by population. Here, we use a data-driven approach to derive population substructure information and use it to characterize the risk of complex disease within high-resolution genetic communities. We identified identity by descent (IBD) segments indicative of recent shared ancestry among nearly 75,000 unrelated individuals genotyped in The Biobank at the Colorado Center for Personalized Medicine (CCPM). Individuals were clustered into 40 different genetic communities using pairwise cumulative IBD as input to iterative Louvain clustering. Communities are enriched in different regions of Colorado and have both overlapping and distinct global ancestry profiles indicative of population substructures within CCPM. We estimated the prevalence of over 1,200 phecodes derived from linked electronic health record data within each genetic community and identified community-specific enrichment or depletion across the phenome using logistic regression models. At FDR=5%, we identify 65 associations between 14 unique communities and 48 unique phecodes reflecting health disparities between communities, including two European ancestry communities with contrasting risk for skin cancer (OR[95% CI]=0.73[0.62-0.86] and 1.6[1.37-1.88]). Genetics is used to identify communities, but differences in risk between communities may largely reflect sociocultural, socioeconomic, and other environmental differences between communities. Communities may therefore be useful in accounting for these factors.

Evolutionary and Population Genetics Posters - Thursday

PB2787. Extensive sex-biased gene flow in Native Americans across the Andes

Authors:

V. Borda¹, L. Fehren-Schmitz², C. Sanchez³, O. Caceres³, C. Padilla³, E. Tarazona-Santos⁴, T. O'Connor¹; ¹Univ. of Maryland Sch. of Med., Baltimore, MD, ²Univ. of California Santa Cruz, Santa Cruz, CA, ³Centro Natl. de Salud - Inst. Natl. de Salud, Lima, Peru, ⁴Univ. Federal de Minas Gerais, Belo Horizonte, Brazil

Abstract Body:

The Central Andes region, including coast, highlands and adjacent Amazon rainforest, was the main scenario for the development of complex societies during the last 5000 years. Archaeological, linguistic and genetic evidence support the idea of two interaction spheres emerging in the North and the South regions of the Central Andes. Recent studies highlighted gene flow events in-between some North Coast/Highland and North Amazon populations. Here we explored how extensive was the gene flow across the Andes into the adjacent Amazon populations and how different were the sex-specific contributions. We used autosomal and x-chromosome genotyping data from previously published Native American samples resulting in 565 individuals. A subset of this data includes 11 populations from the adjacent Amazon forest. By performing genetic clustering analysis on both, autosomal and x-chromosome, we detected two main clusters explaining the genetic composition of the Amazon groups, Amazon related and an Andean related clusters. By comparing autosomal and x-chromosome ancestry proportions, we detect less Amazon related ancestries in x-chromosome with respect to the autosome in all 12 Amazon groups. To explore the nature of this observation, we performed admixture modeling using qpAdm to identify plausible models and admixture proportions that explain the genetic composition of each Amazon group. Nine out of 11 Amazon groups fit as the result of two-way admixture involving North Highlands (Ancient sample from La Galgada 4100BP) and Amazon related (Present-day Karitiana) sources. Interestingly, the ancestry proportions inferred were contrasting between autosomal and x-chromosome data. Furthermore, we computed Z scores to estimate how different were the ancestry proportions between autosomes and the x-chromosome. Six Amazon groups resulted in Z score values higher than 2.5 (2.5-5.19) suggesting a predominant male-based contribution from the Amazon related source into these populations living beside the Andes. We are providing substantial evidence for sex-biased gene flow involving the cultural interactions occurred across the Andes.

PB2788. Fine-scale ancestry mapping revealed population-specific associations with complex disease

Authors:

M. Isshiki^{1,2}, S. Raj¹; ¹Albert Einstein Coll. of Med., New York, NY, ²The Univ. of Tokyo, Tokyo, Japan

Abstract Body:

In this project we aimed to identify the relationship between fine-scale genetic ancestry and prevalence of complex diseases in populations of African descent. Individuals of African ancestry in the United States often have African ancestry from multiple ancestral population groups, which reflect their complex history. We hypothesized that these different ancestries can be identified in the genome, and that each of these ancestries show different correlations to complex disease outcomes. We chose to focus on chronic diseases as nearly half of the US population has at least one chronic disease, and two-thirds of deaths globally are caused by the presence of one or more of the following chronic diseases: heart disease, cancer, stroke, chronic obstructive pulmonary disease, and diabetes. The prevalence and manifestation of these diseases varies among individuals and populations with different ancestral backgrounds. We used the methods PCA and ADMIXTURE to assess population structure of individuals of African descent from the TOPMED and All of Us datasets against a reference panel enriched for African ancestral populations. We then used fineSTRUCTURE to assess fine-scale population structure of these individuals. The methods RFMix, ELAI, and Gnomix were used to infer local ancestry. The accuracy of our local ancestry inference was validated by comparing the global mean values with the results of PCA and ADMIXTURE. We correlated local ancestry proportions with different complex diseases prevalence. We then used admixture mapping to perform association tests with the most correlated traits, adjusting for local ancestry. We found population-specific associations that underscore the importance of understanding fine-scale population structure in under-represented populations with complex ancestries, such as African-Americans. Our results suggest that local ancestry inference can be a powerful tool in understanding the contribution of ancestry to disease risk. Our findings support previous studies showing that African ancestry in the United States is not a monolith. We take this one step further and find associations with common disease phenotypes.

PB2789. Generation of synthetic genotypes with neural networks.

Authors:

M. Geleta^{1,2}, D. Mas Montserrat³, M. Perera², X. Giro-i-Nieto², A. G. Ioannidis^{3,4}; ¹Computer Sci. Dept., Univ. of California, Berkeley, Berkeley, CA, ²Univ. Politècnica de Catalunya, Barcelona, Spain, ³Dept. of BioMed. Data Sci., Stanford Univ., Stanford, CA, ⁴Inst. for Computational and Mathematical Engineering, Stanford Univ., Palo Alto, CA

Abstract Body:

Although the number of sequenced genomes has grown substantially, there remains a clear imbalance between the ancestries that are represented with the vast majority of sequenced samples still coming from populations of European descent. This results in an underrepresentation of training data for non-European populations. Here we investigate genomic data synthesis tools to overcome the problem of imbalanced ancestry groups. We present some of the novel methodologies for the generation of realistic synthetic genotypes using different connectionist approaches: Variational Autoencoders (VAEs) and Generative Moment Matching Networks (GMMN); and introduce an evaluation scheme to qualitatively and quantitatively assess the quality of the synthetic single nucleotide polymorphism (SNP) sequences. Additionally, we show how such synthetic genotypes can be used to address privacy and data sharing concerns.

Evolutionary and Population Genetics Posters - Wednesday

Hlth. and Welfare, Finnish Inst. for Hlth. and Welfare, Helsinki, Finland

Abstract Body:

High-altitude populations have been exposed to environmental stress for thousands of years and provide a unique opportunity to study human evolutionary processes and genetic variants selected for hypoxia tolerance. Prior studies have identified Hypoxia-Inducible Factor (HIF) pathway genes as crucial components of adaptation in human and non-human high-altitude species. However, links between precise variants within adaptive gene regions and physiological traits remain largely unexplained. To elucidate the genetic basis of high-altitude adaptation in Andean highlanders, we conducted a composite of multiple signals selection scan on 40 high-coverage whole genomes. We intersected a list of prioritized candidate genes with strong evidence for positive selection with a list of *a priori* genes and looked for deleterious, non-synonymous mutations within the selected regions. We highlighted a missense variant (rs570553380, A>G, p.[His194Arg]) within the sixth exon of *Endothelial PAS Domain Protein 1 (EPAS1)*. The wildtype histidine at this residue is highly conserved among vertebrates except for the coelacanth, *Latimeria chalumnae*, a lobe-finned fish. In humans, this derived variant is largely unique to Andean populations (Andean: 10.0% vs. 0.20% global allele frequencies) and is likely under early-stage selection (estimated age = 9,845 ± 1969 years, which approximately aligns with the first human habitation of the Andes). As hemoglobin concentration has been correlated with the *EPAS1* locus in the Tibetans, we tested whether rs570553380 was associated with hematocrit in an expanded cohort of Andean highlanders (N = 224) and found males with more copies of the putatively adaptive G allele exhibited lower hematocrit (P < 0.003). We then identified serum-metabolite correlations between rs570553380 and 1 known and 11 unknown metabolites, which are associated with hematocrit in Andeans and also a large genome cohort (FINRISK). Furthermore, we introduced rs570553380 into HEK293T cells using CRISPR ABE base-editing and found that cells with one copy of the adaptive variant demonstrated decreased expression of canonical HIF targets relative to wildtype cells under hypoxia. Associations between *EPAS1* and hematocrit and hemoglobin concentration across Andean and Tibetan suggest

ASHG 2022 Annual Meeting Poster Abstracts

phenotypic convergence, likely via distinct molecular and physiological changes. These findings provide the first example of convergent phenotypes associated with genetic adaptation across high-altitude human populations.

PB2791. Genetic landscape and demographic history of Britain and Ireland

Authors:

A. Shanmugam^{1,2}, A. M. Molloy³, L. Brody⁴, M. Merrigan⁵, S. O'Reilly⁵, G. L. Cavalleri^{1,2,6}, R. McLaughlin^{3,2,6}, R. P. Byrne³, **E. Gilbert**^{1,6}; ¹Royal Coll. of Surgeons in Ireland, Dublin, Ireland, ²The SFI Ctr. for Res. Training in Genomics Data Sci., Galway, Ireland, ³Trinity Coll. Dublin, Dublin, Ireland, ⁴NHGRI (NIH), Bethesda, MD, ⁵Genealogical Society of Ireland, Dún Laoghaire, Ireland, ⁶The SFI FutureNeuro Res. Ctr., Dublin, Ireland

Abstract Body:

Background: Recent studies have identified subtle but discrete genetic groups across Britain and Ireland. Leveraging patterns of identity-by-descent (IBD) segment sharing, we built upon our understanding of fine-scale population structure in Britain and Ireland and derived insights into recent demographic change in these populations.

Methods: We assembled genotype data from 6,724 individuals across four studies with associated regional ancestry. The Leiden community detection algorithm was applied recursively to identify genetic clusters in the dataset. Additionally, we inferred regional effective population sizes across time using IBDNe, and estimated recent migration rates using MAPS to reveal insights into recent demographic history.

Results: We identified fine-scale genetic population structure which stratified by geography and detected new subgroups in Ireland (for ex. Donegal-Cavan) and South-East England (for ex. Norfolk-Suffolk). Using IBDNe, we provide novel insights into changes in regional effective population sizes over time, with all population clusters showing patterns of recent exponential growth. We have also identified evidence of gene flow barriers through estimated migration surfaces.

Conclusions: Our findings extend our knowledge of fine-scale population structure across Britain and Ireland, adding novel findings with previously undetected genetic clusters. The analysis of changes in recent effective population size and migration surfaces deepens our understanding of the history of these population genetic groups.

Evolutionary and Population Genetics Posters - Wednesday

PB2792. Genetic variation related to the regulation and expression of hemoglobin isoforms among global populations

Authors:

J. Hall¹, M. C. Kong¹, W. Gu¹, J. J. Yu¹, C. Anza-Ramirez², K. Fox¹, F. Villafuerte², M. Gotesman³, T. S. Simonson¹; ¹Univ. of California, San Diego, La Jolla, CA, ²Univ. Peruana Cayetano Heredia, San Martín de Porres, Peru, ³The Lundquist Inst., Torrance, CA

Abstract Body:

Despite limited oxygen availability in each breath of air, human populations living at high altitude within the Andes, Tibetan plateau, and Ethiopian highlands exhibit both unique physiological responses to this environmental stress and extremely strong natural selection for genes involved in oxygen transport. In previous studies, we identified several gene regions under natural selection within in an Andean cohort from Cerro de Pasco, Peru, which contained fetal hemoglobin qualitative trait loci (QTLs) that influence variance in fetal hemoglobin levels in patients with sickle cell disease (SCD). Fetal hemoglobin has been suggested to play a role in oxygen transport in high-altitude populations and is upregulated under conditions of stress erythropoiesis and in patients with SCD. We hypothesize that genes involved in fetal hemoglobin persistence and symptom severity in SCD patients also play a role in adaptation to adverse physiological responses to hypoxic stress at high altitudes. Hemoglobin expression relies on the interplay of a multitude of transcription factors and can be influenced by alterations in transcription factor binding sites for the hemoglobin genes or upstream transcription factors. To identify population-specific variations in transcription factor sites that may be involved with variance in hemoglobin regulation and expression, we compiled a comprehensive list of all known single nucleotide variants (SNVs) within genomic regions identified as under selection in our Andean cohort coding for the hemoglobin isoforms and upstream transcription factors. These genomic regions encompass the hemoglobin gene cluster, hemoglobin locus control region, and the genes *BCL11A* and *SOX6*. Variants were filtered to include SNVs with allele frequencies greater than 5% within African (AFR) and East Asian (EAS) populations and the Andean cohort. SNP2TFBS software was used generate SNV lists specific to each population to identify shared and unique transcription factor site SNVs. From this, we identified hundreds of transcription factor binding site variants shared between two or more of the populations, along with 38 unique SNVs in Africans, 18 in Andeans, and 3 in East Asian populations that we hypothesize may play a role in population-specific variation in hemoglobin expression within these populations.

Evolutionary and Population Genetics Posters - Thursday

PB2793. Genome-wide patterns of tandem repeat abundance across species are primarily driven by retrotransposons

Authors:

Y. Jin, M. Maksimov, **M. Gymrek**; Univ. of California San Diego, La Jolla, CA

Abstract Body:

Short Tandem Repeats (STRs) are sequential repeat elements in DNA sequences that are abundant in most eukaryotic species. STRs are known to contribute to variation in gene function and gene expression across species. It has been observed that the abundance and characteristics of STRs vary widely across genomes of different species. However, the evolutionary origins of this variation and its implications remain largely unexplored. Previous work suggested that species- or clade-specific retrotransposon elements may represent a major source of STRs in eukaryotic genomes. Here, we explored the composition of STRs across the tree of life with species ranging from yeast to primates and investigated the critical role retrotransposons play in driving species-specific differences in genomic STR content. Our results confirm previous reports that homopolymers are strongly enriched in primate genomes, and that this trend is driven by SINE retrotransposon elements. Further, we identify DNAREP1_DM and TART_DV elements as drivers of dinucleotide abundance in multiple fruit fly species and CR1-Y1_Ave and CR1-Y2_Aves as drivers of pentanucleotide abundance in birds. Finally, we find that dinucleotide repeats are enriched in abundance and tend to be longer in rodent species, but that this enrichment is likely not driven by rodent-specific retrotransposon elements and is therefore likely driven by alternative mechanisms. Overall, our work highlights the major role retrotransposon elements play in shaping the composition of STRs across the genomes of diverse species.

Evolutionary and Population Genetics Posters - Wednesday

PB2794*. Genomic deserts: A global survey of underrepresented populations in genomics research

Authors:

S. Mangul¹, W. Wolfsberger^{2,3}, K. Chhugani¹, Y-N. Huang¹, D. Yu⁴, S. Knyazev⁵, S. Nataneli¹, J. Hu⁶, V. Munteanu⁷, S. Groppa⁸, T. Abstract Body:

Genomic sequencing provides clues to understand the physiological and pathological mechanisms of humans. Studying population genomics over diverse populations can promote genomics research across all the populations around the world at an unprecedented scale and increase the health equity across diverse populations. Despite the development and contribution of national genome sequencing projects, such projects currently represent only a small fraction of the world populations, primarily in high income and developed countries, and thus contribute to the growing global inequality in genomic research. Typically, high income and developed countries have more resources to develop national genome projects compared to the low income or developing countries, resulting in many countries and regions in the world becoming blind spots lacking their own genomic representation. An effective way to fill the existing blind spots in the global genomic map is to initiate national level genome projects to enable genomic-based medicine for the population of this country. To address the emerging issues of global genomic diversity and to further emphasize the urgent need to engage diverse populations in genomic research, we have completed a systematic survey of national genomic projects across 195 countries and regions of the world in order to show inconsistencies representing worldwide populations in genomics research and data sharing practices. Our results show locations of numerous “genome deserts” in the world across all parts of the world (Europe, Africa, Asia, Australia, Oceania and the Americas). The regions containing the most deserts were South America and the regions with the highest density of genomic projects were Asia. We also illustrated how many genomic projects failed to represent minority populations limiting the capacities of personal medicine for these groups. We observed a large variability of availability of genomic data ranging from sharing the genomic data freely (14.39%) and upon request (85.61%). Among the genomic data, 72.99 % (47,984 samples) of the genomic data is generated from uni-national genome projects and 27.01% (11,761 samples) of the genomic data is generated from international collaborative genome projects. We discussed the advantages and limitations of various sharing models and their role in empowering local scientific communities. We also investigated the data sharing practices adopted by national genomic projects and concluded with discussion with scientists from countries lacking the national genomic projects on recommendations, opportunity and pitfalls on establishing and implementing national genomic projects.

Evolutionary and Population Genetics Posters - Thursday

PB2795. Genomic variation and chromatin structure across the human-specific *NOTCH2NL* duplications

Authors:

T. Real¹, M. Vollger¹, D. Dubocanin¹, P. Dishuck¹, A. Sedeno Cortes¹, X. Guitart¹, K. Munson¹, J. Ranchalis¹, E. Eichler^{1,2}, A. Stergachis¹; ¹Univ. of Washington, Seattle, WA, ²Howard Hughes Med. Inst., Seattle, WA

Abstract Body:

Segmental duplications (SDs) are nearly identical stretches of DNA that exist in multiple copies within the genome. SDs are among the fastest-evolving genomic regions and can underlie human diseases and novel genes with human-specific functions. For example, the *NOTCH2NL* loci, which expanded to 5 gene paralogs selectively in humans, underlies four neurodevelopmental diseases and encodes a novel gene associated with expansion of the human frontal cortex. However, the sequence and function of SDs, including *NOTCH2NL*, has remained largely opaque, as standard sequencing technologies cannot overcome their high sequence identity. Advances in long-read genomic and epigenomic sequencing are beginning to open previously impenetrable portions of the genome for studying. Here, I leverage these emerging technologies to study genetic diversity and gene regulatory function at *NOTCH2NL* loci. Specifically, using 1 human reference and 4 non-human primate (NHP) accurate long-read assemblies of the *NOTCH2NL* loci, I have reconstructed the evolutionary history of *NOTCH2NL* within the Great Ape lineage, demonstrating that *NOTCH2NL* has likely independently evolved in humans. Additionally, using 94 parental haplotype-resolved assemblies from the Human Pangenome Reference Consortium (HPRC) project, I have characterized the scope of genetic variation at these loci across a diverse human population. This demonstrated pervasive large-scale structural and genetic changes affecting all *NOTCH2NL* paralogs. Finally, using single-molecule chromatin fiber sequencing of human brain tissue I have defined the chromatin landscape of each *NOTCH2NL* paralog, showing paralog-specific promoter chromatin architectures. Overall, this study begins to delineate the genetic and epigenetic architecture and evolution of *NOTCH2NL* paralogs in humans, and provides a framework for studying these unexplored segmentally duplicated regions of the genome that likely play an essential role in what makes us human.

Evolutionary and Population Genetics Posters - Wednesday

PB2796*. Germline genetic determinants of T-cell fraction in ~110,000 diverse individuals

Authors:

H. Poisner¹, A. Faucon¹, N. Cox², A. Bick³; ¹Vanderbilt Univ., Nashville, TN, ²Vanderbilt Univ Med Ctr., Nashville, TN, ³Vanderbilt, Nashville, TN

Abstract Body:

T-cell abundance is subject to competing selection in humans. Germline genetic determinants of human T-cell abundance have not been studied at scale, because complete blood counts only assay lymphocyte abundance which is the sum of T-cells, B-cells, and NK-cells. To address this gap, we extended the T-cell ExTRECT method for use with whole-genome sequence data. It estimates T-cell fractions from read depth along the V(D)J recombination region of the T-Cell Receptor Alpha locus. We leveraged the NHLBI BioData Catalyst cloud platform to estimate blood T-cell fractions in the multi-ethnic TOPMed study at scale (N~110k, ~40K non-European) and performed a genome-wide association study. The SNP heritability of T-cell fraction was 0.10 (SD 0.02) in European ancestry and 0.42 (SD 0.04) in African ancestry individuals (SumHer BLD-LDAK model). We identified 12 genome-wide significant loci that affect one or more hematopoietic lineages. Three affect both lymphoid and myeloid lineages (*ACKR1*, *SH2B3*, *IRF8*). Three are lymphocyte-specific (*CD69*, *KLF2*, *IL7*). Three are T-cell-specific (*BCL2L11*, *TRDV2*, *SHH*). Interestingly three are myeloid lineage-specific (*HBB*, *CSF3*, *CSF3R*), implying that changing the relative proportion of myeloid cells changes the fraction of whole blood DNA derived from T-cells. We developed a polygenic model with a Julia port of PRS-cs for estimating T-cell fractions in TOPMed Europeans. Projecting this model into Vanderbilt BioVU (N~72k, EUR) revealed that neutrophil and lymphocyte measurements were inversely correlated with predicted T-cell fractions. This inverse relationship was also replicated in the UK Biobank. We used fine-mapping and manual curation to prioritize causal variants in T-cells. At three of our loci we prioritized four variants found in enhancer regions for *BCL2L11* (T-cell apoptosis), *IL7* (T-cell development), and *CD69* (T-cell proliferation). All three have differential allele frequencies in European and African ancestry populations. Phenome-wide analyses identified associations of these loci with immune-related diseases including Multiple Sclerosis (*IL7*) and hypothyroidism (*CD69*). In summary, by exploiting a new method to estimate T-cell abundance directly from whole blood sequence data, we obtained new insights into the genetic regulation of T-cells in diverse populations, with implications for autoimmune disease susceptibility.

Evolutionary and Population Genetics Posters - Thursday

PB2797. Guaranteeing unbiasedness in selection tests based on polygenic scores.

Authors:

J. Blanc, J. Berg; Univ. of Chicago, Chicago, IL

Abstract Body:

Population stratification is a well-studied problem in genome-wide association studies, leading to biases in the estimated strength of phenotypic association for individual genetic variants. In short, if environmental effects on the phenotype are correlated with ancestry gradients within a GWAS panel, any variant that is stratified along this ancestry gradient will receive a biased effect size estimate. While state of the art methods to correct for stratification are generally effective in reducing the number of significant false positive associations, even subtle biases in effect size estimates can accumulate across loci, leading to systematic biases in polygenic scores. In turn, these biases in the distribution of polygenic scores can lead to false positives in downstream analyses, such as tests for polygenic adaptation or other analyses of among group genetic differences. One approach is to attempt to be overly aggressive in controlling for stratification. However, there is currently no way to tell conclusively if confounding effects have been removed. A second approach is to conduct the GWAS in an evolutionarily diverged sample that is less likely to share population genetic structure with the test panel. This renders potential biases in the effect sizes irrelevant to the test, but comes at the cost of significantly reduced statistical power due to the issue of poor portability of polygenic scores across samples of divergent ancestry. Here using theory from population and statistical genetics, together with simulations, we show how this second approach can be generalized to panels that do share genetic structure, and that it is possible to guarantee the unbiasedness of selection tests without needing to guarantee that the effect sizes are fully unbiased. Specifically, if the researchers performing the GWAS also have access to the panel of test individuals and have identified the specific test to be performed ahead of time, then it is possible to compute a covariate to include in the GWAS, which will guarantee that the test is unbiased. More generally, our results have implications beyond tests for selection as any analysis that attempts to quantify the correlation between polygenic scores and demographic or environmental variables is subject to the same type of stratification biases.

Evolutionary and Population Genetics Posters - Wednesday

PB2798. Haplotype-based analyses of phylogeny and regional genome diversity among laboratory rats using the latest rat reference genome

Authors:

Y. Pan¹, A. Ozel², A. Palmer³, H. Akil¹, H. Chen⁴, J. Li⁵; ¹University of Michigan, Ann Arbor, MI, ²Univ. of Michigan, Ann Arbor, MI, ³UCSD, LA JOLLA, CA, ⁴Univ. of Tennessee, Knoxville, TN, ⁵Univ Michigan, Ann Arbor, MI

Abstract Body:

The common rat (*Rattus norvegicus*) is a key species in biomedical research. We previously reported Illumina whole-genome sequencing of eight inbred rat lines that are founders of the Heterogeneous Stock. Variant calls based on the previous rat reference genome, rn6, revealed regions with unusually high levels of heterozygosity, which span >9% of the genome and harbor >1,700 genes. These regions likely reflect mis-assemblies in rn6. We and colleagues in the International Rat Omics Consortium (IROC) have collaborated with the Vertebrate Genome Project to complete a new reference genome, termed mRatBN7. Re-analyses of the same data with mRatBN7 led to a significant reduction of high-heterozygosity regions (<0.5% of the genome). The two references differ in several large regions (>10 MB), including reversed orientation and placement to a different chromosome. mRatBN7 showed a higher human-rat concordance than rn6, including a 20 MB region on ChrX. Compared to rn6, mRatBN7 led to fewer zero-coverage regions (0.8% vs. 4.5% for males, and 0.3% vs. 2.4% for females), higher rate of mapping (97.3% vs 96.3%), and fewer variants being called (21,497,403 sites vs 23,893,814 sites). IROC investigators have performed linked-read WGS and joint variant calling for 168 samples representing most of the commonly used laboratory rat strains, including inbred lines, several RI panels, and technical replicates. Using the resulting variants data we constructed global phylogenetic trees at the sample, sub-strain and strain levels to investigate their evolutionary relationships, and compared with prior data for a subset of the samples using genotyping platforms. We generated region-by-region phylogenetic trees and defined shared ancestral haplotypes among the strains. In doing so, we developed a clustering-based method to infer local haplotypes and their likely boundaries. Shared haplotypes arise from co-ancestry relationships among various strains and, as a result, an eight-ancestry panel may have fewer than 8 unique haplotype in a given region, sometimes as few as 1. The catalog of the size, distribution, and composition of these ancestral haplotypes along the entire genome provides insights into the evolution of rat strains and informs regional variation of genetic diversity that supports genetic mapping studies.

Evolutionary and Population Genetics Posters - Thursday

PB2799*. High coverage whole genome sequencing of the expanded 1000 Genomes Project cohort including 602 trios

Authors:

M. Byrska-Bishop¹, U. S. Evani¹, X. Zhao², A. O. Basile¹, H. J. Abel³, A. A. Regier³, A. Corvelo¹, W. E. Clarke¹, R. Musunuri¹, K. Nagulapalli¹, S. Fairley⁴, A. Runnels¹, L. Winterkorn¹, E. Lowy⁴, Human Genome Structural Variation Consortium, P. Flicek⁴, S. Germer¹, H. Brand², I. M. Hall⁵, M. E. Talkowski², G. Narzisi¹, M. C. Zody¹; ¹New York Genome Ctr., New York, NY, ²Massachusetts Gen. Hosp., Boston, MA, ³Washington Univ., St. Louis, MO, ⁴European Molecular Biology Lab., Cambridge, United Kingdom, ⁵Yale Univ., New Haven, CT

Abstract Body:

The 1000 Genomes Project (1kGP) is the largest fully open resource of whole genome sequencing (WGS) data consented for public distribution of raw sequence data without access or use restrictions. The final, phase 3 release of the 1kGP included 2,504 unrelated samples from 26 populations and was based primarily on low coverage WGS. Here, we present a new, high coverage WGS 1kGP resource that has been extended to 3,202 samples including 602 complete trios and sequenced to a targeted depth of 30X using the Illumina NovaSeq 6000 system. We performed single nucleotide variant (SNV) and short insertion and deletion (INDEL) calling against the GRCh38 reference using GATK HaplotypeCaller which resulted in discovery of over 111 million SNVs and over 14 million INDELS with false discovery rates of 0.3% and 1.15%, respectively, across the entire cohort of 3,202 samples. We also discovered and genotyped over 173 thousand structural variants (SVs), including insertions, deletions, duplications, inversions, and multiallelic copy number variants, by integrating multiple algorithms and analytic pipelines, including GATK-SV, svtools, and Absinthe. When compared to the low coverage phase 3 1kGP dataset, the variant counts in the high coverage callset reflect an estimated average increase of 190,885 SNVs (1.05-fold), 268,182 INDELS (1.47-fold), and 5,835 (2.81-fold) SVs per genome, and a cohort-level increase of over 18.6 million SNVs (1.24-fold), 9.8 million INDELS (4.05-fold), and ~100 thousand SVs (2.47-fold), across the original 2,504 unrelated samples. Although phase 3 did achieve the goal of capturing almost all common SNVs (MAF > 1%), the higher coverage plus advances in sequencing and analytic methods greatly expanded the discovery of all rare variants and of INDELS and SVs across the frequency spectrum. As part of this work, we also released an improved reference imputation panel based on the high coverage WGS consisting of SNV, INDEL, and SV calls across the 3,202 1kGP samples, including full trios. Our phased panel leveraging pedigree correction provides improvements in power across the board, but particularly in the imputation of many more common INDELS and SVs, making these accessible through imputation for association studies. Given the large effect size of non-SNV variation, this increase in power is likely to enable discovery of new genetic associations that help pinpoint the causative variant. We make all the data generated as part of this project publicly available and we envision this updated version of the 1kGP callset to become the new de facto public resource for the worldwide scientific community working on genomics and genetics.

Evolutionary and Population Genetics Posters - Wednesday

PB2800. Human populations and demographics in Qatar from the Neolithic to the Late Iron Age.

Authors:

A. D'Aurelio¹, M. Baldoni^{2,3}, F. R. Vempalli¹, F. De Angelis², F. Sakal⁴, F. Al-Naimi⁴, M. Al-Hashmi¹, K. Wang¹, L. Wang¹, G. Wang¹, O. Soloviov¹, F. Castorina⁵, C. Martínez-Labarga², S. Tomei¹; ¹Integrated Genomics Services, Res. Dept., Sidra Med., Doha, Qatar, ²Dept. of Biology, Univ. of Rome Tor Vergata, Rome, Italy, ³PhD Program in Evolutionary Biology and Ecology, Dept. of Biology, Univ. of Rome Tor Vergata, Rome, Italy, ⁴Dept. of Archaeology, Qatar Museums, Doha, Qatar, ⁵Dept. of Earth Sci., Univ. of Rome Sapienza, Rome, Qatar

Abstract Body:

Motivation: Despite the production of genetic data related to the Middle East and Qatar specifically is increasing dramatically, a critical unmet research and public need relies on the study of the prehistorical societies living in this region of the World. Recent archaeological studies have discovered thousands of prehistoric burials that represent a great opportunity to investigate the population dynamics and sociocultural changes in prehistorical Qatari societies. The archaeological record has been the only way by which the Qatari prehistoric populations have been researched. Here we have applied the study of ancient DNA (aDNA) to understand the origin, migration patterns, genetic relationships, admixtures, kinship, and changes in prehistorical Qatari societies.

Material and methods: We performed aDNA analyses on 20 samples selected by taking into account preservation status and availability of either tooth or petrous bone. The same samples were also submitted for radiocarbon dating and isotopic and morphological analysis.

DNA was extracted in a dedicated clean lab facility starting from 50-135 mg of bone powder, following a silica-based protocol tailored to aDNA, modified by adding a further digestion step. Illumina double-stranded libraries were prepared and treated with partial uracil-DNA-glycosylase (UDG) to prevent nucleotide misincorporation.

Final NGS libraries were sequenced through NovaSeq 6000 System on an S4 Flow Cell.

Using a combination of bioinformatics tools, we performed quality control analysis on the sequenced reads, selecting endogenous reads with map and base PRHEd score quality above 30.

Results: According to the radiocarbon dating, our samples cover a transect of time going from the Neolithic to the Late Pre-Islamic period (7.4-1.4 kya). We report quality control scores on the sequencing data and their correlation with sample type, burial location and burial time frame. Even though the DNA preservation was mined by detrimental environmental factors, we tried estimating ancestries from both multi-locus genotype data and model-based approaches.

Conclusions: To the best of our knowledge, our study represents the first attempt to analyze aDNA in the Arabian Peninsula. We successfully retrieved aDNA sequences from human samples older than 1500 years excavated in Qatar. We believe that our results have the potential to pave the way for further paleogenetic studies in the region.

PB2801. Improved detection of evolutionary selection highlights potential bias from different sequencing strategies in complex genomic-regions

Authors:

T. Hayeck^{1,2}, Y. Li¹, T. Mosbrugger¹, J. Bradfield³, A. Gleason¹, G. Damianos¹, G-W. Shaw¹, J. Duke¹, L. Conlin⁴, T. Turner⁵, M. Fernandez Vina⁶, M. Sarmady⁷, D. Monos¹; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, ³Quantinuum Res. LLC, San Diego, CA, ⁴Children s Hosp. of Philadelphia, Philadelphia, PA, ⁵Washington Univ. Sch. of Med., St. Louis, MO, ⁶Stanford Univ., Palo Alto, CA, ⁷Children S Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

Balancing selection occurs when multiple alleles are kept at elevated frequencies in equilibrium due to opposing evolutionary pressures. A new statistical method, LD-ABF, was developed to test for selection using efficient Bayesian techniques, accounting for both the density of polymorphisms and strength of linkage disequilibrium. It demonstrated the most robust detection of selection in a variety of simulation scenarios. Established targets as well as 45 novel genes were identified to be under balancing selection after a genome wide scan of hundreds of clinical trios. Selection peaks were observed across multiple gene families whose biological functions favor diversification through both allele polymorphism and gene duplications: olfactory-receptor, immunoglobulin, zinc-finger, etc. Surprisingly, *SIRPA*, demonstrated dramatic selection signal second only to the MHC in most clinical populations and was replicated in separate whole-genome long-read samples from the Pangenome. Despite being known to likely be under strong selection, the MHC is a notoriously complex region that is difficult to properly sequence and characterize. To improve the detection of selection signal in the MHC, we took advantage of high-resolution HLA typing from thousands of diverse individuals and whole-genome long-read sequencing data. This analysis revealed strong balancing selection in expected peptide-binding domains as well as previously understudied intronic and intergenic regions of the HLA genes while demonstrating consistent patterns in diverse populations when taking advantages of higher quality sequencing technologies. The improved statistical method combined with higher quality sequencing results in more consistent findings of selection and improved localization of variants under selection, especially in complicated regions.

PB2802. Imputation around the world: Assessing imputation quality across diverse global populations.

Authors:

J. Cahoon^{1,2}, X. Rui³, E. Tang², C. Simons², J. Langie³, M. Chen³, Y-C. Lo³, C. W. K. Chiang^{3,2}; ¹Dept. of Computer Sci., Univ. of Southern California, Los Angeles, CA, ²Dept. of Quantitative and Computational Biology, Univ. of Southern California, Los Angeles, CA, ³Ctr. for Genetic Epidemiology, Dept. of Population and Publ. Hlth.Sci., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA

Abstract Body:

Genotype imputation is now an essential component in human genetic studies. By predicting unobserved genotypes based on sequenced individuals, imputation increases marker density and enables large-scale genome-wide association studies. The state-of-the-art imputation reference panel released by the Trans-Omics for Precision Medicine (TOPMed) contains a substantial number of admixed African and Hispanic/Latino samples. As a result, these populations are imputed with nearly the same efficacy as European cohorts. However, imputation for ethnic minorities primarily residing outside of North America still falls short in performance due to persisting underrepresentation. To illustrate this point, we curated genome-wide array data from 28 publications published between 2008 to 2021. In total, we imputed over 30k individuals across 145 populations around the world. We identified a number of populations where the imputation accuracy paled in comparison to that of European populations. For instance, the mean imputation r^2 for variants with minor allele frequency (MAF) between 1.0-5.0% for Saudi Arabian (N=1061), Vietnamese (N=1264), Thai (N=2435), and Papua New Guineans (N=776) were 0.79, 0.78, 0.76, and 0.62, respectively. In contrast, the mean r^2 ranged from 0.90 to 0.93 for comparable European populations matched in sample size and SNP content. In addition to overall lower imputation quality, minority populations experienced a steeper drop in imputation accuracy for rarer variants. For example, the mean r^2 for Filipinos (N=1779) declined from 0.93 in alleles with 5-10% MAF to 0.59 in alleles with 0.5-1.0% MAF. In contrast, alleles in the same frequency classes imputed relatively well in Europeans with a decrease from 0.97 to 0.79. Despite tremendous effort in generating large imputation panels like TOPMed, our results suggest that global populations still incur at least a 10% drop in study power due to imputation accuracy alone and even greater power loss for rarer variants. While strategies leveraging smaller population-specific reference panels in conjunction with meta imputation may increase imputation quality, ultimately, reference panels must strive to increase diversity to promote equity within genetics research.

PB2803. Imputation of ancient genomes.

Authors:

B. Mota^{1,2}, S. Rubinacci^{1,2}, D-I. Cruz-Dávalos^{1,2}, C. Guerra Amorim³, M. Sikora⁴, M. Allentoft^{4,5}, E. Willerslev^{4,6,7,8}, A-S. Malaspina^{1,2}, O. Delaneau^{1,2}; ¹Univ. of Lausanne, Lausanne, Switzerland, ²Swiss Inst. of Bioinformatics (SIB), Lausanne, Switzerland, ³California State Univ., Northridge, CA, ⁴Univ. of Copenhagen, Copenhagen, Denmark, ⁵Curtin Univ., Bentley, Australia, ⁶Univ. of Cambridge, Cambridge, United Kingdom, ⁷Wellcome Sanger Inst., Cambridge, United Kingdom, ⁸MARUM, Univ. of Bremen, Bremen, Germany

Abstract Body:

Ancient DNA (aDNA) studies have unraveled significant aspects of our past that help explain the genetic variation we observe today. aDNA is affected by extensive damage, including fragmentation and C-to-T substitutions. As a result, ancient genomes often have low sequencing depth, which is an impediment to confident genotype calling. Imputation has been proposed as a solution to this problem. However, it is unclear whether ancient genomes can be accurately imputed and how imperfect imputation affects downstream analyses. To address these questions, we downsampled 42 high-coverage (>10x) ancient human genomes from different times and continents to low coverage and subsequently imputed them with GLIMPSE, an imputation and phasing tool, using 1000 Genomes as a reference panel. We found that ancient and modern DNA imputation accuracies were comparable. For most 1x genomes, we recovered original high-coverage genotypes with low error rates (<5% for genotypes with at least one copy of the alternative allele). Error rates were higher for African genomes, likely due to underrepresentation in the reference panel. There were no measurable differences between imputation accuracy of transversion and transition sites, although the latter are known to be affected by C-to-T substitutions. To study imputation effects on downstream analyses, we analyzed high-coverage and imputed genomes using principal component analysis (PCA), genetic clustering estimating ancestry contributions for the European individuals, and runs of homozygosity (ROH, an inbreeding measure typically requiring diploid data). For these applications, we obtained similar results with high-coverage and imputed genomes when depth of coverage was at least 0.5x. Finally, we showed that aDNA imputation accuracy can be further improved by making use of methodological improvements, i.e., GLIMPSE2, and larger reference panels, i.e., UK Biobank with 150K whole-genome sequences. For example, in the case of four Viking genomes, error rates at alternative allele sites went down to below 5% at 0.25x, which was previously only achieved at 0.75x. Altogether, our results show that, with an appropriate reference panel and depending on the genome coverage, imputation can be reliably applied to expand and improve aDNA studies.

Evolutionary and Population Genetics Posters - Thursday

PB2804*. Inference of natural selection on epigenetic marks: implications for the evolution of gene regulation and germline mutation rates

Authors:

L. Boukas, A. Razi, H. Bjornsson, K. Hansen; Johns Hopkins Univ., Baltimore, MD

Abstract Body:

Natural selection is one of the fundamental forces shaping the evolution of living organisms, and detecting its presence is a major goal of evolutionary biology. Thus far, focus has been on detecting selection on the DNA sequence. However, natural selection acts on phenotypes; footprints of selection within the DNA sequence only reflect the extent to which the latter causally determines these phenotypes. In turn, the causal effect of the DNA sequence on phenotypes is mediated via intermediate functional molecular features, such as epigenetic marks. Therefore, it is of interest to move beyond DNA, and identify selective pressures on specific molecular features. This represents the main objective of “evolutionary cell biology”.

Here, to the best of our knowledge, we develop the first framework for detecting selection on epigenetic marks. We formalize a notion of neutrality, and use it to derive a test for selection. Our test captures the key aspect of the underlying biology: that epigenetic marks are controlled in trans by transcription factors and chromatin modifiers. We illustrate the generality of our approach by applying it to 3 different modifications (DNA methylation, H3K4me3, H3K36me3) and a broad range of genomic compartments (promoters, gene bodies, transcriptional end regions). Our findings reveal the action of selection on several marks, including an unexpected finding of positive selection on the size of the hypomethylated region around proximal promoters, even though this has a negligible correlation with expression. In addition, we find that the selective pressure on proximal promoter DNA methylation/H3K4me3 and gene-body H3K36me3 is not a passive consequence of selection on gene expression. This provides evolutionary support for an active, causal role of these marks on gene regulation.

Finally, we provide evidence (using comparative analyses, analyses of trio genomic sequencing data, and population genetic simulations) that - in addition to their involvement in gene regulation - the selective pressure on DNA methylation and H3K36me3 may partly be explained by their effect on regional mutation rates in the germline (on promoter CpGs and exons, respectively). There is currently little empirical support for selection on regional mutation rate modifiers, and it has been proposed that such secondary selection is dominated by random drift. However, epigenetic marks affect the mutation rate at multiple locations simultaneously; we show this cumulative effect may overcome drift.

Our framework for selection inference is simple but general, and we anticipate its core idea to be useful for other molecular features beyond epigenetic marks.

Evolutionary and Population Genetics Posters - Wednesday

PB2805. Inference of the distribution of fitness effects using local genealogical trees

Authors:

D. Ortega-Del Vecchyo, A. Izarraras-Gomez; Natl. Autonomous Univ. Of Mexico, Queretaro, Mexico

Abstract Body:

The distribution of fitness effects of new mutations (DFE) measures the proportion of new variants that have a particular selection coefficient. The DFE is a fundamental determinant of levels of genetic and phenotypic variation. Previous methods that estimate the DFE in humans have mainly used information from summary statistics, such as the site frequency spectrum or metrics of linkage disequilibrium. All of the summary statistics are ultimately a function of the collection of local genealogical trees across the genome. Due to this, the collection of genealogical trees should contain all the necessary information to perform an inference of the DFE that could be more accurate than previous approaches that use summary statistics. Here we propose a new maximum likelihood method to infer the DFE using information from genome-wide local trees. This method uses information from the number of lineages seen at different times in the past in a collection of local genealogical trees. We show that our method is accurate using simulations. Furthermore, we show an application of our method in data from the 1000 genomes project to infer the DFE in nonsynonymous sites in the genome and sets of variants predicted to be deleterious based on various algorithms such as CADD and EVE. We show how our method can be applied to infer the distribution of fitness effects of all the variants found in the genome by leveraging functional information that include data from CADD and EVE.

PB2806. Inferences about archaic introgression and positive selection from Lithuanian whole-genome sequences

Authors:

A. Urnikyte, A. Masiulyte, A. Molyte, V. Kucinskas; Dept. of Human and Med. Genetics, Inst. of BioMed. Sci., Faculty of Med., Vilnius Univ., Vilnius, Lithuania

Abstract Body:

The sequencing of archaic and modern human genomes has demonstrated gene flow between modern and archaic populations. To understand the functional and evolutionary consequences of introgression we need to identify the genetic variants inherited from archaic hominin ancestors in local populations. Here we present results of identified introgressed archaic DNA fragments in the genome of present-day Lithuanians and determined whether positive selection has acted on these fragments.

To identify candidate introgressive regions, we analysed whole-genome data (~36.27x coverage) of 50 Lithuanian individuals by using two statistical approaches: Sprime and ArchIE. Signatures of positive selection were investigated using three statistics: Tajima's D, FST, and XP-EHH. Annotation performed with Ensembl Variant Effect Predictor and ANNOVAR in GRCh37 (hg19), RefSeqGene, gnomAD, dbSNP147, and CADD version 1.3.

We found 80 Mb of the Lithuanian genome covered by putative introgressed segments detected by ArchIE, and 0.64 Mb by Sprime. The biggest number of Neanderthal introgressed fragments found with ArchIE was identified in chromosome 6, which has HLA genes, important in the acquired immunity. Also, ArchIE identified a fragment in chromosome 9, that has the BNC2 gene, which has an impact on the level of skin pigmentation in Europeans, and a fragment in chromosome 11, comprising the OR4X1 gene, which encodes olfactory receptor.

We have identified strong genomic regions, already described previously, introgressed from Neanderthals, and under positive selection. The most interesting regions include HLA-DRB1 and BNC2 genes.

Comparative analysis of detected introgressed archaic fragments in the Lithuanian population with Vindija Neanderthal genome identified matching SNPs, which are residing in genes, related to adaptive immunity, mitochondrial translation, and DNA reparation.

This research was funded by the European Social Fund under the No 09.3.3-LMT-K-712 "Development of Competencies of Scientists, other Researchers and Students through Practical research Activities" measure.

PB2807. Inferring between-population genetic variation using admixed populations: challenges and limitations.

Authors:

J. Huang¹, M. D. Shriver¹, A. A. Zaidi²; ¹Penn State Univ., University Park, PA, ²Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

The extent to which phenotypic differences between populations are driven by a difference in mean genetic value is determined using common garden experiments where the environment can be controlled. In humans, where this is neither practical nor ethical, we often analyze admixed populations, where ancestry and environment are decoupled. Here, we describe, using theory and simulations, the quantitative behavior of genetic variance underlying complex traits in admixed populations and our ability to leverage admixture to infer how source populations differ in their genetic values.

First, we show that ancestry-phenotype correlations, which are often used to illustrate that genetic effects underlie phenotypic differences between populations, are mediated both by trait architecture (e.g. heritability and F_{st}) and admixture dynamics (e.g. time(s) since admixture, ancestry-stratified mating, and degree of gene flow). For traits differing in mean genetic value between the source populations, the ancestry-phenotype correlation is highest when the populations first meet and decays over time. The rate of decay is slowed in the presence of ancestry-stratified mating and continued gene flow from source populations.

We show that while ancestry-phenotype correlations can be informative about genetic effects, at least within a few generations after admixture, they can also result from ancestry-related environmental exposures. Thus, ancestry-phenotype correlations alone are not indicative of a mean genetic difference between the source populations.

It has been suggested that in principle, the genetic variance due to local ancestry in admixed populations can be informative about mean differences in genetic value between source populations. However, the local-ancestry genetic variance is mathematically equivalent to the genetic variance between populations but only at the time of admixture. This equivalence decays in subsequent generations at a rate that depends on admixture dynamics and assortative mating.

We provide a quantitative treatment of the genetic variance components of complex traits in admixed populations as a function of their demographic history and the distribution of environmental effects. In doing so, we highlight the challenges and limitations of using admixed populations to make inferences about the difference in mean genetic value between the source populations. Our work also provides a quantitative description of the effects of admixture dynamics on the predictive accuracy of polygenic scores in admixed populations.

Evolutionary and Population Genetics Posters - Thursday

PB2808*. Inferring germline CpG methylation signature accumulated along the human history from genetic variation catalogs

Authors:

Y. Si, S. Zöllner; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

DNA methylation is a key to understanding gene regulatory mechanisms and modeling mutation rate heterogeneity. Genome wide methylation levels are measured by whole genome bisulfite sequencing (WGBS), but it is currently restricted to small sample sizes especially for human germline cells. Moreover, these sequencing measures depend on individual genotypes of the samples, where C to T mutation carriers do not have methylation signature at that site but the ancestral alleles could be methylated, resulting in a systematic bias masking highly methylated thus often mutated sites. Here we present an alternative approach to estimate historical methylation patterns. We estimate mutation rates of germline methylated CpG sites to be 2.8 times that of non-methylated CpG and 11.4 times that of non-CpG sites, consistent with experimental studies. As a large number of whole genomes have been sequenced, at least one mutation event has been recorded in nearly all methylated thus highly mutable CpG sites. Those methylated CpG sites often contain multiple identical alleles that have originated independently in history, distorting the local sample frequency spectrum from the expectation under the infinite site assumption. CpG methylation status is highly localized, a feature distinct from other major factors affecting mutation rates. Here we leverage this locality and introduce a Hidden Markov Model to infer the germline mutation burden and historical germline methylation patterns based on allele frequencies from large genetic variant catalogs. We applied our method to publicly available allele frequencies from the gnomAD and the TOPMed databases. Our estimates are consistent with methylation levels observed in human germ cells by WGBS in 93.7% of measured CpG sites, but we also identified ~442,000 methylated CpG sites that were not captured due to sample genetic variation and inferred methylation status for ~721,000 CpG sites that were missing from WGBS. We observed that due to technical limitations, missingness of WGBS is enriched by 4.8 fold in GC-rich regions such as CpG islands, where our method has the highest accuracy and methylation status are of the most interest to identify active chromatin regions. Thus combining our results and WGBS identifies active non-methylated regions with higher specificity, and characterizes the germline methylation landscape more comprehensively overall than using experimental measures alone. Our estimated historical methylation status can be leveraged to enhance all bioinformatic analysis of methylation status such as predicting mutation constrain, and annotating regulatory and inactivated genomic regions.

Evolutionary and Population Genetics Posters - Wednesday

PB2809. Insights into non-equilibrium population genetics under strong natural selection from a new theoretical formalism

Authors:

D. Balick; Harvard Med. Sch., Boston, MA

Abstract Body:

Natural populations are virtually never observed in equilibrium: no estimate of human demographic history thus far has resulted in a static effective population size long enough to reach equilibrium. Yet, equilibrium assumptions are both ubiquitous in statistical tools and comprise much our understanding of population genetics. Here, I develop a field theoretic formalism for population genetics, using standard tools from stochastic and quantum field theory, that describes the temporal evolution of the allele frequency probability distribution in non-equilibrium settings. I focus on strong purifying selection, where most human disease variation lies, to understand the response to a range of demographic scenarios observed in human history. The dynamics of equilibration to mutation-selection-drift balance in a population with constant size are considered, along with three demographic scenarios: exponential growth (e.g., recent human history), a population experiencing a bottleneck (e.g., the Out of Africa), and oscillatory population size (e.g., seasonal changes in *Drosophila*). This formalism provides a prescription for attaining closed-form approximations for arbitrary moments of the frequency distribution in any demography, or for time-dependent selection or mutation, without time-intensive simulations. The first four moments are presented: dynamics of the mean frequency, variance (and homozygosity), skew, and excess kurtosis, the latter two generally ignored in analysis of the frequency distribution. These moments equilibrate at slightly different rates, but generically take longer than the naïve estimate of order $1/s$. A transient increase in the variance of the frequency distribution is detailed prior to equilibration, which can be intensified by exponential growth, indicating that equilibrium does not maximize the possible variance of frequency distribution. Surprisingly, in a constant population, the skew and excess kurtosis approach fixed values, independent of selection (provided $2Ns > 5$) and dependent only on $\theta = 4N\mu$. Under exponential growth, this can be temporarily attained in a transient quasi-equilibrium, prior to the rapid decay of the drift coefficient; thus, even nearly lethal disease can be temporarily harbored in the high frequency tail of the distribution due to this transient state. This field theory of population genetics provides highly accurate approximations in a range of human-relevant regimes under strong selection, enabling a deeper understanding of non-equilibrium scenarios ubiquitous in human history.

PB2810. Integrative approaches linking divergent selection to disease association studies

Authors:

G-W. Shaw¹, T. L. Mosbrugger¹, Y. Li², D. Monos³, T. Hayeck³; ¹Div. of Genomic Diagnostics, Dept. of Pathology and Lab. Med., Children's Hosp. of Philadelphia, Philadelphia, PA, ²Div. of Genomic Diagnostics, Dept. of Pathology and Lab. Med., Children's Hosp. of Philadelphia; Dept. of Pathology and Lab. Med., Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, ³Div. of Genomic Diagnostics, Dept. of Pathology and Lab. Med., Children's Hosp. of Philadelphia, Philadelphia; Dept. of Pathology and Lab. Med., Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Differences and similarities in genetic variation across world populations help us understand adaptations to evolutionary pressures in response to disease. This study leverages the latest release of 1000 Genomes Project (1KGP), high coverage whole genome sequencing with hundreds of complete trios for improved phasing, to characterize genetic diversity and evolutionary selection across and within world populations. A new test statistic was developed looking at balancing and positive selection, to detect regional differentiation in patterns of linkage disequilibrium and density of polymorphism across populations. Strong evidence of population specific differentiation was mapped throughout the 1KGP both at the super and sub-populations levels. We linked selection signal in 1KGP to summary statistics from large-scale genome-wide association studies (GWAS), matching ancestral group in both. This ties potential divergent evolution to corresponding genes and diseases in specific populations. Divergent selection in and around the BTNL2 gene was seen in East Asians at variants tied to both liver and lung function. Whereas in Africans strong divergent selection signal is observed in and around ALG10B at variants related to cardiomyopathy, along with signal in HLA-C and SPOCK3 related to immune response. Interestingly, consistent patterns enrichment of selection signal across populations were observed in both unprocessed pseudogenes and polymorphic pseudogenes pointing to potential biological functions favoring diversification and development of novel genes. Our results provide insight into both divergent and common patterns of evolutionary selection across world populations with implications in adaptation to disease response

PB2811. Introgressed sequences and positive selection profiles of the Japanese population revealed by the analysis of 3,256 Japanese whole-genome sequencing (WGS) data.

Authors:

K. Tomizuka¹, X. LIU¹, S. Koyama¹, Y. Ishikawa¹, M. Horikoshi², S. Ikegawa³, Y. Kamatani^{1,4}, K. Ito⁵, K. Matsuda⁶, Y. Momozawa¹, C. TERAO^{1,7,8}; ¹RIKEN, Yokohama, Japan, ²RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, ³IMS, RIKEN, Tokyo, Japan, ⁴The Univ. of Tokyo, Tokyo, Japan, ⁵RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, ⁶Osaka Univ. Graduate Sch. of Med., Tokyo, Japan, ⁷Shizuoka Gen. Hosp., Shizuoka, Japan, ⁸Univ. of Shizuoka, Shizuoka, Japan

Abstract Body:

Genetic studies conducted in the Japanese population contributed enormously to our understanding of the genetic basis of various diseases and complex traits. However, the lack of nationwide Japanese whole-genome sequencing (WGS) resources hinders further genetic and translational studies. To fill this gap, we generated a high-depth WGS dataset of 3,256 individuals from different regions of Japan, termed as Japanese Encyclopedia of Whole/Exome sequencing library (JEWEL). We identified 15.4 million unreported variants including rare and functional variants. This valuable resource allowed us to examine several unexplored characteristics of the Japanese population. First, we applied a recently developed reference-free method to detect sequences likely introgressed from Neanderthal or Denisovan, and we identified 44 archaic segments that were significantly associated with clinically relevant phenotypes in the Japanese. Notably, majority of them were specific to East Asian populations. Furthermore, we identified 22 genetic loci under positive selection at the genome-wide significance level including known targets such as *ADH*, *ALDH2*, *MHC* and a dozen of novel loci harboring immune related genes. Collectively, our work revealed new insights into the genetic characteristics of the Japanese population.

Evolutionary and Population Genetics Posters - Thursday

PB2812. Investigating human migrations and genetic diversity in Northeast India over the last ~4,000 years using ancient genomics

Authors:

E. Bandyopadhyay¹, C. de la Fuente¹, D. Witonsky¹, T. Jamir², D. Tetso³, N. Rai⁴, M. Raghavan¹; ¹The Univ. of Chicago, Chicago, IL, ²Dept. of History and Archaeology, Nagaland Univ., Kohima Campus, Nagaland, India, ³Dept. of Anthropology, Kohima Sci. Coll. (Autonomous), Nagaland, India, ⁴Birbal Sahni Inst. of PalaeoSci.s, Lucknow, India

Abstract Body:

Northeast India occupies a strategic position between South Asia, East Asia, and Southeast Asia. Archaeological evidence from cave and rockshelter sites along the Nagaland-Myanmar border suggests that hunter-gatherer societies survived in the forested uplands of Northeast India spanning the mid-Holocene to as late as ~3,500 years before present (yBP). The temporal context to the transition to agriculture in the state of Nagaland is yet to be firmly established. More broadly, across Northeast India, archaeological records reveal that prominent features of farming culture, or the Neolithic, postulated to date back as early as ~4,000 yBP, such as edge ground tools, cord-mark pottery and rice/millet cultivation, display similarities with East Asia and Southeast Asia. Additionally, genetic affinities have been reported between present-day Northeast Indian populations and Eastern Eurasians, though the temporal context and source of this affinity remain unconfirmed by genetic data. This raises an important question about the genetic relationship between hunter-gatherers, early farmers, and present-day inhabitants of the region as well as regional affinities over time with Eastern Eurasian populations. In this study, we aim to characterize the timing and sources of past human movements and interactions in Northeast India by analyzing genome-wide data from samples excavated from the rockshelter site of Photangkhun Longkhap (PTL) in Nagaland State in Northeast India, and archaeologically dated to the hunter-gatherer phase *ca.* 3,700 - 4,300 yBP. Results from this study, representing the first ancient genomic data from this region of the world, will shed light on past genetic diversity and the human movements into Northeast India over the last ~4,000 years.

Evolutionary and Population Genetics Posters - Wednesday

PB2813. Investigating selection and the genetics of height in Central African Rainforest Hunter-gatherers

Authors:

D. Ju¹, M. McQuillan¹, M. Hansen¹, D. Harris¹, C. Zhang¹, A. Ranciaro¹, W. Beggs¹, S. Chanock², C. Fokunang³, A. Njamnshi⁴, M. Yeager⁵, I. Mathieson¹, S. Tishkoff¹; ¹Univ. of Pennsylvania, Philadelphia, PA, ²Natl. Cancer Inst, Rockville, MD, ³Univ. of Bamenda, Bamenda, Cameroon, ⁴Univ. of Yaounde I, Yaounde, Cameroon, ⁵FNLCR/NCI, Rockville, MD

Abstract Body:

Shorter stature has been hypothesized to have been under selection in Central African Rainforest Hunter Gatherer (RHG) populations, but the genetic loci involved remain unclear. We studied a cohort of RHG groups encompassing Baka and Bagyeli (N=207) and an agricultural population, Tikari (N=246), from Western Cameroon that were genotyped on the H3Africa array. We first identified genomic signatures of positive selection in the RHG and then quantified the height variation within RHG that can be explained by global ancestry and European GWAS height-associated SNPs. Finally, we inferred local ancestry tracts in the RHG, comparing two methods, Rfmix and MOSAIC. We used the selscan tool in the Ohana package to identify loci exhibiting the most allelic differentiation in the Baka compared to Tikari, San, and 1000 Genomes CEU. A locus on chromosome 1 that encompasses a cluster of cytochrome P450 genes, involved in drug metabolism and lipid synthesis, showed the strongest signal of selection ($P=2.28E-10$), which was recapitulated as the top hit in a separate population branch statistic (PBS) test. A previously reported shared selective sweep across RHG groups upstream of *TRPS1*, which encodes a transcription factor regulating genes involved in bone and cartilage development, also exhibited an elevated signal in our Ohana ($P=3.34E-7$) and PBS (99.97 percentile) scans. Our integrated haplotype score scan identified a selective sweep in the Baka (normalized $iHS = -7.06$) that harbors a stop gain variant in the last exon of *TLR5*, suggesting adaptation related to immunity. We replicated a previous observation of RHG ancestry being associated with shorter height ($P=0.002$), but it only explained 5.5% of the variance in height in a regression of height on global ancestry, as inferred by ADMIXTURE ($K=2$), controlling for sex and age. We then constructed polygenic scores using SNPs from the UK Biobank GWAS conducted in European-ancestry individuals and found polygenic scores have even less explanatory power within RHG ($R^2=0.025$; $P=0.024$) and do not reflect differences in phenotypic height between RHG and Tikari. Finally, we called local ancestry tracts using Rfmix and MOSAIC and observed MOSAIC systematically called more RHG ancestry in the Baka than Rfmix. Rfmix tended to infer less overall RHG ancestry compared to ADMIXTURE, but concordance was high ($r^2=0.90$). This observation indicates that traditional approaches for inferring local ancestry may be inaccurate in populations with complex demographic histories, especially with old admixture events. Abstract Body:

Ancestry informative markers are being used for biogeographic ancestry inference, at the individual or population levels, for medical, forensic and anthropologic purposes. Due to the use of specific parameters to select a given set of AIMs, coupled with the loss of accuracy introduced by the efforts to reduce the number of markers in a set, additional studies are necessary for assessment of their limitations. In this context the SNP*for*ID 34-plex was developed for a single-tube analysis aiming to differentiate Sub-Saharan African, European and East-Asian populations. The Kidd's Lab set of 55 AISNPs was set to differentiate the Sub-Saharan Africa, Europe, Southwest-Asia, South-Asia, East-Asia, Oceania and the Americas. However, their effectiveness for Latin American admixed populations is still poorly assessed. Moreover, despite the complex and countrywide heterogeneous process of peopling, the majority of studies consider the Brazilian population as tri-hybrid, composed by African, European, and Amerindian inputs. Thus, we aim to analyze these two panels of AIMs in an admixed Brazilian population sample from Ribeirão Preto (Southeastern Brazil), and to evaluate the outcomes of models that consider Ribeirão Preto either as tetra- or tri-hybrid (for this latter case, exploring the interchange between Amerindians and East Asians as the third component). DNA was extracted from 513 individuals by salting-out. These two sets of markers were included into a customized Next-Generation Sequencing assay using HaloPlex Target Enrichment System (Agilent) and the MiSeq Personal Sequencer platform (Illumina). PCA analysis for the 34-plex panel clustered Amerindians with East-Asians populations, while the 55 AIMs provided better separation between them, particularly when considering the third component. This issue has influenced populational and individual ancestry inference: three different methods (Admix 2.0, Admix 95 and STRUCTURE) used to assess the three models revealed that EUR (ranging from 67.4% to 70.2%) and AFR (ranging from 19.9% to 24.4%) contributions are consistent between all analyses. However, AMR ancestry is underestimated while EAS ancestry is overestimated in the sampled individuals when the 34-plex is taken into account. Overall, given the capacity of differentiating EAS from AMR, the Kidd's Lab set of 55 AISNPs is better suited for analyzing the ancestry composition at the individual and population levels when both AMR and EAS ancestries are concerned. FINANCIAL SUPPORT: FAPESP (Grant 2013/154470), CNPq/Brazil (Grant 448242/2014-1 and Fellowship 312802/2018-8), and CAPES/Brasil (Finance Code 001).

LLC, TARRYTOWN, NY, ³List of consortium authors and their affiliations will be provided upon request, Doha, Qatar, ⁴Cornell Univ, Ithaca, NY

Abstract Body:

Arab populations are largely understudied, notably their genetic structure, history as well as underlying disease risk and architecture. We present an in-depth analysis on a novel set of 6,218 whole genomes sequenced at 30x coverage from the Qatar Genome Program (QGP). This revealed extensive diversity as well as genetic ancestries representing the main founding Arab genealogical lineages of Qahtanite (Peninsular Arabs) and Adnanite (General Arabs and West Eurasian Arabs). Peninsular Arabs were found to be the closest relatives of ancient hunter-gatherers and Neolithic farmers from the Levant, and founder Arab populations experienced multiple splitting events 12-20 kya, consistent with the aridification of Arabia and farming in the Levant, giving rise to settler and nomadic communities. As far as recent genetic flow is concerned, these ancestries were found to contribute significantly to European, South Asian as well as South American populations, likely as a result of Islamic expansion over the past 1400 years. In terms of runs of homozygosity (ROH) which are known to be a risk for recessive disease, we found unprecedented lengths ROH particularly amongst Peninsular Arabs, extending to 60-70 Mb. Furthermore, we characterize a cohort of 1,491 men with the ChrY J1a2b haplogroup, identifying 29 unique sub-haplogroups (based on 103 novel SNVs), representing the largest set of subjects sequenced to date with this haplogroup. Based on this QGP dataset of predominantly healthy adults, we built an imputation panel containing 12,432 haplotypes and 69,018,172 SNVs. This provides an unprecedented panel to expand genomic knowledge of Middle Eastern populations, empowering precision genomics studies in the region and worldwide.

PB2816. Late Night Eating or Circadian disruption could be more dangerous than our think Late Night Eating or Circadian disruption could be more dangerous than our think

Authors:

Q. Naz, N. Verma, K. Usman, A. Mahdi; KGMU, Lucknow, India

Abstract Body:

Aim & Objective: The aim of this study is to investigate whether there was a relationship between morningness(MC) (110n) intermediate(IC) (100n) & eveningness chronotype(EC) (35n) in T2DM. **Methods:** A total of 245 subjects' age 18 to 60 years were recruited in Clinical OPD of General Medicine, KGMU. We have tested FBG & PP level, lipid profile HbA1c, Insulin, Leptin and Cortisol level, 48 hours ABPM. **Result:** When we compared these 3 groups, Significant Different parameters found in FBG (P = 0.01) Postprandial (P = 0.03) HbA1c (P = 0.001) TG (P = 0.0001), Total Cholesterol (P = 0.01) & VLDL (P = 0.005). It also shows the complete inversion of the cortisol level (0.003). Insulin, IL-1 beta & IL-6 also show significant change in late night eating T2DM Patients. Systolic / Diastolic readings of ABPM shows significant change between MC and IC (0.005) but not b/w EC & IC (0.007). And for reliability of sleep by actigraphy shows MC (6:15 ± 1:35) & EC (8:18 ± 1:23) take complete sleep but IC total sleep hours (5:10 ± 1:05) are very less. Disruption of Rev Erb (0.003) & Ror α (0.001) gene expression is also a risk factor for Cardio metabolic Diseases in T2DM Patients. **Conclusion:** Eating late at night are more likely to have late night eaters & are associated with greater risk of Metabolic Disorders like Blood Pressure Variability, Dyslipidemia, T2DM & CVD.

PB2817. Leveraging Base Pair Mammalian Constraint to Understand Genetic Variation and Human Disease

Authors:

S. Gazal¹, M. Christmas², M. Dong², D. Genereux³, I. Kaplow⁴, J. Meadows², P. Sullivan⁵, E. Karlsson⁶, K. Lindblad-Toh²; ¹Univ. of Southern California, Los Angeles, CA, ²Uppsala Univ., Uppsala, Sweden, ³Broad Inst. of MIT and Harvard, Cambridge, MA, ⁴Carnegie Mellon Univ., Pittsburgh, PA, ⁵Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ⁶Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract Body:

Although thousands of genomic regions have been associated with heritable human diseases, attempts to elucidate biological mechanisms are impeded by a general inability to discern which genomic positions are functionally important. Evolutionary constraint is a powerful predictor of genome function obtained from genome sequences alone. Previous studies of mammalian constraint were limited by species number and reliance on human-referenced alignments. Here, we used a reference-free whole-genome alignment of 240 species to resolve evolutionary constraint to single base resolution and leveraged this information to understand genetic variation and human diseases and complex traits.

First, we computed single base-level phyloP scores from the whole genome alignment of 240 placental mammals and identified 3.5% of the human genome as significantly constrained (5% FDR). Second, we illustrated that these scores annotate coding variants with a base pair resolution, thus providing a powerful tool to predict deleterious effects of coding variants. Third, we showed that more than 80% of constrained bases are non-coding and that nearly half are unannotated by resources like ENCODE, suggesting yet-to-be-discovered functional elements. Fourth, we performed SNP-heritability of constraint common variants on 63 independent European ancestry GWAS and observed that Zoonomia constraint scores are far more informative than other key functional annotations (i.e. GTEx, ENCODE) on human diseases and complex traits. Specifically, constrained variants were more enriched than key functional annotations, such as non-synonymous coding variants or fine-mapped eQTL-SNPs, validating the ability of constraint to dissect human diseases and complex traits. Finally, we illustrated how Zoonomia constraint scores increase power and interpretation of functionally informed fine-mapping results when using the PolyFun method on UK Biobank traits.

Our results demonstrate the utility of constraint as a functional annotation that can be leveraged to deepen our understanding of heritable human diseases, but also highlight that the regulatory landscape of the human genome still needs to be further explored and potentially used to help decipher mechanisms underlying disease.

Evolutionary and Population Genetics Posters - Thursday

PB2818. Long-range regulatory effects of Neandertal DNA in modern humans

Authors:

D. Yermakovich, V. Pankratov, U. Võsa, B. Yunusbayev, Estonian Biobank Research Team, M. Dannemann; Inst. of Genomics, Univ. of Tartu, Tartu, Estonia

Abstract Body:

The admixture between modern humans and Neandertals has resulted in ~2% of the genomes of present-day non-Africans being composed of Neandertal DNA. Association studies have shown that introgressed DNA significantly influences skin and hair traits, immunity and behavioral phenotypes in people today. Several of the phenotype-associated archaic variants have links to regulatory effects as well. In general, analyses of allele-specific expression, regulatory sequence composition and cis-eQTL have demonstrated a significant contribution of this introgressed DNA to the transcriptomic landscape of modern humans. However, little is known about the impact of Neandertal DNA on long-range regulatory effects that have been shown to explain ~20% of expression variation.

In this study, we investigated one particular mechanism where the trans effect is mediated through cis-eQTLs expression regulation of transcription factors (TFs) genes. We identified 60 TFs genes with their top cis-eQTL SNP being of Neandertal ancestry in GTEx and predicted long-range Neandertal DNA-induced regulatory effects by screening for the predicted target genes of those TFs. We found elevated levels of interactivity between these TFs suggesting a potential for dependency in the functional processes they are involved in. We show that genes in regions devoid of Neandertal DNA are enriched among the target genes of some of these TFs. Furthermore, archaic cis-eQTLs for these TFs included multiple candidates for local adaptation and have associations with various immune traits, schizophrenia, blood cell type composition, and anthropometric measures. Finally, we show that our results can be replicated in empirical trans-eQTLs with Neandertal variants.

Our results suggest that the regulatory reach of Neandertal DNA goes beyond the 40% of genomic sequence that it still covers in present-day non-Africans and that via this mechanism Neandertal DNA additionally influences the phenotypic variation in people today.

Evolutionary and Population Genetics Posters - Wednesday

PB2819. Lower allele frequency among males is a marker for pathogenicity among non-pseudoautosomal X-chromosome variants

Authors:

T. Ciesielski, J. Bartlett, S. Iyengar, S. Williams; Case Western Reserve Univ., Cleveland, OH

Abstract Body:

Pathogenic variants on the X-chromosome can have more severe consequences for hemizygous males, while heterozygote females can avoid severe consequences due to diploidy and the capacity for nonrandom expression. Thus, an allele being more common in females could indicate variant pathogenicity, and large-scale genomic data now makes it possible to compare allele proportions between the sexes. To discover pathogenic variants on the X-chromosome, we analyzed exome data from 125,748 ancestrally diverse participants in the Genome Aggregation Database (gnomAD). After filtering out duplicates and extremely rare variants, 44,606 of the original 348,221 remained for analysis. We placed each variant into one of three a priori categories: 1) Reference (Primarily synonymous), Unlikely-to-be-Tolerated (Primarily missense), and Least-likely-to-be-tolerated (Primarily frameshift). Then we divided the proportion of variant alleles in females by the proportion in males for all variant sites. To assess the impact of ploidy, we compared the distribution of these ratios between pseudoautosomal and non-pseudoautosomal regions. In the non-pseudoautosomal regions, mean female-to-male ratios were lowest among Reference (2.40), greater for Unlikely-to-be-Tolerated (2.77) and highest for Least-likely-to-be-tolerated (3.28) variants. Corresponding ratios were lower in the pseudoautosomal regions (1.52, 1.57, and 1.68, respectively), with the most extreme ratio being 11. Because pathogenic effects in the pseudoautosomal regions should not drive ratio increases, this maximum ratio provides an upper-bound for baseline noise. In the non-pseudoautosomal regions, 319 variants had a ratio over 11. In sum, we identified a metric with a data-set specific threshold for identifying pathogenicity in non-pseudoautosomal X-chromosome variants: the female-to-male allele proportion ratio.

Evolutionary and Population Genetics Posters - Thursday

PB2820*. *MaLAdapt* reveals novel targets of adaptive introgression from Neanderthals and Denisovans in worldwide human populations

Authors:

X. Zhang¹, B. Kim², A. Singh¹, S. Sankararaman³, A. Durvasula⁴, K. Lohmueller⁵; ¹Univ. of California Los Angeles, Los Angeles, CA, ²Stanford Univ., Palo Alto, CA, ³UCLA, Los Angeles, CA, ⁴Harvard Med. Sch., Cambridge, MA, ⁵Univ California Los Angeles, Los Angeles, CA

Abstract Body:

Adaptive introgression (AI) facilitates local adaptation in a wide range of species. Many state-of-the-art methods detect AI with *ad-hoc* approaches that identify summary statistic outliers or intersect scans for positive selection with scans for introgressed genomic regions. Although widely used, these outlier-based approaches are vulnerable to a high false-negative rate as the power of different methods vary, especially for complex introgression events. Moreover, population genetic processes unrelated to AI, such as background selection or heterosis, may create similar genomic signals as AI, compromising the reliability of methods that rely on neutral null distributions. In recent years, machine learning (ML) methods have been increasingly applied to population genetic questions. Here, we present an ML-based method called *MaLAdapt* for identifying AI loci from genome-wide sequencing data. Using an Extra-Trees Classifier algorithm, our method combines information from a large number of biologically meaningful summary statistics to capture a powerful composite signature of AI across the genome. In contrast to existing methods, *MaLAdapt* is especially well-powered to detect AI with mild beneficial effects, including selection on standing archaic variation, and is robust to non-AI selection sweeps, heterosis, and demographic misspecifications. Further, *MaLAdapt* outperforms existing methods for detecting AI based on the analysis of simulated data and on a validation of empirical signals through visual inspection of haplotype patterns. We apply *MaLAdapt* to the 1000 Genomes Project human genomic data, and discover novel AI candidate regions in non-African populations, including genes that are enriched in functionally important biological pathways regulating metabolism and immune responses.

PB2821. Modeling recurrent mutations predicts allele frequencies and enables precise inference in large samples.

Authors:

E. Koch¹, V. Seplyarskiy¹, D. Lee¹, J. Wakeley², L-T. Fan³, S. Sunyaev¹; ¹Dept. of BioMed. Informatics, Harvard Med. Sch., Boston, MA, ²Dept. of Organismic and Evolutionary Biology, Harvard Univ., Boston, MA, ³Dept. of Mathematics, Indiana Univ., Bloomington, IN

Abstract Body:

As sample sizes of human genome sequences reach the range of millions of individuals, previously reliable assumptions in population genetics have started to break down. An important instance is the assumption that each mutation occurs only once in the history of the sample. When sample sizes are large enough and mutation rates sufficiently high, identical variants shared by multiple individuals may represent independent mutational events rather than inheritance from a recent common ancestor. We develop theoretical and computational machinery to account for recurrent mutations in the site frequency spectrum (SFS). The SFS describes variant counts at each possible sample frequency and is a useful summary of sequencing data. We apply our model to a sample of ~120k exomes (gnomAD v2.1.1) using new per-bp estimates of mutation rates (Roulette) and show that the SFS is well-predicted when mutation rates are known with sufficient accuracy. We next demonstrate how recurrent mutations can be used to estimate the remaining residual variance in mutation rate estimates. A new formula, which accounts for recurrent mutation, is presented for the SFS of rare variants in large samples from exponentially growing populations. This expression greatly improves computational efficiency relative to stochastic simulations and numerical integration. Finally, we demonstrate the importance of modeling the recurrent SFS when estimating selective constraint. Current methods applicable to contemporary human sample sizes largely only model the presence or absence of mutations. A model using the frequencies of loss-of-function variants significantly improves the detection of disease genes over presence/absence models.

Evolutionary and Population Genetics Posters - Wednesday

PB2822. Mosaic chromosomal alterations and longevity

Authors:

A. Leshchyk¹, Q. Xiang¹, A. Gurinovich², Z. Song¹, S. Andersen¹, S. Monti¹, K. Christensen³, A. Yashin⁴, M. Wojczynski⁵, K. Schwander⁶, J. Lee⁷, T. Perls¹, P. Sebastiani⁸; ¹Boston Univ., Boston, MA, ²Tufts Med. Ctr., Boston, MA, ³Univ. of Southern Denmark, Odense, Denmark, ⁴Duke Univ., Durham, NC, ⁵Washington Univ Schl Med, St Louis, MO, ⁶Washington Univ. Sch. of Med., St Louis, MO, ⁷Taub Inst. for Res. on Alzheimer's Disease and the Aging Brain, Columbia Univ., New York City, NY, ⁸Inst. for Clinical Res. and Hlth.Policy Studies, Tufts Med. Ctr., Boston, MA

Abstract Body:

Mosaic chromosomal alterations (mCAs) are structural alterations that are associated with mortality, age, cancer, cardiovascular disease, and diverse infections. The distribution of mCAs in long-lived subjects and individuals with familial longevity is not well described. We applied MOsaic CHromosomal Alteration (MoChA) caller on genome-wide genotype samples of 2025 centenarians, their siblings, and offspring and 273 unrelated controls from the New England Centenarian Study (NECS) and 3642 subjects with familial longevity and 920 controls from the Long-Life Family Study (LLFS). MoChA utilizes a Hidden Markov Model to detect mCA-induced deviations in allelic balance at heterozygous sites with Log R Ratio and B-allele frequency (BAF) with phased genotype information. We analyzed somatic mCAs in samples with genome-wide BAF phase concordance less than 0.51, LOD score greater than 10, and estimated cell fraction less than 50% are evidence of mCAs. The results of the two studies showed that autosomal mCAs spanning over 100 kbase pairs increase with older age until approximately 102 years. However, the prevalence of the subjects with mCAs tends to plateau after that age, suggesting that the accumulation of mCAs is less prevalent in long-lived subjects. We also found that offspring and siblings of centenarians accumulate fewer autosomal mCAs (fixed-effect meta-analysis for NECS and LLFS: RR=0.78, p=0.033) compared to unrelated controls. In addition, consistent with results from other studies, mCAs are associated with increased risk for mortality (HR=1.08, p=0.02) and sex (Male RR=1.37, p=4.15e-05), and impact incident events of cancer, dementia, diabetes, and cardiovascular diseases even at extreme old ages.

Evolutionary and Population Genetics Posters - Thursday

PB2823*. Neanderthal introgression modifies anti-inflammatory response in modern humans.

Authors:

C. Boye¹, Y-L. Lin², A. Findley¹, A. Alazizi¹, A. Dumaine², L. Barreiro^{2,3,4}, R. Pique-Regi^{1,5}, F. Luca^{1,5}; ¹Ctr. for Molecular Med. and Genetics, Wayne State Univ., Detroit, MI, ²Section of Genetic Med., Dept. of Med., Univ. of Chicago, Chicago, IL, ³Dept. of Human Genetics, Univ. of Chicago, Chicago, IL, ⁴Committee on Immunology, Univ. of Chicago, Chicago, IL, ⁵Dept. of Obstetrics and Gynecology, Wayne State Univ., Detroit, MI

Abstract Body:

Approximately 2% of the modern Eurasian genome contains variants that humans obtained through interbreeding with Neanderthals. Neanderthal genetic variants may have been beneficial for modern humans (adaptive introgression), for example by providing a selective advantage in new environments. Studies indicated that Neanderthal-introgressed variants may be important for response to pathogens. We previously showed that Neanderthal-introgressed variants regulate genes that are important for the transcriptional response to other environmental challenges. As we cannot study Neanderthal-derived cells directly, we used a massively parallel reporter assay called Biallelic Targeted STARR-seq to study the gene regulatory function of Neanderthal-introgressed variants in human cells. We designed a library of 40,000 synthetic DNA constructs containing introgressed variants predicted to alter gene regulation. We transfected them into human cells and measured their regulatory activity by quantifying self-transcribed enhancer sequences via RNA-seq. To assess the effect of Neanderthal introgressed variants on the anti-inflammatory response, we treated cells with dexamethasone, a synthetic glucocorticoid that inhibits Nuclear Factor Kappa B (NF- κ B) and binds to the glucocorticoid receptor (GR). For 7,129 variants we identified significant differences in regulatory function between the Neanderthal and the modern human alleles. While 5,403 Neanderthal-introgressed variants directly modify the gene expression response to glucocorticoids (response variants, adjusted $p < 0.1$). Constructs containing these response variants and those differentially expressed in response to glucocorticoids were enriched for NF- κ B and GR binding motifs. Strikingly, the introgressed Neanderthal allele resulted in higher expression in cells treated with glucocorticoids in the majority of the constructs containing response variants. Overall, our results are consistent with a role of Neanderthal introgression in modern human anti-inflammatory response, likely through modification of GR and NF- κ B binding, and motivate future studies to identify adaptive advantage of these introgression events.

Evolutionary and Population Genetics Posters - Wednesday

PB2824. Newfoundland and Labrador: A mosaic founder population of an Irish and British diaspora from 300 years ago.

Authors:

E. Gilbert^{1,2}, H. Zurel³, M. MacMillan⁴, S. Demiriz⁴, S. Mirhendi⁵, M. Merrigan⁶, S. O'Reilly⁶, A. Molloy⁷, L. Brody⁸, W. Bodmer⁹, R. Leach¹⁰, G. Mugford⁴, R. Randhawa³, C. Stephens¹¹, A. Ctr., RCSI, Dublin, Ireland, ³Sequence Bioinformatics, Inc., St. John's, NL, Canada, ⁴Sequence Bioinformatics, Inc., St John's, NL, Canada, ⁵Sequence Bioinformatics, Inc, St John's, NL, Canada, ⁶Genealogical Society of Ireland, Dún Laoghaire, Ireland, ⁷Sch. of Med., Trinity Coll., Dublin, Ireland, ⁸NHGRI (NIH), Bethesda, MD, ⁹Weatherall Inst Molec Med, Oxford, United Kingdom, ¹⁰Sequence Bioinformatics, Inc., St. John's, NL, Canada, ¹¹Sequence Bioinformatics, Inc., St John's, NL, Canada, ¹²FutureNeuro SFI Res. Ctr., Dublin, Ireland

Abstract Body:

The founder population of Newfoundland and Labrador (NL) is a unique genetic resource, in part due to geographic and cultural isolation, where historical records describe a migration of European settlers primarily from Ireland and England to NL in the 18th and 19th centuries. Whilst its historical isolation, and increase prevalence of certain monogenic disorders, have been appreciated, the fine-scale genetic structure and ancestry of the population has not been well described. Understanding the genetic background on which functional, disease causing, genetic variation resides on would aid informed genetic mapping efforts in the Province. Here, we leverage dense genome-wide SNP data on 1,807 NL individuals to reveal fine-scale genetic structure in NL that is clustered around coastal communities and correlated with Christian denomination. We show that the majority of NL European ancestry can be traced back to the south-east and south-west of Ireland and England, respectively. We date a substantial population size bottleneck approximately 10-15 generations ago in NL, associated with increased haplotype sharing and autozygosity. Our results elucidate novel insights into the population history of NL, and demonstrate evidence of a population conducive to further genetic studies and biomarker discovery.

Evolutionary and Population Genetics Posters - Thursday

PB2825. No reduction in diagnostic yield of exome sequencing in prenatal and pediatric patients with non-European ancestries.

Authors:

Y. Mavura, N. Sahin-Hodoglugil, M. Kvale, J. Van Ziffle, W. P. Devine, U. Hodoglugil, P-M. Martin, B. A. Koenig, S. Ackerman, A. Slavotinek, P-Y. Kwok, M. Norton, N. Risch; Univ. of California San Francisco, San Francisco, CA

Abstract Body:

Background: It has been hypothesized that the diagnostic yield (DY) from Exome Sequencing (ES) is higher among patients of European ancestry compared to those with non-European ancestries because of poor representation of racial/ethnic minorities in clinical genomic sequencing studies. **Methods:** A diverse cohort of 845 pediatric and prenatal patients with suspected genetic disorders underwent ES for potential diagnosis. Using patients' ES data, continental genetic ancestry proportions were obtained with 1KG and HGDP samples as reference. Race and ethnicity information was obtained by self-report from the parents. We examined the effects of genetic ancestry and race/ethnicity on the odds of receiving a positive versus negative diagnosis by logistic regression. The analyses were conducted overall and stratified by mode of inheritance (dominant de novo, dominant inherited, recessive-compound heterozygous, recessive-homozygous, X-linked). **Results:** Overall, the parents were 41% Latinx, 18% white, 5% East Asian, 4% African American, 3% South Asian, 3% Central Asian, 2% Middle Eastern, 1% Native American, 1% Pacific Islander, 7% multiethnic, and 15% with missing information. The average genetic ancestry proportions in the patients were 47.7% European, 23.2% Native American, 9.8% East Asian, 8.2% Middle Eastern, 6.0% African, 5.4% South Asian. Of the 845 patients, 23.9% had a positive (definitive or probable) diagnosis. The majority of positive cases resulted from autosomal dominant inheritance. For all modes of inheritance combined, there was no difference in DY associated with any race/ethnicity or genetic ancestry. However, a significant increase in DY for autosomal recessive homozygous inheritance was observed for Central Asians ($P=.001$), and a suggestive increase for South Asian and Middle Eastern subjects; a similar statistically significant increase was associated with South Asian and Middle Eastern genetic ancestry ($P=.001$ for both). However, when a child consanguinity coefficient (estimated from the exome data) was included in the logistic model, both the race/ethnicity and genetic ancestry terms were no longer significant, while the consanguinity coefficient was significant ($P=.017$). **Conclusions:** ES in this setting of prenatal and pediatric undiagnosed diseases had a comparable DY for all studied race and ethnicity groups, in particular for autosomal dominant and compound heterozygous recessive inheritance, and DY was also not associated with any genetic ancestry. Recessive homozygous inheritance was increased in those of Middle Eastern, South Asian and Central Asian background due to an increase in parental relatedness.

Evolutionary and Population Genetics Posters - Thursday

PB2826. On the Genes, Genealogies, and Geographies of Quebec

Authors:

L. Anderson-Trocme¹, D. Nelson¹, S. Zabad¹, A. Diaz-Papkovich¹, N. Baya², B. Jeffery³, C. Dina⁴, H. Vézina⁵, J. Kelleher³, S. Gravel¹; ¹McGill Univ., Montreal, QC, Canada, ²Broad Inst. of MIT and Harvard, Cambridge, MA, ³Big Data Inst., Li Ka Shing Ctr. for Hlth.Information and Discovery, Oxford, United Kingdom, ⁴Nantes Univ., Nantes, France, ⁵Université du Québec à Chicoutimi, Chicoutimi, QC, Canada

Abstract Body:

The joint analysis of large-scale genetic and genealogical records provides a unique opportunity to bridge the gap between idealized population genetic models and the actual, intricate demographic histories that they seek to capture. This study considers the combination of a pedigree compiled from four million parish records capturing primarily French-Canadian (FC) population history dating back to the first arrivals of French settlers four centuries ago, and genotype data from 2,276 French individuals and 20,451 genotyped FC individuals, of which 4,882 have been linked to the pedigree. Though genetics reflect known differential contributions from French regions during colonization, we show that these differences are shared across Quebec regions. Most population structure within Quebec thus occurred after settlement. To trace the appearance of this population structure over time, we extend the msprime simulation software to handle large-scale pedigree-aware simulations and applied it to the parish record data. We obtain an excellent quantitative description of most aspects of fine-scale FC population genetic structure. We highlight three regional founding events in the regions of Saguenay-Lac-Saint-Jean, the Bas-Saint-Laurent and Beauce that have led to major axes of genetic variation and followed spatial dynamics reminiscent of distinct classical population genetic models. Despite these distinct regional founding patterns, geographic features played an important role in shaping migrations throughout, and we find enrichments for migration, genetic and genealogical relatedness patterns within river networks across Quebec regions. Finally, we provide a freely accessible simulated whole-genome sequence dataset with spatiotemporal metadata for 1,426,749 individuals linked to a genealogy and reflecting realistic and complex population structure.

Evolutionary and Population Genetics Posters - Wednesday

PB2827. Patterns of selection on human gene regulatory variation

Authors:

L. Colbran, I. Mathieson; Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

The majority of variants associated with phenotypes in modern human populations, and identified in genome-wide scans for selection, are non-coding. Therefore, interpreting the effects of these variants and understanding the mechanisms behind phenotypic variation are limited by our understanding of gene regulatory processes and difficulty in linking non-coding variants to genes. To overcome these challenges, we developed a gene-by-gene test for population-specific selection based on combinations of regulatory variants.

We extended the Qx test for polygenic selection to gene expression models trained using joint-tissue imputation, a transcriptome-wide association method trained on paired genotype and RNA-seq data. We first identified the most accurate expression model to use for each gene by comparing predicted expression with observed expression in lymphoblastoid cell lines (LCLs) from 447 individuals from the 1000 Genomes (1kG) project. We find that, while LCL-specific predicted expression models were not correlated with actual LCL expression (median $\rho = 0.00081$, maximum $\rho = 0.19$), the models that explained the highest variance in expression during training were more highly correlated (median $\rho = 0.021$, maximum $\rho = 0.93$), regardless of the training tissue. Therefore, we used effect sizes and variants from these best performing models to calculate Qx statistics for 27,000 genes based on allele frequencies in the 26 1kG populations. We found that Qx was correlated with the number of variants and other technical characteristics of the gene regulation models. To control for these effects, we calculated p-values by permuting the effect sizes of variants for each gene while holding allele frequencies and linkage disequilibrium structure constant.

We identified 10 genes showing significant evidence ($FDR < 0.1$) for population-specific selection, including *STXBP4*, *MYO5B*, and *HDLBP*. Despite having one of the highest raw Qx scores and previously characterized regulatory selection, *FADS1*, is not significant. This suggests that the large Qx score for *FADS1* is driven by differing allele frequencies at relevant variants (as detected by other tests for selection), rather than consistent selection on a large number of regulatory variants. This interpretation is supported by the low correlation of significance with haplotype-based selection tests (gene rank correlation of 0.02 for iHS vs Qx P-value). Thus, our test may be useful in combination with more traditional selection tests. These results demonstrate the potential in combining population-level information with basic biology to understand human traits and evolution.

Evolutionary and Population Genetics Posters - Thursday

PB2828. Phased, long read assemblies from Central African participants represent a more comprehensive, inclusive future for human pangenomics

Authors:

J. LoTempio¹, D. Spencer¹, K. Mosema², K. Karume³, M. Almalvez¹, Y. Fu¹, C. Musasa¹, J. Nsibu², M. Bramble¹, E. Kamangu³, D. Tshala-Katumbay⁴, D. Mumba², E. Vilain¹; ¹Children's Natl., Washington, DC, ²INRB, Kinshasa, Congo, Democratic Republic of the, ³Univ. of Kinshasa, Kinshasa, Congo, Democratic Republic of the, ⁴Oregon Hlth.and Sci. Univ., Portland, OR

Abstract Body:

Background:

The challenge of representation of diverse populations in genomics is often discussed, and indeed precision medicine cannot be achieved without global participation. However, the solution, on the ground collaboration, can be hard to achieve. While the cost of generating a telomere-to-telomere genome assembly is out of reach for most laboratories, it is feasible to generate human assemblies which approach reference quality. This brings the goal of these collaborations, reference quality genomes, closer. To this end, our team has translated ideas and concepts of equity and inclusion to realized recruitment and consent of participants from genetically diverse trios from the Democratic Republic of the Congo for high quality genome sequencing.

Methods:

Our ethics protocol was based on the 1000 Genomes Project protocol. Peripheral blood mononuclear cells (PBMCs) were isolated from whole blood from participants. Each member of the trio was sequenced with Illumina to a depth of 30x. DNA was extracted from PBMCs and was sequenced on four PacBio HiFi flowcells for each proband, representing approximately 300x coverage. Assemblies were trio binned with yak, assembled with HiFiASM, and scaffolded with Bionano optical maps.

Results:

Trios were recruited in Kinshasa through our network of physician scientists who prioritized geographic and ethnolinguistic diversity. We chose four trios for sequencing by selecting those thought to be historically distant from one another. With these assemblies, we show that unmapped reads from experiments on novel genomes from Congo, aligned to GRCh38p13, can indeed be placed. We further show that African Pangenomic Contigs from (Sherman et al 2019) can be placed on these genomes, resolving outstanding issues in missing data.

Conclusions:

These HiFiASM assemblies, which will be available as a broad use open resource, represent a strong advancement for placement of known, unmapped genomic data, and thus a step forward in precision medicine. Bionano hybrid scaffolds, while an intermediate product in need of polishment, may help groups achieve more contiguous assemblies at low cost. Together, the accessibility of these technologies will contribute to an environment where concepts can be translated to grassroots collaborations that result in the next era for pangenomics.

PB2829. Population-specific Recombination Maps Reduce False Positive Findings in Genomic Scans of Adaptations

Authors:

B. Dinh¹, L. Wilkens², L. Le Marchand², C. Haiman¹, C. W. K. Chiang¹; ¹Univ. of Southern California, Los Angeles, CA, ²Univ. of Hawaii, Honolulu, HI

Abstract Body:

Knowledge of the recombination landscape informs patterns of haplotypic structure in a population and is used in a number of population and statistical genetic analyses such as imputation, local ancestry inference (LAI), identity-by-descent (IBD) inference, and detection of adaptation. However, populations not represented by the 1000 Genomes Project (1KGP) typically do not have a corresponding map. Yet, fine-scale differences in the recombination landscape are known to exist between populations and it may be suboptimal to utilize the recombination map from a distantly related population. The lack of representation may thus contribute to obstacles in effectively extending genomic analyses to understudied populations. To begin to bridge this gap, we create LD- and IBD-based recombination maps using genome-wide array data for the Native Hawaiian population (NH), a minority population encompassing only 0.5% of the U.S. population, with the hope to help improve future studies in NH and other Polynesian cohorts. We find NH maps to be less correlated with those from other 1KGP populations (Spearman's $\rho = 0.79$ between NH and CEU, compared to 0.92 between YRI and CEU at 1Mb resolution) and share the least amount of recombination hotspots with other populations from 1KGP (at 50kb scale, 8% of the top 1 percentile of hotspots are shared between NH and 1KGP CEU, compared to 27% shared between 1KGP YRI and CEU). Additionally, we test the impact of the maps on downstream analyses. We find that NH maps have relatively little impact on analyses such as LAI and imputation. The local ancestry calls are > 95% concordant when comparing the results of the NH map and the omnibus map. Imputation accuracies of variants with minor allele frequency > 5% are 92% for both NH map and the omnibus map when assessed against targeted exon sequencing data of the same individuals. Distribution of called IBD segments and the subsequent relatedness inference are also similar when using the NH-specific map or the omnibus map. However, for genome scans of signals of adaptation using statistics such as integrated haplotype score (iHS), we find a number of loci with apparent genome-wide significant signals (Z -score > 4) that would not be exceptional when analyzed using NH-specific maps. Examination of genes near these ostensibly adaptive loci also do not provide a functional basis for selection. Our results thus suggest that population-specific recombination maps can improve the robustness of haplotype-based statistics such as those used in selection scans, which can help us better characterize adaptive loci that may underlie Hawaiian-specific health conditions today.

Evolutionary and Population Genetics Posters - Thursday

PB2830. Presenilin-1 G206A mutation in Puerto Ricans with Alzheimer Disease reveals it is as a founder event on the African haplotype

Authors:

K. Celis¹, S. Slifer², K. Hamilton-Nelson², F. RAJABLI¹, N. R. Gomez¹, P. Whitehead³, M. Contreras³, S. Tejada³, P. Mena¹, J. J. Sanchez¹, J. Arvizu³, C. G. Golightly¹, L. Adams¹, T. Starks⁴, S. Concepcion¹, M. Cuccaro³, J. Vance¹, G. Byrd⁵, J. Haines⁶, G. Beecham¹, B. Feliciano⁷, A. Griswold¹, M. Pericak-Vance²; ¹Univ. of Miami, Miami, FL, ²Univ. of Miami Miller Sch. of Med., Miami, FL, ³John P. Hussman Inst. for Human Genomics, Miami, FL, ⁴Wake Forest Sch. of Med., Winston-Salem, NC, ⁵NC A&T State Univ, Greensboro, NC, ⁶Case Western Reserve Univ., Cleveland, OH, ⁷PRADI, UCC, SJB Sch. of Med., Caguas, PR

Abstract Body:

Background: Variants in the presenilin-1 gene (*PSEN1*) are known to be pathogenic for Alzheimer disease (AD). The variant G206A in *PSEN1* has been identified in AD Caribbean Hispanic families from Puerto Rico with variable ages of onset and incomplete segregation (Athán et al., 2001). Puerto Ricans have an admixed genetic background which includes European, African and Amerindian ancestry. We investigated the role of G206A in the genetic etiology of AD in Puerto Rico, the ancestral background and founding haplotype in this admixed population. **Methods:** We screened 896 individuals (182 from families; 714 unrelated cases/controls) from the Puerto Rican Alzheimer Disease Initiative (PRADI) using whole genome sequencing (WGS) and identified carriers of G206A. Genotyping data were phased using SHAPEIT to identify local ancestry of the *PSEN1* haplotype followed by RFMix to estimate the genetic ancestry. Haplotype modeling was performed using MERLIN software. In addition, we tested p-Tau181 levels from plasma protein using Simoa chemistry assays (Quanterix HD-X) and data was analyzed using HD-X Analyzer Software v1.6. **Results:** We identified 38 carriers of the G206A variant. 25 carriers (20 AD, two MCI, one neuropsychiatric disorder, and two cognitively unimpaired individuals under 65 years old) were identified in eight families, with the largest family having nine carriers. G206A did not completely explain AD in these eight families as eight other AD cases in the families did not carry the variant. The additional 13 carriers identified were part of the PRADI cases/controls cohort (10 AD, one MCI, and two cognitively unimpaired under 65 years old). Clinically, G206A carriers with AD varied in age of onset (55% with onset before age 65), severity measured by CDR (42% CDR>2) and *APOE* genotype (60% were *APOE3* carriers). Local ancestry indicated that the mutation arose on an African ancestral haplotype. However, no other carriers were identified while screening 4,348 WGS of individuals from Nigeria and African American cohorts. ~37% of the G206A carriers were located in small area of (PR Zone 2), suggesting this region contained the original founding individual. We evidence an increase of p-Tau181 levels in G206A carriers with AD compared to carriers without AD. **Conclusion:** Our results support that G206A contributes to AD in the Puerto Rican population but does not completely explain the genetic risk in multiplex PRADI AD families. We show that the G206A variant occurs on a common haplotype across carriers representing a founder event on an African haplotype background in Puerto Rico.

Evolutionary and Population Genetics Posters - Wednesday

PB2831. Primate comparative genomics and infectious diseases; COVID-19, Monkey Pox and what comes next

Authors:

M. Roodgar¹, X. Shen¹, R. Purohit¹, L. Ramirez¹, M. Snyder²; ¹Stanford Univ., Palo Alto, CA, ²Stanford Univ., Stanford, CA

Abstract Body:

Nonhuman primates (NHP), specifically macaques, share approximately 93% genome homology with humans, making them the most appropriate animal models to study human infectious diseases such as COVID-19, tuberculosis (TB), and HIV. With the emergence of infectious diseases like COVID-19 and recently monkey pox, there is an increasing need in better understanding primate immunogenomic features that correlates with human disease susceptibility and/or disease transmission. In this study, we perform comparative genomics and comparative single-cell transcriptome immune profiling of peripheral blood mononuclear cells (PBMCs) from four macaque species and humans. Rhesus macaque, cynomolgus macaque, pig-tailed macaque, and African green monkeys are NHP species that are the most commonly used animal models to study human infectious diseases including COVID-19. The comparative genomics and immune cells transcriptomic of these macaque species reveals high homology of several immune cell subtypes of pig-tailed macaque with those of humans. Additionally, the comparative analysis of immune gene orthologous isoforms leveraging long-read sequencing reveals novel species-specific immune orthologs and primate repetitive elements. These novel isoforms and repeat elements play a crucial role in resistance to infectious diseases. The genomics information from our study has broad application in understanding human immune system and development of new therapies leveraging primate comparative immunogenomics.

Evolutionary and Population Genetics Posters - Wednesday

PB2833. Recovering signatures of ghost admixture using ancestral recombination graphs.

Authors:

A. Biddanda¹, Y. Zhang², C. O'Dushlaine¹, P. Moorjani²; ¹54 Gene, Washington, DC, ²UC Berkeley, Berkeley, CA

Abstract Body:

With the sequencing of archaic hominin (e.g. Neanderthal and Denisovan) genomes, the contributions of these groups to modern human populations have been well-characterized over the past decade in non-African populations. However, the understanding of archaic ancestry in other modern genomes, particularly contemporary Africans, remains poorly understood due to technical challenges in DNA preservation. Recent evidence suggests that most African groups have ~2-20% of ancestry from an unknown “ghost” archaic hominin (Durvasula and Sankararaman, 2020), and another plausible explanation poses that these patterns can be explained by weak population structure in the distant past of African populations (Ragsdale et al, 2022). Despite these broader results, the model of gene flow remains unclear, since no archaic reference genome for this “ghost” ancestry or outgroup without admixture is available for current methods.

Recent advances in methods to reconstruct the ancestral recombination graph (ARGs) (e.g. Spiedel et al, 2019, Kelleher et al 2019) from large numbers of sequenced genomes has enabled more detailed reconstruction of evolutionary history, including historical gene flow. Importantly, the inferred ARGs from these methods have not been applied to evaluate different scenarios of gene flow between human populations, particularly in the case of ghost ancestry.

We introduce a new approach to characterize the history of archaic ancestry using estimated ARGs from modern genomes alone. Our method is a hidden markov model (HMM) that leverages two key features of genealogies that are distorted in the face of introgression: “long branches”- deep lineages in the coalescent tree, and “long haplotypes”- characteristic of recent gene flow unbroken by recombination. By conducting simulations under a range of demographic scenarios, we characterize the sensitivity and specificity of our method to previously developed methods using ground-truth ARGs and inferred ARGs. Our method works reliably with true ARGs, outperforming available methods to detect archaic admixture, but exhibits lower sensitivity when using inferred ARGs. We also formally compare the models of ancestry in African populations within the HMM - “ghost” introgression or weak population structure, to quantify the ability of ARG-based summary statistics to evaluate competing hypotheses regarding the dynamics of gene flow.

While we have focused on scenarios relevant to human evolutionary history, particularly in Africa, the proposed approach is generalizable to any organism for which reliable ARGs can be estimated and where appropriate archaic references may not be available.

Evolutionary and Population Genetics Posters - Thursday

PB2834. Relatedness inference up to 3rd degree from low coverage ancient genomes in presence of contamination, long runs of homozygosity and ascertainment bias

Authors:

D. Popli, S. Peyrégne, B. M. Peter; Max Planck Inst. for Evolutionary Anthropology, Leipzig, Germany

Abstract Body:

Identifying related individuals from genetic data is a common task in population genetic studies. Inferring relatedness from ancient DNA data is often difficult because sequence coverage is typically low, and present-day DNA contamination is common. In addition, many ancient populations have long runs of homozygosity (ROH) that could impact analyses. Here, we present KIN, a Hidden-Markov-Model-based method to infer relatedness by identifying the parts of the genomes that are shared by descent between a pair of individuals, taking contamination and ROH in each individual into account. Using simulations, we show that we can accurately infer up to 3rd degree relatedness from a sequence coverage as low as 0.1x. We first applied KIN to genetic data from a set of 16 Neandertal specimens from Chagyrskaya Cave, Siberia, generated by targeted enrichment for 713,000 SNPs across the genome. The coverage ranges from 0.01x to 12.34x, and several libraries show evidence of contamination. We find long ROH in most individuals, and are able to detect three specimens that came from the same individual, a father-daughter pair, and a pair of 2nd degree relatives. We also apply Kin to 118 Bronze age individuals from Germany, and compare it two other methods, READ and lcMLkin. We find that the methods generally agree, but KIN is often able to make inference where lcMLkin would require more data, and unlike READ, we are able to distinguish between parent-child and siblings.

Evolutionary and Population Genetics Posters - Wednesday

PB2835. Relating the evolutionary fitness costs of loss-of-function mutations to their pathogenic consequences in humans

Authors:

I. Agarwal^{1,2}, Z. L. Fuller², S. Myers¹, M. Przeworski²; ¹Univ. of Oxford, Oxford, United Kingdom, ²Columbia Univ., New York City, NY

Abstract Body:

A number of recent disease studies have reported an enrichment of causal variants in “mutation intolerant genes”. Here, we consider this relationship explicitly, by relating pathogenic consequences at present-day to inferred fitness effects of loss of function mutations. To this end, we first infer posterior distributions for the evolutionary fitness costs of loss-of-function (LOF) mutations for 17,744 autosomal and 679 X-linked genes, given the observed frequencies of LOF mutations in 56,855 individuals. Estimated fitness costs are on the order of 1% on average; they are typically largest for X-linked genes, whether or not they have a Y homolog, followed by autosomal genes, and smallest for genes in the pseudoautosomal region. We then compare the distribution of fitness effects (DFE) for all possible de novo LOF mutations to the distribution for mutations identified in pedigree studies of individuals diagnosed with one of six severe complex diseases. All six cohorts are enriched for mutations with estimated fitness effects in excess of 10%, indicating that causal mutations tend to be highly deleterious, and are likely to be quite recent in origin. We see an effect of disease severity, with a larger enrichment of such highly deleterious variants for early onset developmental disorders than Schizophrenia or Tourette syndrome. We also detect influences of the pedigree study design on the types of mutations detected for a given diagnosis: thus, we find that in autism studies, mutations identified in probands of simplex family studies are more deleterious on average than those in multiplex family studies, and mutations found in female probands are more deleterious on average than those in males. More generally, this approach allows us to characterize the types of mutations that contribute to complex disease risk and how they are transmitted in populations.

Evolutionary and Population Genetics Posters - Thursday

PB2836. Repeats R/T ratio is associated with Human Y chromosome Haplogroups

Authors:

T. Puurand¹, T. Kivisild²; ¹Univ. of Tartu, Tartu, Estonia, ²KU Leuven, Leuven, Belgium

Abstract Body:

SNP based Y chromosome haplogroup determination for ancestry and relatedness analyses is challenging from ultra-low coverage (<0.1x) sequence data that is often achievable from poorly preserved human remains. These challenges are due to low probability of critical clade-defining markers to be covered by data. While most previous research on genetic ancestry in the last two decades has focused on single nucleotide variants, the completion of human genome sequencing is opening new avenues for the use of structural variation for the analysis of genetic ancestry. More than one half of the human genome contains repeated sequences and the completed sequence of human Y chromosome includes extensive heterochromatin regions. We show how specific k-mers can be used to predict Y chromosome haplogroups and to assess variation in tandemly repeated and single copy regions for the assessment of genetic ancestry as well as, potentially for genetic relatedness. Random repeat (Line) k-mer frequency / tandem repeat k-mer frequency ratios (R/T ratios) of 198 Estonian males are graphically visualized <https://bioinfo.ut.ee/randomtandem/EGV.html>. We show that the clustering of the male samples by the counts of the three Y chromosome-specific tandem repeats (vntr, centromere, heterochromatin) clearly separates the main haplogroups (N3a, I, R1a, R1b, E). We have explored the potential for R/T ratios-based method for assessing specific tandem repeat length ratios in Y chromosome and using these ratios as predictors of Y chromosome haplogroups. We have tested the approach on three Y chromosome-specific k-mers using high coverage (~20x Y chromosome) Illumina WGS reads as a proof of principle. The method can be improved by using more and shorter k-mers for low coverage short read sequencing applications like in NIPT, forensic and ancient DNA studies. Variation inside haplogroups shows potential for ancestry detection from non-imputed data for individual identification, relatedness assessment and for the basic understanding of the rate of structural variation in human genome.

Evolutionary and Population Genetics Posters - Wednesday

PB2837. Resolution of structural variation in diverse mouse genomes reveals dynamic chromatin remodeling due to transposable elements

Authors:

A. Ferraj^{1,2}, P. Audano¹, P. Balachandran¹, J. Flores¹, I. Walawalkar¹, A. Czechanski³, L. Reinholdt³, C. Beck^{1,2}; ¹The Jackson Lab. for Genomic Med., Farmington, CT, ²Univ. of Connecticut Hlth.Ctr., Farmington, CT, ³The Jackson Lab., Bar Harbor, ME

Abstract Body:

Inbred laboratory mice are one of the most popular biomedical research models. Diverse substrains of mice have been utilized to create populations that exhibit genotypic and phenotypic heterogeneity and have enabled mapping of phenotypes to genomic loci. The underlying causes of phenotype variation and the discovery of genetic causes are dependent on high-quality reference genomes and variant catalogues for each of the progenitor strains of mice. Despite recent efforts to construct strain-specific reference genomes, much of the genomic landscape that is variable between these mice remains incomplete, which is attributable to the technological limitations of short-read whole genome sequencing. Recent advances in long-read sequencing have since surpassed the longstanding inability to accurately resolve repetitive DNA and genetic variants of large size. Although large scale studies have utilized long-read sequencing in distinct human populations, to date there have been no efforts to fully resolve and detect structural variation (variants ≥ 50 bp) among diverse mouse genomes with these technologies. We performed Pacific Biosciences (PacBio) long-read sequencing in order to sequence-resolve structural variants across 20 genetically diverse inbred laboratory mouse strains. All variants were merged into a complete catalogue of non-redundant SV calls spanning three major subspecies of *mus musculus*: *domesticus*, *castaneus*, and *musculus*. We identified 413,969 SVs which occur at unique sites in the reference, cumulatively affecting $\sim 13.5\%$ (368 Mb) of the mouse genome. Furthermore, we have detected subspecies-specific as well as inter-subspecies SVs that exhibit high impact consequences, including 654 coding sequence SVs and variants that affect the landscape of mESC chromatin accessibility and gene expression. Our data comprehensively identify the extensive SVs present in diverse mouse genomes and strongly suggest that SVs contribute to phenotypic diversity between recently diverged mice.

Evolutionary and Population Genetics Posters - Thursday

PB2838. Resurrecting the alternative splicing landscape of archaic hominins using machine learning.

Authors:

C. Brand, J. A. Capra; Univ. of California San Francisco, San Francisco, CA

Abstract Body:

While some phenotypic differences between archaic hominins and modern humans are known from the fossil record, most archaic tissues have not survived to the present. Thus, most phenotypes cannot be directly compared. Divergence in gene expression is thought to be a major driver of the phenotypic differences between these closely related groups. Alternative splicing, which increases proteomic diversity, has been shown to contribute to adaptation in various species. Alternative splicing can be measured in extant taxa and machine learning can be used to predict splicing from sequence alone, unmasking this previously unobservable mechanism and associated phenotypes. Here, we apply SpliceAI, a machine learning algorithm that predicts the probability a variant is splice altering, to high-coverage genomes from three Neanderthals and a Denisovan. We identify 5,950 putative splice altering variants, of which 2,343 are archaic-specific and 3,607 also occur in modern humans via introgression or shared ancestry. Collectively, archaic-specific variants are enriched in genes that contribute to many traits such as excessive sweating, platelet volume, and spinal rigidity. We also recovered strong, distinct phenotype enrichment among lineage-specific splice variants. We anticipate that most splice variants have large effects and are likely to be removed by purifying selection. Indeed, archaic-specific variants occur in sites under weaker selection than shared splice variants. Further, we find that high-probability archaic splice variants are more frequently present in more tissue specific genes. We also find that archaic lineages with low effective population sizes are enriched for splice variants compared to shared variants, consistent with selection against most splice variants. We quantified the contribution of introgression to splicing in modern humans, finding that introgressed splice variants were largely shared across all three Neanderthals, suggesting older splice variants were most tolerated in modern human genomes. Our results quantify the previously unobservable splicing landscape of archaic hominins and suggests that this mechanism may underlie phenotypic differences between archaics and modern humans.

Evolutionary and Population Genetics Posters - Wednesday

PB2839. Risk of venous thromboembolism in individuals with supernumerary sex chromosome aneuploidies in two large population-based cohorts

Authors:

A. Berry¹, B. M. Finucane¹, S. M. Myers¹, D. H. Ledbetter², C. L. Martin¹, M. T. Oetjens¹; ¹Geisinger Hlth.System, Lewisburg, PA, ²Univ. of Florida, Gainesville, FL

Abstract Body:

Venous thromboembolism (VTE), which includes deep venous thrombosis (DVT) and pulmonary embolism (PE), is a preventable and treatable condition with high morbidity and mortality. An increased risk for VTE has previously been reported in men with Klinefelter syndrome; however, the prevalence of VTE in other sex chromosome aneuploidies (SCA) has not been well-characterized. Here, we performed an observational study of VTE and SCA by analyzing X- and Y-chromosome dosage and VTE prevalence in 642,544 individuals from two population-scale biobanks, Geisinger's MyCode Community Health Initiative and the UK Biobank. We sought to determine if VTE risk is associated with SCA. The prevalence of SCA was 1 in 528 adults in MyCode and 1 in 832 adults in the UK Biobank, in line with previous estimates of 1 in 450 to 1 in 1,500. Relative to adults with two sex chromosomes, the odds of having a VTE diagnosis in MyCode was four- to six-fold as high among individuals with 47,XXX (OR, 4.5; 95% CI, 2.5-7.7, $P < 1 \times 10^{-6}$), 47,XYY (OR, 3.7; 95% CI, 1.8-7.2, $P < 1 \times 10^{-3}$), and 47,XXY (OR, 6.2; 95% CI, 3.8-10.0, $P < 1 \times 10^{-12}$). Replication in the UK Biobank yielded similar results: the odds of having a VTE diagnosis before the baseline interview was four- to seven-fold as high among individuals with 47,XXX (OR, 4.4; 95% CI, 2.3-7.6, $P < 1 \times 10^{-6}$), 47,XYY (OR, 6.7; 95% CI, 4.0-10.7, $P < 1 \times 10^{-13}$), and 47,XXY (OR, 5.7; 95% CI, 3.6-8.5, $P < 1 \times 10^{-14}$) compared to adults with two sex chromosomes. Additionally, the presence of a supernumerary sex chromosome was associated with a 4.2-fold (95% CI, 2.8-6.3, $P < 1 \times 10^{-11}$) increased risk of VTE in the 10 years following initial assessment in the UK Biobank, compared to individuals with two sex chromosomes. This increased risk was mediated in part by known anthropometric factors and blood biomarkers associated with both VTE and supernumerary SCA, including height and cystatin C; however the majority of the association between VTE and supernumerary SCA remains unexplained (95% CI, 50-74%, $P < 1 \times 10^{-4}$). Our data suggest that supernumerary SCA are underappreciated risk factors for VTE, comparable in magnitude to heritable forms of thrombophilia. Therefore, VTE evaluation and prophylaxis should be considered for adults diagnosed with these relatively common chromosomal disorders. Conversely, the medical work-up of adults who experience VTE should prompt consideration of diagnostic genetic testing for SCA, particularly if other clinical SCA characteristics (e.g., tall stature) are present, to establish an underlying etiology for VTE.

Evolutionary and Population Genetics Posters - Thursday

PB2840. SALAI-Net: Species-agnostic local ancestry inference network.

Authors:

B. Oriol Sabat¹, D. Mas Montserrat², X. Giró-i-Nieto³, A. Ioannidis⁴; ¹Univ. of California Los Angeles, Los Angeles, CA, ²Stanford Univ., Woodside, CA, ³Univ. Politecnica de Catalunya, Barcelona, Spain, ⁴Stanford Univ., Palo Alto, CA

Abstract Body:

Local Ancestry Inference (LAI) is the high resolution prediction of ancestry categories across a DNA sequence. LAI is becoming increasingly important in the study of human history, migrations, and precision medicine applications, including genome-wide association studies (GWAS) and polygenic risk scores (PRS).

Most of modern LAI models do not generalize well between species, chromosomes, or even ancestry groups, requiring re-training for each different setting. Furthermore, such methods can lack interpretability, which is a paramount element in biomedical applications.

We present SALAI-Net, a portable statistical LAI method that can be applied on any set of species and ancestries (species-agnostic), requiring only haplotype data and no other biological parameters. Inspired by Identity By Descent (IBD) methods, SALAI-Net estimates population groups by performing a reference matching approach, which leads to an interpretable and fast technique. We benchmark our models on whole genome data of humans and we test its ability to generalize to dog species when trained on human data. SALAI-Net outperforms previous methods in terms of balanced accuracy while generalizing between different settings, species, and datasets. Moreover, it is up to two orders of magnitude faster and uses considerably less RAM memory than competing methods. We provide an open source implementation and there is publicly available data and trained models on <https://github.com/AI-sandbox/SALAI-Net>.

Evolutionary and Population Genetics Posters - Wednesday

PB2841. Sequence variants affect the genome-wide rate of germline microsatellite mutations.

Authors:

S. Kristmundsdóttir, H. Jónsson, M. T. Hardarson, G. Palsson, D. Beyter, H. Eggertsson, A. Gylfason, G. Sveinbjornsson, G. Holley, O. Stefansson, S. Olafsson, G. Árnadóttir, P. Olason, O. Eiriksson, G. Masson, U. Thorsteinsdóttir, T. Rafnar, P. Sulem, A. Helgason, D. Gudbjartsson, B. Halldórsson, K. Stefansson; deCODE Genetics, Reykjavik, Iceland

Abstract Body:

Microsatellites are polymorphic tracts of short tandem repeats (STRs) with one to six base-pair (bp) motifs and are some of the most polymorphic markers in the genome. Using 6,084 Icelandic parent-offspring trios we estimate 63.7 (95% CI: 61.9-65.4) microsatellite de novo mutations (mDNMs) per offspring per generation. Paternal mDNMs occur at longer repeats, while maternal mDNMs affect more bp. mDNMs increase by 0.97 (95% CI: 0.90-1.04) and 0.31 (95% CI: 0.25-0.37) per year of father's and mother's age at conception, respectively. We found two independent coding variants associated with an increased number of mDNMs transmitted to offspring; A missense variant (allele frequency (AF) = 1.9%) in *MSH2*, a mismatch repair gene, increases transmitted mDNMs from both parents (effect: 13.1 paternal and 7.8 maternal mDNMs). A synonymous variant (AF = 20.3%) in *NEIL2*, a DNA damage repair gene, increases paternally transmitted mDNMs (effect: 4.4 mDNMs). Thus, the microsatellite mutation rate in humans is in part under genetic control.

Evolutionary and Population Genetics Posters - Thursday

PB2842. Sequencing of 230 primate species identifies conserved enhancers underlying complex human disease

Authors:

S. Rashid¹, L. Kuderna¹, A. Cox¹, J. Ulirsch¹, Primate Sequencing and Conservation Consortium, J. Rogers², T. Marques-Bonet³, K-H. Farh¹; ¹Illumina, Foster City, CA, ²Baylor Coll. of Med., Houston, TX, ³Inst. of Evolutionary Biology (UPF-CSIC), Barcelona, Spain

Abstract Body:

Novel functional genomic elements in the primate lineage are prime candidates for understanding the changes that have contributed to the uniqueness of our own species. Although comparisons between the human genome with those of other mammal and vertebrate species have revealed an extensive catalog of conserved genes and regulatory elements, the conserved sequence elements in human that arise particularly from the primate lineage have been very challenging to identify due to the short evolutionary distances separating primate species. At these short timescales, it is unclear whether the absence of changes between species is due to evolutionary constraint, or simply because there has not been the opportunity for random mutations to arise. Compared to the mammalian lineage, which includes over 6000 species separated by ~200 million years of evolution, the primate lineage only consists of 521 species that are separated by a fraction of this time. Prior studies sequenced and aligned only a fraction (43/521) of these primate species constituting a total phylogenetic branch length of only 10% that of the placental mammal alignment. These challenges make it clear that a successful strategy to identify conserved sequence elements in human that stem solely from primate lineage will require improved algorithms for detecting conservation at short evolutionary distances, as well as sequencing data from a far greater number of primate species. To address these challenges, we constructed a multiple sequence alignment of 230 primate species, representing nearly half of all extant species in the primate lineage. Even with 230 primate species, prior methods to calculate per base conservation genome-wide provided insufficient resolution due to the short branch lengths in the primate lineage. To address this, we developed a method for finding conserved nucleotides at very short evolutionary distances, using deep learning to model mutation rates. We identified over 208,000 conserved DNase-hypersensitivity sites and 887,000 conserved transcription factor binding sites in human genome that arise exclusively from the primate phylogenetic branch and not across other placental mammals. However, we observed that only a small fraction of protein-coding exons and genes in the human genome are exclusively conserved in primates. Our results highlight the central role of novel regulatory sequence elements rather than protein-coding sequence in the emergence of humans from other non-primate placental mammals.

PB2843. Signatures of Mutational Processes in Human DNA Evolution

Authors:

D. Ebrahimi¹, H. Hamidi², A. Khosh³, H. Alinejad-Rokny⁴, T. Coorens⁵, R. Sanghvi⁶, S. Lindsay⁵, R. Rahbari⁷; ¹Texas BioMed. Res. Inst., San Antonio, TX, ²Univ. of Calgary, Calgary, AB, Canada, ³Yazd Univ., Yazd, Iran, Islamic Republic of, ⁴UNSW, Sydney, Australia, ⁵Wellcome Sanger Inst., London, United Kingdom, ⁶Wellcome Sanger Inst., CAMBRIDGE, United Kingdom, ⁷Wellcome Trust Sanger Inst., Cambridge, Cambridgeshire, United Kingdom

Abstract Body:

The human genome contains over 100 million SNPs, most of which are C/T (G/A) variations. The type and sequence context of these SNPs are not random, suggesting that they are caused by distinct mutational processes. Deciphering the mutational signatures is a crucial step to discovering the molecular processes responsible for DNA variations across human populations, and potentially for causing genetic diseases. Here, we used four quantitative biology approaches to deconvolute germline mutational signatures using data from diverse human populations. We report that at least four mutational processes are responsible for human genetic variations. One process is European-specific and is no longer active. The signature of this process is only found within genic regions and certain endogenous elements. The remaining three processes are currently active in all human populations. Two of the active processes co-occur and leave a single mixed mutational footprint in human nuclear DNA. The third active process is unique in that it is specific to mitochondrial DNA, and inflicts mostly C-to-T mutations at non-CpG sites and T-to-C mutations at non-TpG sites.

Evolutionary and Population Genetics Posters - Thursday

PB2844. Simple scaling laws control the genetic architectures of complex traits

Authors:

Y. Simons¹, H. Mostafavi², C. Smith¹, J. Pritchard¹, G. Sella³; ¹Stanford Univ., Stanford, CA, ²Stanford Univ., Mountain View, CA, ³Columbia Univ., New York, NY

Abstract Body:

Genome-wide association studies (GWAS) have revealed that the genetic architectures of complex traits vary widely, including in the numbers of independent signals, the magnitudes of the biggest hits, and the frequency distributions of significant signals. However, at present we lack a coherent framework for understanding the similarities and differences among traits. Here, we describe a probabilistic model that combines mutation, drift, and stabilizing selection at individual sites with a genome-scale model of phenotypic variation. We performed inference under this model for 95 diverse quantitative traits from the UK Biobank. Our estimates show that selection plays a major role in shaping trait architectures. One implication is that GWAS hits should be much younger than frequency-matched neutral SNPs; indeed, the distribution of allele ages is well-predicted by our model. Remarkably, we find surprisingly similar distributions of selection coefficients across all traits. Therefore, differences in trait architectures arise almost exclusively from just two parameters: heritability and mutational target size, which vary by 1-2 orders of magnitude across traits. When these two scale factors are accounted for, the architectures of all 95 traits are nearly identical.

Evolutionary and Population Genetics Posters - Wednesday

PB2845. Simulating effects from genetic and experimental perturbations to gene regulatory networks

Authors:

M. Aguirre¹, G. Sella², J. K. Pritchard³; ¹Stanford Univ., Stanford, CA, ²Columbia Univ, New York, NY, ³Stanford, Stanford, CA

Abstract Body:

Gene regulatory networks (GRNs) govern many of the core developmental and biological processes underlying human complex traits. Even as genome-wide transcriptomic resources have grown in scope, it remains challenging to interpret how the structure of GRNs impacts the distribution of genetic effects on gene expression. Learning the genetic architecture of gene expression traits is a key aim in quantitative genomics, but there is an unmet need to model the statistical basis of these traits in the mechanistic context of GRNs. Here, we propose a simple approach to simulate the structure and model the function of GRNs, making use of techniques from small world network theory and dynamical systems models of gene regulation. Specifically, we model gene expression regulation using a stochastic differential equation: the steady-state expression of each gene is given by a baseline transcription term and contributions from its parent nodes (transcription factors) in the GRN. This formulation permits variation in regulatory parameters due to genetic effects on gene expression (i.e., expression quantitative trait loci (eQTLs)) or intracellular interventions (e.g., targeted gene knock-down or knock-outs). We use this approach to generate synthetic samples of gene expression data, and systematically characterize the effects of gene knockouts, finding that perturbation effects flow through key regulatory pathways in the network. We further this analysis by simulating a population of individuals that harbor a substantial burden of eQTLs, investigating the distribution of gene expression heritability introduced by different factors in the network, and exploring how structural properties of the GRN affect the relative contributions of variation in cis and in trans. Finally, we conclude by discussing implications of our work towards understanding the architecture of heritable genetic variation in complex traits beyond gene expression.

Evolutionary and Population Genetics Posters - Thursday

PB2846. Simulating Genome-phenome Dataset of 1,000,000 Individuals for the European 1+ Million Genomes Initiative

Authors:

T. Hiekkalinna¹, V. Heikkinen¹, M. Perola¹, J. D. Terwilliger^{2,3,4}; ¹Finnish Inst. for Hlth.and Welfare, Helsinki, Finland, ²Columbia Univ., New York, NY, ³Dept. of Psychiatry, Dept. of Genetics and Dev., Gertrude H. Sergievsky Ctr., New York, NY, ⁴Div. of Med. Genetics, New York State Psychiatric Inst., New York, NY

Abstract Body:

“The '1+ Million Genomes' (1+MG) initiative aims to enable secure access to genomics and the corresponding clinical data across Europe for better research, personalized health care and health policy making.” For this initiative, we are in the process of creating truly anonymous data set from mosaic of publicly available sequence data sets from European populations. This data is needed to set a founding population (original chromosomes) and parameters for the simulation of million genomes. Simulated data can be used to benchmark the national service implementations, technical standard compatibility and best practices in sensitive human data management. Purpose is to create a truly anonymized data set of million genomes in different formats that can be used and shared without fear for data security issues.

In this simulation we are using chromosome-based rapid simulation method (Terwilliger, 1993) to drop chromosomes through a population for a few hundred generations of drift, while keeping track of recombination events in every meiosis, so that at the end of the simulation we will have a set of families whose genomes will be highly recombined mosaics of the original chromosomes. The data set will have all the characteristics and data issues that any "true" genome set would.

Phenotypes will be simulated based on epidemiological models, comprised of parameters such as heritability, contribution of environmental factors, prevalence, and others which must be hypothesized (number of genes, allelic complexity, relative effect size). Based on such parameters, a genotype > phenotype relationship is simulated. This simulated genotype-phenotype data also allows testing of various genetic models, study designs and testing of statistical approaches to correctly infer the basic genetic architecture of traits of interest (important to public health). And finally, it will help us to guide appropriate sample designs, sample sizes, hypotheses, and analytic methods.

We are already simulating hundreds of thousands individuals with phenotypes and we utilize supercomputer resources of Finnish CSC IT Center for Science. This project is organized by the Finnish Institute for Health and Welfare and funded by the Ministry of Social Affairs and Health, Finland.

Evolutionary and Population Genetics Posters - Wednesday

PB2847. South Asian and Greater Middle Eastern Enrichment of *NOTCH3* p.Arg1231Cys Variant and Associated Stroke Risk

Authors:

J. Rodriguez-Flores¹, S. Khalid^{2,3}, A. Rasheed², S. A. DiGioia¹, B. Ye¹, H. Martinez¹, J. Backman¹, Regeneron Genetics Center, A. Shuldiner¹, D. Saleheen^{2,3}, M. Kapoor¹; ¹Regeneron Genetics Ctr., Tarrytown, NY, ²Ctr. for Non Communicable Disease, Karachi, Pakistan, ³Columbia Univ., New York, NY

Abstract Body:

South Asians represent less than 2% of participants in published genetic studies, despite comprising 25% of the world population. Exome sequencing of 4,882 Pakistani stroke cases and 6,094 controls identified p.Arg1231Cys in *NOTCH3* to be associated with a ~3-fold increased risk of stroke (p value 2.18e-8, odds ratio 2.97 per allele, 95% confidence interval 2.03 to 4.35). In order to better understand the population frequencies of this variant and its implications for stroke risk across South Asia (SAS), a regional survey of p.Arg1231Cys was conducted. We first performed analysis of public datasets such as gnomAD, Greater Middle East (GME) Variome, Iranome, and QChip Knowledgebase. Pooled SAS from gnomAD revealed an alternate allele frequency (AAF) of 0.00536, highest in the world. The variant was not detected in Syrian Desert nor Israeli populations. Elevated AAF was observed in Qatar (AAF = 0.0075), Northwest Africa (AAF = 0.0051), Northeast Africa (AAF = 0.0013), Turkish Peninsula (AAF = 0.0030), and Central Asia (AAF = 0.0076). Multiple Iranian populations had the variant, including Lur (AAF = 0.01), Baloch (AAF = 0.005), Kurd (AAF = 0.005), Persian (AF = 0.005), and Turkmen (AF = 0.005). Further analysis was conducted using 1000 Genomes Phase 3 (1000G) and UK Biobank (UKB) participants reporting birth in SAS or GME. The variant was observed in all 1000G SAS populations (AAF 0.00485 to 0.00521), except for Bangladesh. Within UKB, the variant was absent from participants originating in Egypt but was present in those originating from Turkey, Iran, Afghanistan, Pakistan, and India (AAF 0.0036 to 0.0056). Combined analysis of 37 thousand Pakistani exomes from the Pakistan Genome Resource (PGR), 1000G and UKB identified three major clusters of Pakistanis, and ethnic/caste data was used to label them as Baloch/Pathan (AAF = 0.0074), Punjab/Rajput (AAF = 0.006), and Ansari (AAF = 0.0056). The Punjab/Rajput clustered with 1000G Punjab, the Ansari formed a distinct cluster closer to populations from Eastern India, and Baloch/Pathan clustered with Afghans. Based on this analysis, the p.Arg1231Cys variant appears to be found across a broad geographic range with AAF > 0.003 in South Asia, Central Asia, North Africa and Turkish Peninsula. In contrast, AAF in Europe and other continents is consistently much lower (AAF < 0.0004). This result has precision medicine implications for inhabitants of these understudied populations and their diaspora.

Evolutionary and Population Genetics Posters - Thursday

PB2848. Structure-function analysis of a tRNA-derived SINE.

Authors:

E. Koch, L. E. Kirby, G. Mies, S. Emery, J. B. Moldovan, J. V. Moran, J. M. Kidd; Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract Body:

Transposable elements contribute to the phenotypic diversity present among many mammalian genomes through their ability to insert into new genomic locations. While some transposable elements, such as autonomous Long Interspersed Elements (LINEs), encode proteins required for their own mobilization (i.e., retrotransposition), other transposable elements, such as Short Interspersed Elements (SINEs), are non-autonomous and require the activity of LINE-encoded proteins to mediate their retrotransposition. In canine genomes, SINEs are present at ~1.1-1.3 million copies and are more abundant than their autonomous LINE counterparts.

Retrotransposition of the canine SINE, SINEC_Cf, is responsible for breed-specific phenotypic differences such as merle coat color, cleft palate, narcolepsy, and centronuclear myopathy. As a result, SINEC_Cf is implicated in serving an important evolutionary role in the canine genomic landscape. Unlike 7SL RNA-derived human Alu elements, SINEC_Cf is derived from a tRNA. Although the structures of tRNAs are well established, the structure and functionally important domains of SINEC_Cf RNA require elucidation. To define the relationships between SINEC_Cf structure and function, we determined the putative secondary structure of SINEC_Cf RNA using SHAPE-MaP, a chemical probing technique. The analysis of SHAPE-MaP-informed putative RNA structures, and comparisons among SINEC sequences, identified candidate secondary structural elements that may be important for SINEC_Cf retrotransposition. A sequence difference relative to the RNA polymerase III B-box promoter consensus sequence, in a region predicted to form a stem structure, was tested for retrotransposition activity in a cell-culture based assay. Our initial findings suggest that this mutation in the SINEC_Cf B box, which restores identity to the promoter consensus, results in a 35% reduction of retrotransposition activity compared to wild-type SINEC_Cf ($p=0.0004$ in a paired sample t-test). Furthermore, retrotransposition activity can be restored by a second-site compensatory mutation ($p=0.00015$, paired sample t-test compared to the B box mutant), which is predicted to restore base pairing in stem structure. In sum, our findings help clarify how variation in SINE RNA sequence and secondary structure impacts the function of SINEs and set the stage for a comparative analysis of evolutionarily diverged SINEs in other species to reveal general principles for how SINEs can evolve from tRNAs.

Evolutionary and Population Genetics Posters - Wednesday

PB2849. The differential identification of cross-species lung scRNA expression via integrative analysis

Authors:

W. Lin¹, T. Li², Y. Gong¹, Y. Chen³; ¹Tulane Univ., New Orleans, LA, ²Central South Univ., Changsha, China, ³Hunan Normal Univ., Changsha, China

Abstract Body:

The lung is an essential open organ that acts as the primary site for the respiratory process. Due to their damaging consequences, respiratory and pulmonary diseases continue to be a significant cause of morbidity and mortality on a global scale. For example, the Covid-19 virus has caused millions of deaths and widespread infection around the globe. Due to the difficulty of conducting clinical studies and acquiring human tissues, the study of in vitro cells and model organisms has considerably contributed to our understanding of molecular pathways. In the context of biomedical research laboratories, mice are the species most frequently exploited. It is probable that the evolutionary conservation of functional gene expression, which specifies unique cellular function and structure, predominates between these two species, but it is also conceivable that there may be significant genomic differences between them. Using scRNA-seq data acquired from the GEO database, our purpose was to identify genomic areas whose expression levels differ between humans and mice. The analysis of the study includes a total of 14985 human cells and 14994 mouse cells. We created an impartial atlas of cell types across species by utilizing Seurat. The single-cell weighted gene co-expression network analysis (scWGCNA) was used to identify the modules that are associated with each species. The results reveal that two of these modules have a significantly strong link with their respective species. We conducted a GO enrichment analysis on these two modules to discover the primary function of each, which reveals that these two modules are related to the activity of the Alveolar Type II Cells. These findings may help researchers to better understand the difference between mice and humans at the molecular level, which serves as the foundation of clinical advancement.

Evolutionary and Population Genetics Posters - Wednesday

PB2850. The genetic diversity of Japanese populations inferred from the whole genome sequencing data

Authors:

Y. Kawai¹, Y. Watanabe^{1,2}, Y. Omae¹, R. Miyahara^{1,3}, S-S. Khor¹, E. Noiri¹, K. Tokunaga¹, National Center Biobank Network; ¹Natl. Ctr. for Global Hlth.and Med., Tokyo, Japan, ²The Univ. of Tokyo, Tokyo, Japan, ³Natl. Inst. of Infectious Diseases, Tokyo, Japan

Abstract Body:

The Japanese archipelago is located in the east of Eurasia that is one of the endpoints of human migration since Out-of-Africa. The genetic diversity of the modern Japanese population is influenced by the admixture of hunter-gatherers (Jomon people) who migrated about 16,000 years ago and agriculturalists (Yayoi people) who migrated about 3,000 years ago. Genome studies have revealed genetic differentiation between the mainland (Hondo) and the Ryukyu Islands (e.g., Okinawa), but it is not clear when and where this genetic differentiation occurred. Furthermore, the evolutionary background of population structure within Hondo has not been clarified. In this study, we examined the genetic characteristics of the Japanese population by whole genome sequencing data. We performed a high-coverage WGS analysis of 9,850 samples from the National Center Biobank Network (<https://ncbiobank.org/en/>), which is a federation of biobanks of national hospitals in Japan, and identified more than 122 million variants. The demographic analysis revealed that the Hondo and Ryukyu populations experienced stagnation, but the time and mode are different between them. The analysis of gene genealogy from haplotype analysis identified genes related to alcohol and lipid metabolism that were affected by positive natural selection. Two genes related to alcohol metabolism were found to be 12,500 years out of phase with the time when they began to be affected by positive natural selection.

Evolutionary and Population Genetics Posters - Thursday

PB2851. The genetic making of Bangladesh

Authors:

P. Singh¹, A. Pathak², G. Sultana³, M. Metspalu², G. Chaubey¹; ¹Banaras Hindu Univ., Varanasi, India, ²Univ. of Tartu, Tartu, Estonia, ³Univ. of Dhaka, Dhaka, Bangladesh

Abstract Body:

In terms of global genetic diversity of humans, South Asia holds a central role as a major reservoir of genetic variability second only to that in Africa. However, most of the genetic information is coming from Pakistan and India, whereas Bangladesh remained largely unexplored in spite of being one of the most densely populated nations. Bangladesh is a country that is geographically surrounded on three sides by India, joins a land bridge to Southeast Asia via Myanmar, and in the South, it joins the Indian Ocean with the Bay of Bengal. The populations of Bangladesh constitute mostly Bengali speakers (Indo-Aryan), while the remaining are tribal groups affiliated with Dravidian, Austroasiatic and Tibeto-Burman language families. The number of genetic studies in this region is very limited and mainly restricted to forensic markers for a few caste and tribal populations. To bridge this gap, in the current study, we generated new genomic data from tribal and caste populations sampled across all geographic regions of Bangladesh and analyzed them to the previously published genomes to infer the genetic ancestries, both at the uniparental and biparental genome levels. About 827 individuals were analyzed for haploid analysis and 67 individuals were randomly selected for autosomal genome-wide analysis. We particularly identified the ancestry components, their admixture time, sharing, and range distribution among various caste and tribal populations. We found distinct ancestral origins of caste and tribal populations of Bangladesh. The tribal populations associate well with their linguistic affiliation. Also, we aimed to know the genetic origin of Rohingya people as they are a most debatable minority of South & South-East Asia. We sampled 25 individuals for each group viz. Rohingya, Bangladesh Muslim, and Bangladesh Hindu populations. We performed a comparative analysis with published world data. Our genome-wide analyses suggest that they belong to the South Asian stock with notable East Asian-specific ancestry. We have calculated the admixture dating to detect the admixture events which indicate very recent admixing with East Asian population ancestors. Overall, this is the first comprehensive genetic study on Bangladeshi and Rohingya populations showing their genomic landscape.

Evolutionary and Population Genetics Posters - Wednesday

PB2852. The genomic history of human populations in the North American Central and Southern Plains.

Authors:

L. Sykora¹, J. Tackney¹, B. Morris², C. Kisielinski¹, K. G. Beaty¹, L. E. Y. Norman¹, M. Adair¹, A. Rutherford³, P. Skoglund⁴, A. Reynolds², J. Raff¹; ¹Univ. of Kansas, Lawrence, KS, ²Baylor Univ., Waco, TX, ³Univ. Coll. London, London, United Kingdom, ⁴The Francis Crick Inst., London, United Kingdom

Abstract Body:

The Great Plains of North America have been continuously occupied by humans for over 13,000 years. Although there is extensive archaeological evidence for a dynamic history of adaptation, migration, and sociopolitical interactions among the many populations who have inhabited the area prior to European Contact, our understanding of the biological histories of these peoples is severely limited by a lack of ancient human genomes.

In order to explore the population histories in this region, we performed genome-wide targeted SNP captures on ancient individuals residing in the Plains between 1100-1700 CE (850-250 calibrated years before present, YBP). These individuals lived at several sites in the present-day states of Kansas and Texas, and date to periods spanning key social, environmental, and political changes. This project includes the origin of the descendant tribe, who gave us permission for this research and participates as a collaborating partner.

These Ancient Plains individuals share more genetic drift with present day members of the “Southern Native American” (SNA) lineage, particularly with the Mixe and Pima, than with members of the “Northern Native American” (NNA) lineage. Intriguingly, they also share genetic drift with an ancient member of the NNA lineage, suggesting that there was greater complexity in past population dynamics than are currently accounted for in existing models. Finally, we identified a second-degree kin relationship between two contemporaneous individuals from sites in Kansas and Texas, suggesting long-distance interactions between populations in the Central and Southern Plains, during this time period. This project will highlight the importance of collaborative research with tribal partners in documenting genetic variation in past populations and generating new models of population histories in the Great Plains.

Evolutionary and Population Genetics Posters - Thursday

PB2853. The impact of background selection on deleterious alleles and its consequences on trait evolution and DFE inference

Authors:

X. Li¹, J. Berg¹, J. Novembre²; ¹Univ. of Chicago, Chicago, IL, ²Univ Chicago, Chicago, IL

Abstract Body:

In humans, background selection has been estimated to be a dominant factor explaining neutral variation. It also distorts the neutral site frequency spectrum by reducing variation and leaving an excess of rare variants. However, the impact of background selection on deleterious alleles and its downstream effects on quantitative traits are not well studied.

First, we studied the site frequency spectrum of focal deleterious alleles with different selection coefficients under background selection. We found that for weakly deleterious alleles, background selection reduces the genetic diversity of and leaves an excess of rare variants, similar to its impact on neutral alleles. However, for strongly deleterious alleles, because they are short-lived, background selection has minimal effect.

Second, we investigated how background selection impacts the evolution of complex traits using theoretical models and simulations. We find that background selection shifts the genetic architecture contributing to phenotypic variance toward rare alleles. This agrees with the result in our first section, in that background selection removes weakly selected, more common variants, and has less effect on strongly selected, rare variants. In addition, background selection reduces heritability for traits with a substantial contribution from weakly selected variants. Furthermore, by including background selection in a disease trait model (the liability threshold model), we show that the reduction in diversity caused by background selection leads to a corresponding increase in disease prevalence in order to maintain mutation-selection balance. Using plausible parameter values that generate a diversity reduction of 20% due to background selection (as estimated in humans), we find background selection leads to an increase in disease prevalence by 20%.

Third, while a site frequency spectrum is widely used to infer a distribution of fitness effects (DFE) at functional sites, the distortion of a site frequency spectrum under background selection could potentially bias DFE estimates. We extensively tested the performance of DFE inference under background selection with the 'moments' software (Jouganous et al., 2017). We found that by using synonymous sites with a misspecified demographic model to control for background selection, one can robustly estimate DFE under different demographic histories.

More generally, our work addresses the role of background selection as a factor impacting phenotypic variation, including disease prevalence, and informs best practices for DFE inference from population genetic data.

Evolutionary and Population Genetics Posters - Thursday

PB2854. The influence of demographic history and genetic architecture on complex phenotypes via runs of homozygosity

Authors:

Z. Szpiech; Pennsylvania State Univ., University Park, PA

Abstract Body:

Runs of homozygosity are long stretches of identical-by-descent (IBD) haplotypes inherited from parents with a recent common ancestor. Their abundance and distribution within a population are affected by numerous factors such as population bottlenecks and isolation, founder effects, recent inbreeding, and natural selection, and it has been shown that long ROH are enriched for deleterious homozygotes. Although ROH abundance has been associated with increased risk for various complex traits, it remains unclear the extent to which population history and genetic architecture influence ROH associations with phenotypes. Here we take a simulation approach to characterize the relationship between demographic history, genetic architecture, and a generic complex phenotype. We perform forward-in-time simulations of a three-population human demographic history roughly representing African, European, and Asian continental populations. We simulate a 100 Mb chromosome region with exon structure and a variable recombination map based on the first 100 Mb of human chromosome 1 and allow deleterious mutations with selection coefficients drawn from a gamma distribution. Phenotype is modeled as a function of selection coefficients, with parameters that allow us to vary the relative importance of rare versus common variants in their contribution to the total phenotype. Our results show that demographic history, ROH length, and dominance coefficient are important factors contributing to how much variation in a trait are explained by ROH. We show that ROH influence the simulated phenotype most strongly when alleles are recessive and rare, and that, under these conditions, long ROH (comprised of IBD haplotypes inherited from a very recent ancestor) have more influence than short ROH. These results suggest that the role of ROH in contributing to complex phenotypes may be largely due to the pairing of rare alleles of recessive effect and that incorporating ROH into disease mapping approaches may help the identification of recessive effects.

Evolutionary and Population Genetics Posters - Wednesday

PB2855. The landscape of tolerated genetic variation in humans and primates

Authors:

H. Gao¹, T. Hamp², J. Ed², J. Schraiber¹, J. McRae³, M. Berk⁴, Y. Yang¹, A. Dietrich¹, P. Fizev⁵, P. Fizev¹, L. Kuderna¹, L. Sundaram⁶, Y. Wu¹, A. Adhikari¹, Y. Field¹, C. Chen¹, S. Batzoglou⁷, F. Aguet¹, Primate Sequencing Consortium¹¹, M. Lek⁸, S. Sunyaev⁹, A. O'Donnell-Luria⁴, H. Rehm¹⁰, J. Xu¹¹, J. Xu¹, J. Rogers¹², T. Marques-Bonet¹³, K-H. Farh¹; ¹Illumina, inc., Foster City, CA, ²Illumina, inc., Cambridge, United Kingdom, ³Illumina, Inc, Foster City, CA, ⁴Broad Inst. of MIT and Harvard, Boston, MA, ⁵San Jose, CA, ⁶Illumina, San Diego, CA, ⁷Stanford Univ, Stanford, CA, ⁸Yale Univ. Sch. of Med., New Haven, CT, ⁹Harvard Med. Sch./Brigham & Women s Hosp., Boston, MA, ¹⁰Massachusetts Gen. Hosp., Boston, MA, ^{11,12}Baylor Coll. Of Med., Houston, TX, ¹³Inst. de Biologia Evolutiva (UPF-CSIC), Barcelona, Barcelona, Spain

Abstract Body:

Personalized genome sequencing has revealed millions of genetic differences between individuals, but our understanding of their clinical significance remains largely incomplete. To systematically decipher the effects of human genetic variants, we obtained whole genome sequencing data for 809 individuals from 233 primate species, and identified 4.3 million common protein-altering variants with orthologs in human. We show that these variants can be inferred to have non-deleterious effects in human based on their presence at high allele frequencies in other primate populations. We use this resource to classify 6% of all possible human protein-altering variants as likely benign and impute the pathogenicity of the remaining 94% of variants with deep learning, achieving state-of-the-art accuracy for diagnosing pathogenic variants in patients with genetic diseases.

Evolutionary and Population Genetics Posters - Thursday

PB2856*. The lingering effects of Neanderthal introgression on human complex traits

Authors:

X. Wei¹, C. Robles², A. Pazokitoroudi³, A. Ganna⁴, A. Gusev⁵, A. Durvasula², S. Gazal⁶, P-R. Loh⁷, D. Reich⁸, S. Sankararaman²; ¹Cornell Univ., Ithaca, NY, ²UCLA, Los Angeles, CA, ³UCLA, LA, CA, ⁴Inst. for Molecular Med. Finland, Helsinki, Finland, ⁵Dana-Farber Cancer Inst., Boston, MA, ⁶USC, Los Angeles, CA, ⁷Brigham and Women's Hosp. / Harvard Med. Sch., Boston, MA, ⁸Harvard Univ, Boston, MA

Abstract Body:

The mutations introduced into the ancestors of modern humans from interbreeding with Neanderthals have been suggested to contribute an unexpected extent to complex human traits. However, testing this hypothesis has been challenging due to the idiosyncratic population genetic properties of introgressed mutations. We developed rigorous methods to assess the contribution of introgressed Neanderthal mutations to heritable trait variation relative to that of modern human variants. We applied these methods to analyze 235,592 introgressed Neanderthal mutations and 96 distinct phenotypes measured in about 300,000 unrelated white British individuals in the UK Biobank. Introgressed Neanderthal mutations have a significant contribution to trait variation consistent with the polygenic architecture of complex phenotypes (contributing 0.1% of heritable variation averaged across phenotypes; $p = 9.59 \times 10^{-9}$). However, the contribution of introgressed mutations tends to be significantly depleted relative to modern human mutations matched for allele frequency and linkage disequilibrium (about 57% depletion on average), consistent with purifying selection on introgressed mutations. Different from previous studies (McArthur 2021), we find no evidence for elevated heritability across the phenotypes examined. We identified 348 independent significant associations of introgressed Neanderthal mutations with 64 phenotypes ($p < 1 \times 10^{-10}$). Previous work (Skov 2021) has suggested that a majority of such associations are likely driven by statistical association with nearby modern human variants that are the true causal variants. We therefore developed a customized statistical fine-mapping methodology for introgressed mutations that led us to identify 112 regions (at a false discovery proportion of 16%) across 47 phenotypes containing 4,303 unique genetic variants where introgressed mutations are highly likely to have a phenotypic effect. Examination of these mutations reveal their substantial impact on genes that are important for the immune system, development, and metabolism. Our results provide the first rigorous basis for understanding how Neanderthal introgression modulates complex trait variation in present-day humans.

Evolutionary and Population Genetics Posters - Wednesday

PB2857. The NHGRI Sample Repository for Human Genetic Research: biospecimens and a new genomic data search tool

Authors:

A. Liautaud, D. Kusic, G. Calendo, J. Madzo, B. Kerr, S. Sampson, L. Willis, E. Horton, M. Mitchell, N. Gharani, L. Scheinfeldt; Coriell Inst. for Med. Res., Camden, NJ

Abstract Body:

The NHGRI Sample Repository for Human Genetic Research (NHGRI Repository) housed at the Coriell Institute for Medical Research facilitates studies of human genetic and genomic variation by establishing, characterizing, and distributing a large (over 3,700) and diverse publicly available collection of renewable biospecimens obtained from human populations living around the world, including biospecimens associated with the 1000 Genomes Project. Participants that generously donated to the NHGRI Repository consented to their biospecimens being used for a wide range of general research and to broad sharing of largescale, associated genomic data collected from their biospecimens. Through the 1000 Genomes Project, the majority of this collection has been characterized with publicly available whole genome sequencing data and other large-scale genomic data. We recently developed a user-friendly and integrated genomic data search tool that allows catalog users to dynamically query 1000 Genomes Project whole genome sequencing and RNA-Seq data. The whole genome sequencing data can be searched by individual SNP (rsid), or by gene (HUGO symbol), and the RNA-Seq data can be searched by gene. The SNP search returns an interactive table of each subject, subject affiliation, genotype, and sex that can be filtered or exported to an excel file. The Gene search returns an interactive table of each variant identified in the dataset, chromosome location, and human reference genome build GRCh37 position, alleles, and functional annotation that can be filtered or exported to an excel file. The Gene Expression search returns an interactive table that can be viewed or downloaded (to a .CSV file) with gene expression levels (in counts per million (CPM), fragments per kilobase of exon model per million reads mapped (FPKM), reads per kilobase of transcript per million mapped reads (RPKM), transcripts per million (TMP), or by a variance stabilizing transformation (VST) of the data), and also including the chromosome and chromosomal start and end positions of the gene, and the type of gene (e.g., protein coding). Researchers can view a histogram plot of gene expression levels, and mark where any given sample expression levels fall within the distribution. These tools are intended to enable researchers a fast and simple way to identify biospecimens with the most appropriate genetic variation and gene expression profiles for their research goals. Our Genomic Data Search tools can be accessed at <https://www.coriell.org/1/Browse/Genomic-Data-Search>, and more information about the NHGRI Repository can be found at <https://catalog.coriell.org/NHGRI>.

Evolutionary and Population Genetics Posters - Thursday

PB2858. The spatial distribution of rare deleterious alleles: implications for study design in human genetics

Authors:

M. Steiner¹, D. Rice¹, C. Porras^{2,1}, J. Novembre¹; ¹Univ. of Chicago, Chicago, IL, ²Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Sampling design is a key question in the construction of large-scale sequencing cohorts, which are a priority for human genetics due to the potential of downstream studies to uncover rare, large-effect variants. The geographic component of sampling design can be viewed on a spectrum between two extremes: either sampling many individuals from a single location or fewer individuals from each of multiple locations. The consequences of such "narrow" vs. "broad" sampling for detecting rare variants - which tend to be geographically localized - are largely unknown. To this end, we develop a population genetic model for the distribution of deleterious alleles in a spatially structured population - accounting for dispersal, drift, selection, and mutation simultaneously - while incorporating spatially-variable sampling. Using techniques from the theory of superprocesses, we compute the expected site frequency spectrum (SFS) of a sample as a function of the population genetic parameters and sampling scheme. We then use the SFS to estimate the power to detect and characterize rare variants. In doing so, we identify trade-offs between narrow and broad sampling. Analysis of our model suggests that, as a result of the low population frequency and spatial clustering of rare, deleterious variants, deep sequencing of one or a few populations can be a more efficient means to find multiple carriers of a rare variant, as is needed to understand phenotypic effects. Yet, we find that in the case of association studies or individual risk assessment, sampling individuals from only a few geographic regions limits transferability across populations, with potential consequences for the deployment of precision medicine techniques such as polygenic risk scores. Our approach allows us to quantify these trade-offs and thus we expect the results will inform existing discourse regarding optimal strategies for designing sequencing cohorts. Moreover, improving the ascertainment and characterization of deleterious alleles has the potential to unveil novel disease mechanisms and drug targets, refine precision medicine approaches, and improve understanding of genetic architectures of complex traits.

PB2859. Tracing the genetic link of Mizo people of India: Genetic & archaeological evidence

Authors:

B. Bankura^{1,2}, P. Singh³, G. Chaubey³, M. Das²; ¹Med. Coll., Kolkata, Kolkata, India, ²Univ. of Calcutta, Kolkata, India, ³Banaras Hindu Univ., Varanasi, India

Abstract Body:

The Himalayan region played a crucial role in the human dispersal and colonization of South Asia. It forms a unique and narrow passage that connects the Indian sub-continent to East and South East Asia. Archaeological and anthropological studies suggest migration and cultural diffusion in this region with the Tibetan plateau in the north. Mizoram is the southernmost state in the northeast region, sharing its borders with Tripura, Assam, and Manipur, along with Myanmar and Bangladesh. The Mizo people are believed to be a part of the Mongoloid feature and Mizoram has the highest number of tribal people among all states of India. Therefore, our study is an attempt to clarify the origins of the Mizo people and their migration roads to their present settlements. Thus, issues of ethnicity and migration are complex but highly relevant to the modern state. A more concentrated effort is required to track these population movements and dispersals linking archaeology and genetics. Plausible migration histories of these groups have been addressed based on linguistic, ethnographical, historical, and folkloristic data however; less attention has been given to genetics or modern genome mapping. Given the vastness of the region and considerable diversity in the topography, a specific region has been selected for the study: the region adjoining the Indo-Myanmar border in the Champhai district of Mizoram. Therefore, our study is an attempt to clarify the origins of the Mizo people and their migration roads to their present settlements. In the present study, we have investigated 110 individuals belonging to different clans of Mizo people for a genome-wide autosomal marker study. Our results suggest that they are a unique and isolated tribal group and have a very distinct population history. Haplotype and allelic frequency-based analyses indicate that they substantially shared ancestry primarily with East Asian populations and Tibeto-Burman speakers of India but also differentiated from them and became a distinct population with time.

PB2860. Understanding ancestry-specific disease allelic effect sizes by leveraging multi-ancestry-matched single-cell RNA-seq and GWAS datasets

Authors:

J. Wang, S. Gazal; Univ. of Southern California, Los Angeles, CA

Abstract Body:

Genome-wide association studies (GWAS) have highlighted that human diseases and complex traits are dominated by common regulatory risk variants. However, some of these variants have ancestry-specific effects, as suggested by the poor transportability of polygenic risk scores across populations. One explanation would be that regulatory differences across ancestries (due to different genetics and/or environments) lead to ancestry-specific disease effect sizes. Here we leveraged multi-ancestry-matched single-cell RNA-seq (scRNA-seq) and GWAS datasets to detect genes differentially expressed across ancestries (ANC-DE genes) at the cell-type level and to test if genetic variants around those genes tend to be enriched in GWAS ancestry-specific effects. First, we analyzed scRNA-seq data in peripheral blood mononuclear cells (PBMCs) from 45 individuals of East-Asian (EAS) or European (EUR) ancestry (Perez et al. 2022 Science). We detected 320 genes significantly differentially expressed (FDR 5%) across EAS and EUR ancestries in at least one cell type. The majority of these genes (85%) tend to be differentially expressed in a single cell type, and were enriched in genes involved in the immune response to the environment. Second, we leveraged 15 GWAS datasets of blood and immune-related traits available in both EAS (average N = 53K) and EUR populations (average N = 55K), and ran S-LDXR (Shi et al. 2021 Nat Com) to test if genetic variants surrounding ANC-DE genes were enriched in ancestry-specific GWAS effects. We determined that the squared multi-ancestry genetic correlation is 0.66 ± 0.05 for SNPs surrounding PBMCs ANC-DE genes, which represents the lowest existing correlation obtained by S-LDXR (vs 0.94 ± 0.01 for SNPs surrounding any gene). We observed a (non-significant) lower depletion around lymphoid ANC-DE genes (0.59 ± 0.06) compared to myeloid ANC-DE genes (0.65 ± 0.06); these depletions were driven by B cells ANC-DE genes (0.28 ± 0.06) and by conventional dendritic cells ANC-DE genes (0.26 ± 0.09) in lymphoid and myeloid cells, respectively. Finally, we leveraged our findings to interpret different discordant results between EAS and EUR Lymphocyte Count GWAS around the MCL1 gene. Altogether, our results highlight that genes with ancestry-specific levels of regulation in PBMCs are enriched in genes involved in the immune response to the environment and enriched in genetic variants with different effect sizes in blood and immune-related traits. These results suggest that ancestry-specific regulation leads to ancestry-specific genetic effect sizes and disease risk.

Evolutionary and Population Genetics Posters - Wednesday

PB2861*. Understanding natural selection in the European Holocene using Ancient DNA.

Authors:

D. Pandey^{1,2}, M. Harris³, N. R. Garud³, V. Narasimhan¹; ¹The Univ. of Texas at Austin, Austin, TX, ²Indian Inst. of Technology Kharagpur, Kharagpur, India, ³Univ. of California, Los Angeles, CA

Abstract Body:

Ancient DNA (aDNA) has been a revolutionary technology in understanding human history but has not been used extensively to study natural selection as large sample sizes to study allele frequency changes over time have thus far not been available. Previous methods to study selection using aDNA have been limited to examining the most recent time period or looking at specific alleles already known to be under selection. Here, we examined a time transect of 885 published samples over the past 12,000 years using haplotype homozygosity based selection scans that do not require additional demographic models to uncover selective events. We used f_4 -statistic, date of the sample, archeological context, and geographic location to group the data into five time periods: the Mesolithic (M), Neolithic (EN), Bronze Age (BA), Iron Age (IA), and Historical period (H), with sample sizes of 177 individuals each. As aDNA data is affected by high missingness, ascertainment bias, DNA damage, random allele calling, and is unphased, we first validated our selection scan (a modified version of the G12 statistic) on simulated data resembling aDNA under a demographic model that captures broad features of the allele frequency spectrum of European genomes. Our scan was sensitive enough to detect events that occurred at different time depths, selection intensities, and modes of selection. By utilizing samples from the H period, which are 1000 years older than modern samples, we also validated our scan on several positive controls that have been previously identified and functionally validated in modern European datasets. We then applied our statistic to real data and used our time transect to examine the timing of selection on well-studied loci (*LCT*, *SLC22A5*, and *SLC24A5*) and show that we detect selection on *LCT* in the H period and for *SLC24A5* in the BA, while *SLC22A5* appears to be under selection in the EN. We also found that functional categories of SNPs showed a significantly higher signal than SNPs that were not annotated as being functionally relevant, with the HLA region the most elevated. In the earliest time period studied (M), we obtained an elevated signal for loci that had previously not been identified by any selection scans in modern European data, including in the gene *ALDH*, which is the principal catalyst for the oxidation of acetaldehyde during alcohol metabolism as well as in *AOAH* which prevents prolonged and damaging inflammatory responses from bacteria. Our results suggest that applying selection scans to aDNA uncovers putative selection signals at loci in the ancient past that might have been masked in modern samples due to population structure, admixture, and genetic drift.

Evolutionary and Population Genetics Posters - Thursday

PB2862. Understanding the structure of regional populations with founder effects.

Authors:

L. Gagnon, C. Moreau, A. Girard, J. Bouchard, C. Laprise, H. Vézina, S. Girard; Univ. of Quebec at Chicoutimi, Chicoutimi, QC, Canada

Abstract Body:

Background/objectives: Quebec is an example of a young and non-uniform founder population. By combining genetic and genealogical data from different regions in Quebec, it's possible to study in detail the regional subdivisions and better understand the associated founder effects. **Methods:** The genetic and genealogical data are available for 666 individuals from 8 Quebec regions. We have characterized the identity-by-descent (IBD) sharing, the genealogical kinship, the number of most recent common ancestors (MRCA), the inbreeding of MRCA and the ancestors' occurrences per generation using bioinformatic tools such as refinedIBD and genlib R package. **Results:** The IBD length distribution analysis reveals more numerous and longer segments in individuals from Saguenay and Acadians from Gaspésie. However, genealogical information, such as kinship, MRCA and ancestors' occurrences, indicates that despite the similar IBD distribution, the demographic and historical phenomena behind are specific to each subpopulation. Last, using the genealogical kinship of ancestors, it is possible to follow the evolution of the population structure at each generation from the beginning of the colony until today. **Conclusion:** These results demonstrate a fine and specific regional genetic structure in Quebec subpopulations. Notably, Saguenans and Acadians from Gaspésie have different historical particularities that lead to similar patterns of genetic sharing: a strong founder effect for Saguenay and high levels of kinship among Acadians' ancestors. This difference is however observable within the genealogical data. Finally, this approach integrating population genetics and genealogical structure will be used for studying complex diseases, such as asthma, epilepsy, and schizophrenia, in future projects.

Evolutionary and Population Genetics Posters - Wednesday

PB2863. Unsupervised Learning of Ancestry Informative Markers and Genetic Admixture Coefficients From Biobank Data

Authors:

S. Ko, E. Sobel, H. Zhou, K. Lange; Univ. of California, Los Angeles, Los Angeles, CA

Abstract Body:

Admixture estimation plays a crucial role in ancestry inference and genomewide association studies (GWAS). Computer programs such as ADMIXTURE and STRUCTURE are commonly employed to learn the admixture proportions of sample individuals. However, these programs can be overwhelmed by the computational burdens imposed by the 10^5 to 10^6 samples and millions of markers commonly found in modern biobanks. An attractive alternate strategy is to run these programs on a small set of ancestry informative SNP markers (AIMs) that exhibit substantially different frequencies across populations. Unfortunately, existing methods for identifying AIMs require knowing ethnicity labels for a subset of the sample. This supervised learning approach creates a chicken or the egg scenario. Here, we present an unsupervised, scalable framework that carries out AIM selection and estimation of admixture coefficients seamlessly. Our simulated and real data examples show that this approach is scalable to biobank size. Our implementation of this method is called OpenADMIXTURE. For the first part of our pipeline, AIM selection, we use the SKFR (sparse K-means with a feature ranking) method. Our procedure is highly parallelized and effective in AIM selection. SKFR's unsupervised clustering is insensitive to a small fraction of labeling errors and admixed samples. SKFR also delivers an explicit ranking of AIMs. Our experiments suggest that 100,000 informative SNPs deliver better clusters than full SNP sets. Uninformative SNPs simply constitute noise that slows clustering and obscures subpopulations. For the second part of our pipeline, admixture estimation, we created an open-source re-implementation of ADMIXTURE in the Julia programming language. The original paper announcing ADMIXTURE has garnered over 5000 citations. Our implementation in OpenADMIXTURE is 8 times faster than the original ADMIXTURE on CPUs with multithreading, and 35 times faster on an Nvidia V100 GPU. Both our results and our total computation time is comparable to SCOPE, the only previous admixture method known to be scalable to biobank data. However, our method results in a ranking of AIMs and is based on a likelihood model that incorporates basic population genetics concepts. Both SCOPE and OpenADMIXTURE can estimate admixture coefficients for a biobank data set with 500,000 subjects and 600,000 SNPs in about 2 hours with a 64-thread CPU and a V100 GPU. However, the peak memory demands of OpenADMIXTURE is less than 30% that of SCOPE; for this data set, under 75 GB of RAM versus 250 GB. OpenADMIXTURE's efficiency is partly due to its systematic exploitation of Plink's binary format for both storage and computation.

Evolutionary and Population Genetics Posters - Thursday

PB2864. Using a population-specific reference panel improves genotype imputation accuracy in individuals of African ancestry

Authors:

R. Mayanja^{1,2}, A. B. Kamiza³, O. Soremekun¹, K. Hatzikotoulas⁴, W. N. Rayner⁴, A. P. Morris⁵, M. Crampin³, T. Chikowore⁶, S. Fatumo¹; ¹Uganda Virus Res. Inst./Med. Res. Council/London School of Hygiene and Tropical Medicine, Entebbe, Uganda, ²Makerere Univ., Kampala, Uganda, ³Malawi Epidemiology and Intervention Res. Unit, Lilongwe, Malawi, ⁴Inst. of Translational Genomics, München, Germany, ⁵Ctr. for Genetics and Genomics Versus Arthritis, Ctr. for Musculoskeletal Res., Div. of Musculoskeletal and Dermatological Sci., The Univ. of Manchester, Manchester, United Kingdom, ⁶Sydney Brenner Inst. for Molecular BioSci., Faculty of Hlth.Sci., Univ. of the Witwatersrand, Johannesburg, South Africa

Abstract Body:

Genotype imputation uses densely genotyped haplotypes to predict genotypes of untyped variants in a target dataset. It boosts the power of genome-wide association studies (GWAS) and can be used for meta-analysis, fine mapping, and developing genetic risk scores. Factors such as the reference panel's representation of the target population influence the quality of imputation. We investigated the best performing imputation reference panel in people of African ancestry by comparing the performance of the five most commonly used imputation reference panels containing African ancestry data (Trans omics for Precision Medicine (TopMed), Haplotype Reference Consortium (HRC), 1000 Genomes Project (1000G), Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA), and African Genome Resource (AGR)). Data from 288 Malawi Epidemiology Intervention Research Unit (MEIRU) cohort members who were genotyped on the H3A genotyping array were used in this study. The total number of SNPs imputed with an imputation quality > 0.3 and mean imputation quality scores across a range of minor allele frequency (MAF) bins were used to evaluate imputation performance. TopMed and AGR reference panels imputed the most SNPs (73,553,040 and 26,131,641, respectively), while HRC reference panel imputed the fewest (17,998,233). TopMed and AGR had similar mean r² values and outperformed all other reference panels with MAF > 0.2. However, AGR had a higher mean r² than all other reference panels for SNPs with MAF > 0.2. In conclusion, when performing genotype imputation on people of African ancestry, AGR and TopMed should be prioritized to improve imputation coverage and accuracy.

Evolutionary and Population Genetics Posters - Wednesday

PB2865. Variable representation of duplicated sequence in recent canine genome assemblies.

Authors:

A. Nguyen¹, J. Kidd²; ¹Univ. of Michigan, Ann Arbor, MI, ²Univ MICHIGAN, Ann Arbor, MI

Abstract Body:

Gene duplications arise through two means: the reverse transcription and integration of RNA transcripts, or the duplication of DNA segments. DNA-level duplications take the form of either whole genome duplications, or smaller and restricted segmental duplications, which can create additional copies of genes or gene clusters. When these additional copies differ in number between individuals or populations, they are referred to as copy number variants (CNVs), which can lead to the evolution of novel gene functions as well as alteration of normal gene expression patterns. Over time, changes in CNVs can result in the evolution of gene families and are associated with a range of adaptive and detrimental phenotypes. However, despite the importance of duplication, systematically identifying and analyzing these variants has been challenging. The recent explosion of new canine long-read genome assemblies allows for a finer investigation of duplicated sequences in the canine model than ever before. However, the extent to which duplicated sequences are accurately represented in these new assemblies remains unclear. By conducting genome assembly self-alignment using the computational program BISER, and read depth analysis using fastCN and QuicK-mer2, we have assessed the representation of genomic sequence in nine published, long-read, high-quality, reference-level canine genome assemblies. Our analysis has three major conclusions. The first is that recently published genome assemblies, including canFam4, the current canine reference genome, include several notably-misassembled areas. The second, a subset of genes appear to be proliferating through the genome at extremely high levels in some assemblies, and based on exon-exon coverage, these gene duplicates appear to be retrogenes. Finally, certain differences between assemblies are representative of polymorphic duplications that are segregating among canines.

PB2866. A bioinformatics pipeline to aid in the design of allele-specific antisense oligonucleotides for patients with rare genetic conditions

Authors:

Q. Zhang¹, T. Huang², T. Cole³, T. Truong², K. Cung¹, R. Wang¹, A. Crawford¹, R. Taft¹; ¹Illumina Inc, San Diego, CA, ²Illumina Inc, Foster City, CA, ³n-Lorem Fndn., San Diego, CA

Abstract Body:

Antisense oligonucleotides (ASO) are short, synthetic oligodeoxynucleotides which are able to modify gene function; they can be developed rapidly, while being highly specific and relatively inexpensive. ASOs are a promising treatment for many rare genetic diseases, especially those caused by dominant gain-of-function mutations, where effective allele-specific ASO design requires discriminating the parental haplotypes to target the corresponding mutant pre-mRNA. However, a standard short-read sequencing approach often fails to confidently phase the two haplotypes, especially at highly homozygous or low-complexity regions. Illumina's Infinity technology, which expands read length to up to 10kb, helps to resolve phasing in the remaining cases. We developed a computational pipeline to aid ASO design with Infinity alignments, while leveraging the highly accurate call set from short-read sequencing. The haplotype with the known de novo pathogenic variant was used as a target to design gene silencing ASO candidates; while the other haplotype, together with haplotypes from functionally associated paralogs, were used as a background database to remove ASOs that have high affinity to them. Next, the specific ASO candidate sequences were compared against a patient-specific genomic or transcriptomic database to further increase specificity. Finally, in-vitro and in-vivo functional screening will be carried out to evaluate the efficacy and specificity of proposed ASOs. Therapy development for rare disease is often hindered by the small number of patients. This work showcased a clinical application of infinity long reads to bridge variant identification with personalized medicine.

Omics Technologies Posters - Thursday

PB2867. A Cloud-scalable Software Suite for Large-Scale Proteogenomics Data Analysis and Visualization

Authors:

A. Gajadhar, H. Auluck, M. K. R. Donovan, K. Motamedchaboki, Y. Lou, T. Platt, S. Batzoglou; Seer, Redwood City, CA

Abstract Body:

Assessment of the flow of genetic information through multi-omic data integration can reveal the molecular consequences of genetic variation underlying human disease. Next-generation sequencing (NGS) can be used to identify genetic variants, while mass spectrometry can be used to assess the proteome. Integration of proteomics and genomics data requires many tools of which require complex workflows that can act as a barrier for researchers to adapt new analysis tools. Proteograph™ Analysis Suite (PAS) software application is a dedicated, cloud-based software solution removes barriers for proteomics researchers by enabling processing, analyzing, and visualizing proteomics data sets generated by liquid chromatography-mass spectrometry (LC-MS). PAS includes an experiment data management system, analysis protocols, analysis setup wizard, and result visualizations. PAS can support both Data Independent Analysis (DIA) and Data Dependent Analysis (DDA) workflows. PAS includes visualizations to assess data quality, as well as enables biological insights through differential protein abundance analyses. Further, we present a new, proteogenomics integration to PAS that enables the identification and exploration of peptides with protein sequence altering genetic variants through the integration of Proteograph proteomics data with NGS variant information. This proteogenomic analysis first enables users to build a customized protein sequence database, which involves uploading a custom or sample-specific variant call file (VCF) to identify genetic variants that may result in single amino acid variants (i.e., peptide variants) not captured in the reference human proteome. Custom peptide variants are then combined with reference human proteome to generate custom peptide sequence databases. Using the customized protein sequence database, DDA data is searched for peptide variants using an MS/MS search engine. Results are then accessible through a peptide variant browser and proteogenomic data explorer. The peptide variant browser summarizes results in an interactive table and plots, which enables users to explore the identified peptides and their intensities variants across samples. The Proteogenomic data explorer is an interactive browser to examine how Proteograph peptide and variant peptide data maps in genomic space (at protein- and at nucleic acid/amino acid- scale resolution). From data to insight, PAS provides an easy-to-use and efficient suite of tools to enable proteogenomic data analysis.

Omics Technologies Posters - Wednesday

PB2868. A Comparative Bioinformatics Analysis to Propose a COVID_19 Candidate Vaccine Epitope at the ACE-Bioinformatics in Mali (West Africa)

Authors:

M. Kouyate¹, M. HAIDARA², B. Sacko³, M. Sangare⁴, S. Doumbia⁵, M. DIAKITE⁶, M. Wele¹; ¹ACE-USTTB, street 171/ door 85, Mali, ²Univ. of Sci., of Techniques and technologies of Bamako, Bamako, Mali, ³Univ. of Pennsylvania Sch. of Med., Pennsylvania, PA, ⁴Univ. of Sci., Techniques and Technologies of Bamako (USTTB), Bamako, Mali, ⁵USTTB, Bamako, Mali, ⁶Malaria Res. and Training Ctr., Bamako, Bamako, Mali

Abstract Body:

Coronaviruses are host-specific unless a mutation occurs in the viral genome. Human coronavirus 229E (HCoV-229E), Middle East respiratory syndrome (MERS-CoV), and severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) are three of six human coronaviruses that are ubiquitous and could persist on inanimate surface. COVID barrier measures and drug treatment are useful, however effective vaccinations are key to stopping the propagation of COVID-19. Our aim was to identify COVID-19 vaccine candidate epitopes using bioinformatics approaches. We obtained SARS-CoV-2 sequence from 2019nCoV, NCBI, GISAID and TAURAU/T-bio-info server. We reviewed the viral origin and compared the sequencing data to identify the consensus motive “**KRSFIEDLLFNKVTLADAGF**” (a target binding site) in the spike domain. This motif has unanimously been found in both newly identified and previous 2019-nCoV strains, which makes it a potential good candidate epitope. The receptor binding domain (RBD) in spike proteins are responsible for the contact between the virus and its host. We found that highly conserved -with 70 % identity- residues in the receptor-interacting motive, five important amino acids (L455, Y473, N479, F486, and Q493) on the RBD in spike proteins and D480, and T487 in the SARS-CoV_RBD that allow interspecies infection. In SARS-CoV-2, a slight modification of some of these residues could improve the interaction with the human cellular receptor. In SARS-CoV, two main residues N479 and T487, which correspond to Q493 and N501 in SARS-CoV-2 have been associated with the recognition of the human angiotensin converting enzyme 2 (ACE2) receptor. These residues drive energetically favorable changes for a strong interaction with the human receptor. The motif **KRSFIEDLLFNKVTLADAGF** sat on a region around one of the known cleavage sites of the SARS virus, which are believed to be required for virus activation for cell entry. This sequence motif and surrounding variations could be further investigated as a specific synthetic COVID-19 vaccine epitope. Nevertheless, the epitope we are proposing is presumably a good target for a good COVID-19 vaccine candidate in clinical trials. Although new research data are emerging on COVID-19 at an explosive rhythm, our work can easily be replicated by others.

Omics Technologies Posters - Thursday

PB2869*. A comparison of the sensitivity and diagnostic rate of long-read vs. short-read whole genome sequencing in critically ill infants in the SeqFirst Project

Authors:

D. Miller¹, M. Galey¹, T. Wenger², M. Sikes³, A. Scott², C. Davis¹, K. Buckingham¹, J. Chong¹, D. Veenstra⁴, K. Dipple¹, D. Copenheaver⁵, J. Juusola⁶, K. Retterer⁶, M. Kirsty⁶, A. Snook⁶, P. Kruszka⁶, E. Eichler⁴, M. Bamshad¹; ¹Univ. of Washington, Seattle, WA, ²Seattle Children's Hosp., Seattle, WA, ³Seattle Children's, Seattle, WA, ⁴Univ of Washington, Seattle, WA, ⁵Gene Dx, Gaithersburg, MD, ⁶GeneDx, Gaithersburg, MD

Abstract Body:

Evaluation and testing of critically ill neonates for an underlying genetic condition is strongly influenced by a provider's a priori level of suspicion for a genetic condition. SeqFirst is a project whose main aim is to develop and test approaches toward centering equity for obtaining a precise genetic diagnosis at the initial point of care for infants with a critical illness using simple exclusion criteria (i.e., presentation fully explained by prematurity, trauma, or infection) rather than complex inclusion criteria to identify infants eligible for rapid short-read whole genome sequencing (srWGS). While there have been anecdotal reports of using long-read WGS (lrWGS) to detect variants missed by srWGS, no systematic comparison has been performed in a clinical setting. From January of 2021 to January of 2022 the electronic medical records for every infant under 6 months of age (n=411) admitted to the NICU at Seattle Children's Hospital were reviewed and 125/233 eligible families agreed undergo rapid srWGS at GeneDx. A result that fully or partially explained clinical findings was achieved in 70 (56%) families.

To evaluate the sensitivity (i.e., ability to detect previously identified explanatory variants) and added diagnostic value of lrWGS, we sequenced the same families using lrWGS on the Oxford Nanopore platform. Each individual was sequenced to a target depth of 40x coverage and evaluated using a standard analysis pipeline. Single nucleotide and insertion or deletion variants were called with Clair3, phased with LongPhase, and annotated using VEP. Structural variants were called using Sniffles2, CuteSV, and SVIM and prioritized using allele frequencies from publicly available datasets. Methylation was called using Guppy and differentially methylated regions (DMRs) were identified using MeOW. We report a comparison of sensitivity and diagnostic rates as well as highlight explanatory variants that were challenging or not possible to detect using srWGS.

Omics Technologies Posters - Wednesday

PB2870*. A computational approach to design a COVID-19 vaccine against a predicted SARS-CoV-2 variant: high immunogenicity, efficacy and safety of DELLERA vaccine.

Authors:

R. Paone, A. Infascelli, G. Valoti, P. Graziani, R. Ottalevi, N. Sabatini, M. Masciovecchio, C. Ciace, D. Clementoni, A. Lo Iacono, G. Iodice, M. Luciano, M. Brown, J. Caceres, I. Baldini; Dante Labs, L'Aquila, Italy

Abstract Body:

Severe acute respiratory syndrome coronavirus-2 (SARS-Cov-2) caused 6,259,945 deaths worldwide since its first identification in 2019. Even if the development of coronavirus disease 2019 (COVID-19) vaccines has proceeded at an extremely rapid pace, achieving global vaccine coverage remains a major hurdle due to the constant evolution and selection of vaccine escape variants. Therefore the tireless development of new candidate vaccines remains critical. In this study, we use a computational approach for the design of a novel candidate vaccine for a predicted SARS-CoV-2 variant. A total of 393,594 Spike (S) protein genomes of SARS-CoV-2 were analyzed with the aim to find a reference sequence of the virus most widely spread in Europe at the time and predicted (MaxEnt niche-based model) to remain as the dominant clade for the next COVID-19 wave. Therefore, we selected the viral S protein of an UK-Alpha variant of SARS-CoV-2 from a real sample (hCoV-19/England/MILK-B94A53/2020) as the basis for our vaccine design. This predicted reference shares mutations with current circulating variants, such as Omicron BA.1, BA.2, and BA.4&5. Computational screening of amino acid mutagenesis on the hotspot residues at protein-protein interfaces (between SARS-CoV-2 and ACE2 receptor) using relative free energy calculations was performed to increase the strength of the immune response against the target S protein. The preclinical study consists of 3 injections (0, 14, 28 days) per individual with two different dosages (1 μ g and 10 μ g). The results were used to evaluate: toxicity (Sprague Dawley rats, n=30), immunogenicity (Sprague Dawley rats, n=30; C57BL/6J and BALB/c mice, n=60) and efficacy (Syrian hamsters, n=24). No treatment-related deaths were reported. Evaluation of physical and clinical parameters showed lack of adverse or toxic effects. High titers of anti-RBD antibodies for ancestral and Omicron (P=.0018) variants and anti-S1/S2 antibodies for UK-Alpha (P=.0016) variant suggested the induction of a robust immune response. Increased IFN- γ (P=.00001) and IL-2 (P=.00001) levels showed a clear polarization of Th1 immune responses. Antibodies developed by the animals demonstrated effective neutralization capability virus (P<.0001). Preliminary data suggest robust protective efficacy against the ancestral SARS-CoV-2 strain as shown by less signs of lung damage in Syrian hamsters challenged with an high intranasal Sars-CoV-2 inoculum. Successful preclinical data on safety, immunogenicity and efficacy of Deller vaccine suggest that our approach represents a promising choice to design vaccines against new predicted variants of SARS-CoV-2.

Omics Technologies Posters - Thursday

PB2871. A deep learning framework for structural variant discovery and genotyping

Authors:

V. Popic¹, C. Rohlicek¹, F. Cunial¹, K. Garimella¹, D. Meleshko², I. Hajirasouliha²; ¹Broad Inst. of MIT and Harvard, Cambridge, MA, ²Weill Cornell Med., New York, NY

Abstract Body:

Structural variants (SV) are a major driver of genetic diversity and disease in the human genome and their discovery is imperative to advances in precision medicine and our understanding of human genetics. Existing SV callers rely on hand-engineered features and heuristics to model SVs, which cannot easily scale to the vast diversity of SV types nor fully harness all the information available in sequencing datasets. Since deep neural networks can learn complex abstractions directly from the data, they offer a promising approach for general SV discovery. Here we propose a novel generalizable deep learning framework, Cue, to call and genotype SVs, which effectively leverages deep learning to automatically discover the underlying salient features of different SV types, including complex and somatic subclonal SVs. In particular, we formulate SV discovery as a multi-class keypoint localization task, where keypoints correspond to breakpoints of different SVs in multi-channel images that juxtapose two genome intervals (thus capturing both SV breakpoints regardless of SV size) and simultaneously represent multiple alignment signals (such as read depth and split reads) as separate image channels. We use a stacked hourglass network to predict the type, genotype, and genomic locus of the SVs captured in each image. We allow multiple SVs to be present in the same image, thus enabling our model to easily handle nested or clustered SVs. This formulation allows Cue to be easily generalizable by design to different sequencing technologies and new SV types. To date, we have trained Cue to detect deletions, tandem duplications, inversions, inverted duplications, and inversions flanked by deletions larger than 5kbp using short reads. We have evaluated Cue using synthetic and real short-read whole-genome sequencing datasets and show that Cue outperforms state-of-the-art methods on benchmarks where high-confidence SV calls are available (namely, in simulation and the HG002 GIAB Tier1 benchmark). To further analyze Cue's performance on real data, we have used several long-read callers to orthogonally validate the results of the short-read tools. In particular, we compared the performance of short-read and long-read methods on the CHM1 and CHM13 genome mix using short-read Illumina and long-read PacBio datasets. We show that Cue achieves the highest relative concordance with long-read methods for CHM1 and CHM13 deletions. Finally, we show a proof-of-concept extension of Cue to long-read and linked-read sequencing platforms and its performance gains, especially in complex SV discovery, as compared to several state-of-the-art long-read and linked-read SV callers.

PB2872. A Deep-learning based RNA-seq Germline Variant Caller

Authors:

D. Cook¹, A. Venkat², Y. Pouliot², F. De La Vega², P. Chang¹, A. Carroll¹; ¹Google, Mountain View, CA, ²Tempus Labs, Chicago, IL

Abstract Body:

RNA-seq is a widely used method for transcriptome analysis. The technology is often used to study gene expression, but RNA-seq data can be used for other applications including germline variant calling. Here, we introduce DeepVariant RNA-seq, a new method for performing germline variant calling from RNA-seq data. Our method encompasses updates to DeepVariant software that allow for compatibility with RNA-alignment data and a newly trained RNA-seq model.

DeepVariant is a deep-learning based variant caller that turns variant calling into an image classification problem. It does this by extracting sequence features from alignment files and encoding them as a series of "channels" that form an image. These images are then used to train a model capable of accurately calling genotypes. DeepVariant demonstrated high performance in germline variant calling from whole genome sequencing, however, RNA-seq variant calling has not previously been explored.

We demonstrate that DeepVariant RNA-seq outperforms existing methods including GATK and Platypus. We trained and evaluated DeepVariant RNA-seq on Genotype-Tissue Expression (GTEx) RNA-seq samples. In CDS regions, DeepVariant RNA-seq achieves a median F1 of 0.933 across 200 samples vs 0.903 for GATK and 0.898 for Platypus. DeepVariant also outperforms other callers in terms of indel performance, achieving a median F1 of 0.73 (precision=0.897, recall=0.614) which is a substantial improvement over GATK (F1 = 0.485) and Platypus (F1 = 0.414). We also observed improved performance across all other examined stratifications including exonic regions, gene regions, and transcript regions.

We also examine factors that influence DeepVariant RNA-seq performance. For example, we examine performance across a series of coverage thresholds, finding that restricting evaluation to regions with at least 8x coverage allows for high precision (0.985) and sensitivity (0.958). Additionally, we find that RNA integrity number and tissue type do not substantially impact DeepVariant RNA-seq performance. Instructions for downloading and using DeepVariant RNA-seq are available at <https://www.github.com/google/deepvariant>.

PB2873. A demonstrated workflow to unleash the multiomic potential of a single blood draw.

Authors:

B. Nui¹, H. Latif¹, V. Tumilasci², Y. Han¹, Y. Fan¹, D. Corney¹, P. Vishwanath¹, W. Wei¹, A. Staffa², I. DeVito¹, L. Turner¹, C. Mozdierz¹, P. Nowacki², G. Zhou¹; ¹Azenta, South Plainfield, NJ, ²Azenta, Quebec, QC, Canada

Abstract Body:

The Omics Era has greatly expanded the repertoire of approaches available for researchers and clinicians to unravel the complexity underpinning human health. Molecular biology approaches were disrupted with the advent of Next Generation Sequencing (NGS) which can elucidate the genome, epigenome, and transcriptome. NGS has been coupled with advanced DNA barcoding and microfluidics to enable multiomic characterization of single cells. More recently, highly multiplexed DNA barcoded protein/aptamer panels have been combined with NGS platforms to detail the proteome. Peripheral blood mononuclear cells (PBMCs) offer a window into the immune system that, when combined with omics tools, can provide a near holistic view of immune processes across patient cohorts. Here, we detail a proof-of-principle workflow which utilizes a single blood draw to rapidly produce a diverse set of datatypes interrogating the genome, epigenome, transcriptome, and proteome. To do so, blood draws using heparin tubes were collected and processed within 24 hours of draw to ensure high viability and yield of PBMCs. Plasma was collected and frozen during the processing of blood for PBMCs isolation and ultimately processed using Olink's kit for exploration of the proteome. PBMCs were aliquoted and cryopreserved with different vials processed for whole exome sequencing, 10X single cell sequencing, and epigenetic characterization. All of these datatypes can be produced within days of PBMC collection and in different combinations, as needed, to address the biological question at hand. With increased accessibility of omics approaches, integrative workflows such as the one described here will gain broader adoption and drive greater insights and innovation in human health applications.

PB2874. A framework for evaluation of new or modified sequencing technologies for use in human genomics

Authors:

M. Gatz, C. Kachulis, M. Fleharty, M. Cipicchio, S. Low, B. Blumenstiel, K. Larkin, S. Gabriel, N. Lennon; Broad Inst. of MIT and Harvard, Cambridge, MA

Abstract Body:

The rapid pace of development and innovation in sequencing technologies accelerates the genomics community's ability to understand the genetic underpinnings of disease, develop and deploy new screening and diagnostic assays, and advance the creation of new therapeutic modalities. When a new sequencing technology is released, or an existing technology is significantly changed (new instrument, new chemistry) there is a need to quickly understand the performance and limitations of the new platform so that decisions can be made about what applications may be most appropriate. The NIST Genome in a Bottle curated truth reference samples HG001 and HG002 are a critical resource for the community as they represent a standard against which we can compare all new technologies in an unbiased manner. This is particularly applicable to understanding the performance of the platforms for human genomics but also highlights performance characteristics that can be used to predict strengths and weaknesses as it relates to microbial, somatic, and other applications. We have created a framework for assessment of new technologies (or changes to existing technologies) that gives a first pass insight into the performance of the technology across variant types and genomic contexts. Genomic contexts used are those defined by the GA4GH group and include tandem repeats and homopolymers, segmental duplications, low mappability regions and a range of GC content regions. We have also included the 273 genes included in the 'challenging medically-relevant genes' set that has been curated by NIST in HG002. We have applied that framework to a variety of currently available (or soon to be available) technologies including Illumina (NovaSeq), Ultima Genomics (UG100), Element Biosciences (Aviti), Singular Genomics (G4), PacBio (Sequel IIe) and Oxford Nanopore (PromethION). We share here the results of those evaluations as well as the code and contexts required for researchers to apply this framework in their own hands. Additional sequencing metrics-based evaluations and alternative reference sample types for this analysis are also discussed.

PB2875. A High Throughput Dual Nucleic Acid Extraction Method Enables Whole Genome Sequencing from PAXGene Blood RNA Tubes

Authors:

C. Alba¹, X. Zhang¹, G. Sukumar¹, M. D. Wilkerson², C. L. Dalgard²; ¹Henry M. Jackson Fndn., Bethesda, MD, ²Uniformed Services Univ. of the Hlth.Sci., Bethesda, MD

Abstract Body:

Next-generation sequencing methodologies for genomes and transcriptomes are powerful approaches for population genetic studies. However, it is often challenging to obtain the quantity of starting material required from retrospective sample collections, particularly when the desired outcome is PCR-free library preparation for whole genome sequencing (WGS). PAXgene Blood RNA Tubes contain an additive that stabilizes transcript abundance in blood, making them ideal for long term storage of whole blood specimens intended for isolation of total RNA. While it provides high quality and yield of total RNA, no standard vendor-provided procedure for isolating genomic DNA (gDNA) from this blood tube exists. Standard gDNA extraction methods reported by other studies resulted in a low recovery rate from PAXgene Blood RNA Tubes in part due to this additive. Validating a workflow for isolation of gDNA suitable for PCR-free WGS from non-standard blood tubes would expand the specimens usable in population genomic studies. Here, we present a high-throughput dual nucleic acid extraction method from a single PAXgene Blood RNA tube. When processed on the Qiagen QIASymphony instrument, this method results in a batch of 24 sequencing-grade gDNA and total RNA pairs, from single PAXgene Blood RNA tubes, within hours, in a cost efficient manner. DNA concentrations measured by a fluorescence-based assay resulted in dual method yields which, while lower per mL of blood input, all passed the threshold for PCR-free DNA library preparation by ligation. Sequencing library yield and size distribution were comparable to sources from EDTA blood tube, with an average library size of 575bp and library concentration of 7.3 nM. Libraries were sequenced on an Illumina HiSeq X in single library, single lane topography. All parameters for sequencing quality metrics (clusters passing filter, q30, percent alignment, error rate) were above technical thresholds. More importantly, alignment and variant calling resulted in high concordance rate (>99.9%) between whole genome data from PAXGene Blood RNA tube and EDTA blood tube-derived DNA sources. Variant-level analysis for discordant variant calls did not result in a statistically significant enrichment for a specific base-substitution at specific genomic sites. Further, the data indicated that isolated gDNAs from PAXgene Blood RNA tubes were of sufficiently high molecular weight (>60kb) to potentially provide input for long read sequencing approaches. These results suggest that cohort-scale retrospective genomic studies may be enabled by PAXGene Blood RNA tubes when canonical blood tube sources are not available.

Omics Technologies Posters - Wednesday

PB2876. A Hybrid Machine Learning and Regression Method for Cell Type Deconvolution of Spatial Barcoding-based Transcriptomic Data

Authors:

X. Yan^{1,2}, N. Li^{2,3}, Y. Liu², A. Justet¹, T. Adams¹, A. Balayev¹, N. Kaminski¹, Z. Wang²; ¹Yale Univ. Sch. of Med., New Haven, CT, ²Yale Sch. of Publ. Hlth., New Haven, CT, ³Sch. of Life Sci. and Biotechnology, Shanghai Jiao Tong Univ., Shanghai, China

Abstract Body:

Spatial barcoding-based transcriptomic (ST) technologies unbiasedly measure mRNA expression of cells with physical locations in intact tissue. However, these technologies measure the average expression profile of a few unknown cells in each capture spot, lacking single-cell resolution and requiring cell type deconvolution to enable cellular level downstream analysis. In this study, we developed a novel hybrid method that considers platform effects, spatial information and sparsity in deconvolution of ST data using reference single cell RNA sequencing (scRNA-seq) data of the same tissue type. The hybrid method consists of two steps. In the first step, a conditional variational autoencoder (CVAE) is used to remove platform effects, i.e., the systematic differences between ST data and reference scRNA-seq data. In the second step, a graph Laplacian regularized regression model (GLRM) is fitted which assumes the ST data of each capture spot to follow a Poisson-loglinear model of expression profiles of cell types present in the spot. Spatial information is considered by graph Laplacian regularization to encourage cell type composition of neighboring spots to be similar. Sparsity is enforced using L1 regularization to shrink the number of unique cell types present per spot. To evaluate and compare the performance of our method and six existing methods, we simulated spot data by coarse-graining the image-based *in situ* spatial transcriptomic data with single-cell resolution, which aggregated expression profiles of cells located within a neighborhood of a center location. Method performance was evaluated by comparing the estimated cell type composition to the ground truth in the coarse-grained *in situ* spatial data. The results showed that our method was robust to the platform effects and achieved the most accurate estimation of cell type compositions regardless of whether platform effects are present or not. When platform effects were present, machine learning-based approaches achieved the second-best performance and regression model-based approaches had the worst performance. When there were no platform effects, regression model-based approaches had the second-best performance, and machine learning-based approaches had the least accurate results. Application to real ST data with histology staining images also demonstrated accurate results of our method. In summary, by considering platform effects, spatial information and sparsity using a combination of CVAE and GLRM model, our method achieved significantly more accurate and robust results than existing methods in ST data deconvolution.

Omics Technologies Posters - Thursday

PB2877*. A Machine Learning-based approach to extract the gene-disease association discovery information from OMIM

Authors:

K. Rahit, V. Avramovic, M. Tarailo-Graovac; Univ. of Calgary, Calgary, AB, Canada

Abstract Body:

For decades, researchers have been associating disease-causing variants in genes with specific Mendelian disease (MD) conditions. Online Mendelian Inheritance in Man (OMIM) has been tracking the Gene Disease Associations (GDAs) from the first reported association. This online catalogue is curated manually and updated regularly, and contains information on the number of unrelated individuals identified in the study reporting the GDA, as well as model organisms used to validate the GDAs. However, most of the information in OMIM is textual, and heterogeneous (e.g. summarized by different experts), which complicates automated reading and understanding of the data to extrapolate GDA trends. Here, we have used Machine Learning, Natural Language Processing (NLP) in particular, to make a tool that could semantically understand OMIM text and extract the data of interest. The Gene-Phenotype Association Discovery (GPAD) tool utilizes a language-based model to the text obtained from OMIM API to extract GDA discovery-related information.

Using GPAD, we have observed a recent decline in GDA discovery. Before the era of sequencing technologies, about ~150 new GDAs were described annually. The advent of exome sequencing increased that rate to ~250 per year. It was estimated that we would be able to uncover much of unknowns about rare diseases by 2020, and by 2027 we will be able to diagnose all and might provide therapy for many of the MDs. Still, the genetic origin of thousands of known MDs remains elusive, with many more discoveries anticipated. However, our analyses revealed that in the last three (2019-2021) years, the gene-disease discovery rate decreased significantly to ~120 GDAs per year. Together by also looking into the utilization trends of patient matchmaking and model organisms for GDA discovery over the years, we may be able to speculate about the reasons behind the declining GDA trends.

Given the real-time analyzing capacity of our tool, the GPAD offers an up-to-date OMIM-dependent view of GDA discovery. Therefore, researchers and clinicians could quickly look for their gene of interest and understand the trend that could potentially help in planning and managing the research strategy accordingly; allowing to approach the GDA discovery study more efficiently.

PB2878*. A massive proteogenomics screen identifies thousands of novel human coding sequences

Authors:

J. Xing¹, S. Sun¹, X. Cao^{1,2}; ¹Rutgers, the State Univ. of New Jersey, Piscataway, NJ, ²Zhujiang Hosp., Southern Med. Univ., Guangzhou, China

Abstract Body:

Accurate annotation of genes in the human genome is fundamental for biomedical research and genome interpretation. The Ensembl, RefSeq, and GENCODE consortiums continuously update the human genome annotations based on new computational and experimental evidence, and new genes were identified constantly. These new genes are from noncanonical open reading frames (ORFs) of known genes, genes that were previously treated as long non-coding RNAs, or from newly annotated genes. The Genotype-Tissue Expression (GTEx) project generated more than 15,000 RNA sequencing dataset from multiple-tissues of more than 800 donors, which allows to model almost all transcripts and proteins in the human genome. Using proteins translated from the GTEx transcript model, more than 21 million *in-silico* trypsin-digested peptides were generated. To identify high-confidence novel proteins with proteomics support, in this study we screened proteomic projects in the PRIDE database and selected more than 50,000 mass spectrometry (MS) runs from 923 projects. These MS data were used to validate the predicted novel peptides by GTEx. With a stringent standard, we identified almost 20,000 novel peptides and about 2,000 novel proteins that met the Human Proteome Project (HPP) Data Interpretation Guidelines. These peptides and proteins were from noncanonical ORFs, new isoforms of known genes, and un-annotated genes. Our method has shown a promising and remarkable potential in identifying novel proteins with high confidence using large public datasets. These findings will greatly improve our understanding of coding genes in the human genome and facilitate the interpretation of genomic data in biomedical research.

Omics Technologies Posters - Thursday

PB2879. A method for ABO genotyping by Sanger DNA sequencing

Authors:

E. Schreiber; Thermo Fisher Scientific, South San Francisco, CA

Abstract Body:

Same ABO blood group matching between donor and recipient decreases graft versus host disease risk in allogeneic solid organ transplantation. A recent publication (Zhou et al doi: 10.3389/fimmu.2020.608716) has documented a case of early graft dysfunction due to an ABO genotype mismatch that was not evident by conventional serotyping. Here we present a research method for genotyping the seven major ABO alleles A101, A201, B101, cis-AB01, O01, O02, O03 by Sanger-based DNA sequencing exons 6 and 7 of the human ABO gene. The method entails bi-directional sequencing of four PCR-generated amplicons and analyzing the resulting sequence trace files using Applied Biosystems SeqScape software. Deciphering the mixed sequencing traces from heterozygous alleles can often be challenging for genotyping complex loci like the ABO gene. The SeqScape analysis software generates a genotype report of the 15 alleles that determine the seven major blood types. The report is then imported into an Excel-based macro that transforms the genotype information to a searchable (query) code. Here the query is aligned and matched by a simple find operation in a look-up table to a list of codes representing the 28 different homo- and heterozygous genotype scenarios. This workflow enables the determination of common and rare ABO genotypes with possible weak phenotypes that may evade correct typing by serology. For Research Use Only. Not for use in diagnostic procedures.

Omics Technologies Posters - Wednesday

PB2880. A multi-omics approach to study monozygotic twins discordant for amyotrophic lateral sclerosis.

Authors:

M. Tosi¹, M. Zuccalà¹, F. Favero¹, L. Corrado¹, R. Croce¹, C. Basagni¹, N. Barizzone¹, L. Follia¹, A. Costa¹, F. De Marchi², E. Chinni³, L. Mazzini², D. Corà¹, M. Leone³, S. D'Alfonso¹; ¹Univ. of Eastern Piedmont, Novara, Italy, ²ALS Ctr. AOU Maggiore della Carità, Novara, Italy, ³SC Neurologia, Dipartimento di Scienze Mediche, IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy

Abstract Body:

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease, characterised by progressive death of upper and lower motor neurons, whose aetiology is still partially understood. The majority of ALS cases are sporadic (sALS), while 10% are familial (fALS). To investigate genetic and epigenetic factors underlying ALS, we studied a monozygotic twin pair discordant for ALS with a multi-omics approach, combining whole exome sequencing with genome-wide methylome- and transcriptome data from whole blood and PBMCs. For methylation, we used the Illumina EPICArray and ChaAMP software for the analyses, while for gene expression study Illumina TruSeq Stranded mRNA sequencing was performed. Results of the three omics were considered independently and in combination. We identified 59 differentially expressed genes (DEGs) ($p_{adj} < 0.1$; $|\log_2FC| > 1$) and confirmed the up or downregulation for 6 of them by digital droplet PCR (ddPCR). Functional analyses on DEGs performed by GSEA, IPA and G-Profiler revealed the involvement of adaptive and innate immune system pathways. After QC, we found 2 differentially methylated probes (DMPs) ($p_{adj} \leq 0.1$) in *CACNA1G* and *VAX1* genes; while filtering by delta beta ($\Delta\beta$) values, we identified 2 probes with $\Delta\beta \leq -0.25$ (in an intergenic region and *RUSCI-AS1*) and 2 probes with $\Delta\beta \geq 0.25$ (in *AARS* and *KPNA4*). None of them fell into the highlighted DEGs. These results were compared with different larger literature datasets that included sALS and fALS patients, non-symptomatic *FUS* and *C9ORF72* mutation carriers and healthy controls, without finding any correspondence at DMP and pathway levels. For exome analyses, ExomeDepth and ClassifyCNV identified 3 deletions and 1 duplication of uncertain significance in the ALS twin. Analyses of SNV, after filtering for frequency ($\leq 0,00005$) and QC (PASS), identified 25 variants classified as VUS (n=18) or likely benign (n=7). In conclusion, we integrated different omics performing functional analyses with several bioinformatic tools that underlined a possible role of the immune system in the disease. Further understanding of these immunological results and the validation of DMPs by methylation-specific droplet digital PCR (ddMSP) combined with methylation-dependent restriction enzymes are ongoing to elucidate possible somatic genetic factors that could underlie susceptibility to sporadic ALS.

Omics Technologies Posters - Thursday

PB2881. A new approach to assess the allele frequency of small insertions and deletions

Authors:

H. Milo Rasouly, S. Bheda, S. Krishna Murthy, A. Gharavi; Columbia Univ., New York, NY

Abstract Body:

Background: Genetic diagnostics and gene discovery efforts rely on accurate estimation of population allele frequency (AF) and identification of rare protein-truncating variants. However, estimation of AF for small insertion and deletions (indels) is often inaccurate due to differences in mapping and variant calling methods. We developed a “regional AF” method to more accurately estimate AF for indels. **Method:** To calculate a regional AF, we created a python script that bins indels within different base pair windows (10, 20, 30 and 40bp) and calculates the regional AF within a bin. Variants included (1) indels with identical genomic position but different insertion or deletion, (2) overlapping indels with different genomic positions, and (3) indels within fixed genomic windows. We next calculated a regional AF for indels with gnomAD AF < 10%, using unrelated individuals from the Columbia Institute for Genomic Medicine (IGM, N= 40,762) and the publicly available gnomAD v2.1.1 exome data set (N=125,748). Rare variants were defined as gnomAD global AF smaller than 10^{-4} . We calculated the statistical difference between the mean number of rare indels in individuals using the pairwise t-test. **Results:** The proportion of rare indels with a regional AF greater than 10^{-4} was 28% for the 10bp, 32% for the 20bp, 35% for the 30bp and 38% for the 40bp windows in the IGM cohort and 14% for the 10bp, 19% for the 20bp, 22% for the 30bp and 25% for the 40bp windows in the gnomAD cohort. Amongst constrained genes ($pLi > 0.5$) with rare indels with regional AF greater than 10^{-4} (10bp window), 1169/4667 (25%) and 860/3463 (25%) are associated with diseases in OMIM in the IGM and gnomAD cohort respectively. All 860 genes identified in the gnomAD cohort were also identified in the IGM cohort. When assessing the impact of the application of a regional AF $< 10^{-4}$ on the mean number of high impact rare indels (Ensembl definitions) in the IGM cohort, the regional AF significantly reduced it from 6.61 per individual to 5.67 for the 10bp window (p -value= 2.77×10^{-08}), 5.26 for the 20bp (p -value= 2.81×10^{-17}), 4.9 for the 30bp (p -value= 2.44×10^{-28}) and 4.56 for the 40bp (p -value= 9.78×10^{-42}). **Conclusion:** Our binning method identified rare indels in regions with a high frequency of indels, enabling better estimation of AF. The differences between the results in the IGM and the gnomAD cohorts may reflect variability in mapping and variant calling. Application of indels regional AF may eliminate false positive signals and facilitate detection of novel gene- disease associations.

Omics Technologies Posters - Wednesday

PB2882*. A new framework for efficient Perturb-seq enables cheap large-scale dissection of the innate immune response and provides insight into regulatory eQTL relationships.

Authors:

D. Yao¹, L. Binan², J. Bezney², B. Simonton², C. Frangieh³, A. Regev⁴, A. Gusev⁵, B. Cleary²; ¹Harvard Univ., Cambridge, MA, ²Broad Inst., Cambridge, MA, ³MIT, Cambridge, MA, ⁴Genentech, South San Francisco, CA, ⁵Dana Farber Cancer Inst., Boston, MA

Abstract Body:

Perturb-seq is a technology that combines droplet-based single-cell RNA sequencing with pooled CRISPR screening, enabling one to study the effects of many CRISPR perturbations on the entire transcriptome simultaneously. Although the technology has been very useful in probing transcriptional regulation in diverse model systems, it remains prohibitively expensive. Moreover, large-scale eQTL studies are a population-based alternative to Perturb-seq for understanding trans-regulatory networks and human disease, but the connection between Perturb-seq and eQTL studies remains mostly unexplored. Here, we developed a new experimental and analytic framework that substantially reduces the cost of Perturb-seq experiments. First, we generate special “composite measurements” (representing random combinations of perturbations) that require only small changes to the conventional Perturb-seq protocol. We accomplish this in two ways: by encapsulating multiple cells in each droplet prior to sequencing, or by knocking out multiple random genes at a time in each cell. Next, we use a novel inference procedure to infer the effect sizes of individual perturbations from these composite measurements. We used our approach to conduct a Perturb-seq screen of 600 genes in a human macrophage cell line stimulated with LPS, which to our knowledge represents the largest Perturb-seq screen conducted in immune cells. For validation, we conducted the same screen using the conventional Perturb-seq approach. By comparing the two experiments, we show that **our efficient Perturb-seq screen produces accurate perturbation effect sizes at only 10-25% the cost of conventional Perturb-seq**. Using the causal effect estimates from our screens, we gained several new insights into the innate immune response, including a novel complex comprising two genes without prior immune annotations, XPR1 and KIDINS220, that act as negative regulators of inflammatory signaling. We also investigated whether cis-by-trans causal links learned from Perturb-seq are concordant with cis-by-trans eQTLs in a population-scale study of the same cell type and treatment as our experiment (Fairfax et al. 2014 Science). Surprisingly, we found that **cis-by-trans gene pairs implicated from Perturb-seq contain a slightly smaller proportion of significant cis-by-trans eQTLs than random gene pairs (1.5% vs. 1.7%)**, suggesting that trans-regulatory relationships learned from Perturb-seq are not reflected in eQTL datasets. Our results demonstrate that large disparities still exist between experimental assays and population-level genetic data, and further work is needed to reconcile these differences.

Omics Technologies Posters - Thursday

PB2883*. A new method for detecting genes differentiated in expression variance using single-cell RNA sequencing data

Authors:

M. Chen, A. Dahl; Univ. of Chicago, Chicago, IL

Abstract Body:

The development of single-cell RNA-sequencing (scRNA-seq) technology offers opportunities to characterize cellular heterogeneity at an unprecedented resolution and scale. This technology has been widely used to identify differentially expressed genes (DEG) that change in expression mean between cell types, such as cells before and after drug treatment. However, there could be functionally important genes that change in expression variance across cell types while remaining relatively stable in mean. Furthermore, expression variance may inform underappreciated form of cellular heterogeneity. We propose mixed models for cell type-specific gene expression (GxCTMM) to characterize variation in gene expression between cell types. We model both overall pseudobulk expression and cell type-specific pseudobulk expression. In simulations, we showed that GxCTMM is powerful and well-calibrated even for modest sample sizes (e.g., dozens of individuals). We also showed cell type-specific pseudobulk analyses add dramatic power compared to pseudobulk (up to 10 fold), illustrating the utility of scRNA-seq data. We applied GxCTMM to scRNA-seq from differentiating human iPSCs; by defining cell differentiation stages as cell types, we found many well-known genes for pluripotency and differentiation had differential variance expression; for example, the strongest differential variance signal was for POU5F1, one of three core transcription factors regulating pluripotency genes. Furthermore, GxCTMM identified 83 genes with differential variance across cell types that did not have differential mean. Finally, we extend GxCTMM to model cell type-specific *heritability* of gene expression, and present preliminary results uncovering cell type-specific genetic regulation in lupus. Overall, GxCTMM is a powerful tool to identify genes differentiated in expression variance between cell types from scRNA-seq data.

Omics Technologies Posters - Wednesday

PB2884. A novel auto-normalizing pooled library construction method that streamlines sample preparation prior to targeted hybrid capture.

Authors:

M. Costello, C. Leong, D. Bays, M. Rahardja, J. Smith, G. Rush, J. Mellor; seqWell, Inc., Beverly, MA

Abstract Body:

Hybrid capture is a well-established method for targeted sequencing, enabling cost effective analysis of larger and more complex regions than amplicon-based approaches. Most hybrid capture methods require pooling of libraries prior to capture to improve robustness and streamline downstream hybridization and capture workflows. However, there is a high cost and labor burden in individually preparing, sizing, quantifying, normalizing, and evenly pooling libraries prior to capture.

Here, we describe an approach for hybrid capture targeted sequencing based on a novel library preparation chemistry that permits pooling of samples immediately following transposase (tn5) mediated tagging, using the seqWell purePlex library preparation technology. In the purePlex process, genomic DNA is fragmented and full-length adapters containing i7 and i5 unique dual indexes (10 bp) are added in a single step. This tagging chemistry has been optimized to enable auto-normalization of libraries and consistent insert sizes across a 4-fold DNA input range between 50-200 ng, enabling equal volume pooling of samples immediately after tagging and before any downstream steps into flexible batch sizes from 8 to 96 based on target design size and desired coverage. In the example of 24-plex pooling, this reduces the number of PCR amplifications, bead based clean ups, and library QCs required for a full plate of samples from 96 at each step to just 4, enabling significant savings in time, labor, reagents, and tips. We demonstrate the suitability of this library construction method on a range of hybrid capture bait designs including human exome and compare the ease of workflow and performance to other commonly used library protocols. We anticipate that the method will have wide applicability to targeted NGS workflows that have significant multiplexing requirements, and that also require the sensitivity and performance benefits of unique dual indexing.

Omics Technologies Posters - Thursday

PB2885. A novel Bayesian factor analysis method improves detection of genes and biological processes affected by perturbations in single-cell CRISPR screening.

Authors:

Y. Zhou, K. Luo, M. Chen, X. He; Univ. of Chicago, Chicago, IL

Abstract Body:

Recent years have seen major efforts in understanding how perturbations in the genome affect gene expression phenotypes. High-throughput methods such as CROP-seq and Perturb-seq that combine multiplexed CRISPR screening with single-cell RNA readout have made it possible to assess the impact of gene knock-outs/downs on the transcriptome at a single-cell level. However, due to the sparsity and complex structure of data, analysis of single-cell CRISPR screening data remains challenging. In particular, standard differential expression analysis methods are often under-powered to detect genes affected by CRISPR perturbations.

Our proposed approach is motivated by the observation that genetic perturbations typically affect expression, not one gene at a time, but many related genes simultaneously. Indeed, transcriptomes often vary across cell types, conditions, and individuals in a modular fashion, reflecting the underlying coordinated regulation of genes in the same or related pathways. These gene modules can be inferred by matrix factorization and related techniques. We propose to infer gene modules from single-cell RNA-seq data, and borrow information across genes to improve the power of detecting differentially expressed genes. Existing factor analysis methods, however, are not readily applied to single-cell CRISPR screening data, as the factors are not directly linked with genetic perturbation, and the effects of perturbation on the expression of individual genes are not assessed.

Here we present Guided Sparse Factor Analysis (GSFA), a novel computational framework for analyzing single-cell CRISPR screening data. GSFA infers latent factors that represent co-regulated genes or gene modules, and by borrowing information from these factors, infers the effects of genetic perturbations on individual genes. We demonstrated through extensive simulation studies that GSFA detects perturbation effects with much higher power than state-of-the-art methods. Using single-cell CRISPR data from human CD8⁺ T cells and neural progenitor cells, we showed that GSFA identified biologically relevant gene modules and specific genes affected by CRISPR perturbations, many of which were missed by existing methods, providing new insights into the functions of genes involved in T cell activation and neurodevelopment.

Omics Technologies Posters - Wednesday

PB2886. A novel enzymatic fragmentation library preparation workflow that prevents sequencing artifacts for production-scale DNA-seq

Authors:

J. Haimes¹, Z. Jaafar¹, T. Harrison¹, L. Peterkin¹, M. Ranik¹, K. Scott², K. Giorda¹, B. Kudlow¹; ¹Watchmaker Genomics, Boulder, CO, ²Colorado State Univ., Dept. of Cell & Molecular Biology, Fort Collins, CO

Abstract Body:

NGS is at a turning point as the cost of sequencing has plummeted while capacity has grown rapidly. In light of these advances, library preparation methods need to be revamped for scalability without compromising quality for clinical and translational research. The clinical utility of whole genome sequencing has been well established and has tremendous potential to improve disease diagnosis and treatment.

Historically, acoustic sonication has been the preferred method for DNA fragmentation as it produces evenly sized fragments and uniform GC sequencing coverage. Yet Covaris shearing is associated with a high upfront investment, expensive consumables, and is a time consuming bottleneck in sample preparation. Here, we utilized sophisticated enzyme engineering and a multidimensional Design of Experiment approach to develop a novel library preparation method that harnesses the process benefits of enzymatic fragmentation while delivering data quality on-par with sonication.

To evaluate the performance of this approach, PCR-free whole genome sequencing (WGS) was performed using the GIAB pilot genome (NA12878) as a direct measurement of library preparation efficiency, sensitivity, and accuracy. Libraries generated using our optimized workflow exhibited a 4 to 10-fold reduction in chimeric reads and terminal hairpin artifacts compared to other enzymatic methods, and reached comparable levels to mechanically sheared DNA controls. All enzymatic fragmentation methods produced low GC-bias libraries and sufficient depth for genotyping analysis. Higher coverage combined with lower sequencing artifacts produced the highest variant calling sensitivity and specificity of the enzymatic library preparation methods, as determined using the genome in a bottle high confidence regions as ground truth. In addition to the data quality benefits, we provide workflow modifications which allow precise insert size tuning and enable rapid protocol customization for existing and emerging short read platforms.

Altogether, this enzymatic fragmentation and library preparation workflow avoids library preparation artifacts that convolute variant calling, is highly scalable, and suitable for production-scale WGS studies.

Omics Technologies Posters - Thursday

PB2887. A platform for high-resolution morphology analysis reveals tumor heterogeneity and enables label-free enrichment of target cell subpopulations

Authors:

A. Jovic¹, V. Lu², C. Johnson¹; ¹DeepCell Bio, Menlo Park, CA, ²Deepcell, Inc, 4025 Bohannon Dr., CA

Abstract Body:

Methods to study cancer at single cell resolution and capture tumor heterogeneity are crucial for better understanding and treatment of cancer. However, current isolation of tumor cells from tissue typically relies on targeting biomarkers, such as EpCAM, resulting in the isolation of tumor cell population subsets used for further molecular and functional analysis. The Deepcell platform performs high-dimensional morphology analysis of single cells using deep learning on high resolution bright-field images captured in microfluidic flow to phenotype and enrich target cells that are label-free in real-time.

We applied the Deepcell platform to train a deep convolutional neural network classifier to identify and enrich for malignant cells from non-small cell lung cancer (NSCLC) dissociated tumor cell (DTC) samples. The enriched NSCLC cells are label-free, unperturbed, and viable, making them amenable to diverse molecular and functional analyses. Importantly, the cell images can be used to generate high-dimensional morphological profiles that can be visualized by Uniform Manifold Approximation and Projection (UMAP) to uncover morphologically heterogeneous cell populations that can also be sorted for and further molecular work performed that can also be sorted out for further molecular work.

We verified enrichment of malignant cells by performing RNA and DNA analysis on the enriched sample. scRNA-Seq analysis showed populations of cells with high levels of EpCAM expression in sorted cells. CNV analysis demonstrated increased amplitude of deletion and amplification peaks relative to the pre-sorted DTC sample. Further, mutational analysis shows increased allele frequency of mutations including P53 and KRAS in sorted compared to pre-sorted samples. Multiple clusters of morphologically unique tumor cell populations were detected by UMAP analysis. We further trained the classifier to detect and enrich for each of these subpopulations; CNV, mutation, bulk RNA-Seq, and scRNA-Seq analysis revealed molecular differences between the morphologically unique subgroups. Additionally, scRNA-Seq identified EpCAM positive and negative populations underscoring the ability of the classifier to identify carcinoma cells in a label-free manner.

Here, we demonstrate the use of the Deepcell platform to perform high-dimensional morphological profiling of NSCLC tumor cells from DTC, revealing a new dimension for identifying and understanding heterogeneous tumor cell populations. Further work is planned to evaluate the link between the morphological, molecular, and functional characteristics of each subpopulation.

Omics Technologies Posters - Wednesday

PB2888. A rigorous benchmarking of methods for SARS-CoV-2 lineage detection in wastewater

Authors:

S. Knyazev^{1,2}, T. Tao², K. Wang³, B. Tyshchenko⁴, W. Ouyang⁵, A. Frolova⁴, P. Baykal^{6,7}, B. Pasaniuc¹, N. Beerenwinkel^{6,7}, N. Wu⁵, A. Zelikovsky⁸, A. Smith⁹, S. Mangul²; ¹Geffen Sch. of Med. at UCLA, Los Angeles, CA, ²Univ. of Southern California, Sch. of Pharmacy, Los Angeles, CA, ³Univ. of Southern California, Keck Sch. of Med., Los Angeles, CA, ⁴Ukraine Kyiv Academic Univ., Inst. of Molecular Biology and Genetics, Kyiv, Ukraine, ⁵Univ. of Illinois at Urbana-Champaign, Urbana, IL, ⁶ETH Zurich, Dept. of Biosystems Sci. and Engineering, Basel, Switzerland, ⁷SIB Swiss Inst. of Bioinformatics, Basel, Switzerland, ⁸Georgia State Univ., Atlanta, GA, ⁹Univ. of Southern California, Astani Dept. of Civil and Environmental Engineering, Los Angeles, CA

Abstract Body:

The COVID-19 pandemic showed that an efficient real-time response to pandemics is required to minimize the economic, social, and public health burdens resulting from pandemics. As the SARS-CoV-2 virus continues to spread, evolve, and mutate, the need for a cost-effective and efficient way to detect the presence of lineages is beyond urgent. Using wastewater-based surveillance for COVID-19 showed its efficacy in numerous countries around the globe for monitoring viral prevalence in the population. Wastewater-based surveillance has numerous advantages including that it does not require interaction with patients and can simultaneously monitor entire communities including underserved and vulnerable populations as well as asymptomatic cases. The vast majority of current SARS-CoV-2 wastewater monitoring facilities are qPCR-based and can only quantify viral load without differentiating viral strains, which prevents monitoring strain prevalence and detecting novel strains. To quantify the novel and existing strains, the sequencing of wastewater samples coupled with advanced computational tools can promise to elucidate the relative abundances of known and novel strains. Some studies show that this approach allowed monitoring not only for the number of cases but also to quantify the prevalence of viral variants including detecting strains that were absent from clinical databases-suggesting that clinical databases may be delayed. However, scalable and effective methods are yet to be developed because wastewater genomic surveillance poses technical challenges including viral genome degradation in wastewater facilities resulting in poor sequencing quality and incomplete genome coverages. We propose benchmarking existing methods for lineage detection in wastewater samples containing SARS-CoV-2. We will get state-of-the-art methods and apply them to our in-house benchmarks. The in-silico benchmarks are based on real wastewater samples and mimicking its lineage composition, genome degradation, and genomic bias identical to real samples. The genome-engineered in-vitro gold benchmarks provide positive and negative control for testing the tools. A total of 26 methods are going to be benchmarked in order to give a reference for wastewater genome-based monitoring.

Omics Technologies Posters - Wednesday

PB2890. A software platform for real-time and automated simultaneous analysis and detection of genetic diseases

Authors:

M. Garrido Navas¹, C. Kyriakidis², G. Madjarov³, D. Galevski³, A. Schack⁴, L. Krych⁴, A. Nikov⁵, Z. Velkoski⁶; ¹GENYO Ctr. for Genomics and Oncological Res.: Pfizer, Univ. of Granada, Andalusian Regional Government. Liquid Biopsy and Cancer Interception Group, Granada, Spain, ²gMendel ApS, Copenhagen, Denmark, ³Univ. Ss Cyril & Methodius, Skopje, Macedonia, The Former Yugoslav Republic of, ⁴Univ. of Copenhagen, Copenhagen, Denmark, ⁵Netcetera, Zurich, Switzerland, ⁶gMendel ApS, Copenhagen, Denmark

Abstract Body:

Eight out of ten rare diseases have a genetic cause. Often, they are chronic and life-threatening, and it takes seven years on average to receive an accurate diagnosis. Because of that, we developed Phivea[®], a software platform for real-time and automated simultaneous analysis and detection of genetic diseases using Oxford Nanopore Technologies (ONT). It enables extensive numerical and visualization analysis and accurate, systematic and timely diagnosis significantly improving disease management. The Phivea[®] platform analyzes the .fastq files generated by GridION x5 (ONT) and accesses them using a shared file system. The analysis process includes four phases:

1. Quality check (read length 900-1200bp with average Phred quality score above
2. Demultiplexing (this is done using Tochlex, a method for real-time demultiplexing ONT reads)
3. Chromosome classification (BLAST algorithm is used to compare the sequence with a library and find the sequence characteristic specific for a particular chromosome)
4. Genetic disease classification and analysis report generation (Phivea[®] performs discriminant analysis of the patients' samples compared to controls and calculates the probability of presence of genetic disorder)

The Phivea[®] platform can be applied directly on the stream of base-called DNA reads generated by the ONT device. It exceeds the limits of the real-time monitoring and analysis per DNA sample, which can significantly reduce the overall costs. The calculated throughput of the analysis pipeline is 4120 reads/s measured on a referent hardware architecture using thread parallelism of 10. Also, the current version of the Phivea[®] platform managed to correctly identify 6 different genetic disorders (Klinefelter, Turner, Down, Edwards, Patau and Prader-Willi/Angelman syndromes) with sensitivity and specificity higher than 90% on a patient level. Our technology was tested and validated on a mix of real and synthetically prepared samples, but the obtained results can be directly extrapolated for analysis and detection of other genetic disorders.

Omics Technologies Posters - Thursday

PB2891*. A spatial map of neurodevelopmental disorder risk in the developing human cortex

Authors:

F. Segato Dezem¹, S. Chen², B. Davis¹, I. Glass³, K. Aldinger⁴, J. Plummer¹; ¹Cedars Sinai Med. Ctr., Los Angeles, CA, ²Cedars-Sinai Med. Ctr., Los Angeles, CA, ³Univ of Washington, Seattle, WA, ⁴Seattle Children's Res. Inst., Seattle, WA

Abstract Body:

The diagnosis, prognosis, and treatment stratification for most neurodevelopmental disorders (NDD) remain uncertain in large part due to their high clinical and genetic heterogeneity. The genes associated with NDD are expressed during early human brain development. To understand these genes' role in pathogenicity, we sought to examine the relationship between NDD genes and their spatial expression in the context of the developing human cortex, an affected structure in NDD. Using single-cell RNAseq paired with spatial transcriptomics, we generated a high-resolution atlas of the developing human prefrontal cortex, neocortex, thalamus, and striatum (130 days old). This multi-omic approach resolved geographical, subcortical localization within developing brain architectures which are not seen by scRNAseq, or spatial RNAseq alone. After defining cell identities from the scRNAseq/spatial atlas, an integrative analysis of known NDD genes with our refined spatial map was conducted for spatial resolution of cell type with pathogenesis. To do so, we employed an empirical binary classifier (ROCit) on 345 syndromic NDD and autism genes, (curated from SFARI high confidence gene list) against gene expression profiles from the four cortical regions. From this analysis, we identified 2 clusters enriched for Glutamatergic Neuron subpopulation (GluN7) highly associated with NDD genes in the pre-frontal cortex (AUC > 0.75). The genes within this cluster most highly enriched included MEF2C, FOXP1, DPYSL2 and MEIS2. In comparison, NDD genes most enriched in the thalamus included the NDD genes: AUTS2, TCF7L2, PTMS, PPP2R1A and ACTB. Partitioning cell type identities revealed that these enriched NDD genes were most highly represented in the GluN3 and MGE Interneuron cell type. Understanding spatial gene expression during brain development and in the context of NDD risk genes provides a framework for understanding which genetic perturbations during neurodevelopment can lead to disease.

Omics Technologies Posters - Wednesday

PB2892. A submodular fairness metric for sequence-to-function models in precision genomics

Authors:

E. Robson, N. M. Ioannidis; Univ. of California, Berkeley, Berkeley, CA

Abstract Body:

Deep learning promises to revolutionize precision genomics, but the creation of clinically relevant sequence-to-function models faces significant challenges in ensuring model accuracy and model fairness, especially when participation in training datasets is largely confined to individuals from particular ancestry groups. To ensure equitable access to precision genomic technology, new tools are necessary to both measure and overcome such algorithmic bias in genomics. Here we present a label-free fairness metric to estimate a priori the portion of algorithmic bias in sequence-to-function models due to generalizability error across individuals. Its intended use case is sequence-to-function datasets in genomic machine learning, and unlike SNP counts against a reference genome, our fairness metric has no need for a pre-specified reference sequence. We provide a comparative risk analysis for individual genotypes and 26 populations in the 1000 Genomes Phase 3 dataset before extending our analysis to a supervised setting on the Geuvadis gene expression subset of 1000 Genomes. We demonstrate the utility of our proposed fairness metric in both evaluating the representativeness of a human genome sequence database and in estimating sequence-to-function model biases, and we outline key risks and preprocessing considerations for fairer genomic AI models.

Omics Technologies Posters - Thursday

PB2893. A systems biology framework to evaluate the contribution of cellular crosstalk in Alzheimer's disease genetic risk and other psychiatric traits

Authors:

R. D'Oliveira Albanus¹, L. Brase¹, S. You¹, C. Soriano-Tarraga¹, C. Cruchaga¹, B. Benitez^{2,3}, C. Karch¹, O. Harari¹; ¹Washington Univ. Sch. of Med., Saint Louis, MO, ²Beth Israel Deaconess Med. Ctr., Boston, MA, ³Harvard Med. Sch., Boston, MA

Abstract Body:

Cellular crosstalk plays an important role in brain physiology, mediating detrimental and protective processes in neurodegeneration. How crosstalk ligand/receptor proteins modulate genes associated with disease genetic risk has not been systematically characterized.

We developed a systems biology framework to characterize cellular crosstalk networks and apply it to estimate the role of crosstalk in the genetic risk of Alzheimer's disease (AD) and other psychiatric traits. We analyzed single-nucleus transcriptomic profiles of ~294K high-quality nuclei from parietal cortex of 67 donors from the Knight ADRC and DIAN brain banks, including neuropathological-free controls and AD cases. We estimated crosstalk patterns among the brain cell types based on the expression of known ligand-receptor pairs (CellPhoneDB). Crosstalk interactions involving genes implicated in AD genetic risk as receptor or ligand were enriched in microglia (OR=2.35, p=1.22e-5). Using control donors, we calculated the enrichment of crosstalk genes in other psychiatric diseases. We observed nominal enrichment of GWAS-nominated risk genes in crosstalk interactions involving oligodendrocyte precursors (schizophrenia; OR=2.6, p=1.91e-7), neurons (depression; OR=1.72, p=0.0036), and astrocytes (Parkinson's; OR=2.23, p=0.03). Focusing on AD, we determined the preferential crosstalk partners for microglia. AD crosstalk interactions were enriched between neurons and microglia (OR=2.74, p=4.41e-15), and most (64.9%) codified for microglial cell membrane receptors. These interactions included semaphorin and the PlexinA1 complex, which is mediated by the AD risk gene TREM2. We identified genes and pathways involved in the crosstalk between the emitter and receptor cells by adding functionality to CytoTalk, which infers co-expression networks using information and graph theories. The microglia network was enriched for known AD genes (OR=3.66, p=5.96e-15) and included subnetworks positively and negatively associated with Braak stage. We predict that the PlexinA1-semaphorin interaction directly modulates a sub-network associated with microglia activation and protective against AD (association with Braak stage GLM β =-0.25, p=4.6e-38), involving TREM2, APOE, and HLA genes previously implicated in AD. We replicated these results in public snRNA-seq data and are planning experimental validations.

We present a generalizable framework to investigate crosstalk in disease genetic risk quantitatively. We identify neuron-microglia interactions as an important component of AD pathology and predict that this crosstalk modulates genes associated with AD genetic risk.

Omics Technologies Posters - Wednesday

PB2894. A two-channel deep learning framework for accurate prediction of the change in protein folding free energy upon mutations

Authors:

Q. Liu¹, M. Schiller¹, Z. Zhao²; ¹Univ. of Nevada Las Vegas, Las Vegas, NV, ²Univ Texas HSC Houston, Houston, TX

Abstract Body:

Background: A stable folding is critical for a protein to perform its biological functions, and protein folding is frequently affected by various mutations. This mutational effect can be measured via the change of protein folding free energy ($\Delta\Delta G$). Thus, accurate prediction of this mutational effect on protein folding directly measures biological activities of proteins. So far, both structure-based and sequence-based methods have been proposed to predict $\Delta\Delta G$ upon mutations via machine learning techniques. However, both approaches have limitations on handcrafted features of proteins and small size of training data when applying deep learning algorithms. Pre-training of deep learning-based methods have great potential to increase the power in accurate prediction of $\Delta\Delta G$. **Methods:** We develop a two-channel learning framework (DL2ddG) for the estimation of $\Delta\Delta G$ with deep learning-based sequence representation. Sequence presentation of deep learning pretrained on Uniref90 protein sequences generates a novel feature for each position of protein sequence, and also makes it feasible to accurately predict mutation effect on limited training data with $\Delta\Delta G$. To further characterize mutation effect, we design a two-channel learning to predict $\Delta\Delta G$: one channel is for wild-type sequence representation and the other for mutant sequence representation. The difference of the two channel is learned for $\Delta\Delta G$ prediction via a neural network framework. DL2ddG can estimate $\Delta\Delta G$ for both single-point and multiple-simultaneous mutations. **Results:** We train DL2ddG on ProTherm data and evaluate it with both cross-validation and cross-dataset testing strategies on the sequence datasets of Ssym, p53, myoglobin and frataxin mutants. In our comparison with a number of sequence-based prediction methods, we demonstrate that our framework DL2ddG mostly outperforms existing methods with ~ 0.7 Pearson correlation coefficient between experimental $\Delta\Delta G$ and predicted $\Delta\Delta G$. **Conclusion:** We propose an accurate method to predict folding free energy change upon mutations. It does not need human-designed features of protein sequences and performs well on limited training data with deep learning frameworks. Our method will help for deeper understanding of protein functions affected by mutations and variant interpretation of mutant proteins, leading to potential disease marker discovery and therapeutical targets of drug development.

Omics Technologies Posters - Thursday

PB2895. A unified computing environment for genomics data storage, management, and analysis: NHGRI Genomic Data Science Analysis, Visualization, and Informatics Lab-Space (AnVIL)

Authors:

S. Mosher¹, M. C. Schatz¹, A. A. Philippakis², A. The AnVIL Team³; ¹Johns Hopkins Univ., Baltimore, MD, ²Broad Inst., Boston, MA, ³The full list of contributors is available at: <https://anvilproject.org/about/team>, NA, MD

Abstract Body:

Recent years have seen astronomical growth in human genomics. Together with single-cell and functional genomics, electronic medical records and other biomedical data, the field is well-positioned to make great advances in human health. However, the complexity of genomic data sharing, where data is downloaded from centralized datastores for local analysis, is unsustainable and cost prohibitive. Furthermore, housing genomic data across redundant institutional compute infrastructures makes assuring data security and compliant usage of protected data a massive challenge.

The NHGRI Genomic Data Science Analysis, Visualization, and Informatics Lab-Space, or AnVIL (<https://anvilproject.org/>) was developed to address these and other concerns by providing a unified cloud-based computing environment for genomics data storage, management and analysis. The AnVIL platform inverts the genomics data sharing model by eliminating the need for data movement, which in turn allows for active threat detection and monitoring and provides scalable, shared computing resources for researchers as needed. AnVIL currently provides harmonized access to more than 300,000 genomes from several key NHGRI projects, such as as the CCDG (Centers for Common Disease Genomics), CMG (Centers for Mendelian Genomics), eMERGE (Electronic Medical Records and Genomics), and GTEx (Genotype-Tissue Expression Project), with many more on the near horizon.

The platform is built on a set of established components that have been used in a number of flagship scientific projects. The Terra platform provides a compute environment with secure data and analysis sharing capabilities. Dockstore provides standards based sharing of containerized tools and workflows. Jupyter, R/Bioconductor and Galaxy provide analysis environments for users at all skill levels to interactively explore and understand data with thousands of tools available. The Gen3 data commons framework provides data and metadata ingest, querying, and organization. Together, AnVIL provides a collaborative environment for creating, analyzing, and sharing data and analysis workflows for even the largest projects.

Long-term, the AnVIL will provide a unified platform for ingestion and organization for a multitude of current and future genomic and genome-related datasets. Importantly, it will ease the process of acquiring access to protected datasets for investigators and drastically reduce the burden of performing large- scale integrated analyses across many datasets to fully realize the potential of ongoing data production efforts.

Omics Technologies Posters - Wednesday

PB2896. A validated clinical whole genome sequencing system for the detection of germline variants.

Authors:

C. Glidewell-Kenney, V. Onuchic, M. Bekritsky, M. Mehan, F. Fiocco, N. Khan, J. Kleinert, K. Eluwa, R. Akula Suresh Babu, Y. Liu, D. Naidu, K. Magdirila, J. Su, S. Iyer, C. Ludman, A. Leelin, C. Abaya, L. Rivas Yepes, T. Nguyen, J. Vo, D. Andrews, K. Sabourov, J. Lee, V. Corey, N. Dukler, S. Kim, F. Long, A. Crawford, R. Taft; Illumina Inc, San Diego, CA

Abstract Body:

Clinical whole-genome sequencing (WGS) has been shown to increase diagnostic yield and decrease time to diagnosis over usual care in patients with undiagnosed genetic disease. Despite the positive potential impact on patients with a suspected genetic condition, and historical cost reductions, WGS adoption by laboratories has been slowed by the complexity of bioinformatic analysis and the burden of analytical validation.

To address these needs, Illumina has developed the TruSight Whole Genome system, a fully validated clinical WGS solution for the detection of germline variants, including single-nucleotide variants (SNVs), insertions and deletions (Indels), copy number variants (CNVs), runs of homozygosity (ROH), short tandem repeat (STR) expansions, and mitochondrial SNVs. The assay starts from genomic DNA extracted from peripheral whole blood and includes library preparation reagents, sequencing on NovaSeq 6000Dx system, and variant calling with DRAGEN 3.9 software. The output of TruSight Whole Genome system includes a sample QC report and high confidence variant calls. These outputs can be utilized in a number of downstream clinical applications such as genetic disease testing.

Development included in-depth characterization and optimization of library preparation, sequencing and bioinformatic analysis. Modeling of empirical data was used to set the reportable ranges for each reportable variant type and the stratification of variants into different genomic context categories (high, intermediate, and low confidence). Filtering by these reportable ranges and genomic context categories in the analysis pipeline improved variant calling accuracy (assessed with clinical reference samples, Genome in a Bottle (GIAB) and Platinum Genome truth sets) and reproducibility (assessed by the Jaccard Similarity Index with NA12878 replicates). A set quality control metrics (coverage, bias of coverage, base quality, and contamination) for the routine monitoring of sample data were selected and shown to be effective using a dataset of over 5000 genome sequencing libraries. Validation showed the assay to be robust, with a low incidence of sample failure, no interference from endogenous or exogenous substances, and accurate and reproducible across all variant types. Taken together, these data demonstrate that the TruSight Whole Genome system can produce high quality genomes with substantially reduced laboratory validation or operating overhead and may serve as a platform for molecular genetic testing across multiple clinical indications.

Omics Technologies Posters - Thursday

PB2897. Age-dependent accumulation of somatic mutation and cell fusion in human cardiomyocytes revealed by single-cell whole-genome sequencing

Authors:

Y. Huang^{1,2}, S. Choudhury^{1,2}, J. Kim^{1,2}, Z. Zhou^{1,2}, K. Morillo¹, E. A. Maury^{1,2}, J. W. Tsai^{1,2}, M. B. Miller^{1,2,3}, M. A. Lodato⁴, S. Araten¹, N. Hilal^{1,2}, E. Lee^{1,2}, M-H. Chen¹, C. A. Walsh^{1,2,5}; ¹Boston Children's Hosp., Boston, MA, ²Harvard Med. Sch., Boston, MA, ³Brigham and Women's Hosp., Boston, MA, ⁴Univ. of Massachusetts Med. Sch., Worcester, MA, ⁵Howard Hughes Med. Inst., Boston, MA

Abstract Body:

The accumulation of somatic DNA mutations is a hallmark of aging in many dividing cells and has been reported to play critical roles in tumorigenesis and an increasing number of non-cancer diseases. Here we survey the landscape of somatic single-nucleotide variants (sSNVs) in heart muscle cells (cardiomyocytes) which normally do not proliferate but often become polyploid with age. Using single-cell whole-genome sequencing, we analyzed sSNVs of 56 single cardiomyocytes obtained from 12 postmortem donors with 0.4 - 82 years of age. Cardiomyocyte sSNVs increased strikingly with age, at rates faster than reported in non-dividing neurons. In addition to an age-related “clock-like” mutational signature commonly present in many cell types, cardiomyocytes showed a distinct mutational signature that is absent in other non-cancer cells, implicating failed nucleotide excision repair (NER) and base excision repair (BER) of oxidative DNA damage, and defective mismatch repair (MMR). A lineage tree of ~500 single cardiomyocytes, constructed using clonal sSNVs, revealed that a significant portion of cardiomyocytes with tetraploidy or higher ploidy derive from distinct clonal origins, implying cell fusion as a mechanism contributing to the polyploidization of human cardiomyocytes. Since age-accumulated sSNVs create dozens of damaging exonic mutations, cell fusion to form multiploid cardiomyocytes may represent an evolutionary mechanism of cellular genetic compensation that minimizes the complete knockout of essential genes during aging. The rates and patterns of accumulation of cardiac mutations provide a paradigm to understand the impact of genomic aging on age-related heart diseases.

Omics Technologies Posters - Wednesday

PB2898. Algorithmic and Assay-based Simplification of Multiallelic Variants for Genotyping

Authors:

B. Main, D. Oliver, V. Missirian, J. Brodsky, B. Wong, J. Gollub; Thermo Fisher Scientific, Santa Clara, CA

Abstract Body:

The Applied Biosystems™ Axiom™ genotyping microarray platform uses a two-color, hybridization- and ligation-based assay. Genotyping interrogates a SNP or indel, biallelic or multiallelic. Multiallelic genotyping uses a set of probes that is specific for each allele. Calling multiallelic variants is more complex and can be less successful than calling biallelic variants, as it uses more probe sequences and a more complex calling algorithm with more degrees of freedom. In many applications, such as research in inherited diseases, only a few pathogenic alleles are of interest, while benign alleles do not need to be distinguished from the reference or wild-type allele. We present two methods to simplify the multiallelic genotyping problem by reducing the number of alleles to distinguish, both at the algorithmic and the assay levels. Algorithmic simplification consists of summarizing a set of allele-specific signals into a single value, representing an abstract, “uninteresting” allele. Probe signals for the interesting alleles are preserved individually, or possibly could be combined as well. The number of alleles that the calling algorithm must distinguish is reduced, simplifying the task, including reducing it down to a biallelic problem. We evaluated this approach using signals from the Coriell 1000 Genomes Project sample collection on several hundred samples, assayed at 40759 3-allele loci using probes designed to be specific to each allele. Signals for the two most common alleles were computationally combined before being evaluated by the AxiomGT1 calling algorithm. 74.1% of these 3-allele loci were successfully collapsed to 2 alleles, reducing the complexity of the calling problem, resulting in equivalent or better accuracy than was achieved using multiallelic calling. Moreover, loci with improved accuracy were distinguished by standard QC measures. Assay simplification consists of intentionally designing probes that ambiguously match two or more alleles that do not need to be distinguished. We assessed the resulting probe design algorithm on a set of ~48k multiallelic variants from ClinVar, of which ~11k had two or more benign alleles. Nonspecific probe design was able to reduce the number of probes required for ~9k variants, of which ~2k (20%) were reduced to a biallelic calling problem. A test array with both allele-specific and ambiguous probes will be used to confirm equivalent sensitivity of this approach. Together, these methods of simplifying multiallelic genotype calling serve to increase the accuracy and accessibility of many variants of interest.

Omics Technologies Posters - Thursday

PB2899*. An Algorithm for Sequence Location Approximation using Nuclear Families (ASLAN) Validates Regions of the Telomere-to-Telomere Assembly and Identifies New Hotspots for Genetic Diversity

Authors:

B. Chrisman¹, K. Paskov¹, N. Stockham¹, D. Wall², J-Y. Jung¹, C. He¹, P. Washington¹; ¹Stanford Univ., Stanford, CA, ²Stanford, Stanford, CA

Abstract Body:

Although it is heavily relied on to study genetic contributors to health and disease, the current human reference genome (GRCh38) is incomplete in two major ways: it is missing large sections of heterochromatic sequence, and as a singular, linear reference genome it does not represent the full spectrum of genetic diversity that exists in the human species. In order to better understand and characterize gaps in GRCh38 and genetic diversity, we developed a method - ASLAN, an Algorithm for Sequence Location Approximation using Nuclear families - that identifies the region of origin of short reads that do not align to the GRCh38. Using unmapped reads and variant calls from whole genome sequencing (WGS) data from nuclear families, ASLAN relies on a maximum likelihood model to identify the most likely region of the genome that a subsequence belongs to, given the phasing information of family and the distribution of the subsequence in the unmapped reads. Validating ASLAN on a synthetically generated dataset, and on true reads originating from the alternative haplotypes in the decoy genome, we show that ASLAN can localize more than 90% of 100-basepair sequences with above 92% accuracy. We then run ASLAN on 100-mers from unmapped reads from WGS from over 700 families, and compare ASLAN localizations to alignment of the 100-mers to the T2T-CHM13 assembly, recently released by Telomere-to-telomere (T2T) consortia. We find that many unmapped reads in GRCh38 actually originate from telomeres and centromeres that are gaps in GRCh38 reference. We also confirm that ASLAN localizations are in high concordance with T2T-CHM13 alignments, except in the centromeres of the acrocentric chromosomes. Comparing ASLAN localizations and T2T-CHM13 alignments, we identify sequences missing from T2T-CHM13 or sequences with high divergence from their aligned region in T2T-CHM13, thus highlighting new hotspots for genetic diversity.

Omics Technologies Posters - Wednesday

PB2900*. An algorithmic framework for isoform-specific functional analysis

Authors:

P. Robinson¹, G. Karlebach¹, L. Carmody¹, S. C. Jagadish¹, E. Casiraghi², P. Hansen¹, J. Reese³, C. Mungall⁴, G. Valentini⁵; ¹The Jackson Lab., Farmington, CT, ²Università degli Studi di Milano, Italy, Milan, Italy, ³Lawrence Berkeley Natl. Lab., Berkeley, CA, ⁴Lawrence Berkeley Lab., Berkeley, CA, ⁵Università degli Studi di Milano, Milan, Italy

Abstract Body:

Gene Ontology (GO) overrepresentation analysis, which characterizes the biological mechanisms common to sets of differentially expressed genes, has proven to be one of the most successful approaches to interpreting data from high-throughput omics experiments. So far, GO overrepresentation analysis has mainly been used to evaluate differentially expressed genes, but short- and long-read RNA-seq technologies now allow increasingly accurate identification of differential alternative splicing. The availability of genome-wide isoform-level annotation remains an unsatisfied prerequisite for effectively extending this approach to interpretation of differential alternative splicing. To address this problem, we present isopret (Isoform Interpretation), a new paradigm for isoform function prediction. We observe that an isoform-level annotation is essentially an assignment of GO terms to isoforms that is consistent with gene-level annotations and is maximally consistent with isoform sequence similarity. isopret optimizes this objective using an expectation-maximization framework. It addresses several inherent computational challenges by utilizing prior knowledge and machine learning heuristics, generating an annotation that is more comprehensive and accurate than any curated or computational annotation to date. This annotation enabled us to adapt GO overrepresentation analysis to assess overrepresentation of GO annotations in differentially spliced isoforms. We used this procedure to study the relationship between differential gene expression and differential alternative splicing. We collected and uniformly processed data from 100 RNA-seq studies including investigations of development, cancer, and common disease, and used them to demonstrate that expression and splicing regulate different sets of biological functions. We found that GO terms related to protein-protein interactions (PPI) we most commonly overrepresented in sets of differentially spliced isoforms. This was further supported by enrichment of experimental PPI between the corresponding gene's products, and inclusion of known PPI domains in differential transcripts. In contrast, differential gene expression was most commonly associated with extracellular functions or signals. Isopret also implements a visual summary of analysis results, which we utilized to identify differential splicing events that provide a plausible explanation to several conditions, based on known protein domains and the scientific literature. The software and predictions are freely available at <https://github.com/TheJacksonLaboratory/isopret>.

PB2901. An empirical comparison of calling pipelines for whole genome sequencing demonstrates the importance of mapping and alignment

Authors:

A. Ziegler¹, R. O. Betschart¹, A. Thiéry¹, R. Twerenbold², D. Aguilera-Garcia³, M. Zoche³, H. Moch³, T. Zeller⁴, S. Blankenberg²; ¹Cardio-CARE, Davos, Switzerland, ²UKE, Hamburg, Germany, ³USZ, Zurich, Switzerland, ⁴Med. Univ. Hamburg-Eppendorf, Hamburg, Hamburg, Germany

Abstract Body:

Rapid advances in high-throughput DNA sequencing technologies have enabled the conduct of whole genome sequencing (WGS) studies, and several bioinformatics pipelines have become available. We conducted a WGS study involving >9000 subjects, sequenced on one Illumina NovaSeq 6000 with an average coverage of 35x using a PCR-free protocol and unique dual indices (UDI). As part of the quality control, we sequenced one genome in a bottle (GIAB) sample 70 times in different runs, and one GIAB trio in triplicate. In this study, we compared the performance of 6 pipelines, involving two mapping and alignment approaches (GATK utilizing BWA-MEM2 2.2.1, and DRAGEN 3.8.4) and three variant calling pipelines (GATK 4.2.4.1, DRAGEN 3.8.4 and DeepVariant 1.1.0). The truth set of the GIABs was used for comparison, and performance was assessed by computation time, F₁ score, precision and recall. In the mapping and alignment step, the DRAGEN pipeline was faster than the GATK with BWA-MEM2 pipeline. DRAGEN showed systematically higher F₁ score, precision, and recall values than GATK for single nucleotide variations (SNVs) and Indels in both simple-to-map and complex-to-map regions. In the variant calling step, DRAGEN was fastest. In terms of accuracy, DRAGEN and DeepVariant performed similarly and both superior to GATK, with slight advantages for DRAGEN for Indels and for DeepVariant for SNVs. The DRAGEN pipeline showed the lowest Mendelian inheritance error fraction for the GIAB trios. Mapping and alignment played a key role in variant calling of WGS, with the DRAGEN substantially outperforming GATK.

PB2902*. An evaluation of the Ultima Genomics sequencing platform: Scalable, high-throughput sequencing for low-cost whole genome sequencing

Authors:

M. Coole¹, T. Howd¹, F. Oberstrass¹, M. Sosa², S. Low¹, T. Clark², A. Bernier¹, J. Stohlman¹, M. Shand¹, C. Nolet¹, Y. Farjoun³, N. Lennon⁴, S. Gabriel⁵; ¹The Broad Inst. of MIT and Harvard, Cambridge, MA, ²Ultima Genomics, Newark, CA, ³Lady Davis Inst., JGH, Montreal, QC, Canada, ⁴Broad Inst. Genomic Services, Cambridge, MA, ⁵Broad Inst. of MIT and Harvard, Cambridge, MA

Abstract Body:

The cost for Human Whole Genome Sequencing (WGS) has stabilized at a little less than \$1,000 over the past few years, but the path to significant reduction is not clear. Lower WGS costs offer the chance to dramatically increase the production of population-scale studies and ultimately drive discovery and demonstration of utility of such data in the healthcare system. Ultima Genomics (UG) is a platform designed to enable continual cost decreases from a starting point of \$1/Gb and operate at an industrial scale. Here we introduce and evaluate the performance of the UG novel DNA sequencer in our lab at the Broad Institute and demonstrate an automated, production-ready library construction workflow.

In order to operationalize the platform, we leveraged an off the shelf library preparation kit, coupled with Ultima Genomics indexed adapters, to generate PCR-Free libraries. After library quantification, normalization, and pooling, samples undergo a proprietary process to anneal library pools to sequencing beads. We evolved a highly manual sample preparation process into a robust and automated workflow which results in a final bead-bound sequencing library.

Sequencing was performed on UG sequencers, which utilize mostly-natural bases in a single-read, sequencing by synthesis process. To achieve a target read length greater than 300bp, sequencing runs were 464 flows (116 cycles across the four nucleotides). Our early version of the UG sequencer has an overall runtime (including instrument setup) of 24 hours and consistently generates enough data to drive 12 samples to > 30x mean genome coverage (average = 40.1x) per run. We will present on the benchmarking performance of a large cohort of HapMap samples using early versions of the chemistry and instrumentation. Utilizing a new sequencing analysis pipeline developed to analyze the single-read, flow-based nature of the UG sequencing systems, we observe high quality SNP and short INDEL calling over the High Complexity Regions of the genome, with lower quality for long homopolymers and in Low Complexity Regions. In addition to developing an end-to-end workflow for generating PCR Free WGS data on the Ultima platform in a scalable manner that is suitable for large scale population studies, we have also explored utilizing the tool for an array of other applications including perturbation sequencing.

Omics Technologies Posters - Thursday

PB2903. Analysis of alternative polyadenylation from long-read or short-read RNA-seq with LAPA

Authors:

M. Celik, A. Mortazavi; UC Irvine, Irvine, CA

Abstract Body:

Alternative polyadenylation (APA) is a major mechanism that increases transcriptional diversity and regulates mRNA abundance. Existing computational tools to analyze APA have low precision because these tools are designed for short-read RNA-seq, which is a sub-optimal data source to study APA. Long-read RNA-seq (LR-RNA-seq) accurately detects complete transcript isoforms with polyA-tails, providing an ideal data source to study APA. However, current computational tools are incompatible with LR-RNA-seq.

Here, we introduce LAPA, a computational toolkit to study alternative polyadenylation (APA) from diverse data sources such as LR-RNA-seq and 3' sequencing (3'-seq). LAPA counts, clusters reads with polyA tails, and performs peak-calling to detect poly(A)-site in a data source agnostic manner. The resulting peaks are annotated based on genomics features and regulatory sequence elements such as polyA-signal. Finally, LAPA can perform robust statistical testing and multiple testing corrections to detect differential alternative polyadenylation. We analyzed ENCODE LR-RNA-seq data from human WTC11, mouse C2C12, and F129/Castaneus ES cells using LAPA. Benchmark of LR-RNA-seq from multiple platforms and libraries against 3'-seq with LAPA shows that LR-RNA-seq detects poly(A)-sites with high precision. Moreover, LAPA consistently improves TES site support by at least 20 % over baseline transcript annotation generated by TALON, independent of protocol or platform. Differential APA analysis detects 528 statistically significant genes with unique polyadenylation signatures between undifferentiated and differentiated C2C12 cells. Among these genes, 3' UTR elongation is significantly associated with higher expression, while shortening is linked with lower expression. This analysis reveals a link between cell state/identity and APA. Overall, our results show that LR-RNA-seq is a reliable data source to study post-transcriptional regulation by providing precise information about alternative polyadenylation.

LAPA is publicly available at github.com/mortazavilab/lapa and PyPI.

Omics Technologies Posters - Wednesday

PB2904. Analysis of pathogenic tandem repeat variation in congenital disorders.

Authors:

G. Altman, W. Lee, B. Jadhav, A. Martin Trujillo, A. J. Sharp; Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Tandem repeat expansions (TREs) are known to underlie over 60 different human diseases. Pathogenic expansions of coding or intronic repeats occur in nine different genes that cause different congenital disorders. However, despite evidence TREs can act as the causative mutation in multiple congenital disorders, there have been no systematic screens for novel TREs in cohorts of patients with congenital disorders. We hypothesized that some cases of congenital disorders are caused by rare, highly penetrant pathogenic variations of short tandem repeat (STRs). Here we report results from a screen of novel TREs in 1,591 parent/offspring trios across six different congenital disorder cohorts, using whole-genome sequencing (WGS) data from the Gabriella Miller Kids First Pediatric Research Program. This represents the largest genome-wide screen of pathogenic TREs in congenital disorders to date. We genotyped STR loci genome-wide using three bioinformatic tools, optimized to identify a full range of STR variants. We used *HipSTR* to genotype STRs enclosed within single reads (less than 150 bp), *STRetch* to genotype expanded STRs (greater than 150 bp), and *ExpansionHunter Denovo (EHdn)* to genotype expanded STRs not previously cataloged. After genotyping, we searched for rare, de novo TREs present in probands but not their unaffected parents.

In the European ancestry orofacial cleft (OFC) cohort (n=330 trios), each proband had an average of 42 rare, de novo TR variants identified by *HipSTR*, 51% of which occurred in exons, introns, or UTRs. We identified multiple examples of de novo TREs in exonic, intronic, and regulatory regions of genes functionally related to OFCs, such as genes previously associated with OFCs, craniofacial super-enhancers, and genes important for early embryonic development. We performed outlier calling on the genotyping results from *STRetch*, identifying an average of 3 rare TREs per proband, including several in genes that have previously been implicated as causal for OFCs. Using the results of *EHdn*, we filtered to retain only rare, de novo TREs in probands, supported by multiple independent reads, identifying an average of 1.1 expansions per proband. Genes associated with this set of rare de novo TREs were functionally enriched for involvement in cell morphogenesis ($p=8 \times 10^{-5}$), biological adhesion ($p=9 \times 10^{-4}$), and anchoring junction ($p=0.008$), indicating functional relevance for OFCs. Our study indicates that TREs likely contribute to the genetic basis of congenital disorders, which have been missed with traditional variant analysis pipelines.

Omics Technologies Posters - Thursday

PB2905. Application of a novel scRNA-seq method based on Pre-templated Instant Partitions (PIPseq) to evaluate therapeutic induced intestinal epithelium regeneration

Authors:

P. Hettige¹, A. May-Zhang², L. Chen³, O. Pellon-Cardenas⁴, A. Dupre⁴, X. Qiu⁴, M. Verzi³; ¹Fluent BioSci.s, Watertown, MA, ²Fluent BioSci., Watertown, MA, ³Rutgers Univ., New Brunswick, NJ, ⁴Rutgers Univ., Piscataway, NJ

Abstract Body:

The intestinal epithelium is a complex, fragile, and highly labile tissue that undergoes continuous regeneration and remodeling throughout an organism's lifetime. In order to understand transcriptomic changes in the cells over time, single cell techniques are preferred over bulk RNA-seq, as it allows studying individual cellular responses in heterogeneous cell mixtures that occur in intestinal crypts or organoid cultures. Single-cell transcriptomics enables important research focused on mechanisms of intestinal homeostasis and epithelium regeneration over time. Here, we have used a novel scRNA-seq method based on Pre-templated Instant Partitions (PIPseq) to evaluate therapeutic-induced intestinal epithelium regeneration after irradiation of primary murine intestinal organoid cultures. In response to therapeutic intervention, we observe emergence of regenerative stem cell populations over time. RNA velocity plots have shown that regenerative expression profiles emerge in populations of treated cells within 24 hours after treatment. Overall, the flexibility of the PIPseq workflow, cost efficiency, and convenient stable stopping point after cell capture and lysis are particularly enabling for therapeutic interventions in time course studies as presented here.

Omics Technologies Posters - Wednesday

PB2906. Application of DRAGEN Graph read alignment to challenging medically relevant genes and other difficult regions in GRCh38 and T2T-CHM13 genomes.

Authors:

C. Roddey¹, S. Catreux¹, W-T. Chen¹, C. Colombo², J. Gimbernat², V. Jain¹, Z. Tasev¹, M. Ruehle¹, J. Han¹, R. Mehio¹; ¹Illumina, San Diego, CA, ²Illumina, Cambridge, United Kingdom

Abstract Body:

The recently released Telomere-to-Telomere (T2T) CHM13 human reference genome enables improved read mapping and variant identification for diverse samples, mainly due to the addition of about 200 million bases of sequence and the correction of structural errors present in GRCh38. To better understand the nature of these improvements, the T2T consortium developed small variant benchmarks on GRCh38 and T2T-CHM13 for 269 challenging medically relevant genes (CMRG) in the Ashkenazi son HG002. The benchmarks were used to test the accuracy of several short and long read variant calling (VC) pipelines. The DRAGEN Bio-IT Platform, which placed first in multiple categories in the 2020 PrecisionFDA VC challenge, was not included in that study, so we evaluated its performance versus the CMRG benchmarks and in other difficult regions.

The key feature driving DRAGEN's performance in the PrecisionFDA challenge was its graph read-mapping capability ('DRAGEN graph'). The GRCh38 genome was augmented with more than 800,000 short alternate contigs derived from phased population haplotypes, and 400,000+ population SNPs. These graph contigs and SNPs provide diverse haplotypes for improving read alignment in difficult regions of the genome. For the PrecisionFDA challenge, using DRAGEN graph, we observed an almost 50% reduction in DRAGEN's genome-wide VC error count (false positives + false negatives) compared to using the conventional DRAGEN read mapper ('DRAGEN non-graph').

For the current study, we created two graph references (for GRCh38 and T2T-CHM13) which included population haplotypes and SNPs in difficult-to-map and CMRG regions. We then assessed the SNP and indel VC accuracies for the DRAGEN graph and non-graph references, using Illumina read data from the recent T2T study. For GRCh38, the DRAGEN graph CMRG VC error count was 30% lower than that of DRAGEN non-graph, almost 40% lower than that of the short read VC pipeline in the T2T study, and on par with the best performing long read pipeline in that study. For T2T-CHM13, DRAGEN graph's CMRG error count was 40% lower than the non-graph count, and 55% lower than the T2T short read pipeline error count. Over GRCh38 difficult-to-map regions (GRCh38_allowmapandsegdupregions.bed), DRAGEN graph's VC error count was 50% lower than that of DRAGEN non-graph, and 70% lower than that of the T2T short read VC pipeline.

In conclusion, DRAGEN graph delivers dramatic gains in variant calling accuracy in CMRG genes with either GRCh38 or T2T-CHM13, and in GRCh38 difficult-to-map regions.

Omics Technologies Posters - Thursday

PB2907. ASCoT - Application for Sanger COncfirmatory Testing - A graphical software interface for management of confirmatory sequencing in genomic medicine

Authors:

G. Smith, E. Gilliland, K. Crooks, C. Gignoux; Univ. of Colorados Med. Campus at Anschutz, Aurora, CO

Abstract Body:

As genomic medicine programs and institutional biobanks grow, there is an increasing need for software to manage and track biospecimens needed for downstream analyses such as in confirmatory sequencing. Here, we have developed a standalone and containerized cross-platform software package for sample management particularly tailored for user-friendliness. ASCoT is developed using Python and javascript relying on the flask libraries and encodes changes in workflows via text in JSON format, allowing for high reproducibility and downstream parsing by other software packages. The software takes candidate pathogenic variants per patient as input and allows the user to sort and assign individuals to plates for simplicity. It intersects the user-submitted data with a modifiable database of amplicons and primer pairs for targeted efforts such as Sanger sequencing. It has participant, variant, and plating views allowing for ease of aliquoting and sample management to improve recording and sample workflow, with controlled signing in the user log. The program does not require an internet connection for use thus making it suitable for use in secure environments with PHI/PII as is common in clinical settings. Overall, ASCoT provides a useful tool suitable for the academic genomic medicine environment that is designed for purpose while maintaining recording and reproducibility necessary in biobanks and clinical labs

Omics Technologies Posters - Wednesday

PB2908. Assessing the impact of bioinformatics tools on genomic reproducibility: opportunities and pitfalls.

Authors:

F. Liu¹, M. Kim¹, P. I. Baykal^{2,3}, N. Beerenwinkel^{2,3}, S. Mangul⁴; ¹Dept. of Quantitative and Computational Biology, Dornsife Coll. of Letters, Arts, and Sci., Univ. of Southern California, Los Angeles, CA, ²ETH Zurich, Basel, Switzerland, ³SIB Swiss Inst. of Bioinformatics, Basel, Switzerland, ⁴Dept. of Clinical Pharmacy, USC Sch. of Pharmacy, Univ. of Southern California, Los Angeles, CA

Abstract Body:

Introduction: The reproducibility of results obtained using bioinformatics analysis is crucial, especially if such results are used in clinical settings and in the development of genomic based medicine. To assess the reproducibility of bioinformatics tools, one would repeat the same experiment multiple times across multiple laboratory sites and compare the bioinformatics results. However, such an approach carries an additional cost and is often infeasible. In this study we expand the existing approach with new *synthetic replicates* alternatives by altering the properties of sequencing reads. In this study we evaluated the reproducibility of read alignment tools and structural variant (SV) callers. We found that some bioinformatics tools failed to maintain consistent results across synthetic replicates.

Methods: We have developed a scalable and robust method to assess the reproducibility of bioinformatics tools. We generate two types of synthetic replicates, one obtained by randomly shuffling the order of reads (type 1), and the other obtained by taking the reverse complement of reads (type 2). Using these two types of synthetic replicates we assess reproducibility of selected read alignment tools and SV callers using DNA-seq paired end data. We only consider unambiguous reads, which are read reported as primary alignment only. We ran each alignment tool with original data, synthetic replicate type 1, and synthetic replicate type 2. We compared BAM files obtained from synthetic replicates to the BAM file obtained from original data.

Results: Overall, *Bowtie2*, *HISAT2*, *Minimap2*, *NextGenMap*, *SMALT*, *SNAP* and *Subread* produce consistent alignments with more than 99% of identical reads across original and technical replicate type 1 data while *BWA-mem* has the lowest percentage of ~96.5%. On the other hand, with technical replicate type 2 data we observe that apart from *NextGenMap* all other tools produce inconsistent alignments. The percentage of identical reads varies from ~99% (*NextGenMap*) to ~79% (*Bowtie2*) across the tools. We also observe that deletion coordinates reported from original data and synthetic replicate type 1 data differ for the majority of the SV caller ranging from 0% to more than 60%.

Conclusion: Our results confirm that the majority of the tools fail to maintain results across all types of technical replicates limiting applicability of bioinformatics tools in the clinical settings. We believe our method would be a useful and scalable solution for the biomedical community to assess reproducibility of newly developed bioinformatics tools at no cost and help choosing the most appropriate tool for bioinformatics analysis.

Omics Technologies Posters - Thursday

PB2909. Assessing the utility of genomic deep learning models for disease-relevant variant effect prediction

Authors:

P. Kathail¹, R. Shuai¹, R. Chung¹, C. Ye², G. Loeb², N. Ioannidis¹; ¹Univ. of California, Berkeley, Berkeley, CA, ²Univ. of California, San Francisco, San Francisco, CA

Abstract Body:

Over the past several years, highly accurate deep learning models have been developed to predict epigenetic features such as chromatin accessibility directly from DNA sequence. These models have the potential to assign function to disease-relevant non-coding variation, but their utility for variant effect prediction remains limited. It was recently noted that predictions from current deep learning models contain limited unique information about complex disease heritability, when conditioned on a broad set of coding, conservation, and regulatory annotations. **Here, we identify two features of these models that may limit their utility for disease variant functionalization.** Using two ATAC-seq datasets from kidney and immune cells, we train deep learning models, similar to the Basset architecture, to predict chromatin accessibility in multiple cell types from DNA sequence. We base our analysis of our trained models on two key ideas. First, disease-relevant non-coding variation is not uniformly distributed throughout the genome. Cell-type specific *cis* regulatory elements (CREs) are known to harbor a large fraction of the heritability of complex diseases. **We find that our models have reduced performance in cell-type specific CREs (0.30 avg. Pearson R for immune cell types; 0.39 avg. Pearson R for kidney cell types), as compared to ubiquitously accessible CREs (0.68 avg. Pearson R for immune cell types; 0.69 avg. Pearson R for kidney cell types).** Second, the accuracy metric—which we refer to as reference accuracy—used to evaluate models measures correlation between experimental measurements and model predictions for the reference genome, but does not directly measure a model’s ability to predict variant effects. Using allele-specific accessibility data to measure variant effects, we compare the reference and variant effect accuracy of several different model architectures and training procedures. We find that reference and variant effect accuracy are not correlated across these different models, **highlighting the importance of directly assessing variant effect accuracy** for the task of non-coding variant functionalization. Our results highlight the importance of evaluating models within disease-relevant regulatory regions, and show how allele-specific accessibility data and variant effect accuracy can be used as a tool for model selection.

Omics Technologies Posters - Wednesday

PB2910. Assessment of Whole Genome Sequencing Quality Metrics from a Large Cohort of Saliva-derived DNA Samples.

Authors:

G. Smith¹, D. Hupalo¹, G. Sukumar¹, C. Alba¹, J. Martin¹, C. L. Dalgard²; ¹The Henry M. Jackson Fndn., Bethesda, MD, ²Uniformed Services Univ. of the Hlth.Sci., Bethesda, MD

Abstract Body:

Whole genome sequencing (WGS) is essential for profiling genetic variation. DNA samples for WGS can be derived from variable sources. Saliva offers the advantage of being non-invasive and more stable at room temperatures which widens the cohort possibilities. However, these techniques present a greater risk of contamination by extra species DNA content. Previously, DNA from paired blood and saliva samples showed high quality WGS, low microbial contamination, and comparable detection of SNVs in both cases. Another larger scale study with non-paired samples recommended correction for the impact of non-human reads on alignment and variant identification using decoy references that include known bacterial genres. Saliva library preparation, sequencing dropout rates and quality metrics have not been previously reported in detail and may provide insight for future study design when phlebotomy is not available. Saliva samples were collected using the OraGene OG-500 kit, DNA extracted using the user guide recommended kit, and quantification performed using a fluorescence-based assay. Sequencing libraries were prepared with a semi-automated PCR-free library preparation. Fragment analysis was used to determine bp size and qPCR was used to determine the yield. Sequencing was performed on Illumina Novaseq 6000 using a plexity of 24 or 26 for saliva and blood derived samples respectively. Raw sequencing data was demultiplexed and analysis was conducted on the HAS2.2 pipeline for alignment and variant calling.

For this comparative analysis of quality metrics, we conducted whole genome sequencing for 1755 saliva-derived and compared to 1718 blood-derived DNA samples. Library QA resulted in 0.57% of samples failing library preparation compared to 0.2% for samples extracted from blood. Median alignment percentage was determined at 91.62% and 98.23% for saliva and blood derived libraries, respectively. For single depth sequencing targeting 30x coverage, 84% of the saliva-derived libraries reached the coverage threshold while blood-derived cohorts passed at 95%. Low coverage libraries made up 16% of the total sequenced samples, and requeueing saliva-derived libraries for increased depth was possible for 12.4% of the total. Comparative analysis of SNV count, het/hom ratio, and within sample contamination (via VBID) between high (>33%) and low (<33%) extraspecies DNA content displayed no observable cohort-wide differences. Variant calling metrics were not associated with extra species DNA content as a function of percentage of aligned reads. Large cohorts with stabilized saliva using OG-500 kits should have confidence in sequencing metrics produced by WGS.

Omics Technologies Posters - Thursday

PB2911. Associations between genetically predicted levels of blood metabolites and pancreatic cancer risk

Authors:

H. Zhong, S. Liu, J. Zhu, L. Wu; Cancer Epidemiology Div., Population Sci. in the Pacific Program, Univ. of Hawaii Cancer Ctr., Univ. of Hawaii at Manoa, Honolulu, HI

Abstract Body:

Background: Pancreatic ductal adenocarcinoma (PDAC) is one of the most aggressive solid malignancies, which is featured by systematic metabolism. A growing number of conventional studies report associations between serum levels of several metabolites and PDAC risk. However, these studies could be influenced by incoherent limitations of traditional epidemiological study design. The design of genetic instruments may decrease many of these limitations. Furthermore, compared with the design of merely using metabolite associated quantitative trait loci as instruments, a design of leveraging comprehensive metabolite genetic prediction models could capture higher proportions of genetically regulated components of metabolites levels in blood, thus providing an improved power to detect the metabolite-PDAC associations. Specific microbiome features may also play a role in the metabolite-PDAC associations. **Methods:** In this study, we performed a large metabolome-wide association study (MWAS) to systematically explore associations between genetically predicted metabolite levels in blood and PDAC risk. Using data from 881 subjects of European descent in the TwinsUK Project, comprehensive genetic models were built to predict serum metabolite levels. These prediction models were applied to the genetic data of 8,280 cases and 6,728 controls included in the PanScan (I, II, and III) and PanC4 consortia. Integrated with gut microbial information, two-sample Mendelian randomization (MR) analyses were further performed to investigate the relationship among serum metabolites, gut microbiome features, and PDAC. **Results:** After assessing the metabolite-PDAC risk associations by a slightly modified TWAS/FUSION framework, we identified five metabolites (including two dipeptides) showing significant associations with PDAC risk at false discovery rate (FDR) < 0.05. Of them, three metabolites (alpha-glutamylglycine, glycylglycine, and X - 21849) showed negative associations while other two (X - 21735 and X - 24309) showed positive associations with PDAC risk. Of them, metabolite X - 21849 was found to be associated with flavonoid-degrading bacteria *Flavonifractor sp90199495*, which was also shown to be associated with PDAC risk. **Conclusion:** In summary, our research provides information of novel metabolite biomarkers for PDAC risk that warrants further investigation, which could lead to new insights into the etiology of PDAC and improved treatment options.

Omics Technologies Posters - Thursday

PB2912. Autoencoder-based Model for Genotype Imputation

Authors:

M. Song¹, J. Greenbaum², J. Luttrell¹, W. Zhou³, C. Wu⁴, Z. Luo², C. qiu², L. Zhao², K-J. Su², Q. Tian², H. Shen², P. Gong⁵, X. Shi⁶, C. Zhang¹, H-W. Deng²; ¹Univ. of Southern Mississippi, Hattiesburg, MS, ²Tulane Univ., New Orleans, LA, ³Michigan Technological Univ., Houghton, MI, ⁴Florida State Univ., Tallahassee, FL, ⁵U.S. Army Engineer Res. and Dev. Ctr., Vicksburg, MS, ⁶Temple Univ., Philadelphia, PA

Abstract Body:

Background: Genotype imputation has a wide range of applications in genome-wide association studies (GWAS), such as fine-mapping, meta-analysis, and boosting the statistical power of association tests. In recent years, a deep learning (DL)-based approach, named as sparse convolutional denoising autoencoder (SCDA), has been proposed for genotype imputation. However, it remains a challenging task on how to achieve higher imputation accuracy by optimizing the learning process in DL-based methods. **Methods:** We proposed a convolutional autoencoder (AE) model for genotype imputation. Instead of using sequential or functional methods to define the neural network architectures, we utilized the model subclassing method to build the AE model since it can be easily extended to other omics data (e.g., gene expression). The encoder of the AE model includes two 1D convolutional layers and an embedding layer. The decoder of it has an inverted symmetry structure with the encoder, including two 1D convolutional layers and an output layer with “Softmax” as its activation function. For the loss function of the AE model, we utilize categorical cross entropy (CCE) to train it as genotype data are discrete values. The main difference between our AE model and SCDA model is that we implemented a customized training loop and modified the training process by using a single batch loss rather than the average loss over batches used by SCDA. **Results:** We developed the convolutional AE model for genotype imputation with tolerance to high missing ratios. This model was evaluated using three different genotype datasets from yeast, the human leukocyte antigen (HLA) region in the 1000 Genomes Project, and the Louisiana Osteoporosis Study (LOS). Taking the HLA region imputation results as an example, the AE model achieved an average accuracy of 1.0, 0.952 and 0.950 at missing ratios of 0%, 10%, and 20%, respectively. In addition, it yielded comparable accuracy of 0.932, 0.917, and 0.906 at higher missing ratios of 50%, 70%, and 90%, respectively. Our modified AE imputation model systematically outperformed the existing SCDA model in terms of several evaluation metrics including accuracy, squared Pearson correlation coefficient, Imputation Quality Score (IQS), Hellinger score, and Scaled Euclidean Norm (SEN) score. **Conclusions:** We developed a convolutional AE imputation model with an improved learning process and achieved better imputation performance compared with SCDA model. The AE imputation model with improved accuracy has the potential to increase the power of GWAS for the LOS data generated in our ongoing research projects and other GWAS data beyond.

Omics Technologies Posters - Wednesday

PB2913. Automated Walk away NGS Sample Preparation Using a Flexible Library Prep System with Enhanced Error Correction

Authors:

S. Bigdeli¹, J. Godoski¹, D. Rhodes¹, B. Vaughan¹, R. Aguilar¹, B. Buehler¹, B. Arezi¹, J. Zhu², R. Allen¹; ¹Agilent Technologies, La Jolla, CA, ²Agilent Technologies, Santa Clara, CA

Abstract Body:

Next Generation Sequencing (NGS) target enrichment protocols for preparation of Illumina sequencing-ready libraries from samples of varying quality and input such as tissue, blood, FFPE specimens and circulating tumor DNA are in high demand. Automation of these complex protocols eliminates the need for highly trained specialists while considerably improving the NGS library prep turnaround time, quality, and reproducibility. We have developed a fully automated walk-away protocol on the Magnis NGS Prep System that is optimized for a wide range of DNA input (10-200 ng), various sample types (intact, FFPE, or ct DNA samples), different shearing methods (mechanical or enzymatic within the same automated protocol) and equipped with 192 Unique Dual sample Indices (UDI) to minimize the effects of possible index hopping. Furthermore, we incorporate inline duplex molecular barcodes at the ligation step to filter out PCR or sequencing errors by making consensus calls using MBC information. The automated workflow on Magnis is easily set up from pre-aliquoted single-use reagents to minimize contamination risk, delivers up to eight target-enriched NGS Illumina sequencing-ready libraries per run in ~ 9-10 hours without the need of any user intervention. Both catalog and custom probes can be utilized, and PCR cycles can be easily adjusted from the touchscreen to optimize the library yields. For Research Use Only. Not for use in Diagnostic procedures.

Omics Technologies Posters - Thursday

PB2914. Automation of single-cell NGS library preparation for Tapestri platform to accelerate oncology discoveries.

Authors:

A. Barner¹, K. Patel², E. Cervantes¹, E. Carvajal¹, S. Mandali¹, D. Mendoza², T. Libby², A. Li², B. Schroeder²; ¹Miroculus, San Francisco, CA, ²Mission Bio, South San Francisco, CA

Abstract Body:

In the oncology field, from discovery to diagnostics, next-generation sequencing (NGS) has played a critical role over the last decade. However, bulk NGS sequencing has limitations in truly measuring the complexity of tumor heterogeneity at a cellular level. The development of single-cell sequencing technologies allowed researchers to elucidate the intricacy of tumor clonal heterogeneity, which is pertinent for studying underlying mechanisms in cancer progression; as well as clinical applications where identifying minimal residual disease comprised of low prevalent cells carrying mutations could guide treatment regimens. Tapestri®, a high-throughput single-cell sequencing platform developed by Mission Bio, Inc., enables single-cell targeted DNA sequencing to best interrogate tumors' genomic landscape. It provides high-quality single-cell variant calling of SNV and indels, as well as clonal level CNV analysis. The entire workflow, which includes sample preparation, single-cell encapsulation, cell-specific barcoding PCR, and NGS library preparation, takes two days. The automation of NGS library preparation utilizing the digital micro fluidic system 'Miro Canvas' is demonstrated here. All of the phases in the NGS library processing were successfully translated onto Miro Canvas, including enriched library purification, enzymatic digestion, library amplification, and bead-based purification. The automation procedure reduces hands-on time significantly by 5-fold, from 2.5 hours to 30 minutes. The library quality in terms of yields, size distribution, and sequencing results from Miro Canvas is comparable to that of manual preparation. Combining Tapestri® and Miro Canvas in a stream-lined workflow greatly enhances the efficiency and sample turnaround time to accelerate discoveries in cancer biology.

PB2915*. AUTOSurv: Interpretable autoencoder aided deep learning framework for breast cancer survival analysis incorporating multi-omics data

Authors:

L. Jiang¹, C. Xu², Y. Bai³, A. Liu¹, Y. Gong¹, Y-P. Wang³, H-W. Deng¹; ¹Tulane Univ. Sch. of Med., New Orleans, LA, ²The Univ. of Oklahoma Hlth.Sci. Ctr., Oklahoma City, OK, ³Tulane Univ. Dept. of BioMed. Engineering, New Orleans, LA

Abstract Body:

Accurate prognosis for cancer patients can provide critical information for optimizing treatment plans and thereby improving their life quality. Furthermore, combining omics data (e.g., gene expression data, miRNA expression data) and demographic/clinical information (e.g., age, ethnicity, disease stage) can give a more comprehensive view of cancer prognosis and reveal the underlying disease mechanisms at molecular level. One of the biggest challenges in utilizing omics data, however, is the high-dimension-low-sample-size issue. This may cause severe overfitting problem, undermine the generalizability of the model, and reduce the reliability of prediction results. In this study, we developed a specially designed Variational Autoencoder (VAE) to extract lower-dimension latent features from high-dimensional gene expression and miRNA expression data simultaneously. A downstream Multi-Layer Perceptron Neural Network (MLPNN) then combines the extracted latent features with some clinical variables and conducts the prognosis prediction. The VAE incorporates pathway information in its structure for better interpretability and reduced risk of overfitting. Moreover, the results suggest that a KL-annealing training scheme made our VAE more efficient in multi-omics integration. To tackle the “black-box” nature of deep neural networks, we applied an activation-based interpretation approach (i.e., DeepSHAP) on the trained model. We identified features (i.e., genes, miRNAs, clinical variables) with biggest contributions to distinguishing predicted high- and low-risk patients. In addition, by virtue of our VAE’s interpretation-friendly design, we obtained importance scores for the pathways directly and linked the highlighted pathway to the important genes. We collected demographic/clinical data, survival data, gene expression data and miRNA expression data for 1058 female patients with stage I to stage IV breast cancer from the GDC TCGA Breast Cancer cohort (BRCA) on the UCSC Xena online portal. When comparing the prediction performance of our model with conventional Cox Proportional Hazard model (Cox-PH) and other existing deep learning approaches, our model achieved significantly better prognosis prediction in various settings.

PB2916*. Bayesian Causal Inference Method applied to CRISPR perturbations Estimates the Causal Gene Regulatory Network of CD4+ T cells

Authors:

J. Weinstock^{1,2}, J. W. Freimer^{1,3}, M. Arce^{1,3}, A. Marson³, A. Battle², J. K. Pritchard^{1,4}; ¹Dept. of Genetics, Stanford Univ., Stanford, CA, ²Dept. of BioMed. Engineering, Johns Hopkins Univ., Baltimore, MD, ³Gladstone-UCSF Inst. of Genomic Immunology, UCSF, San Francisco, CA, ⁴Dept. of Biology, Stanford Univ., Stanford, CA

Abstract Body:

INTRODUCTION: Complex traits are influenced predominately through the contribution of regulatory genetic variation. The bulk (60-90%) of expression heritability is mediated through trans-regulatory variation. Despite the importance of trans-regulatory variation, mapping trans-regulators through natural genetic variation, including eQTL mapping, has been challenging. Experimental perturbations facilitate the identification of trans-regulation, thus enabling deeper understanding of the etiology of complex traits in general, and mechanistic understanding of trait specific gene regulatory networks. However, to estimate direct regulatory effects, novel computational approaches are needed to distinguish direct regulatory pathways from indirect effects to construct full causal networks. **OBJECTIVES:** We recently utilized CRISPR knockouts of 24 autoimmune associated disease genes in primary CD4+ T cells to experimentally perturb a key autoimmune network, including IL2RA, STAT5A, and JAK3 (Freimer et al., 2021). To distinguish direct regulatory effects from indirect effects, we developed a novel Bayesian structure learning method to estimate the causal regulatory network from RNA-seq, enabling a probabilistic causal estimate of the regulatory network. **METHODS:** In contrast to most causal inference procedures, which assume an acyclic directed graph, we utilized the perturbations to enable identification of a causal cyclic graph, as preliminary inspection indicated that feedback loops are prevalent among these genes. We construct a linear estimator of the perturbed RNA-seq data that estimates directed regulatory relationships that are constrained by the total regulatory effects. We include a batch effect correction and infer the posterior using Markov chain Monte Carlo. We demonstrate the feasibility of our approach using simulations. **RESULTS:** We identified a highly interconnected causal network, observing 83 directed edges among the 24 genes (posterior inclusion probability > 50%). MED12 has a direct effect on 17 of the 24 genes, suggesting that it may be a master regulator. We observe that indirect effects between genes contribute 19.5% of the variance in total regulatory effects, and we explore how the 24 perturbed genes affect non-perturbed genes. **CONCLUSION:** We use a Bayesian structure learning approach to estimate the causal directed regulatory network from perturbations in primary human immune cells. We anticipate that our approach applying bespoke causal inference methods to experimental perturbations will provide a roadmap for mapping causal regulatory networks in other cell types and contexts.

Omics Technologies Posters - Wednesday

PB2917. Benchmarking algorithms for joint integration of unpaired and paired single-cell RNA-seq and ATAC-seq data

Authors:

M. Lee^{1,2}, K. K. Kaestner¹, M. Li³; ¹Dept. of Genetics, Univ. of Pennsylvania, Philadelphia, PA, ²Graduate Group in Genomics and Computational Biology, Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA, ³Dept. of Biostatistics, Epidemiology and Informatics, Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

With the development of single-cell multi-omics technologies, we can now simultaneously measure two modalities such as mRNA and chromatin accessibility (enabled by ATAC-seq) in the same cells. These technologies allow researchers to decipher cell types/states, and their functions in health and disease with unprecedented resolution. While useful, single-cell multi-omics are expensive to generate. On the other hand, many single-modality datasets that measure either RNA or ATAC have been generated. It is desirable to integrate single-modality and multi-modality datasets to maximize the number of cells for cell type identification and facilitate consistent annotations of all cells. However, it is unclear to what extent multi-modality data such as 10x multiome aid cell type identification and the understanding of transcriptional regulation. There is also no consensus on what the best way is to integrate these three data types. One key advantage of the exclusive to multiome samples is that the paired presence of mRNA transcripts and open chromatin region indicates a likely regulatory relationship. It is worth investigating if integration methods could help recover these gene-peak associations in unpaired single-modality data. To answer these questions, we benchmarked 7 integration methods that fall into 2 categories: (1) *unpaired* integration methods that ignore the paired information provided by multiome samples and integrate them as RNA-only/ATAC-only cells; (2) *unpaired + paired* methods that integrate three data types together by treating the multiome as the reference, or that embed the three datasets into one joint space in an unsupervised manner. Using 2 publicly available multiome datasets, we simulated the 3 data types by splitting multiome cells into RNA-only, ATAC-only, and RNA+ATAC datasets. We evaluated how cell number, sequencing depth, and presence of batch structure influences the performance. For each scenario, we evaluated performance on cell type identification, batch mixing, and the recovery of gene-peak pairs (for methods that can impute RNA expression for ATAC-only cells). Preliminary results show that annotation accuracy plateaued after a certain number of multiome cells. Thus, when identifying 6 or 7 cell types, no further improvement is gained after 2000 multiome cells. Among the methods, Seurat 4, Seurat 3, and MultiVI consistently performed best at cell type identification. Seurat 3 and FigR were better at recovering gene-peak pair. However, even the best performing method only recovered 60% of gene-peak pairs. Thus, this benchmarking project serves as a guide for integrating single-cell unpaired and paired multi-omics data.

Omics Technologies Posters - Thursday

PB2918. Benchmarking NGS Integration Site Analysis Methods in Support of Long-Term Safety Monitoring of Cell and Gene Therapy Products

Authors:

J. Otto¹, Y. Fan¹, G. Bao¹, D. Corney², Q. Yu¹, B. Khan¹, L. Turner¹, C. Mozdierz¹, H. Latif¹, G. Zhou¹; ¹Azenta Life Sci., South Plainfield, NJ, ²Azenta, South Plainfield, NJ

Abstract Body:

The FDA Guidance to Industry on Long Term Follow-Up (LTFU) After Administration of Human Gene Therapy Products states the importance of longitudinal testing of gene products introduced into human subjects. Depending on the delivery mechanism, the therapeutic gene product may or may not integrate into the genome. Of particular interest are gene-product integrations near proto-oncogenes which might lead to malignancies. The FDA LTFU guidance states that recipients of an integrating gene therapy modality should be tracked for 15 years, while those receiving a non-integrating therapy modality should be tracked for 5 years. Therefore, advanced analytical methods are needed to identify, quantify, and track integration events across the genome. Here, we provide a comprehensive evaluation of methods leveraging next-generation sequencing approaches for genome-wide analysis of lentiviral integration events. Our analysis employed well-characterized standards consisting of varying copy number and known integration sites.

The approaches we characterized can be bucketed into two major groups: PCR amplification approaches and target capture-based approaches. All methods detected true positives with strong correlation to theoretical integration site dosage levels down to 1% allele frequency. Comparatively, PCR amplification-based approaches have lower data requirement per sample suggesting higher sensitivity, greater molecular capture, and lower limit of detection compared with target enrichment-based approaches. Target enrichment-based approaches can afford the flexibility to capture the integrated vector, which is of interest for characterizing partial integration events. While all methodologies performed well in our study, the choice of assay (or assays) for testing will depend on numerous factors including but not limited to the viral vector system and construct and starting material availability.

Omics Technologies Posters - Wednesday

PB2919*. Benchmarking of computational methods for ancestry prediction from RNA-seq data.

Authors:

A. Yadav¹, Y. Patel¹, W. Wen², S. Mangul¹; ¹Univ. of Southern California, Sch. of Pharmacy, Los Angeles, CA, ²Univ. of Southern California, Keck Sch. of Med., Los Angeles, CA

Abstract Body:

Advances in omics technologies have reshaped the landscape of current research providing a rich set of tools and methods. Of late, much interest has also been placed on identifying the role of genetic architecture on differential risk patterns based on admixture or one's ancestry. Outside of the gold-standard traditional methods such as WGS (whole genome sequencing), WES (whole exome sequencing) or genotype data from the 1000 Genomes project, RNA-sequencing (RNA-seq) is now popularly used to call genomic variants providing inferred estimates for single nucleotide variants (SNVs) via the GATK pipeline. RNA-seq is a prominent technology for transcriptome profiling and provides accurate measurement of the level of transcripts and genes, and is highly favorable for its low usage costs. The aim of our study is to utilize the SNVs inferred from RNA-seq data to accurately predict both global and local genetic ancestry based on individual genetic variants inferred from RNA-seq data to capture the proportion of ancestral estimates across the genome and locus specific allelic ancestral effects respectively. We then compared the ancestry inferred from RNA-seq to the gold standard methods (WGS, WES or genotype data) inferred from genomics data and identified differences and measurements for percentage of accuracy between the methods. These comparisons served as a benchmark method and in total, we have benchmarked 33 existing tools which were able to infer local and global ancestry from RNA-seq genetic variants and compared the RNA-seq based ancestry estimates with the ground truth. We also explore the effect of sequencing parameters such as the length of the RNA-seq reads, throughput and error rate. Finally, we compared the results from different tools' analyses and identified the tools with the best performance across various human populations. Our study highlights the use of RNA-seq data for ancestry estimation and will inform the genomics community about the best computational tools for identifying ancestries from RNA-seq data. We can leverage our benchmarking results that will allow the biomedical field to effectively annotate the much larger cohort of 80,000 public RNA-Seq samples to evaluate the complex population substructure by expression quantitative trait loci (eQTL) analysis within and across ancestries in a diverse cohort.

Omics Technologies Posters - Thursday

PB2920. Benchmarking splice variant predictive algorithms with saturation screens.

Authors:

C. Smith, J. O. Kitzman; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Messenger RNA splicing plays key roles in gene regulation and proteome diversification, and its disruption is implicated across a variety of human disease genes. Variants beyond essential splice dinucleotides can disrupt splicing but are challenging to identify due to the degenerate and redundant underlying sequence determinants. The over-representation of canonical splice mutations in clinical databases makes it difficult to establish a representative set of splice-disruptive variants to evaluate computational splice effect predictors. Massively parallel splicing assays (MPSAs) avoid this ascertainment bias by measuring the impact of all possible point mutations to nominate candidate splice disruptive variants. We compared high-throughput functional splicing measurements from four recent MPSAs (targeting exons of *BRCA1*, *POU1F1*, *RON*, and *FAS*) with predictions from seven contemporary variant prediction algorithms. We also benchmarked informatic predictors across a set of clinically observed variants in *MLH1* curated from the literature ($n=297$). As expected, a median of 94.5% of essential splice site mutations were correctly identified as disruptive across the tools, however at positions beyond splice sites, less than half (median across predictors=45.6%) of the splice-altering variants identified by MPSA were predicted as such informatically. Across tools and datasets, exonic variants were more challenging to predict than intronic ones. In 23 of 24 database/predictor combinations, the area under the balanced precision-recall curve (prAUBC) values - a metric of classifier performance - were lower for exonic vs intronic variants, a trend that holds even after removing canonical sites from the intronic sets. This result indicates these algorithms have room for improvement within exons. Pangolin and SpliceAI - two deep learning-based tools trained on gene annotations - corresponded best with MPSA-measured splicing outcomes, both at intronic and exonic positions (median prAUBC = 0.925 and 0.912 respectively). We then use the results of each MPSA screen and *MLH1* patient variants to propose a clinical threshold for each tool that best identifies splice disruptive variants. As a measure of genome-wide specificity, we then scored randomly selected genic variants with each tool, and found that at optimal cutoffs, the tools call 4.9-43.0% (median = 17.7%) of coding and proximal intronic SNVs as pathogenic, indicating that at acceptably sensitive empirically derived thresholds, splicing effect predictors may call a large number of false positives.

Omics Technologies Posters - Wednesday

PB2921. Beyond the "one gene, one disease" paradigm with DIVAs, an Explainable AI tool for phenotype-driven digenic variants interpretation.

Authors:

F. De Paoli¹, G. Nicora¹, I. Limongelli¹, **E. Rizzo**¹, P. Magni², R. Bellazzi², S. Zucca¹; ¹enGenome S.r.l., Pavia, Italy, ²Dept. of Electrical, Computer and BioMed. Engineering, Univ. of Pavia, Pavia, Italy

Abstract Body:

Introduction

Extending genetic analysis beyond the "one gene, one disease" paradigm can significantly uplift the diagnostic yield for rare diseases. To support scientists in the investigation of complex inheritance patterns, enGenome developed DIVAs, a phenotype-driven Artificial Intelligence (AI) tool for digenic variant interpretation that prioritizes the causative digenic combination among thousands. DIVAs can identify Dual Molecular Diagnoses (DM), wherein two disease-causing primary variants in two different genes lead to two independent clinical diagnoses, True Digenic combinations (TD), where the mutations co-occurrence in the two genes is required to trigger the disease and Composite combinations (CO), with a driver-modifier mechanism.

Materials and Methods

DIVAs is an ensemble of AI classifiers trained on almost 400 pathogenic digenic combinations extracted both from DIDA (<http://dida.ibsquare.be>), from an internal curated dataset and on a large set of benign combinations. Starting from the patient's variants, our tool computes all possible digenic combinations and exploits gene-gene interaction, gene-phenotypes association and variants impact to evaluate each gene pair. Unlike other recent tools (ORVAL, DiGePred), DIVAs also considers the patient's traits, expressed through Human Phenotype Ontology (HPO) terms, to identify the causative digenic combination. Family analysis mode is also available. Once a causative digenic combination is identified, DIVAs applies on it an additional layer of AI, based on the SHAP Explainability (XAI) methodology. The combination can be further subclassified as DM or TD/CO, allowing the user to further investigate the digenic mechanism.

Results

On 500 repeated hold-out, DIVAs showed promising results (94% of sensitivity, 97% of precision and 99% of specificity). Among 500 samples analyzed so far, here we focus on 18 clinical samples with heterogeneous phenotypes (e.g. skeletal dysplasia, hearing impairment), whose genetic diagnosis includes two concurrently mutated genes. DIVAs was able to predict as pathogenic the causative digenic pairs in 77% of them (14 out of 18). On 8 predicted pathogenic gene pairs with known digenic mechanisms, DIVAs correctly subclassified 7 of them (3/4 DM and 4/4 TD/CO). Benchmark analysis with currently available automatic digenic interpreters, such as ORVAL and DiGePred, is ongoing.

Conclusion

DIVAs is a reliable tool to identify digenic combinations. Applied to undiagnosed cases, it can uncover missing heritability of genetic disorders and uplift the diagnostic yield.

Omics Technologies Posters - Thursday

PB2922. Biallelic *CORO1A* Mutation in a Patient with Late-onset Cutaneous Tuberculosis, Epidermodysplasia Verruciformis, and Staphylococcus Aureus Infection

Authors:

H. Vahidnezhad¹, L. Youssefian², F. Palizban³, A. Saeidian⁴, A. Tavasoli¹, J. Park⁵, M. Mesdaghi⁶, H. Mahmoudi⁷, S. Zeinali⁸, V. Béziat⁹, J-L. Casanova¹⁰, J. Uitto¹; ¹Thomas Jefferson Univ., Philadelphia, PA, ²Dept. of Pathology and Lab. Med., David Geffen Sch. of Med., Univ. of California Los Angeles, Los Angeles, CA, ³Lab. of Complex Biological Systems and Bioinformatics, Inst. of Biochemistry and Biophysics, Univ. of Tehran, Tehran, Iran, Islamic Republic of, ⁴Children's Hosp. of Philadelphia, Philadelphia, PA, ⁵Geisinger Commonwealth Sch. of Med., Scranton, PA, ⁶Immunology and Allergy Dept., Mofid Children's Hosp., Shahid Beheshti Univ. of Med. Sci., Tehran, Iran, Islamic Republic of, ⁷Dept. of Dermatology, Razi Hosp., Tehran Univ. of Med. Sci., Tehran, Iran, Islamic Republic of, ⁸Dept. of Molecular Med., Biotech Resea, Tehrn, Iran, Islamic Republic of, ⁹Imagine Inst., Paris Univ., Paris, France, ¹⁰The Rockefeller Univ., New York, NY

Abstract Body:

Biallelic mutations in the *CORO1A* gene causes severe combined immunodeficiency (SCID) with susceptibilities to multiple infections including granulomatous tuberculoid leprosy, epidermodysplasia verruciformis, HHV-4, molluscum contagiosum, mucosal HHV-1, HHV-3, HHV-8 and visceral leishmaniasis. We describe a novel association of a homozygous *CORO1A* with late-onset cutaneous tuberculosis (CTB) and Staphylococcus aureus infection. Clinical and immunological evaluations, including fluorescence-activated cell-sorting and lymphocyte-transformation test, provided evidence for immunophenotype of SCID. Combined whole-exome sequencing and genome-wide homozygosity mapping were utilized to disclose candidate sequence variants. With a novel bioinformatic pipeline we utilized whole-transcriptome sequencing (RNA-Seq) to concomitantly detect the viral and bacterial agents and the consequences of detected sequence variants in the host. The proband, a 17-year-old male, was found to be homozygous for the *CORO1A*:NM_007074:exon3:c.248_249del: p.P83Rfs*10, this variant was located inside the 26 Mb of runs of homozygosity on 16p11. RNA-Seq confirmed the deleteriousness of the *CORO1A* variant in four skin biopsies revealing significant downregulation of *CORO1A*. Reads unaligned to the human genome were applied to a catalog of 926 different viruses, and pathogenic bacteria, β -HPV5, Mycobacterium tuberculosis (TB) H37Rv, and Staphylococcus aureus were detected. Collectively, we describe a previously unrecognized inborn error of immunity to CTB, indicating that autosomal recessive *CORO1A* deficiency can underlie EV and CTB. In addition, we innovatively harnessed the RNASeq data to detect abnormal microbiota underlying recalcitrant skin lesions.

Omics Technologies Posters - Wednesday

PB2923*. Blended Genome Exome (BGE) Sequencing as an Alternative to SNP Arrays for Cost Effective Imputation of Variants in Globally Diverse Cohorts.

Authors:

M. DeFelice, J. Grimsby, M. Lee, D. Zdeb, S. Anderson, B. Blumenstiel, G. Nakashian, S. DeLuca, M. Giles, M. Cipicchio, S. Chapman, C. Stevens, H. Huang, K. Yuan, D. Howrigan, A. Martin, B. Neale; The Broad Inst. of MIT and Harvard, Cambridge, MA

Abstract Body:

Due to the cost of whole genome sequencing it is not yet economical to sequence high-coverage genomes for large cohorts of samples. As a result, researchers often combine single nucleotide polymorphism (SNP) array data with whole exome sequencing to capture both rare and common variants for the study of associations between genetic variants and disease. However, SNP arrays have been developed primarily based on data from European populations impacting their utility for population genetic estimates and analyses in more diverse global populations. To overcome the bias introduced by the selection of specific probes on an array, we developed a combined, “blended genome exome” (BGE) in which we construct PCR-free whole genomes, take an aliquot for PCR amplification, select the exome from the amplified genome through hybridization and capture, blend the exome libraries (33%) back with the PCR-free whole genome libraries (67%) (same index ligation event) into a single tube, and sequence them together (Illumina Nova S4, 2x151 bp reads, 64 samples/lane). This creates a single BAM file with a low-coverage whole genome combined with a higher coverage exome that can be used for imputing variants throughout the genome. Using high-throughput processing (384 sample batch sizes), reduced-reaction volumes and automated liquid-handling, we produced 836 BGEs from blood and saliva-derived DNA (including 64 South African, 320 Ethiopian, and 384 Chinese) samples yielding, on average, 2.6x estimated whole genome coverage and 34.1x mean exome coverage per sample. Prior development experiments showed >0.99 r^2 concordance between 30X whole genome sequencing data and imputed data derived from BGEs using Genotype Likelihoods Imputation and Phasing Method (GLIMPSE). Use in non-European association studies was the original driver for creating this new BGE sequencing product, but it will likely prove useful in many areas of genomics (i.e. polygenic and monogenic risk scores) due to its low cost, ease of lab-processing, and the quality of the data that it provides for accurate imputation of genome wide genetic variants. The process also enables the flexibility to utilize specific portions of the workflow for other non-BGE methods (i.e., exome only, non-exome targeted panels, PCR-free whole genome).

Omics Technologies Posters - Thursday

PB2924. Brain transcriptomic profiling of Parkinson's disease patients reveals disease stage specific gene expression patterns.

Authors:

C. Cappelletti¹, S. P. Henriksen², H. Geut³, A. J. M. Rozemüller³, W. D. J. van de Berg³, L. Pihlstrøm², M. Toft²; ¹OsloMet, Oslo, Norway, ²Oslo Univ. Hosp., Oslo, Norway, ³Vrije Univ.it, Amsterdam, Netherlands

Abstract Body:

Parkinson's disease (PD) is a neurodegenerative disorder mainly characterized by the appearance of motor symptoms and, in approximately 30-60% of the patients, by the development of dementia in later stages of the disease (PDD). Protein aggregates, called Lewy bodies (LBs), can be found in neurons and neuronal processes of all patients. LBs appear in different brain regions with a specific pattern described by the Braak staging system. LBs can also be found during routine postmortem examination in the brains of clinically healthy individuals that are regarded as pre-symptomatic PD individuals, termed incidental Lewy body disease (iLBD). The etiology of PD and PDD has not been elucidated yet. Genome-wide transcriptomic studies have implicated a variety of molecular mechanism in PD and PDD pathogenesis. However, these studies focused on differences between clinically defined groups and had some limitations: a small sample size, low quality samples and exclusion of long non-coding RNAs. In this study we meticulously collected the frontal cortex from a total of 84 donors including neurologically healthy controls, iLBD, PD and PDD individuals and we sequenced both the coding and non-coding RNAs. We divided our samples in four groups based on their Braak stage aiming to recapitulate disease progression. Using this setup and carefully selecting the covariates to include in our analysis, we found no differences in cell composition between the neuropathological groups. Moreover, we discovered major transcriptional changes, involving also lncRNAs, in the frontal cortex when LBs first appear in this brain region. We provided insights into the pathological mechanisms driving PD and PDD development showing functional enrichment of pathways related to mitochondrial dysfunction throughout all Braak stages. We found enrichment of pathways related to the immune response up-regulated in early stages and down-regulated in late stages of the disease (Braak stage 1-4 and 6, respectively), whereas Braak stage 5 was characterized by the functional enrichment of brain specific pathways. Additionally, we reported an association between a PD risk variant and the expression of its nearest gene.

Omics Technologies Posters - Wednesday

PB2925. Breast Cancer Specific Enhancer-Interactome Analysis Identifies Candidate Target Genes Enriched in Common Variant Risk Regions

Authors:

B. Davis¹, F. Segato Dezem², K. Ayaluri², S. Chen³, S. Gayther², J. Plummer²; ¹Cedars Sinai, LOS ANGELES, CA, ²Cedars Sinai Med. Ctr., Los Angeles, CA, ³Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract Body:

Chromatin interaction data from genome-wide interactome methods like HiChIP can provide context-specific resolution to validate candidate genes associated with common variant risk regions identified in genome wide association studies (GWAS) that are predicted to connect with functionally significant regulatory elements (REs). We used this principle to identify novel candidate genes in breast cancer risk regions where no gene associations have been found and to validate previously identified candidate susceptibility genes using transcription wide association studies (TWAS). We established enhancer-interactomes for normal breast cancer precursor cells (MCF10a) and ER+ breast cancer cells (MCF7) and then integrated this disease-specific looping data with 150 fine mapped breast cancer risk regions and 132 candidate susceptibility genes. HiChIP identified strong evidence for multiple interactions between risk alleles and gene promoters in breast cancer risk regions. We identified 3,627 genomic interactions in MCF7 cells and 374 genomic interactions in MCF10a cells linking the most likely target gene to risk alleles, gene promoter and one or more enhancers. These data show that genetic risk at chromatin loops is relevant for understanding breast cancer genetics. We interrogated global contact propensity and cell type specificity of looping for our candidate genes and detected 15,899 differential loop regions (DLR) between MCF7 and MCF10a, representing 7.8% and 20.4% of the interactions respectively. These quantitative differences in contact frequency were associated with larger changes in gene expression, assessed through RNA sequencing. We found 15 eQTL associated genes specific to MCF7 in DLRs enriched in MCF7 cells in connection with an enhancer, and 6 eQTL genes in DLRs in MCF10a cells connected predominantly with enhancers. HiChIP offers high resolution and validation of putative target genes because looping is relatively static, helping inform on the context-specific nature of disease pathogenesis. In summary, this study describes a functional framework to provide a greater understanding of the biological significance of risk alleles and candidate gene targets at breast cancer susceptibility loci identified by GWAS.

Omics Technologies Posters - Thursday

PB2926. Building a transcriptomic atlas of adult human ovarian tissue to gain insight into folliculogenesis.

Authors:

D. Hannum¹, A. S. K. Jones¹, S. Hammoud¹, J. Li², A. Shikanov¹; ¹Univ. of Michigan, Ann Arbor, MI, ²Univ Michigan, Ann Arbor, MI

Abstract Body:

Background: Folliculogenesis in the ovary is the process by which female germ cells develop into a mature fertilizable egg. As part of the Human Cell Atlas Seed Networks, we used the emerging technologies of single-cell RNA sequencing (scRNAseq) and spatial transcriptomics to generate a comprehensive map of the adult human ovary. One of our goals is to gain deeper insights into the steroidogenic cells, which play a crucial role in folliculogenesis. **Methods:** We used the NanoString GeoMx platform to generate spatial transcriptomic data for 74 Regions of Interest (ROIs), selected by staining patterns of DAPI and several histological markers. RNA samples from individual ROIs were profiled for ~18,000 coding genes. Separately, we used the 10X Genomics platform to collect scRNAseq data for >21,000 dissociated cells from the ovaries of three healthy donors. **Results:** After stringent QC, cluster analysis of our scRNAseq data revealed four major cell types: stroma, immune, pericyte, and endothelial cells. The immune cells can be further separated into T cells, natural killer cells, macrophages, and mast cells. Refinement of the stroma cluster proved to be more difficult, as these cells occupy a continuum of transcriptome states. Iterative re-clustering, velocity analysis, marker gene-based scoring, and comparison to NanoString data helped to define a provisional set of 14 stroma sub-clusters, two of which were annotated as steroidogenic cells. By leveraging differentially expressed genes between the granulosa-enriched and theca-enriched ROIs from GeoMx data we were able to distinguish subtypes of steroidogenic cells in the scRNAseq data. Other GeoMx ROIs included a set of 12 consecutive cortical layers to study the gradual change of transcriptomic profile from the surface of the cortex towards medulla, and multiple concentric rings surrounding the oocyte in antral follicles. **Conclusion:** By using both scRNAseq and spatial transcriptomics we were able to create an atlas of cell types and spatial gene expression patterns in healthy ovarian tissue. The two data types reinforce each other, especially for subtypes of stromal cells that are difficult to distinguish by using one data type alone. These data resources contribute to the Human Cell Atlas' goal of building a reference catalog of cell types, molecular features, and spatial organization of healthy human tissues.

Omics Technologies Posters - Wednesday

PB2927. bulk and single-cell gene co-expression network analysis of AD using PyWGCNA

Authors:

N. Rezaie, A. Mortazavi; Univ. of California, Irvine, Irvine, CA

Abstract Body:

Mouse models of human diseases such as Alzheimer's disease (AD) are one of the most important tools for studying pathogenic mechanisms and testing interventions and therapeutics. While much of the characterization of gene expression changes to date has been done with “bulk” RNA-seq in tissues such as the hippocampus and cortex, the advent of single-cell and single nucleus functional genomics assays allows us to analyze those changes at the level of individual cell subtypes. However, we would like to compare the relatively sparse and noisy single-cell assays to bulk RNA-seq to deconvolve which cells are driving the changes observed in the previously collected bulk datasets.

Here we develop a python package called PyWGCNA that is designed to identify and compare gene co-expression modules in bulk RNA-seq data as well as compare them to scRNA-seq data and snRNA-seq clusters. As a proof of concept, we apply this to bulk RNA-seq of the cortex and hippocampus from 5xFAD and 3xTgAD as well as matching control mice from MODEL-AD to identify gene modules associated with the genotype and phenotypes. Comparisons of these modules to single-nuclei and modules associated with AD in humans from AMP-AD reveal the specific cell types driving specific modules in a region-specific manner. This deconvolution approach allows us to interrogate existing bulk datasets using single-cell data to look for the signature of cell-type-specific changes in gene expression.

PB2928. Calling structural variants in extended rat pedigree using PacBio HiFi sequencing.

Authors:

D. Chen¹, K. Nguyen¹, K. Cohen¹, O. Poleskaya¹, J. Sebat^{1,2,3,4}, A. Palmer^{1,2}; ¹Dept. of Psychiatry, Univ. of California San Diego, La Jolla, CA, ²Inst. for Genomic Med., Univ. of California San Diego, La Jolla, CA, ³Beyster Ctr. for Psychiatric Genomics, Univ. of California San Diego, La Jolla, CA, ⁴Dept. of Cellular and Molecular Med., Univ. of California San Diego, La Jolla, CA

Abstract Body:

Genome-wide association studies (GWAS) in mammalian model organisms, such as rats, are valuable compliments to GWAS in humans, and present the opportunity to confirm associations with direct experimental manipulations, which can elucidate novel biological mechanisms. However, determining the causal genes within an associated locus remains challenging for a variety of reasons. The causal alleles may not be single nucleotide polymorphisms (SNPs), and SNPs may not always adequately tag the causal variants, such as structural variants (SVs) and short tandem repeats (STRs). To address this limitation, we are using Pacific Biosciences (PacBio) high fidelity (HiFi) sequencing to discover structural variants and perform GWAS using SVs for gene expression and complex behavioral traits in rats. All analyses are performed on our in-house SVs calling using ~10x coverage HiFi reads. SVs discovery is being performed in the 8 inbred founders of the outbred heterogeneous stock (HS) population, which we are using for GWAS. By imputing SVs into the outbred population, we will be able to identify associations between SVs and a variety of traits in more than 10,000 outbred HS rats that have been extensively genotyped and phenotyped with the goal of revealing novel genetic mechanisms underlying drug abuse and other human diseases.

PB2929. Cas9 targeted enrichment and adaptive sampling for characterizing repetitive elements.

Authors:

C. Mumm, K. Van Deynze, W. Zhou, J. Switzenberg, C. Maltby, P. Todd, R. Mills, A. Boyle; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

The characterization of complex and repetitive structural variation in the genome remains a challenge using short read sequencing technologies. Examples of such variation include mobile element insertions (MEIs), short tandem repeat (STR) expansions, and Human Papilloma Virus (HPV) integrations. Transposable elements and viruses have the potential to cause disease through insertional mutagenesis as well as through effects on local gene expression and chromatin architecture, and accurate characterization of these elements is important in understanding about disease risk and clinical diagnosis. In addition, STR expansions are associated with over 50 neuropathological disorders and the mechanism by which these expansions bring about disease is not yet fully understood. Here, we combine two Oxford Nanopore Technology (ONT) long-read sequencing enrichment strategies to characterize repetitive elements, nanopore Cas9-targeted sequencing (nCAsTs) and readfish adaptive sampling. CRISPR-Cas9 enrichment uses sgRNA to selectively ligate adapters to target sequences and we use a combination of internal and flanking sgRNAs to capture our regions of interest. Computational selection during sequencing using readfish further allows us to enrich for our targets. Using these reads we can also investigate the CpG methylation at these loci and surrounding regions to further explore how they can contribute to disease. Additionally, we can use these techniques to identify events on a per-cell basis. We apply these techniques to selectively capture our targets and characterize complex structural variation in GM12878, as well as patient derived cell lines and tissues.

Omics Technologies Posters - Thursday

PB2930. Causal relationship analysis of DNA openness and RNA expression at the single cell level using scRNA-seq and scATAC-seq data.

Authors:

J. Park, B. Han; Seoul Natl. Univ. Coll. of Med., Seoul, Korea, Republic of

Abstract Body:

Single cell RNA sequencing (scRNA-seq) is widely used to analyze the expression environment of individual cells and classify the cell types. Recently, Assay for Transposase-Accessible Chromatin using sequencing (ATAC-seq) was also implemented at the single cell level. While RNA-seq can figure out the expression level of the gene, ATAC-seq can recognize whether the chromatin region is opened. In general, chromatin needs to be opened so that the general expression process involving the access of transcription factor (TF) into DNA can progress. Therefore, there is a causal relationship from chromatin openness to expression, and we can expect that this relationship can be inferred from the RNA-seq and ATAC-seq data. In this study, we tried to analyze whether ATAC-seq and RNA-data show any causal relationship, especially at the single cell level. If the causality is clear, the expression level of the gene will be high in the vicinity of the open region, and vice versa. We analyzed this relationship by employing the PBMC 10K public data provided by 10x genomics, in which scRNA-seq and scATAC-seq were performed simultaneously for the same cell. For analysis, we used Signac which is an R package for analyzing single-cell chromatin data (Stuart et al., 2021). We were able to obtain a notable correlation between gene expressions and open chromatin regions at the single cell level. For example, the Pearson correlation coefficient was 0.466 for a most correlated peak of *MS4AI*, and was 0.196 for *LYZ*. However, in the region where the expression count exists, a lot of cells with an open count of 0 were found (i.e. 889 cells out of 1366 *MS4AI* expressed cells, 6879 cells out of 7569 *LYZ* expressed cells). This phenomenon (expressions at not-detected-as-open region) was consistent with recent reports that the sensitivity of ATAC-seq was as low as 5-15% (Preissl et al., 2018). Because of this low sensitivity, the causal relationship between scATAC-seq and scRNA-seq could not be directly inferred from the current data. Until the sensitivity of ATAC-seq phenomenally increases in the future, it is unclear whether the development of a new methodology for modeling the causal relationship between openness and expressions will be necessary.

Omics Technologies Posters - Wednesday

PB2931. CCC: An efficient not-only-linear correlation coefficient based on machine learning.

Authors:

M. Pividori¹, M. D. Ritchie¹, D. H. Milone², C. S. Greene³; ¹Univ. of Pennsylvania, Philadelphia, PA, ²Univ. Nac. del Litoral, Consejo Nac. de Investigaciones Científicas y Técnicas (CONICET), Santa Fe, Argentina, ³Univ. of Colorado Sch. of Med., Aurora, CO

Abstract Body:

Background. New technologies have vastly improved data collection, generating a deluge of information across different disciplines that provides unique opportunities to address unanswered scientific questions. Correlation analysis is an essential statistical technique for discovering relationships between variables, and it has been used in exploratory data mining methods such as clustering or community detection.

These techniques compute a similarity value between a pair of variables of interest, such as genes or disease-relevant lifestyle factors. In transcriptomics, many genomic analyses start with estimating the correlation between genes. More sophisticated approaches built on correlation analysis can suggest gene function, capture important interactions in a living organism that can uncover molecular processes in other species, and reveal complex transcriptional mechanisms underlying human diseases. The Pearson correlation coefficient is widely used because it reveals intuitive relationships and can be computed quickly. However, it can only capture linear patterns and may miss complex yet critical relationships. Thus, improvements in these techniques could have enormous consequences in industry and research.

Methods. We introduce the Clustermatch Correlation Coefficient (CCC), an efficient not-only-linear coefficient based on machine learning models. CCC assumes that if there is a relationship between two variables measured on a set of objects, then the clusterings of those objects using each variable should match. CCC has a single parameter that limits the maximum complexity of relationships found and computation time. To assess its performance, we applied Pearson, Spearman, Maximal Information Coefficient (MIC) and CCC to gene expression data from GTEx and used the Genome-wide Analysis of gene Networks in Tissues (GIANT, without GTEx samples) for replication.

Results. CCC captured both strong linear relationships and novel nonlinear patterns, which were entirely missed by standard coefficients. For example, *UTY* and *KDM6A* (paralogs) showed a consistent nonlinear relationship across all tissues, which is explained by sex differences in expression. Gene pairs detected by CCC had significantly higher interaction probabilities in tissue-specific gene networks from GIANT. We also found that CCC behaves similarly to MIC, although it is up to two orders of magnitude faster to compute. Furthermore, the CCC's ability to efficiently handle diverse data types (including numerical and categorical features) reduces complex preprocessing steps and makes it appealing to analyze large and heterogeneous repositories.

Omics Technologies Posters - Thursday

PB2932. Cell manufacturing genome integrity analysis by optical genome mapping.

Authors:

A. Pang, A. Reyes, A. Chaubey, A. Hastie; Bionano Genomics, San Diego, CA

Abstract Body:

There are several types of cell lines and manufactured cell-based products used in research and therapeutics, such as transformed cell lines for constitutional and oncological research, stem cell lines like iPSC, CAR-T cells, and various types of engineered cells. Cells in culture can lose genome integrity often seen as structural and numerical abnormalities. While quality control (QC) by karyotyping is effective in detecting large DNA rearrangements, it is very low resolution, laborious, and highly specialized. PCR and targeted sequencing can characterize small variants at specific loci, but they are not able to identify rearrangements beyond the targets. Finally, while whole genome sequencing can identify small variants genome-wide, it has limited sensitivity in finding structural variants (SVs), especially at low allele fraction. Optical genome mapping (OGM) is an emerging technique for SV analysis in cell manufacturing applications. Here we present the performance of three workflows for genome integrity analysis. To detect clonal variants, 400 Gbp of data is collected from the pre-edited and edited samples. Homozygous or heterozygous SVs are called for each sample and then compared with a built-in comparison tool to identify unique SVs in the edited samples and not in the pre-edited controls. Alternatively, to discover somatic SVs down to 5% or 1% variant allele fraction (VAF), one would generate 1.5 or 5.0 Tbp of data with a longer machine run (24-65 hour runs). We designed a series of simulations to examine the limit of detection of OGM. We targeted a total coverage of 5 Tbp, and ran the SV analysis workflow to detect variants from 100% to <1% VAF. The results indicated that OGM has a sensitivity of detecting small insertions and deletions (> 5kbp) at about 0.25% to 2.5% with large megabase duplications, deletions, and translocations down to ~1%. We have applied clonal and subclonal workflows to verify integrity of genomes after cell line immortalization, induce pluripotency, transgene-integration, and gene-editing. With easy, cost effective, robust, and sensitive workflows, we envision that the OGM technique to be a valuable solution for genome modification and integrity QC.

Omics Technologies Posters - Wednesday

PB2933. Characterizing the genetic etiology of patients with neuromuscular disease through the integration of omics data

Authors:

V. Triassi^{1,2}, É. Bareke¹, S. Audet^{1,3}, C. Brunel-Guitton⁴, M. Tétreault^{1,3}; ¹CRCHUM, Montréal, QC, Canada, ²Dept. of BioInformatics, Université de Montréal, Montréal, QC, Canada, ³Dept. of NeuroSci.s, Université de Montréal, Montréal, QC, Canada, ⁴BC Children's Hosp., Vancouver, BC, Canada

Abstract Body:

Advances in sequencing technologies have played an important role in the molecular diagnosis of rare diseases, such as myopathies and muscular dystrophies. However, several patients with these neuromuscular diseases remain undiagnosed. This is due to the great clinical and genetic heterogeneity as well as the highly polymorphic nature of the genes associated with myopathies and muscular dystrophies. The interpretation of genetic data is a great challenge and genetic testing often results in the identification of variants of unknown significance. Several of these variants may disrupt normal RNA splicing or affect gene expression.

To determine if variants have a functional impact, our pipeline focuses on alternative splicing as well as the integration of exome and transcriptome data. Our aim is to put in place a pipeline identifying and characterizing variants of interest in a pathological context. We hypothesize that a portion of patients without a diagnosis for their neuromuscular disorder is explained by intronic variants having a regulatory role or affecting mRNA splicing and abundance. This multi-omics approach will make it possible to determine whether the variants have a functional impact.

To do so, we performed exome and RNA sequencing using muscle biopsies from 4 patients. Data was aligned with STAR (RNA) or BWA (exome) and annotated with ANNOVAR as well as custom scripts. To identify splicing events, we used two tools: SpliceAI, an effective tool to predict the impact of variants on alternative splicing, and rMATS, which best predicts whether an alternative splicing event occurs from exon-intron junctions. A combination of these two tools further increases detection efficiency. Since we do not have replicate for our data, an exploratory differential expression analysis was performed with LPEseq. Lastly, several custom python scripts filter and integrate transcriptomic and genomic data. For now, potential pathogenic variants are found for two of our patients, but further investigations are needed. The variants sought are rare and therefore require a coherent and efficient pipeline to facilitate the detection of these events. In addition, the integration of omics data provides a more interesting and prioritized gene research avenue. This project will have a significant benefit for patients by allowing them to obtain a diagnosis and thus have access to better clinical follow-up. Ultimately, we want to identify pathogenic variants for our patients with our pipeline, recruit additional patients without molecular diagnosis, optimize and automate the pipeline with the intention that it can be used by other researchers working on rare diseases.

Omics Technologies Posters - Thursday

PB2934. Characterizing the immune dysfunction in X-CGD using single-cell transcriptomics.

Authors:

S. Muzumdar¹, S. Ballouz², F. Lam³, M. DeGrange⁴, S. Kreuzburg⁴, H. Chong⁵, C. Zerbe⁴, A. Jongco³, J. Gillis⁶; ¹Cold Spring Harbor Lab., Cold Spring Harbor, NY, ²GARVAN Inst. OF Med. RESEARCH, Darlinghurst, Australia, ³Northwell Hlth.Long Island Jewish Med. Ctr., Great Neck, NY, ⁴NIAID/NIH, Bethesda, MD, ⁵Univ. of Pittsburgh Med. Ctr., Pittsburgh, PA, ⁶Donnelly Ctr. for Cellular + Biomolecular Res., Univ. of Toronto, Toronto, ON, Canada

Abstract Body:

X-linked chronic granulomatous disease (X-CGD) is a rare primary immunodeficiency affecting about 1 in 200,000 live births associated with specific bacterial and fungal infections owing to the inability of phagocytes to generate reactive oxygen species (esp. superoxides) due to inactivating mutations in cytochrome b-245, beta chain (*CYBB*), a key component of the NADPH oxidase complex. Patients and carriers are typically also subject to a higher burden of autoimmune morbidity indicating potential systemic consequences of the loss of *CYBB*. Constituting the largest sequenced cohort in X-CGD, we recruited 14 probands, 10 carriers, and 15 age- and sex-matched controls (onto IRB-approved protocol NCT00404560), and subjected total PBMCs and isolated monocytes to scRNA sequencing. Cluster-specific differential expression analysis revealed a predominant type I interferon-driven signal across all identified cell-type clusters. This was complemented by an enrichment of genes involved in antigen processing and presentation through the MHC class I pathway, important for presenting intracellular antigens to immunocytes, and crucial in maintaining self-tolerance as well as immunity from viruses and several intracellular bacteria. Interferon signaling and dysregulated antigen presentation have been previously implicated in several autoimmune processes, and might play an important role in driving the predisposition to autoimmunity seen in X-CGD probands and carriers. We were also able to define proband-derived, cluster-specific disease signatures which could differentiate carriers from controls in a train-test setting (average AUROC=0.79). Disease penetrance is linked with X-inactivation skew in carrier females, however, expression of these disease signatures appeared to be uncorrelated with residual oxidative burst in female carriers, pointing towards a non-cell autonomous origin. Expression of these signatures also appeared to be highly linked in control human data, as well as across several chordate species using 1-1 orthologs, suggesting the disruption of a deeply conserved mechanism crucial in immune homeostasis in X-CGD. Genes upstream of a canonical type I interferon response such as *IRF5* and *MNDA* were also observed to be highly co-expressed with *CYBB*, and might constitute novel drug targets in this disease.

Omics Technologies Posters - Wednesday

PB2935. Circulating proteomic signatures of pulmonary function

Authors:

M. Lee, S. J. London; NIH/NIEHS, Research Triangle Park, NC

Abstract Body:

Pulmonary function is the basis of COPD diagnosis and respiratory health. Many genes have been associated with pulmonary function from genomic and epigenomic studies; proteomic profiles have been less examined. We analyzed plasma proteomic profiles in relation to pulmonary function in 1828 participants in the Agricultural Lung Health Study, a case-control study of asthma nested within a farming cohort. Forced expiratory volume in one second (FEV₁) and forced vital capacity (FVC) were measured using spirometry, and 4979 human protein analytes were measured with the Slow Off-rate Modified Aptamer (SOMA)Scan platform. We evaluated associations between plasma protein abundances and pulmonary function traits: FEV₁, FVC, and FEV₁/FVC. Using robust linear regression, we modeled pulmonary function as the predictor of natural log-transformed analyte levels and adjusted for potential confounding factors. Seventy-five analytes were differentially abundant in relation to one or more pulmonary function traits after Bonferroni multiple-testing correction ($P < 1.0e-05$). A network constructed using the significant analytes using the STRING database had more protein-protein interactions than expected for a random set from all analytes examined ($P = 1.8e-08$). Follow-up analyses will include replication in an independent population and functional interpretation. To our knowledge, this is the first large-scale study of plasma proteins in relation to pulmonary function. Findings from this study could aid development of novel biomarkers of respiratory health.

Omics Technologies Posters - Thursday

PB2936*. Clinical genome and RNA sequencing with a novel, cheaper sequencing-by-synthesis technology

Authors:

P. Liu¹, J. Sinson¹, C. Yeh¹, K. Schulze¹, C. Eng¹, K. Worley¹, S. Pollock², I. Soifer², D. Lipson², Undiagnosed Diseases Network, B. Lee¹; ¹Baylor Coll. of Med., Houston, TX, ²Ultima Genomics, Newark, CA

Abstract Body:

Clinical genome sequencing has been shown to be effective in revealing molecular diagnoses for patients with Mendelian disorders. However, its clinical uptake is still lagging due to the high sequencing cost of most current technologies.

We have evaluated the analytical validity of a novel sequencing technology (Ultima Genomics) employing a mostly-natural sequencing-by-synthesis chemistry. The Ultima platform significantly reduces the cost of the sequencing consumable, and thus has the potential to overcome the high sequencing cost barrier.

Single nucleotide and insertion/deletion variants (SNVs, indels) were benchmarked in the sample NA12878. High-quality variant calling performance was observed across high-confidence non-repetitive genomic regions with accuracy for SNVs > 99% and error rate for indels < 0.5%. We found that the limitation of the technology is in calling indels in homopolymers >10nt, but anticipated this caveat to have minimal impact on the clinical diagnostic yield, as regions of long homopolymers tend to be intronic or non-genic.

We obtained high concordance results for >20 clinically confirmed pathogenic SNVs or indels both in the nuclear and the mitochondrial genome, including challenging regions where mapping is complicated by pseudogenes. We tested >25 clinically validated pathogenic copy number variants (1.6 kb-4.5 Mb in span), and 2 balanced structural variants. Each event was detected by a read-depth and/or a split-read algorithm.

Furthermore, we piloted a study in a different diagnostic context, bulk RNA-sequencing to clarify abnormal splicing consequence of disease-causing variants. By increasing the sequencing yield 20-30 fold (approximately >1 billion), i.e., DeepRNAseq over the standard 30-50 million read data output, challenging illegitimate splicing events in genes with low or promiscuous expression from clinically accessible tissues can be readily detected. We then performed RNA-sequencing at >100 million reads on multiple patient specimens with previously identified diagnostic splicing or expression abnormalities. The expected molecular findings were identified with similar or improved transcriptome analysis workflows that we previously implemented on Illumina data. Importantly, DeepRNAseq has the potential of increasing diagnostic yield in combination with WGS in undiagnosed disease cases by providing function correlation of genomic variants from accessible clinical tissues.

These data highlight the potential impact of low-cost sequencing technology on improving clinical diagnostic yields, increasing research discovery, and potentially, reducing disparity to genomic testing.

Omics Technologies Posters - Wednesday

PB2937*. Clinical use of the amniotic fluid cells transcriptome in deciphering Mendelian disease

Authors:

H-Y. Chung¹, M. Lee¹, A. S. Y. Kwong¹, M. M. C. Chui¹, J. F. T. Chau¹, C. C. Y. Mak¹, S. L. K. Au¹, H. Lo¹, K. Y. K. Chan¹, V. A. Yepez², J. Gagneur², A. S. Y. Kan¹; ¹The Univ. of Hong Kong, Hong Kong, China, ²Technical Univ. of Munich, Garching bei München, Germany

Abstract Body:

RNA sequencing (RNA-seq) is an emerging technology that is becoming increasingly useful to facilitate the detection and diagnosis of genetic disorders because it provides functional validation to support the interpretation of variants of uncertain significance (VUS). Blood, skin fibroblasts, and muscle are the most commonly used clinically accessible tissues for RNA-seq (Kremer et al., 2017; Fresard et al., 2019 and Vicente et al., 2022); however, the use of amniotic fluid (AF) cells, a prenatally clinically accessible tissue, has yet to be explored in RNA-seq.

Here, we examined the expression of clinically relevant genes in AF cells compared with blood and skin fibroblasts by collecting AF cells from 52 pregnant women to perform RNA-seq. Furthermore, we evaluated an RNA-seq analytical pipeline, DROP, in three prenatal cases with splice-region variants in *CHD7*, *MYRF*, and *COL1A2*.

We showed that AF cells have a similar expression profile to skin fibroblasts as they have a similar embryonic origin. The number of well-expressed genes in AF cells was comparable to that in skin fibroblasts and much higher than that in whole blood for 2,020 clinically relevant genes. Similar patterns were observed when analyzing their expression profiles in 11 disease categories.

Using AF cells RNA-seq with DROP, we successfully detected the disease-causing genes *CHD7*, *MYRF*, and *COL1A2* as splicing outliers. We demonstrated that AF cells RNA-seq is feasible and could be beneficial in prenatal diagnosis as transcriptomic data helped elucidate the molecular mechanisms of the candidate variants and upgraded the pathogenicity of VUS in *COL1A2*. It could also be a logical choice for postnatal patients with advantages over fibroblasts and whole blood as it avoids further invasive procedures. Moreover, the use of AF cells rather than blood in RNA-seq maximizes the number of testable genes. This study may lead a new era of non-invasive diagnostics for all patients whose AF is readily available.

Omics Technologies Posters - Thursday

PB2938*. Closing the gap: Solving complex medically relevant regions of the human Genome

Authors:

F. Sedlazeck¹, M. Mahmoud¹, H. Corbitt², J. Harting³, X. Chen³, S. Jhangiani¹, H. Doddapaneni¹, Q. Meng¹, T. Hon³, I. McLaughlin³, Y-C. Tsai³, T. Han², G. Metcalf¹, R. Gibbs¹, M. Eberle³, S. Kingan³, C. Morrison⁴, G. Henno³, D. Muzny¹; ¹Baylor Coll. of Med., Houston, TX, ²Twist BioSci., South San Francisco, CA, ³Pacific BioSci.s, Menlo Park, CA, ⁴Twist BioSci., Oceanside, CA

Abstract Body:

This year marks the release of an improved reference (T2T-CHM13), but despite this effort, many medically relevant regions within the human genome are still lacking detailed characterization with standard short-read methods due to their repetitiveness (*SMN1 and SMN2*), interaction with pseudogenes (*GBA*), and complex nature (*LPA*). Furthermore, several genes show complex mutational patterns that are challenging, but important to resolve. To overcome this at scale and cost-efficiently, we partnered with TWIST Bioscience and Pacific Biosciences to design and implement a long-read panel to capture the entire length of the 396 genes. Furthermore, we developed new computational approaches to optimize analytics to fully characterize the 396 genes across the human genome. These genes are reported to impact a range of diseases including neuropathies (~15%) to immunodeficiencies (~7%) down to vision-related diseases (1%) and also include cancer driver genes (e.g. *PTEN*). Over the past months, we have optimized this approach using Laboratory optimizations to improve the on-target rate (60%) and also evaluated PCR free methodologies to reduce GC bias. We will present results showing the ability to multiplex samples in a single HiFi SMRTcell, optimizing the cost and efficiency. In addition to the lab optimizations, we designed novel analytical methodologies to identify all types of variants. Most of these genes can be characterized and provide single nucleotide variants, small insertions and deletions, complex structural variation, and copy number alterations together with phasing information per gene, enabling the most comprehensive insight into the gene diversity. Additionally, our pipeline utilizes assembly approaches and specialized per gene methods (e.g. graph genomes) for certain complex genes such as *Cyp2d6*, *LPA*, and *SMN1&2* to detangle its complex repetitive nature and provide key insights into the e.g. mutations across the KIV-2 repeat unit. We demonstrate the utility of this panel across HG002, five control samples and have started to apply the panel across several research cohorts including cardiovascular and neurological phenotypes. Using these samples, we demonstrate highly accurate variant identification. Together using laboratory optimization and analytical development we present a cost-efficient method to further investigate medically relevant genes missing from existing short read datasets. Our approach is easily scalable, allowing it to be run with every short-read whole-genome data to improve key insights in the so-far dark regions of the human genome that play a critical role across a variety of diseases.

Omics Technologies Posters - Wednesday

PB2939. Combination of annotation enrichment approaches for characterization of blood-based RNA sequencing biomarkers.

Authors:

S. Listopad, T. M. Norden-Krichmar; Univ. of California, Irvine, Irvine, CA

Abstract Body:

Background: Gene set enrichment analysis is commonly performed on RNA sequencing (RNA-seq) biomarkers in order to glean biological insight. However, all annotation enrichment tools are inherently biased by the contents of their knowledgebases and statistical methods used. Our goal in this study was to apply four different enrichment analysis tools to our data in an effort to extract the maximum amount of information from our biomarker gene set. **Methods:** This study was conducted on RNA sequencing data from peripheral blood mononuclear cells (PBMCs) from participants, consented for an IRB-approved study in the Southern California Alcoholic Hepatitis Consortium (SCAHC), with alcohol-associated hepatitis (n=38), alcohol-associated cirrhosis (n=40), non-alcohol-associated fatty liver disease (n=20), chronic hepatitis C viral infection (n=19), and healthy controls (n=20). The RNA-seq data was aligned to the human genome hg38 using the STAR software and ENSEMBL gene annotation. Distribution normalized counts were generated using Cuffnorm, and differential expression analysis was performed using Cuffdiff. We identified a set of 75 genes that was highly effective at discriminating between the four liver diseases and controls. Annotation enrichment was performed on the 75 genes using four different software tools: Enrichr, Ingenuity Pathway Analysis (IPA), Gene Set Enrichment Analysis (GSEAPreranked), and BloodGen3Module. **Results:** Application of all four tools resulted in many common pathways, such as various immune system processes, complement cascade, inflammatory response, and oxidative stress. Additionally, the top enriched tissue gene sets across the four tools were peripheral blood, granulocytes, and neutrophils. However, there were also some differences in the results. For example, chemical and iron homeostasis were among the top hits returned by GSEAPreranked and IPA, but were absent from the Enrichr and BloodGen3Module top hits. GSEAPreranked returned very few statistically significant hits, while IPA, Enrichr, and BloodGen3Module resulted in up to hundreds of significant hits. **Conclusion:** Each of the tools tested had some advantages and disadvantages that primarily had to do with ease of use, availability of in-built visualizations, and quality of knowledgebase. However, when used in combination, we found that these tools provided confirmation of similar enrichment annotations, as well as complementary information and visualizations that added novel dimensions to the biological interpretation of our data. From these results, we encourage the use of multiple annotation enrichment tools for gene set analysis.

Omics Technologies Posters - Thursday

PB2940. Combination of low-coverage whole genome and deep-coverage exome sequencing is the cost-effective way to drive large-scale genetics studies forward.

Authors:

M. Yu^{1,2}, M. DeFelice¹, M. Daly^{2,1,3}, B. Neale^{2,1}, R. Xavier^{1,4,5}, D. Howrigan^{2,1}, A. Martin^{2,1}, K. Yuan^{2,1}, H. Huang^{2,1}; ¹Broad Inst. of MIT and Harvard, Cambridge, MA, ²Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA, ³Inst. for Molecular Med. Finland, Helsinki Inst. of Life Sci., Univ. of Helsinki, Helsinki, Finland, ⁴Dept. of Molecular Biology, Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, ⁵Ctr. for Computational and Integrative Biology, Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA

Abstract Body:

Over the past decade, large-scale genetic studies have been very successful in finding genetic loci associated with human complex traits and disorders. Given the high cost of deep whole genome sequencing, a commonly used strategy for large-scale genetic studies is to use genotyping array to capture genome-wide common variants and deep whole exome sequencing for rare coding variants. This strategy, however, complicates studies as the two technologies involves two independent pipelines with different equipment, experimental protocols, reagents, materials and technicians, increasing the cost of data generation. In addition, there has not been a widely accepted solution in harmonizing the two sets of genomic data generated using this strategy.

Here we introduce a new sequencing method that combines low-coverage whole genome sequencing with deep whole exome sequencing. Using PCR free library spiked into TWIST exome capture, sequencing of the genome-wide content and the deep exome content can be done in one experiment and the reads will be processed in a harmonized manner, reducing cost and batch effect.

We tested this new technology on 68 subjects diagnosed with the inflammatory bowel diseases (IBD), an autoimmune disorder implicated by both common and rare variants. We performed genotype imputation on low-coverage sequencing data using GLIMPSE, a recently published method tailored to this utility, and haplotype reference panel from Haplotype Reference Consortium. With 4x coverage, 99.64% variants in the reference panel with minor allele frequency(MAF) > 5% can be imputed with quality score > 0.8, and 98.69% for MAF > 1% variants. With 30x coverage in the exome, we captured 29919 coding variants that have MAF between 1% and 0.01% in the gnomAD callset, 11.56% of the total variants in the same MAF range captured in gnomAD callset.

We searched for the 45 established IBD causal variants (Huang et al., Nature 2017) in the sequencing data. These variants cover the full range of allele frequency (0.2% to 49.2%), located in both coding and non-coding genome, and include indels and splicing variants that can be challenging to capture by exome sequencing. Despite these challenges, our sequencing data covered all the sites for these variants.

In conclusion, we showed using a sequencing pilot on 68 IBD cases that our new method combining low-coverage whole genome and deep-coverage exome sequencing is a cost-effective approach to drive large-scale genetic studies for human complex disorders and traits across allele frequency spectrum.

Omics Technologies Posters - Wednesday

Hosp., Taipei, Taiwan, ⁴Graduate Inst. of Clinical Med., Natl. Taiwan Univ. Coll. of Med., Taipei, Taiwan, ⁵Dept. of Biomechanics Engineering, Natl. Taiwan Univ., Taipei, Taiwan

Abstract Body:

Structural variants (SVs) define as genomic changes > 50 bp, and SV calling tools with different algorithms have been proposed. Genome in A Bottle (GIAB) consortium has released a benchmarking workflow and large insertion/deletion variants (NIST_SV0.6) as the benchmark truth set. We adopted SV benchmarking pipeline and analyzed the truth set composition, including sequencing technologies, calling tools and variant sizes. We utilized HG002 35x WGS data to test different SV callers, including Dragen, Manta, Lumpy, Delly, GATKHC and the combination of their output. We evaluated caller performance by different SV types and variant sizes in each subset. We found Dragen had the highest recall rate (74%) in deletion. Delly and Lumpy were appropriate for detecting large size of deletions. In addition, we observed the combination of multiple callers' output could increase the overall recall rate. For large insertion, we found poor performance for short read data, with a higher false-negative rate (40%) than deletion. Even combination strategy cannot overcome it due to the lack of SV caller suitable for covering large size of insertions. In conclusion, we utilized the GIAB benchmarking pipeline to evaluate SV caller performance, especially in short-read data. Moreover, it could also designate the best combination of SV callers for clinical testing and population database.

PB2942. Community detection analysis in multilayer COVID-19 patient similarity networks

Authors:

P. Sliwa, COMBAT Consortium, H. A. Harrington, G. Reinert, J. C. Knight; Univ. of Oxford, Oxford, United Kingdom

Abstract Body:

Advancement of biological assays has enabled generation of datasets containing multiple modalities, such as single cell RNA-seq data and proteomics data, per patient for large cohorts. Integrating the information from different modalities is an open research challenge; a popular method is Similarity Network Fusion. Here we propose an alternative network-science based approach, where we construct patient similarity networks in a principled fashion, one network per modality, and then combine these similarity networks into a multilayer network. On this network, communities are detected using the Leiden algorithm. We apply this approach to a recent comprehensive multimodal dataset, the Covid-19 Multi-omics Blood Atlas (COMBAT), containing among others information on COVID-19 and sepsis patients and healthy volunteers across modalities spanning proteomics, bulk and single cell transcriptomics and mass cytometry, and explore the resulting communities for correlations with important clinical variables and activity of drug-relevant and immune system related molecular pathways. The analysis reveals a signal which differentiates between healthy, COVID-19, and sepsis patients. We show that using multilayer networks we can refine classifications made using one modality. Our pipeline can also be applied to other similar datasets and may help to better understand multimodal molecular health data.

Omics Technologies Posters - Wednesday

PB2943. Comparison of exome performance in an inherited cancer context

Authors:

C. Johnson, A. Ramesh, K. Shortt, K. Eyring, S. Raghunath; Intermountain Hlth.care, St George, UT

Abstract Body:

Background: Whole-exome sequencing has excellent utility in clinical genomics due to the breadth of coverage. In this setting however it is important to evaluate if the exome can detect clinically significant variants with high accuracy. In this study we compared 3 exomes (Agilent WESv7, Twist WES, and IDT Research Exome) and 2 panels (IDT Inherited Disease Panel and Agilent BrExome 1.3pM Panel) against cell lines with NIST high-confidence datasets and clinically relevant variants. These were evaluated for sensitivity (PPA) and positive predictive value (PPV), as well as coverage and other quality control (QC) metrics.

Methods: We sequenced 4 cells lines with NIST high confidence variants datasets (NA12878, NA24143, NA24631, and NA24694) to evaluate broad PPA and PPV of each panel. We also sequenced one engineered control with 22 SNVs and Indels relevant in inherited cancer, and 3 CNVs across 3 cell lines (NA02718, NA14626 and NA10401) to evaluate how the assays would perform on clinically relevant variants. BED files of regions common to all exomes or panels were generated for this analysis. QC was performed using Fastp and Picard. SNV and Indel calling was done using GATK. CNV calling was done using CNV Kit, ExomeDepth, and DECON.

Results: The two exomes which use UMIs (Agilent and IDT) had a similar mean depth of coverage, but the IDT exome had a higher % target bases covered at 50x than Agilent (80.1% vs 69.2%). This was true for the panel designs as well (89.4% vs 73.2%). For NIST cell lines, all 3 exomes had similar sensitivity, with IDT having higher mean PPA (99.7%), followed by Twist (99.5%) and Agilent (99.3%). Twist, with no UMIs, had a lower PPV than the other exomes. The Twist exome and Agilent panel had the highest PPA for tested clinically significant SNVs and indels (95.5%), followed by the IDT exome (90.9%). The Agilent exome had higher depth of coverage than IDT for these variants. All tested CNVs were detected using Decon and Exome Depth, and 2/3 using CNVKit.

Conclusions: This study suggests that the IDT exome had better coverage uniformity and higher overall PPA for exomes, while the Agilent exome had reads concentrated in clinically significant regions and higher PPA in panels. While the Twist exome had high PPA, it also had the lowest PPV.

Omics Technologies Posters - Thursday

PB2944. Comparison of genotyping arrays and low-pass sequencing for predictive genomics research.

Authors:

J. Gollub, A. Mittal, K. Schweighofer, J. Schmidt; Thermo Fisher Scientific, Santa Clara, CA

Abstract Body:

Predictive genomics is a powerful capability to help predict disease risk and understand drug response. Key considerations include high genome-wide coverage, high accuracy of genotyping calls and low cost. Genotyping by array has proven to be an excellent technology to support predictive genomics research, due to its overall high accuracy and favorable cost structure. Recently, low-pass whole genome sequencing (lpWGS) at a target coverage of 1x or less, combined with imputation, has emerged as a possible alternative technology. We compare the relative performance of lpWGS with respect to genotyping arrays. We focused on evaluating genome-wide imputation performance as well as the performance of calling specific variants of interest which had not previously been extensively investigated. We evaluated genome-wide imputation accuracy on 60 samples of European and African ancestries from the 1000 Genomes project. For microarray data we assessed imputation performance using the pan-ethnic Applied Biosystems™ Axiom™ PMD array. For lpWGS we used publicly available data at 0.5x and 1x coverage from Gencove [<https://gencove-sbir.s3.amazonaws.com/index.html>]. For the specific variant performance analysis, we used 44 samples of diverse ancestries with known pathogenic variants associated with severe Mendelian conditions or pharmacogenomic relevance. The samples were sequenced at a target coverage of 0.5x and 1x lpWGS and genotyped on CarrierScan 1S and PMD array. The PMD array showed an imputation accuracy comparable to 1x lpWGS for the European cohort, and between 0.5x and 1x lpWGS for the African cohort. For the 38 pathogenic variants associated with severe Mendelian conditions, the array provided 100% non-reference allele concordance (NRC) across all MAF ranges in 144 carriers and 25 affected individuals. In contrast, the NRC using lpWGS ranged between 95.1% (0.5x) and 97.6% (1x) for the common variants, between 87.5% (0.5x) and 93.8% (1x) for low frequency variants and between 73.3% (0.5x) and 96.7% (1x) for the rare variants. For the pharmacogenomic variants (N=3191), PMD array showed an overall NRC of 99.6±4.9 and lpWGS showed NRC of 96.1±12.8 and 97.3±10.4 for 0.5x and 1x respectively. In conclusion, our results show that low and rare frequency variants and the variants in complex regions cannot be imputed with high accuracy using lpWGS at a depth of 1x or less. On the other hand, these variants can be directly genotyped on the array, making microarrays well suited for predictive genomics research applications that rely on high genome wide imputation accuracy as well as highly accurate genotyping of specific variants of interest.

Omics Technologies Posters - Wednesday

PB2945. Competing sampling biases balance concordance of single-cell and nucleus RNA-seq

Authors:

J. Chamberlin¹, G. Marth², A. Quinlan³; ¹Univ. of Utah, Salt Lake City, UT, ²Univ. OF UTAH, SALT LAKE CITY, UT, ³Univ of Utah, Salt Lake City, UT

Abstract Body:

Single-nucleus RNA-seq (snucRNA-seq) is typically used as an alternative to single-cell RNA-seq (scRNA-seq) when dissociation of whole cells is problematic. Nuclei contain less RNA than cells, are depleted of mRNA (inferred from exon-mapped reads), and are enriched for pre-mRNA (inferred from intron-mapped reads). mRNA and pre-mRNA are subject to distinct sampling biases; however, the standard pre-processing workflow does not distinguish the origin of measured transcripts, which obfuscates these biases and their variable impact across cell types. In particular, mRNAs exhibit gene-specific localization within the cell, while pre-mRNAs are typically captured by a gene length-associated process called internal priming. Because pre-mRNA contributes more of the data in nuclei, overall gene abundance estimates show stronger length bias than in cells. Here, we re-analyze public scRNA-seq and snucRNA-seq data from mouse cortex in order to dissect the relative role of these biases across cell types, with an emphasis on a recently-published normalization method intended to increase comparability of the two assays by accounting for discrepant gene length (10.1101/gr.275509.121).

We show that pre-mRNA abundances are consistently more similar than mRNA abundances across all cell types. This is unsurprising given that all pre-mRNAs are inside the cell, but not all mRNAs are inside the nucleus. However, we also find that the proportion of pre-mRNA captured in nuclei is not predictive of the proportion in cells of the same type, such that the magnitude of inter-assay gene length bias is variable and unpredictable. These properties are important to the proposed normalization scheme, which attempts to remove gene length bias by scaling all pre-mRNA derived transcript counts by a factor of gene length, indirectly increasing the relative contribution of mRNA sampling. We observe adverse performance in nearly every cell type, and that performance is worst where inter-assay gene length bias is smallest.

These results are not inconsistent with those reported in the original study system, where the relative difference in pre-mRNA content between cells and nuclei was considerably higher than any cortex cell type. However, they suggest that normalization of raw data is only appropriate when pre-mRNA bias is stronger than mRNA bias, inference of which is only possible when matched samples are available. We argue that data should be pre-processed in a manner conducive to assessing these sampling biases and suggest that post hoc normalization is more appropriate in typical experiments.

Omics Technologies Posters - Thursday

PB2946. Comprehensive characterization of structural variants in human brain genomes using single flow cell nanopore sequencing protocol

Authors:

M. Kolmogorov¹, K. Billingsley², M. Mastoras³, M. Meredith³, R. Lorig-Roach³, P. Jerez¹, L. Malik¹, K. Shafin⁴, T. Pesout³, P. Carnevali⁵, A. Rhie⁶, M. Jain⁷, S. Scholz⁶, B. Traynor⁸, W. Timp⁹, A. Phillippy¹⁰, F. Sedlazeck¹¹, C. Blauwendraat⁶, B. Paten³, R. Karra¹²; ¹NIH, Bethesda, MD, ²NIH, Bethesda, MD, ³Univ. of California, Santa Cruz, Santa Cruz, CA, ⁴Google LLC, Mountain View, CA, ⁵Chan Zuckerberg Initiative, Redwood City, CA, ⁶NIH, Bethesda, MD, ⁷Northeastern Univ., Boston, MA, ⁸Natl. Inst Aging, Bethesda, MD, ⁹Johns Hopkins Univ., Baltimore, MD, ¹⁰NIH/NHGRI, Bethesda, MD, ¹¹Baylor Coll. Med., Houston, TX, ¹²Lab. of Neurogenetics, NIA, NIH, Silver Spring, MD

Abstract Body:

Many recent studies highlighted the improved capability of long-read sequencing to detect structural variation in the human genome. Long read sequencing was also recently used to produce the first complete assembly of the human genome by the Telomere-to-Telomere consortium. Further, Human Pangenome Reference Consortium has recently released 30 nearly-complete haplotype-resolved human genomes from diverse backgrounds sequenced using multiple long-read technologies.

Despite the recent advances, the cost of generating long-read sequencing remains a barrier for large-scale association studies. In this work, we developed a specialized DNA preparation protocol for Oxford Nanopore PromethION to optimize the yield of a single flow cell. We combined it with a novel computational pipeline to produce haplotype-resolved de novo assemblies and characterize small and structural genomic variants. The developed protocol is currently being used to sequence 4000+ human brain samples at the Center of Alzheimer and Related Dementias at the NIH.

Using our DNA preparation protocol we produced Oxford Nanopore sequencing data for three cell lines (HG002, HG02723, HG00733) and 15 postmortem brain tissue samples from the National Institute of Aging collection. Each genome was sequenced using one flow cell, on average yielding 142 Gb of reads with average read N50 30 kb.

We performed reference-based small variant calls using PEPPER-Margin-DeepVariant, and compared the performance against Illumina and HiFi-based variant calls. On the HG002 genome within the GIAB confidence intervals, our SNP calls outperformed Illumina calls (F1-score 0.9976 vs 0.9965). HiFi calls slightly improved over ONT-based calls (F1-score 0.9986 vs 0.9976). Two other cell line datasets showed similar small variant detection performance. In difficult-to-map regions, the improvement of ONT-based SNP calls over Illumina becomes more noticeable: MHC F1-score 0.9946 vs 0.9732, SegDup F1-score 0.9799 vs 0.9512.

Next we used Shasta to assemble each genome into haploid contigs. To produce haplotype-resolved assemblies, we developed a new pipeline called Hapdup that converts a haploid assembly into a pair of locally phased haplotypes. The resulting assemblies had mean NG50 ~20 Mb with base-level quality ~QV35.

Using the generated assemblies, we produced structural variant (SV) calls via reference alignment. On HG002 genome, Shasta/Hapdup SV calls had slightly better concordance with GIAB HG002 callset (F1 score = 0.9555), compared to Sniffles2 (F1-score = 0.9523). Hifiasm assemblies produced using HiFi and parental Illumina data only slightly improved on both approaches (0.9628).

Omics Technologies Posters - Wednesday

PB2947. Comprehensive detection of trait-associated structural variations using short read sequencing data.

Authors:

C. Terao¹, S. Kosugi¹, Y. Kamatani², K. Tomizuka¹, Y. Momozawa¹, T. Morisaki², The Biobank Japan Project; ¹RIKEN IMS, Yokohama, Japan, ²The Univ. of Tokyo, Minato-ku, Tokyo, Japan

Abstract Body:

Genomic structural variation (SV) affects genetic and phenotypic characteristics in diverse organisms, but the lack of reliable methods to detect SV has hindered genetic analysis. We developed a computational algorithm (MOPline) that iteratively merges optimized overlapping calls from multiple algorithms in each SV category to increase precision and genotypes SV sites including reference alleles to increase recall using short-read whole genome sequencing (WGS) data. The genotyping method, called SMC, restores missing variants and increases high confidence variants by ~43%. Evaluation with multiple real datasets demonstrated that the SV detection and genotyping accuracy of MOPline outperforms existing SV detection and genotyping algorithms. Validation using NA12878 PacBio CCS long-read alignment data showed 95-98% precision for any SV types except for INVs. Using 414 high coverage 1000 Genomes WGS data and 3,258 BioBank Japan (BBJ) WGS data, MOPline stably detected ~16,000 SVs per individual, which is over 2-fold higher than previous large-scale projects while exhibiting a comparable level of the statistical quality metrics. Principal component analysis and allele frequency comparison using the detected SVs and SNVs showed that the genetic architecture in multiple populations observed for the SVs was consistent with that observed for the SNVs. The overall AF concordance of common SVs matched between the BBJ-SVs and gnomAD-EAS-SVs was 0.94 (Pearson correlation coefficient). BBJ-SVs included many rare coding SVs that disrupt known and potential novel disease risk genes and common SVs in high linkage disequilibrium with published disease genome-wide association study (GWAS) variants. Using the BBJ-SVs as a reference panel, we imputed SVs from 181,622 Japanese individuals for 42 diseases and 60 quantitative traits. SVs had lower imputation quality than SNVs in the lower AF range, but almost 90% of SVs were imputed with > 85% overall precision. GWAS with the imputed SVs revealed 41 top-ranked or nearly top-ranked genome-wide significant SVs, including 8 exonic SVs with 5 novel associations (height-associated 1.9 Kb DEL in *MUC22*, HbA1c- and MCHC-associated 119 Kb DUP in *GYPB/GYPB*, ALP-associated 24 Kb DEL in *FUT2*, and A/G-associated 23 Kb DEL in *RP11-219A15.2*). The trait-associated DELs and INVs were enriched for DNase I transcription factor footprints and mobile element insertions, respectively. These results demonstrate that short-read WGS data can be used to identify rare and common SVs associated with a variety of traits. The methodology and the SV datasets created in this study provide a valuable resource for SV analyses in diverse research areas.

Omics Technologies Posters - Thursday

PB2948. Comprehensive discovery of CRISPR-targeted sequences in the human gut metagenome

Authors:

R. Sugimoto, L. Nishimura, I. Inoue; Natl. Inst. of Genetics, Mishima, Japan

Abstract Body:

Bacteriophages, or phages, are viruses that infect bacteria. There are about 10^9 viruses per gram of human stool. Through lytic or lysogenic interaction, these viruses involve the bacteria composition and diversity in the human intestine. The intestinal bacteria play important roles in human health. On the other hand, the implication of bacteriophages to human health remains unknown due to the little knowledge about them. To understand viral evolution and its interactions with the hosts, viral genomes provide essential information. Metagenomics, a method that sequences all DNA extracted from a given sample, became a popular approach to collecting unculturable viral genomic sequences. However, there are several challenges to extracting viral genomes from metagenomic sequences. Firstly, there is no marker gene for viruses such as the 16S rRNA which is commonly used for bacteria studies. Secondly, the majority of viral genes show little or no homology to known genes. Therefore, we need a method to detect viral sequences from the metagenome without relying on reference genes. For this, we developed a virus detection method that utilizes CRISPR. CRISPR is a prokaryotic adaptive immunological memory that encodes the fragments of viral genomes previously infected the cell. Using these viral genome fragments, we successfully discovered about 11 thousand complete viral genomes from human gut metagenome datasets. The discovered genomes include 4 novel Jumbo-phages and many small novel phages. Furthermore, we resolved the hosts of nearly 70% of discovered viruses. This host information could be particularly useful for some clinical applications such as phage therapy. We continuously apply our method to further metagenome sequences from a variety of environments and will provide a comprehensive viral genome database which will be basal information to resolve the implication of phages to human health.

Omics Technologies Posters - Wednesday

PB2949. Comprehensive Structural Variant Detection: From Population to Mosaic level

Authors:

L. Paulin¹, M. Smolka¹, C. M. Grochowski², M. Mahmoud^{1,2}, S. Behera¹, M. Gandhi³, K. Hong⁴, D. Pehlivan^{2,5}, S. Scholz^{6,7}, C. M. B. Carvalho^{3,2}, C. Proukakis^{8,9}, F. Sedlazeck^{1,10}; ¹Baylor Coll. of Med. Human Genome Sequencing Ctr., Houston, TX, ²Dept. of Molecular and Human Genetics Baylor Coll. of Med., Houston, TX, ³Pacific Northwest Res. Inst., Seattle, WA, ⁴Bionano Genomics, San Diego, CA, ⁵Div. of Neurology and Dev.al NeuroSci., Dept. of Pediatrics, Baylor Coll. of Med., Houston, TX, ⁶NIH, Bethesda, MD, ⁷Johns Hopkins Univ. Med. Ctr., Baltimore, MD, ⁸Univ. Coll. London, London, England, United Kingdom, ⁹Aligning Sci. Across Parkinson's (ASAP) Collaborative Res. Network, Chevy Chase, MD, ¹⁰Dept. of Computer Sci., Rice Univ., Houston, TX

Abstract Body:

Long read Structural Variation calling remains a challenging, but a highly accurate way to identify simple and complex genomic alterations. To address this challenge, we developed Sniffles2, a successor to SV-detection method Sniffles. Sniffles2 increases both accuracy (e.g., genotype and insertion sequence), speed (higher parallelism), and has more advanced functionality to further promote new insights into the organism or diseases. Sniffles2 outperforms its closest competitors (e.g., SVIM and CuteSV) in the well-established GIAB benchmark, both in terms of accuracy and speed. Additionally, Sniffles2 also outperforms its competitors in the more challenging SV data set across 386 medically relevant challenging genes, where Sniffles2 is 12% more accurate than the second-fastest SV caller and almost 10 times faster than the second most accurate. Furthermore, Sniffles2 solves the problem of population level SV calling by producing fully genotyped VCF files orders of magnitude faster than current methods. Sniffles2 population mode introduces a gVCF file concept to then, efficiently and accurately identify SV across a collection of samples from familial trios up to large-scale cohorts of hundreds to thousands of individuals. We used Sniffles2 population mode coupled with copy number data to determine the breakpoints of complex SVs in individuals affected with a Mendelian disease that often is caused by extreme complex alleles impacting the *MECP2* gene at the Xq28 locus. Sniffles2 is able to detect a complex allele which consists of a duplication-normal-duplication (DUP-NML-INV/DUP) with breakpoints spanning segmental duplications. Moreover, we also used Sniffles2 population mode to improve tumor-normal comparison and detected multiple candidates including deletion of the two exons of the *PTEN* gene in the COLO892 cancer cell line. Sniffles2 further enables the detection of somatic SV across bulk long-read data. We used Sniffles2 somatic mode on the genomic data from the brain of a patient with multiple system atrophy, a rare sporadic neurodegenerative condition similar to Parkinson's disease, with 55x WGS ONT coverage. We were able to identify multiple somatic SVs for this brain region. For example, a repeat contraction in *KCNIP4* an interactor of neuronal voltage gated potassium channels. We are now applying Sniffles2 across 4000 brain samples across multiple neurological diseases. Thus, overall demonstrating the utility and versatility of Sniffles2 to identify SV from mosaic to population levels and pushing the field of SV calling further.

Omics Technologies Posters - Thursday

PB2950. CRISPR Streamline: Creating a Pipeline That Evaluates Phenotype Information From Off-Target Sequence Identification

Authors:

P. Anderson¹, J. Gold¹, K. Pinnipati¹, C. Viridi¹, J. Davidson²; ¹California Polytechnic State Univ., San Luis Obispo, CA, ²Cal Poly, San Luis Obispo, San Luis Obispo, CA

Abstract Body:

CRISPR/Cas9 is a tool which is undergoing rapid growth in the fields of genetic engineering due to its ability to target edits to highly specific genomic sequences in vivo. However, suboptimal gRNA design can lead to frequent off-target splicing events at unintended genome locations which can greatly decrease CRISPR/Cas9 efficiency. Numerous bioinformatics programs exist which attempt to predict potential off-target sites within genomes, however, no such programs exist to further predict potential phenotypic effects from those off-target splices despite the value such information holds to scientists. Here we present, Crispr Streamline: a command-line program which builds on the previously established off-target prediction tool FlashFry by passing output genome locations to the ClinVar database as a means of predicting consequential phenotypic effects. This program accumulates in a web-based tool which is freely accessible for those performing CRISPR/Cas9 experiments or gRNA validation. Optimal design of such gRNA's is crucial to genome editing success and is an active area of study in bioinformatics. Previous observations reveal that CRISPR/Cas9 gRNA sequences frequently introduce double strand breaks (DSB's) unintentionally at sites outside a target gene commonly referred to as off-target sites, due to mismatched base pairing between gRNA and genomic sequences. Introduction of DSB's at off-target's compromise overall sequence specificity and genome editing efficiency for any CRISPR/Cas9 system, hence it is of great importance to be able to predict the locations and effects of off-target's associated with any gRNA sequence for optimization before in vivo experiments. Crispr Streamline is a program that utilizes a contemporary off-target identifier and genomic databases containing phenotypic annotation data to predict both the locations and phenotypic consequences of potential off-target sites in the GRCh38 human reference genome from target sequence input. Omics Technologies Posters - Wednesday

PB2951. Cryptic splice variants contribute to the genetic etiology of congenital heart disease

Authors:

R. Lesurf¹, J. Bouwmeester¹, G. Persad¹, R. Yao¹, T. Papaz¹, G. Blue², C. Bezzina³, D. Winlaw⁴, S. Mital¹; ¹The Hosp. for Sick Children, Toronto, ON, Canada, ²The Children's Hosp. at Westmead, Westmead, Australia, ³Amsterdam Univ. Med., Amsterdam, Netherlands, ⁴Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract Body:

Congenital heart disease (CHD) affects 1 in 100 live births and is a leading cause of neonatal deaths. Pathogenic variants in protein-coding regions and in canonical splice sites have been associated with CHD. Yet 80% CHD cases remain gene-elusive using conventional genetic testing. Recent developments into deep-learning classifiers (e.g. SpliceAI) have extended our ability to accurately identify cryptic splice variants outside of canonical splice sites, which in turn have established a role for cryptic splice variants in human diseases such as cardiomyopathy. Our goal was to investigate the role of cryptic splice variants in CHD. We performed whole genome sequencing (WGS) in 1264 CHD probands and their family members, including 839 probands with tetralogy of Fallot (TOF) and 229 probands with D-transposition of the great arteries (TGA). 1,002 patients were gene-elusive i.e., did not harbor pathogenic coding or canonical splice site variants. Within these gene-elusive probands, we searched for rare (gnomAD popmax allele frequency < 0.0001), cryptic splice variants (SpliceAI delta score > 0.65), in 158 Tier 1-3 known and candidate disease-causing CHD genes that have an autosomal dominant mode of inheritance. This identified 32 rare cryptic splice variants in 3% of TOF probands and 2% of TGA probands. Variants were observed in seven genes associated with isolated CHD (Tier 1), nine associated with syndromic CHD (Tier 2), and five candidate CHD genes (Tier 3). The effect of the putative cryptic splice variants was validated in RNA-sequencing and proteomics profiles generated from myocardium available in 101 TOF probands, further supporting their pathogenicity. These findings demonstrate that cryptic splice variants contribute to the genetic etiology of CHD, and underscore the improvement in genetic yield with WGS compared to standard clinical and exome tests.

Omics Technologies Posters - Thursday

PB2952. Custom morphology markers allow better tissue stratification to study tumor heterogeneity using NanoString® GeoMx® Cancer Transcriptome Atlas

Authors:

J. Runyon, V. Baichwal, C. Nievera; Canopy BioSci.s, St. Louis, MO

Abstract Body:

Understanding tissue heterogeneity is a key goal in oncology research and new spatial biology technologies are now available to address this. These platforms provide spatial context about cells and their interactions within a tissue or tumor sample while also producing high-plex gene expression data. The NanoString® GeoMx® Digital Spatial Profiler platform combines spatial and molecular profiling technologies and uses fluorescently labeled morphology markers to guide selection of regions of interest on tissue samples. These markers broadly target tumor and immune cells within tissue, while the probes from these regions of interest are collected and analyzed to generate gene expression profiles for each sample.

To evaluate the capability of this technology to selectively enrich specific cell types, we stained tonsil sections with CD3 and CD20 and compared transcriptional profiles and determined whether they reflected those of T and B lymphocytes. In other experiments regions of interest in tonsil sections were segmented into CD4 and CD8 positive sub-populations. Analysis of the transcriptional profiles with cell deconvolution algorithms confirmed enrichment of these T-cell sub-types. Using similar approaches, segmentation of adenosquamous lung carcinoma samples with markers specific for squamous cell carcinomas (p40) and adenocarcinoma (TTF-1) revealed significant differences in transcriptional maps of these two tumor cell types.

For all experiments, transcriptional profiles were assessed with the Cancer Transcriptome Atlas (CTA), a sequencing panel for the GeoMx platform that covers 1,800 key oncology gene targets to profile the tumor, tumor microenvironment and immune response. Analysis of this data set was performed using the GeoMx DSP Analysis Suite software. The findings, including the inferred presence or absence of specific cells based on gene expression profiles, support the notion that custom morphology markers enable better tissue stratification providing more meaningful gene expression analysis data. Studies with additional tumor types and different morphology markers are ongoing to further explore utility of this technology for analyzing gene expression in specific cells within different tumor types.

Omics Technologies Posters - Wednesday

PB2953. D-CoMEx: Differential co-expressed module extraction to identify phenotype-specific miRNA biomarkers related to diseases.

Authors:

T. Kakati^{1,2}, D. Bhattacharyya², J. Kalita³, T. Norden-Krichmar¹; ¹Univ. of California, Irvine, Irvine, CA, ²Tezpur Univ., Tezpur, India, ³Univ. of Colorado, Colorado Springs, Colorado Springs, CO

Abstract Body:

Introduction: Investigating mRNA-miRNA associations helps reveal how they regulate biological pathways and contribute to diseases. In this study, we report a novel method, D-CoMEx (Differential Co-expressed Module Extraction) to extract differentially co-expressed (DCE) modules from mRNA-miRNA expression data to ascertain interactions between miRNA and dysregulated biological pathways.

Methods: The proposed approach integrates a co-expression network (CEN) module extraction technique, THD-Module Extractor, with a differential expression analysis technique. Using THD-Module Extractor, the co-expressed modules were extracted from control and disease states of both mRNA and miRNA expression profiles of Parkinson's disease (PD) and Breast Cancer (BC) datasets. Differential co-expression analysis was performed on the mRNAs and miRNAs of the co-expressed modules extracted from the disease datasets. The differentially co-expressed mRNAs and miRNAs which were found to be dysregulated across control and disease states were then mapped to pathways using the ToppGene Suite, Panther, and MiRSystem. From the dysregulated pathways, we filtered the miRNAs using a reverse search technique in DIANA (mirPath v.3).

Results: D-CoMEx identified biologically and statistically significant dysregulated pathways from the DCE mRNA and miRNA modules of both datasets. For example, Apoptosis signaling and Dopamine receptor mediated signaling pathways were found to be significant for PD, and pathways such as T-Cell receptor and WNT signaling pathways were identified for BC. The corresponding miRNAs associated with these pathways may be potential biomarkers regulating progression of the two diseases. Several examples of the miRNA biomarkers mapped from dysregulated pathways related to PD were hsa-miR-195 and hsa-miR-153, while miRNA biomarkers mapped from pathways related to BC were hsa-miR-205 and hsa-miR-155. The proposed approach, D-CoMEx outperformed the existing methods, namely, DCGL, MODA and DiffCoEx, in terms of statistical and biological significance of the dysregulated pathways.

Conclusion: D-CoMEx identified miRNA biomarkers in dysregulated pathways mapped from differentially co-expressed modules of mRNA-miRNA expression profiles which were related to the etiology of the PD and BC diseases. This approach and analysis of dysregulated pathways focused on pathway-miRNA interactions, which may aid in further understanding these diseases.

Omics Technologies Posters - Thursday

PB2954. *De novo* variant detection with HiFi reads

Authors:

J. A. Lake, W. J. Rowell, M. A. Eberle; Pacific BioSci.s, Menlo Park, CA

Abstract Body:

Unencumbered by the process of selection, *de novo* mutations (DNMs) are more likely to be deleterious than inherited variants and account for much of the variation driving rare disease. Spontaneous germline mutations are implicated in many severe early-onset genetic diseases such as congenital malformation syndromes and neurodevelopmental disorders and postzygotic (somatic) mutations are the primary cause of cancer. Advances in genomic technologies, especially the development of whole-genome sequencing (WGS), have enabled detection of DNMs, thereby increasing discovery rates of causal variants in rare undiagnosed genetic disease studies. However, many rare disease cases with a strong presumption of a genetic cause remain unexplained despite comprehensive short-read WGS.

Compared to short reads, high-quality long reads provide a more complete assessment of global variation, improving detection of both small variants and structural variants (SVs) especially in difficult-to-map regions of the genome that are not accessible with short-reads. While detection and identification of true *de novo* variants can be important for identifying the causes of rare diseases, a high false-positive (FP) rate can also increase the burden of manually curating call sets. To appropriately leverage the strengths of HiFi sequencing in detection of DNMs, we must first establish a baseline.

To quantify the number of *de novo* single nucleotide variants (SNVs), small indels (<50 bp), and SVs, we analyzed trios using sequence data derived from either cell lines or blood where each sample was sequenced with PacBio HiFi reads to ~30x depth. Additionally, because parents are often sequenced to lower depth, we quantified the *de novo* variation identified from a high-depth (~30x) proband with two low-depth (~10x) parents.

In three trios where blood-derived DNA was sequenced, the total number of *de novo* variants detected in each child ranged from 501 to 742, including 25 to 41 SVs, 114 to 197 SNVs and 501 to 742 small indels. In two trios sequenced from cell lines, the total number of *de novo* variants detected in each child ranged from 555 to 2086, including 48 to 69 SVs, 176 to 1350 SNVs, and 310 to 688 small indels. Reducing the parental sequencing coverage from ~30x to ~10x in these two samples increased the number of variants identified as *de novo* variants by 49% and 264%. We will develop and present a more extensive analysis using larger pedigrees to further assess the FP *de novo* rate by variant type, and characterize reference regions where these putative *de novo* variants are found. These results support development of strategies for reducing FPs, especially in trios with low-depth parental sequencing.

Omics Technologies Posters - Wednesday

PB2956. Deep immune repertoire analysis of SARS-CoV-2 antibodies from a vaccinated human patient via mass-spectrometry and synthetic long reads.

Authors:

N. Castellana¹, T. Lima¹, S. Bonissone¹, A. Patel¹, R. Carson¹, R. Kelley²; ¹Abterra BioSci.s, Inc., San Diego, CA, ²Element BioSci.s, San Diego, CA

Abstract Body:

The immune system of an individual contains the capacity to produce trillions of unique antibody proteins. Identifying the antibodies selected for secretion in serum is key to understanding the human immune response to disease and crucial for future antibody therapeutic development. Mass spectrometry can be used to analyze serum antibodies that are reactive to a target, however, recovering complete antibody sequences requires a comprehensive database of candidate antibodies. Deep antibody repertoire analysis from B cell sequencing can provide this database but is currently expensive and low throughput. The combination of synthetic long read technology and high-throughput short read sequencing is a cost-efficient method to enable deep immune repertoire analysis. In this study, blood was collected from a human donor vaccinated against SARS-CoV-2. One hundred million B cells were isolated from whole blood and sorted based on B-cell receptor (BCR) reactivity to the SARS-CoV-2 receptor binding domain (RBD), with collection of both reactive and non-reactive B cells. LoopSeq synthetic long reads and the AVITI sequencing platform were used to sequence antibody variable regions of both samples. Serum antibodies from the same donor were enriched for reactivity to RBD and spike trimer, analyzed by mass spectrometry, and matched to the NGS-derived antibody repertoire using the Alicanto platform to identify antibodies critical to the SARS-CoV-2 immune response.

Omics Technologies Posters - Thursday

PB2957. Deep learning approaches for predicting virus integration sites in the host genomes

Authors:

Z. Zhao^{1,2}, H. Xu¹, J. Jia^{1,2}; ¹Univ Texas HSC Houston, Houston, TX, ²MD Anderson UTHlth. Graduate Sch. of BioMed. Sci., Houston, TX

Abstract Body:

Background: Virus infection is commonly observed in nature. Recently, SARS-CoV-2 has caused a global pandemic with over 530 million infected cases (as of June 9, 2022). Currently, the main challenges include effective detection of viruses in the host cells and predicting how they interrupt gene regulation in the host genomes. **Methods:** To predict virus integration sites (VISs) in the host genomes, we first collected and curated highly accurate VISs in the literature. Such VISs are typically discovered from next generation sequencing data followed by experimental validation. Then, we developed two deep learning methods based on a convolutional neural network (CNN) architecture with attention mechanism: DeepVISP for VIS prediction and motif discovery of oncogenic DNA viruses and DeepHTLV for VIS prediction of retroviruses. **Results:** Using our benchmark VIS datasets (77,632 VISs from 108 studies covering 15,064 target genes of five DNA viruses and four retroviruses), DeepVISP achieves high accuracy and robust performance for DNA viruses through automatically learning informative features and essential genomic positions from the DNA sequences. Our comparison with classical machine learning methods indicated an enhancement of 8.43-34.33% area under curve (AUC) values. Many promising *cis*-regulatory factors involved in virus integration were identified, such as HOXB7, IKZF1, and LHX6. DeepHTLV has similar VIS prediction when applied to human T-lymphotrophic virus 1 (HTLV-1), which has the largest VISs in the retrovirus category. Decoding the informative features captured by DeepHTLV resulted in eight representative clusters with consensus motifs for potential HTLV-1 integration. DeepHTLV revealed many interesting *cis*-regulatory elements in regulation of VISs. Literature evidence demonstrated nearly half (34) of the predicted transcription factors were involved in HTLV-1 associated diseases. **Conclusion:** We introduce robust deep learning models, DeepVISP and DeepHTLV, for rapid and accurate VIS prediction from primary sequence information. DeepVISP and DeepHTLV can elucidate the *cis*-regulatory landscapes of VISs in both oncogenic DNA viruses and retroviruses, respectively.

Omics Technologies Posters - Wednesday

PB2958. Deep plasma protein profiling of Alzheimer's subjects with a novel unbiased and scalable proteogenomics approach

Authors:

A. Siddiqui, M. Zamanighomi, H. Guturu, J. Wang, T. Huang, R. Benz, S. Batzoglu; Seer, Redwood City, CA

Abstract Body:

Biofluids are a rich source of protein biomarkers for early detection of diseases, but the large dynamic range of protein concentrations in some biofluids like plasma necessitates complex workflow and trade-offs between throughput, coverage, and precision. Here we use an unbiased, deep, and rapid proteome interrogation approach, which leverages multiple physicochemically distinct nanoparticles to provide broad coverage of the plasma proteome at scale. In this study, we aim to identify protein biomarkers that distinguish early and late-stage Alzheimer's disease (AD) from blood plasma. Plasma samples from 200 subjects, comprising 100 AD and 100 controls, were interrogated using the Proteograph™ Product Suite (Seer Inc.). Proteins were quantified by data-dependent acquisition (DDA) and data-independent acquisition (DIA) liquid-chromatography mass-spectrometry (LC-MS) analysis. Across the samples, DIA detected 39,699 peptides, and 5,060 plasma proteins. DDA yielded similar results, detecting 36,496 peptides, and 4,706 proteins. Additionally, for DDA data, we performed a semi-tryptic peptides and phosphorylated peptides search, which increased the peptide identification by 41%, and the protein group identification rate by 2%, resulting in higher sequence coverage per protein. Differential expression analysis using DDA/DIA peptide intensities from the cohort showed 788, 96/608, 83 significantly over-expressed peptides and 132, 93/85, 74 significantly under-expressed peptides for age and sex, respectively. Furthermore, 126/129 protein groups were identified that are enriched in the early stage of AD; resulting in a robust classifier with blood plasma samples that can separate healthy controls from any stage of AD with an AUC-ROC of 0.75/0.72. Finally, pQTL analysis was conducted on a subset of the individuals (139) genotyped on the Global Screening Array platform. We used BOLT-LMM to apply a simple linear model with a χ^2 statistic with 1-degree of freedom to establish significance of association between every SNP and Protein:Nanoparticle intensity. We further performed shuffled cohorts for FDR < 0.01 to achieve high confidence in our associations. We were able to identify 73/59 cis-pQTLs associated with 20/20 proteins and 41/38 SNPs, and approximately 1,527/3,288 trans-pQTLs from DDA/DIA. These analyses identified a combination of known and potential new candidate plasma protein markers, demonstrating the Proteograph platform's ability to perform unbiased, deep, and rapid interrogation of the plasma proteome, enabling large-scale studies to detect novel insights with clinically relevant potential.

Omics Technologies Posters - Thursday

PB2959. DeepCell, A novel cell type specific marker detection machine learning tool for single cell transcriptome

Authors:

A. Ali¹, N. Nassir¹, A. Ahmed¹, A. Nazir², M. Uddin^{1,3}; ¹Mohammed Bin Rashid Univ. of Med. and Hlth.Sci., Dubai, United Arab Emirates, ²Zayed Univ., Abu Dhabi, United Arab Emirates, ³GenomeArc Inc., Cellular Intelligence Lab, Toronto, ON, Canada

Abstract Body:

We can gain critical insight into the development and differentiation of multicellular organisms at the cytological level using single cell transcriptomics. However, due to a lack of robust cell marker genes, cell type annotations pose a challenge. In this study, we try to develop a method for detecting markers in single cell clusters. DeepCell is a tool that uses machine learning algorithms, characteristically, artificial neural networks and support vector machines to annotate cell types from single cell transcriptome data. DeepCell was applied to Single nuclei sequencing data from brain tissues of patients with progressive supranuclear palsy (PSP), in addition to publicly available data such as single cell transcriptome data from the developmental single cell atlas of gene regulation and expression. This facilitated detecting robust gene markers relevant for different cell types. We were able to correctly discern cell types using pretrained DeepCell with high classification accuracy (greater than 90%) and minimal running time. The analysis identified known canonical gene markers of sub clusters such as *GFAP* in astrocytes from the PSP data, in addition to, *NPHS2* and *SLC12A1/NKCC2* in podocytes and thick ascending limb of the loop of Henle respectively using metanephric data from the fetal single cell transcriptome atlas. We were also able to find less well-known gene markers such as, *OBII-ASI* in astrocytes and *KIRREL3* in podocytes, which clustered well within their respective cell types ($P < 1.00 \times 10^{-3}$). To identify other novel markers, this analysis was repeated for multiple cell types in different tissues. DeepCell is an efficient method that uses multiple machine learning algorithms to identify gene markers with good performance on real Single cell genomics data in terms of sub cluster annotation and novel marker identification.

Omics Technologies Posters - Wednesday

PB2960. DeepConsensus v0.3: Gap-aware sequence transformers for sequence correction.

Authors:

A. Belyaeva¹, G. Baid¹, D. E. Cook¹, K. Shafin¹, T. Yun¹, F. Llinares-López¹, Q. Berthet¹, A. Töpfer², A. M. Wenger², W. J. Rowell², H. Yang¹, A. Kolesnikov¹, W. Ammar¹, J-P. Vert¹, A. Vaswani¹, C. Y. McLean¹, M. Nattestad¹, P-C. Chang¹, A. Carroll¹; ¹Google LLC, Mountain View, CA, ²Pacific BioSci.s, Menlo Park, CA

Abstract Body:

Pacific Biosciences (PacBio) circular consensus sequencing (CCS) generates long (10-25 kb), accurate "HiFi" reads by combining serial observations of a DNA molecule into a consensus sequence. The standard approach to consensus generation uses a hidden Markov model (pbccs). We have developed DeepConsensus, a deep-learning based approach for correcting errors in HiFi sequence data. DeepConsensus uses a novel alignment-based loss to train a gap-aware transformer-encoder (GATE) for sequence correction. Here, we introduce DeepConsensus v0.3, which includes significant speed and accuracy improvements.

DeepConsensus v0.3 reduces errors in PacBio HiFi reads and improves Q30 yield by 62% compared to pbccs in human sequence data (an improvement of 12% from DeepConsensus v0.2). Additionally, DeepConsensus v0.3 reduces model runtime by 4.5x compared to v0.2. These improvements are achieved via changes to the training data (CHM13), filtering (at read and window level), and model architecture. For downstream applications, DeepConsensus has been shown to improve the contiguity, completeness, and correctness of genome assembly when compared to assemblies generated using pbccs reads. DeepConsensus also demonstrates improved accuracy of variant calling when using DeepConsensus reads in comparison to pbccs reads. Instructions for downloading and using DeepConsensus v0.3 are available at <https://www.github.com/google/deepconsensus>.

Omics Technologies Posters - Thursday

PB2961. *DeepLoop* robustly maps chromatin interactions from sparse allele-resolved or single-cell Hi-C data at kilobase resolution

Authors:

S. Zhang, D. Plummer; Case Western Reserve Univ., Cleveland, OH

Abstract Body:

Hi-C has transformed our understanding of mammalian genome organization and can reliably identify high-order 3D genome features such as compartments and topological associated domains (TADs). However, the Hi-C contact heatmaps quickly become noisy due to the increasingly complex bias structure and severe data sparsity. To date, genome-wide mapping of chromatin loops, especially the enhancer-promoter (E-P) interactions within TADs (sub-TAD), remains a major challenge in Hi-C analyses. Here we present DeepLoop, which performs rigorous bias-correction followed by deep-learning-based signal-enhancement for robust chromatin interaction mapping from low-depth Hi-C data. The lower limit of read depth is ~10M mid-range cis contacts, typically can be obtained from 50~100M total reads. Nearly all published Hi-C datasets have adequate reads for DeepLoop reanalysis. Existing single-cell Hi-C technologies can yield enough reads from a few dozen cells. DeepLoop also achieves a cross-platform convergence between different Hi-C protocols and micro-C. DeepLoop allowed us to map the genetic and epigenetic determinants of allele-specific (AS) chromatin interactions in human genome. We nominate new loci with AS-interactions governed by imprinting or allelic DNA methylation. We also discovered that in the inactivated X chromosome (Xi), local loops at the DXZ4 “megadomain” boundary escape X-inactivation, but the FIRRE “superloop” locus does not escape. Importantly, DeepLoop can pinpoint heterozygous SNPs and large structure variants (SVs) that cause allelic chromatin loops, many of which rewire enhancers with transcription consequences. Taken together, DeepLoop expands the use of Hi-C to provide loop-resolution insights into the genetics of 3D genome.

Omics Technologies Posters - Wednesday

PB2962. DeepMod2: A deep learning framework for DNA and RNA modification detection using Oxford Nanopore sequencing.

Authors:

M. Ahsan¹, A. Goulu¹, K. Wang^{1,2}; ¹Raymond G. Perelman Ctr. for Cellular and Molecular Therapeutics, Children's Hosp. of Philadelphia, Philadelphia, PA, ²Dept. of Pathology and Lab. Med., Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

DNA and RNA modifications, such as 5-methylcytosine (5mC) and N6-methyladenosine (m6A), play important regulatory roles in gene transcription, translation and other biological processes. Additionally, base analogs with synthetically introduced DNA or RNA modifications can serve as markers for DNA replication speed and transcription velocity in a variety of biological contexts.

DeepMod2 is a deep learning framework for DNA and RNA modification detection using Nanopore sequencing. It extracts features from ionic current signals of Nanopore sequencing and uses deep neural networks to identify modified bases at single-base and single-molecule resolution. DeepMod2 expands upon our previous work, DeepMod, by enabling modification detection from FAST5 files generated by Guppy basecalling or Tombo resquiggle, with a significant improvement in runtime and accuracy. For genome-wide methylation detection, given per-read predictions, DeepMod2 incorporates haplotype phasing with context-aware features such as CpG density and proximity to promoters and enhancers to produce accurate per-site predictions. Similarly, for RNA modification detection, DeepMod2 considers 3' UTR localization and short sequence motifs to accurately predict m6A methylation.

On the 72X HG002 ONT dataset, DeepMod2 can carry out whole genome 5mC detection in 45hrs using 16 CPUs, 1GPU, and 180GB of memory, achieving an F1-score of 99% for per-site modification detection. In addition to naturally occurring modifications, DeepMod2 also provides models for synthetic modifications such as IdU and BrdU. In summary, DeepMod2 allows accurate detection of base modifications from DNA or direct mRNA sequencing data on the Oxford Nanopore platform.

Omics Technologies Posters - Thursday

PB2963. Delivering Comprehensive, Single-molecule Proteomics Using Protein Identification by Short-epitope Mapping (PrISM)

Authors:

G. Kapp, J. D. Egertson, C. Stawicki, T. Gillies, J. Joly, N. Steiner, K. Cardenas, J. Leano, K. Chen, S. Watts, H. Boyce, D. DiPasquo, A. Killeen, V. Lobanov, S. Patel, P. Mallick; Nautilus Biotechnology, San Carlos, CA

Abstract Body:

Genomics has been revolutionized by next-generation sequencing technologies that made comprehensive genome analysis widely accessible. The field of proteomics is poised for a similar revolution to enable comprehensive analysis of all the proteins in a sample with increased sensitivity, reproducibility, and ease of use. The ability to detect and quantify a wider array of proteins, including low expressers, should complement genomic and transcriptomic data to enhance our understanding of mechanisms linking genotype to phenotype in complex biological systems. Here we present a novel approach for protein detection and quantification, Protein Identification by Short-epitope Mapping (PrISM). PrISM is a single-molecule protein analysis method where intact proteins are immobilized and analyzed massively in parallel by using non-traditional fluorescently-labeled affinity reagents to create a pattern of binding that allows for the identification of each individual protein molecule at scale. PrISM uses reagents with high affinity and low specificity that bind to short epitopes in multiple proteins. Simulations using these reagents show that the accumulated information from multiple rounds of detection of short, 2-4 amino acid epitopes enables identification of more than 95% of the human proteome with just 300 reagents. We have developed reagents that bind to short, three amino acid epitopes with low picomolar affinity. PrISM leverages a novel algorithm to process single-molecule binding data to determine protein identity. With single-molecule detection, sensitivity across a wide dynamic range is directly related to the number of molecules analyzed. We demonstrate a prototype chip that can immobilize 10 billion individual proteins to provide up to 9 orders of magnitude dynamic range in plasma. We measured millions of single protein molecules and successfully identified a set of model proteins with a smaller number of affinity reagents, exemplifying the PrISM approach. By combining single-molecule analysis, intact (non-digested) proteins, and iterative probing, PrISM provides a new tool for the discovery and quantitation of proteins. Paired with genomics, PrISM will enable insight into mechanisms linking genotype to phenotype to uncover novel biology, identify more effective biomarkers, and better understand the molecular mechanisms of disease.

Omics Technologies Posters - Thursday

PB2964. Depth normalization for single-cell genomics count data

Authors:

S. Boeshaghi, I. Hallgrimsdottir, Á. Gálvez-Merchán, L. Pachter; California Inst. of Technology, Pasadena, CA

Abstract Body:

Single-cell genomics analysis requires normalization of feature counts that stabilizes variance while accounting for variable cell sequencing depth. We discuss some of the trade-offs present with current widely used methods, and analyze their performance on 526 single-cell RNA-seq datasets. The results lead us to recommend proportional fitting prior to log transformation followed by an additional proportional fitting.

Omics Technologies Posters - Wednesday

PB2965. Detecting and assembling non-reference LINE-1 insertions using clustered long reads.

Authors:

M. Blacksmith, J. V. Moran, J. M. Kidd; Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract Body:

Accurately detecting and mapping genetic variation is one key to understanding the evolutionary history of a species. This process can be relatively straightforward when investigating single nucleotide variants or short insertions and deletions because Illumina sequencing reads typically span the length of the variant. However, for variants that cannot be spanned by a single Illumina read, such as dimorphic Long Interspersed Element 1 (L1) retrotransposon insertions, other approaches need to be used to accurately define variation. L1s replicate via a copy and paste mechanism termed retrotransposition. Mutations derived from the activity of L1 contribute to multiple canine phenotypes. Analyses using long-read DNA sequence data indicate that dimorphic L1s are eight-fold more common in canines than humans. However, non-reference L1 sequence reads often align to reference L1s, while other segments of the non-reference L1 reads align to alternative integration sites, leading to the generation of supplementary alignments that often are ignored by existing tools. To overcome these mapping challenges, I developed a computational pipeline, Alternative long-Read Alignment Clustering to Identify non-reference L1 insertions (ARACIL) to assemble non-reference L1 insertion locations from Pacific Biosciences (PacBio) long-read sequence data. ARACIL identifies the alternative alignment locations of putative non-reference L1 sequence reads. After extracting the alternative alignments, nearby alignments are clustered to generate candidate non-reference L1 insertion loci. Reads overlapping candidate loci are assembled using various assemblers (*i.e.*, Flye, Canu, and Wtdbg2) and the resultant assembled contigs are remapped to the reference genome to determine the location of the non-reference L1s. Non-reference L1 insertions are then assessed for L1 structural hallmarks, including the presence of a 3' poly(A) tail, flanking target site duplications, and 3' sequence transductions. Of 704 non-reference L1s discovered in a recently published Great Dane genome assembly, ARACIL confirmed 657/704 (93.3%) L1 insertions at identical genomic coordinates and revealed that 30/704 (4.3%) were located within 50 bp of previous annotations. In addition, I identified 3,030 L1s that were greater than 50 bp away from known non-reference L1 insertions. I currently am using ARACIL to systematically identify non-reference LINE-1 insertions in PacBio reads from six additional samples, which include four breed dogs, one wolf, and one dingo. These analyses will help elucidate how L1s have generated and may continue to generate genetic diversity in the *Canis* lineage.

Omics Technologies Posters - Thursday

PB2966. Detection of 5-hydroxymethylcytosine using a modified EM-seq protocol.

Authors:

D. Evanich, V. Ponnaluri, V. Panchapakesa, A. Erijman, M. Campbell, N. Dai, B. Langhorst, R. Vaisvila, T. Davis, L. Williams; New England Biolabs, Ipswich, MA

Abstract Body:

DNA methylation is an epigenetic regulator of gene expression with important functions in development and diseases such as cancer. The modified cytosines, 5-methylcytosine (5mC) and 5-hydroxymethylcytosine (5hmC), are routinely detected by sequencing Illumina libraries generated using an enzyme-based workflow called EM-seqTM or bisulfite. However, these methods cannot differentiate between 5mC and 5hmC. There is also increasing interest in identifying 5hmC sites due to its role in regulating gene expression in embryonic stem cells and a variety of neuronal cell types. Methods currently exist to enable discrimination of 5mC and 5hmC (e.g., oxBS-seq and TAB-seq), however both require a bisulfite conversion step leading to increased DNA damage. Here we describe a fully enzymatic method that enables specific detection of 5hmC. 5hmC libraries are generated by ligating adaptors onto sheared DNA. Next, 5hmCs are glucosylated, which protects them from deamination by APOBEC. Unprotected cytosines and 5mCs are deaminated resulting in their conversion to uracil and thymine, respectively. Libraries are amplified and 5hmC is discriminated from cytosine and 5mC by Illumina sequencing. 5hmCs are sequenced as cytosines whereas 5mC and cytosine are sequenced as thymines. Additionally, subtracting 5hmC data from EM-seq data (detects 5mC and 5hmC) enables the precise localization of individual 5mCs and 5hmCs. 5hmC data were generated for 0.5 ng to 200 ng DNA isolated from adult human brain (Biochain). The global level of 5hmC in the CpG context measured by these libraries was approximately 20% and was highly consistent across inputs. In addition, 5hmC levels were profiled during mouse E14 cell differentiation over a period of 10 days. 5hmC levels dropped from 3% to 0.7% over the time course as observed by both LC-MS quantification and Illumina sequencing. The 5hmC libraries had similar characteristics to EM-seq libraries with no detectable DNA damage, and as a result the libraries have expected insert sizes, low duplication rates and minimal GC bias. T4147 phage DNA was used as an internal control (all cytosines are 5hmC), with 97-99% of cytosines correctly identified. This provides a high level of confidence in the detection of 5hmC using this method. The specific profiling of 5hmC along with EM-seq analysis are key tools that will enable future studies of 5mC and 5hmC in the epigenetic control of genes.

Omics Technologies Posters - Wednesday

PB2967. Detection of somatic variation in human neurons using long-read sequencing approaches

Authors:

W. Zhou¹, C. Mumm¹, J. Switzenberg¹, P. Todd¹, M. McConnell², A. Boyle¹, R. Mills¹; ¹Univ. of Michigan, Ann Arbor, MI, ²Lieber Inst. for Brain Dev., Baltimore, MD

Abstract Body:

Somatic mutations leading to genomic mosaicism in neurons can alter the expression of brain genetics and behavior and contribute to the complex regulatory landscape of neuropsychiatric and neurodegenerative diseases. While single-nucleotide variants in the genomes of human neurons have been well characterized, the identification of large-scale deletions and cryptic insertions has been elusive due to technical barriers. Here, we explored somatic mosaicism of these copy number variants (CNVs) in bulk tissue and at the single-cell level. First, we developed a Cas9-based enrichment pipeline for targeted whole-genome nanopore sequencing and demonstrated the robustness of our pipeline in a cell-line mixing experiment. Our pipeline is able to detect mosaic non-reference insertions as low as 3% frequency in one sequencing flow cell. We then applied our approach to the bulk frontal cortex and cerebellum tissue from a representative Alzheimer's disease brain and identified potential somatic insertions that could potentially alter gene expression. Next, we developed a single-cell analysis pipeline to identify CNVs with whole-genome nanopore sequencing of MALBAC-amplified DNA from flow-sorted cortical neurons of a neurotypical individual. Our pipeline can identify germline and somatic heterozygous large deletions and cryptic types of insertions, e.g., transposable elements, in single human neurons and identify some events with breakpoint resolution. We report the genomic distribution of these CNVs and explore their mechanistic origins and potential impact on gene expression. Overall, both complementary approaches increase our understanding of the prevalence and relevance of somatic mosaicism in human brains and aid in studies of neuropsychiatric and neurodegenerative diseases.

Omics Technologies Posters - Thursday

PB2968. Developing local compute capacity - a Ugandan experience Integrated Biorepository of H3Africa Uganda, Makerere University College of Health sciences.

Authors:

D. Kezimbira¹, N. L. Lwanga¹, E. Katagirya²; ¹Makerere Univ. Coll. of Hlth.Sci., Sch. of BioMed. Sci., Kampala, Uganda, ²Coll. of Hlth.Sci., Makerere Univ., Kampala, Uganda

Abstract Body:

Background:Data-intensive sciences, including bioinformatics, are relatively new to most parts of Africa, Uganda inclusive. Close to a decade ago, Wellcome Trust, together with the American National Institutes of Science (NIH), co-founded a consortium of projects dubbed the Human Health and Heredity Africa (H3Africa) with the aim of developing capacity on the African continent both of human resource and infrastructure to bridge the south-north disparity in genetics and genomics research gap including but not limited to developing human resource and setting up computational infrastructure among other things. Makerere University College of Health Sciences was one of the collaborators in one of the consortia projects named the Collaborative African Genomics Network (CAfGEN). CAfGEN comprised five institutions, mainly in Africa, i.e., Botswana, Eswatini and Uganda and one collaborating institution in the United States - the Baylor College of Medicine in Houston, Texas. Under CAfGEN servers were set up at Makerere University with the following specifications with 32TB of storage and 128GB of RAM. After a decade, several other servers have been set up at the Infectious Diseases Institute also at Makerere University as well as at the Uganda Virus Institute (UVRI) in Entebbe, Uganda. These servers have varying computational capacities and have been supported by different funding agencies. **Aim:** This study aimed to assess the capacity, accessibility, challenges, and opportunities that have been experienced locally. **Methods:** We used key informant interviews and anecdotal evidence from conversations with the users and administrators of these servers. **Findings:** We found that there was increased computational capacity at all the sites with capacity ranging from 20TB to 80TB of storage and up to 1PB of computational space. All the servers were freely accessible to local users within the institutions within which they were located, although they were also open to non-local users under specific predefined arrangements. The commonest challenges faced were limited space, lack of adequate administrative support, as well as unreliability arising from power failures and poor internet connectivity. **Conclusions and recommendations:** There is a need for additional computational capacity with improved internet connectivity. There is also a need for local funding from the government and other local organizations, as most of the financing for the servers was funded mainly by foreign funding agencies.

Omics Technologies Posters - Wednesday

PB2969. Development of computational methods for analyzing single-cell spatial transcriptomic data with applications to murine spermatogenesis.

Authors:

A. Vargo, D. Hannum, G. Manske, S. Hammoud, J. Li; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Single-cell RNA sequencing (scRNAseq) methods have transformed our ability to characterize cellular heterogeneity in complex tissues. The next frontier is spatial analysis, adopting new imaging approaches that are high-resolution (for single RNA molecules) and highly multiplexed (for hundreds of different genes at the same time using MERFISH-like combinatorial coding approaches) to survey the spatial layout of mRNA molecules in large tissue sections. Unlike existing transcriptomic data, these spatial data reveal the physical organization of intact tissues, allowing for the classification of spatial domains based on architectural features or distinct patterns of cell type heterogeneity.

In this work, we develop methods for analyzing single-molecule spatial data for hundreds of target genes. Our focus is on examining the spatial layout of the transcriptome in cross sections of testes from multiple adult mice to develop a deeper understanding of mammalian spermatogenesis. Each testis cross section contains hundreds of thousands of cells and millions of observed transcripts, and gleaning insights from these massive data sets involves multiple levels of computational challenges.

An early task in our analysis is to learn cell boundaries based on the distribution patterns of detected transcripts, DAPI, and three cell surface markers. Some testis cell types, e.g., Sertoli cells, consist of cells with irregularly shaped boundaries; this makes cell segmentation difficult. Another task is cell type annotation, which is often accomplished by integrating spatial data with existing scRNAseq data. We can then start to investigate higher-level biological questions that have been difficult to explore with past approaches. For instance, germ cells move radially inward towards the center of the seminiferous tubule as they develop into mature sperm. This radial organization, which shifts along the length of the tubule, has traditionally been defined in terms of cycles of tubule stages. We can now provide precise transcriptomic descriptions of tubule stages using our single-molecule spatial data. More specifically, we can annotate the biological staging of the seminiferous tubules at multiple levels: from intracellular transcript distributions, to cell types, to heterogeneous cell communities. This culminates in the ultimate goal of this study: the construction of a 3D reference atlas of a typical tubule, containing the locations of thousands of cells, each with hundreds of detected mRNA molecules.

Omics Technologies Posters - Thursday

PB2970. Diagnosis of neurodevelopmental disorders by RNA-Seq : From urine derived stem cells to induced neural stem cells, a promising alternative tissue.

Authors:

K. Riquin¹, T. Besnard^{2,1}, E. Trochu², S. Bezieau², B. Cogné²; ¹INSERM, CNRS, UNIV Nantes, l'institut du thorax, Nantes, France, ²CHU de Nantes Hôtel-Dieu, Nantes, France

Abstract Body:

Intellectual disability (ID) is a clinically and genetically heterogeneous group of neurodevelopmental disorders (NDD). It is characterized by deficits in intellectual and adaptive functioning beginning before adulthood, with a lasting effect on development. During the last decade, the implementation of genome sequencing helped to improve molecular diagnosis of ID. Even if this technique has a high diagnostic yield, one third of cases stay without candidate variant. In addition, many variants of interest are located in non-coding regions and are *de facto* difficult to interpret.

RNA-Seq have the potential to highlight pathogenic variants outside coding regions. Most recent studies showed an increased diagnostic rate of up to 17% in WGS negative patients with diverse genetic disorders (Murdock et al., 2021). To date, two tissues are frequently used : whole blood and fibroblast. It has been observed that RNA-Seq on fibroblasts enable a better diagnostic yield compare to whole blood. It is particularly true in the context of ID because few genes associated to neurodevelopment are expressed in blood. We recently performed RNA-Seq on fibroblast in 10 patients negative after genome sequencing. We showed that RNA-Seq on fibroblasts can successfully identify differentially expressed genes, to allow studying variants that were previously undetected or not considered during genome analysis.

Nevertheless, fibroblasts culture requires a skin biopsy, an invasive procedure sometime refused by the patient. We thus studied, Urine derived Stem Cells (USC) as an alternative tissue. USC are a subpopulation of cell collected in urine with self-renewal and multipotency capacities (Bharadwaj et al., 2013). They are easy to obtain by a non-invasive procedure and clonal colonies can be isolated in culture. We showed that 63% of ID-associated genes are expressed with a TPM>10, a threshold that should allow to study aberrant expression, monoallelic expression and aberrant splicing. We thus are collecting urine samples from patients suffering from NDD and their parents to study the diagnostic potential of USCs. Additionally, USC can be transdifferentiated to a neuron-like cell type called induced neural stem cells (iNSC). Depending on the protocol followed, iNSC can express up-to 78% genes associated to ID and are thus an interesting cell type to study the expression of genes only expressed in neurons and conduct functional assays.

We will present how RNA-Seq can be highly valuable in combination with exome or genome sequencing for the diagnosis of neurodevelopmental disorders. We will also discuss advantages and limitations of RNA-Seq using two promising cell types : USC and iNSC.

PB2971. Diagnostic metabolomic profiling of hypomyelinating leukodystrophy caused by DEGS1 deficiency

Authors:

C. Gijavanekar¹, N. Liu^{1,2}, R. Logan³, S. Keller^{3,4}, S. H. Elsea^{1,2}, V. R. Sutton^{5,1,2}, Q. Sun^{1,2}; ¹Baylor Coll. of Med., Houston, TX, ²Baylor Genetics, Houston, TX, ³Children's Hlth.care of Atlanta, Atlanta, GA, ⁴Emory Univ. Sch. of Med., Atlanta, GA, ⁵Texas Children's Hosp., Houston, TX

Abstract Body:

DEGS1 (NCBI Gene ID: 8560, chr1q42.11) encodes the sphingolipid delta 4-desaturase 1 (NCBI RefSeq NP_003667.1, NM_003676.3) which catalyzes last step of ceramide de novo biosynthesis in the endoplasmic reticulum (ER) by introducing a double bond between positions 4 and 5 of dihydroceramide. Ceramide is the precursor of all sphingolipids which are essential cellular membrane components. Biallelic pathogenic variants in *DEGS1* have been recently associated with hypomyelinating leukodystrophy 18 [MIM: 618404]. Untargeted metabolomic analysis was performed using the Global Metabolomic Assisted Pathway Screening test (Global MAPS®, Baylor Genetics) to assess metabolic abnormalities associated with ceramide and sphingomyelin pathway in two unrelated individuals with variants in *DEGS1* gene: One with a novel homozygous variant of uncertain significance, c.775C>T (p.His259Tyr) and second with a novel homozygous likely pathogenic variant c.825+4_825+5delinsTT (p.?), predicted to affect normal splicing. Both had global developmental delay, leukodystrophy, epilepsy, microcephaly, and failure to thrive. In both individuals, metabolomic profiling identified elevated levels of dihydroceramide (Z-scores +3.4, +4.0) and its various metabolites dihydrosphingomyelins (Z-scores +6.8, +5.0), sphinganine-1-phosphate (Z-scores +2.4, +3.2) which are upstream of the enzyme defect. In addition, analytes downstream of enzyme defect, including multiple ceramides and their metabolites, such as glycosylceramides, lactosylceramides were not detected. Notably, among more than 2000 plasma metabolomic profiles tested, only these two individuals showed absent ceramides. Numerous sphingomyelins (Z-scores < -4.0 and as low as -19.3), and sphingosine-1-phosphate (Z-scores -5.8, -6.6) were reduced. This metabolomic profile is consistent between both unrelated patients, and unique compared to >2000 patient in our database. Functional validation of this ceramide pathway defect supported the reclassification of the novel *DEGS1* VUS, c.775C>T in case 1 and aided in reclassification as likely pathogenic. In conclusion, clinical biochemical assessment and functional validation of the *DEGS1*-metabolic pathway and VUS were achieved by plasma Global MAPS analysis, for which enzyme assay or targeted biochemical testing is not currently available in clinical laboratories. Global MAPS may be utilized for diagnosis of disorders associated with ceramide and sphingomyelin metabolism. In addition, metabolomic testing may potentially aid biomarker screening in developing and monitoring therapeutic targets.

Omics Technologies Posters - Thursday

PB2972*. Direct haplotype-resolved 5-base HiFi genome sequencing allows for linking rare disease variants to non-coding function

Authors:

T. Pastinen¹, W. Cheung¹, W. Rowell², D. Portik², R. Hall², A. Wenger², E. Grundberg¹; ¹Children's Mercy Kansas City, Kansas City, MO, ²Pacific BioSci.s, Menlo Park, CA

Abstract Body:

Long-read PacBio HiFi genome sequencing (GS) allows for accurate detection of single nucleotide variants (SNV), indels and structural variants (SV). Recent algorithmic development now enables the simultaneous detection of CpG methylation (mCpG). The phasing power of long contiguous reads (12-16kb) uniquely accesses haplotype information on allelic mCpG at 10X increased efficiency as compared to whole genome bisulphite sequencing (WGBS). We previously showed that allelic regulatory element (RE) hyper-mCpG reflects allelic regulatory silencing. Leveraging our large rare disease program "Genomic Answers for Kids" (GA4K), we have generated a comprehensive haplotype-resolved mCpG dataset for investigating unsolved pediatric rare disease. WGBS derived from GA4K patients (n=1085) were screened for hyper-mCpG outliers which were then validated in matching HiFi-GS data (n=77). Mean, standard deviation (SD) and 99th quantile (Q99) was summarized for 27M WGBS CpGs. Extreme hyper-mCpG tiles (200bp) were identified if >1 CpG/tile had mCpG >3 SD than Q99. The average mCpG from HiFi-GS were then calculated for each extreme hyper-mCpG tile. We validated the HiFi-GS hyper-mCpG tiles at known rare disease loci including diagnostic mutations (e.g. *DMPK* repeat expansion) and imprinted genes (e.g. *GNAS*). In unsolved cases we identified 5-20 rare (<0.5%) hyper-mCpG tile/genome. Majority of the hyper-mCpG events were observed only in maternal or paternal allele and predicted to cause LRE. The most common cause of LRE was rare SNV within the RE causing a short-range (~250bp) hyper-mCpG event. The second most common cause was local SV (INS, DUP, DEL) yielding large hyper-mCpG events (>1 kb). Similarly, unstable tandem repeats (STR) accounted for larger hyper-mCpG tiles, including novel GCC repeats with complete promoter hyper-mCpG predicting allelic gene silencing in 8% of validated regions. Less than 5% of hyper-mCpG events were biallelic that may represent either rare homozygous regulatory effects (*cis*) or upstream regulatory perturbation by genetic (*trans*) or environmental mechanisms. Interestingly, 1% of validated hyper-mCpG tiles appeared to originate from transcriptional silencing caused by local loss of splice donor sites. Finally, minority of events remained unsolved and may represent distal *cis* (allelic hyper-mCpG) or tissue variation (non-allelic, variable hyper-mCpG). In conclusion, we have identified patient-specific hypermethylation events with evidence of functional impact of non-coding rare variation. We propose that unsolved rare disease genomes sequenced by HiFi-GS will allow detection of unconventional diseases alleles due to LRE.

Omics Technologies Posters - Thursday

PB2973. Magnified Convolutional Enrichment Representation Model

Authors:

G. Chen, W. Zheng; Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX

Abstract Body:

Feature representation and the learning process formed the cornerstones of machine learning. Feature representation mathematically characterizes domain entities by encoding input features followed by feature normalization and feature extraction. It may immensely reduce the cost of the learning process and improve performance. In this work, we introduced an advanced model to represent entities with a dynamic mechanism, which was further enhanced by fusing the local and global over-representation on the basis of encyclopedic knowledge bases. The model has been evaluated and demonstrated good fitness for predicting the associations of complex diseases.

Omics Technologies Posters - Thursday

PB2974. Efficiency of mutagenesis promoted by CRISPR-Cas9 in *THRAB* gene in zebrafish.

Authors:

L. Rodrigues; Univ.e do Algarve, Faro, Portugal

Abstract Body:

Background: Gene editing tools allowed the study of isolated genes and complex gene networks and have been an asset in several lines of research, especially the CRISPR-Cas9 method. This technique differs from the others as the mutations produced are transmitted to offspring, conferring a stable expression/phenotype. However, despite this efficient tool for DNA editing, the frequent disagreement between genotype and phenotype is notorious, so the existence of genetic compensation mechanisms as the *Transcriptional Adaptation* is already known and remains open. The loss of function of the *THRAB* gene was promoted in order to establish the relationship between the functions of the nuclear receptor TR α B expressed by it and the phenotype observed during embryonic neurodevelopment. Excluding the hypothesis of genetic compensation promoted by the *THRAA* paralog gene in the offspring of the mutant line. **Methods:** The results were analyzed in offspring of zebrafish whose *THRAB* gene was deleted by CRISPR-Cas9 (a deletion of 9.000 bp), verifying the efficiency of the method in producing the mutation by sequencing its product. The description of the phenotype of the mutant line was then carried out, establishing the relationship between the TR α B receptor and the phenotype observed in this period. **Results:** The efficiency percentage of the method was 7.2% in F0 injected generation and 26.8% in F1. Through the phenotypic analysis in F2 homozygous generation, it was observed that the expression of the TR α B receptor is important in the development of the anteroposterior axis of the Central Nervous System. Changes in eye size and hindbrain and midbrain dysfunctions/disruptions associated with cognitive impairment have been described. **Discussion/Conclusion:** The CRISPR-Cas9 method is effective in producing loss of gene function, however there are particularities to be considered, such as the different molecular mechanisms of compensation and the type of mutation produced. From the described phenotype, new hypotheses emerge about the implications of TR α B in neuroembryonic development. Furthermore, the study contributes to the advancement and improvement of promising technology for gene therapy of thyroid hormone resistance syndrome (RTH).

Omics Technologies Posters - Wednesday

PB2975. Efficient DNA sample contamination metric estimation using a novel variant representation and algorithm.

Authors:

W. Lu^{1,2}, L. Gauthier¹, T. Poterba^{1,2}, C. Vittal^{1,2}, D. King^{1,2}, C. Stevens^{1,2}, M. Daly^{2,3,4}, C. Seed^{1,2}, B. Neale^{2,3}, K. Karczewski^{1,2}; ¹Broad Inst. of MIT and Harvard, Cambridge, MA, ²Massachusetts Gen. Hosp., Boston, MA, ³Broad Inst Harvard & MIT, Cambridge, MA, ⁴Inst. for Molecular Med. Finland, Helsinki, Finland

Abstract Body:

DNA sample contamination is a major issue in clinical and research applications of whole genome and exome sequencing. Even modest contamination can dramatically affect the quality of variant calls and lead to widespread genotyping errors (e.g., contamination leads to systematic undercalling of homozygous genotypes in gnomAD). Currently, the most popular tool for detecting contamination (i.e., DNA from two or more humans in a single sample) is VerifyBamID, which is computationally expensive as it operates on underlying short read data (CRAMs or BAMs). For some datasets, the reads are no longer accessible, necessitating a different approach.

The more efficient gVCF format scales effectively to large sequencing studies and retains information on variant calls and genotyping quality sufficient to evaluate contamination. Capitalizing on the gVCF format, we present the Scalable Variant Call Representation (SVCR), which jointly represents multiple samples in storage space that scales linearly in the number of samples and variants and stores reference blocks and variant calls separately. An implementation of the SVCR in the Hail system, the Variant Dataset (VDS), provides the opportunity for devising gVCF-based metrics using only non-reference variant calls at a much lower computational cost.

Inspired by the VDS format and the empirical observation that contaminated samples contain more heterozygous calls with unusually high allele balance, we devise a novel gVCF-based contamination metric. Using only the non-reference component from the VDS, we compute the mean reference allele balance of the homozygous alternate genotypes of autosomal and biallelic SNPs with high coverage (sequencing depth $\geq 10\times$). We evaluate this metric on 73,456 whole genome samples from gnomAD v3 with 58,983 samples from the Broad Institute and 14,473 from other sequencing centers. Both platforms demonstrate strong correlations ($r=0.99$, $r=0.98$; $p < 2.2e-16$) between the new metric and the VerifyBamID contamination estimate. The correlation is consistent when computing the metric using common variants at various allele frequency cutoffs. This metric can be obtained through fast computation using only the variant calls from a VDS or gVCF and provides an accurate evaluation of sample quality. Our results demonstrate that the metric can efficiently replace the existing tools for estimating DNA sample contamination, which, in turn, will improve the accuracy and efficiency of downstream analyses of ultra-large whole genome and exome sequencing datasets in the future.

Omics Technologies Posters - Thursday

PB2976. Empowering Discovery in Childhood Cancer: Genomic Harmonization at the Kids First Data Resource Center

Authors:

D. Miller¹, M. Brown¹, Y. Zhu¹, B. Zhang¹, D. Higgins¹, B. Farrow¹, M. Mattioni², Z. Li³, K. Wang¹, A. Heath¹, A. Resnick¹; ¹The Children's Hosp. of Philadelphia, Philadelphia, PA, ²Seven Bridges, Cambridge, MA, ³Sentieon Inc, San Jose, CA

Abstract Body:

The Gabriella Miller Kids First Pediatric Research Program (GMKF) is an NIH Common Fund initiative focused on providing large-scale clinically annotated genomic data for pediatric cancer and structural birth defect cohorts.

Kids First is challenged with taking genomic data from a wide range of sources and providing researchers and physicians with harmonized genetic data. Preparing large-scale harmonized datasets presents unique challenges in scalability, reproducibility, and transparency. The Kids First Data Resource Center (DRC) tackles these challenges using open-source, community-standard workflows that are deployed in cloud-based HPC environments. Our workflows, written in Common Workflow Language (CWL), are modeled after established best practices workflows, optimized and verified through internal benchmarking, and, when possible, made in collaboration with our network of researchers. These workflows are made freely available both as open-source code on Github and as public apps via CAVATICA, an Amazon Web Services (AWS) based cloud computing platform associated with the Kids First DRC Portal co-developed by Seven Bridges Genomics, where workflows feature scatter-gather parallelization, conditional execution, and AWS resource optimization.

Today, the DRC has six production level workflows producing harmonized datasets at scale for whole genome sequencing, exome sequencing, and RNA-seq technologies. Additionally, we have over a dozen non-production workflows for everything from germline to tumor-only to long reads applications. These workflows have been run across the 24 Kids First studies and 20,000 participants already released on the Kids First Data Resource Portal. In total, we have more than 1.0 PB of data, with more being released yearly. Here we present our process for creating, validating, and distributing these workflows.

Omics Technologies Posters - Wednesday

PB2977. Enabling flexible low throughput sample preparation for multiple sequencing platforms using the Miro Canvas

Authors:

A. Day¹, M. Gildea¹, R. Kafrawi¹, A. Barner², S. Kumar², E. Carvajal², K. Cunningham², C. Ramnarine¹, E. LaRoche¹, K. Larkin¹, T. Howd¹, C-C. Lee², A. Chavan², T. DeSmet¹, N. Lennon¹, S. Gabriel¹; ¹Broad Inst. of MIT and Harvard, Cambridge, MA, ²Miroculus, San Francisco, CA

Abstract Body:

Over the last five years, declining sequencing and library preparation costs have driven the demand for whole genome sequencing for both research and clinical applications. The Broad Institute's Genomics Platform has built the capacity to process thousands of long read samples and hundreds of thousands of short read samples per year. Advances in both automated liquid pipetting and quantification technologies have transformed library preparation into an efficient and more cost effective process. While high throughput processing is essential for meeting large project demand, there is a market need for an automated low throughput workflow that provides on-demand sample processing for time-critical applications. Ideally this workflow includes expedited processing to facilitate quick turnaround times and increased flexibility while maintaining high quality results.

Miroculus's Miro Canvas is an emerging technology that constructs one DNA library per run. This compact, digital microfluidic platform requires twenty minutes for sample preparation, after which the Miro Canvas runs independently. Using the same universal cartridge, it performs all enzymatic reactions, incubations and purifications that are required to produce sequencer-ready libraries for both short read and long read platforms. This instrument has the potential to fill the Genomics Platform's need for flexible, low throughput processing.

Here, we present data on the performance of PCR-free whole genome libraries made using the Miro Canvas and sequenced on Illumina, Pacific Biosciences, and Oxford Nanopore platforms. While the Miro Canvas has the functionality to construct libraries from mechanically sheared DNA, it also has the ability to perform enzymatic fragmentation. Samples prepared on the Miro Canvas performed equivalently to libraries prepared both manually and with automated liquid handling in terms of library yield (33.5% vs 29.9%) and sequencing quality (average Q35.3 vs Q35.9) even with a fraction of the reagents.

Furthermore, the Miro Canvas maintains line balance with similar run times and less touch points than manual or other automated processes. The instrument is straightforward to set up and requires minimal training translating to fewer user errors. The ability to alter protocols allows for rapid integration of R&D efforts in less time.

In the future, we see the Miro Canvas as a way to reduce turnaround times and increase lab flexibility especially when applied to niche applications, namely rapid WGS processing. The ability for the platform to achieve both high and low throughput demand will open a breadth of genomic capabilities and resources for the community.

Omics Technologies Posters - Wednesday

PB2979. Ensure sample identity in sequencing workflows with the Twist Sample ID Kit.

Authors:

S. Oh, M. Bocek, P. Wani, C. Littler, D. Murphy, E. Toro; Twist BioSci., South San Francisco, CA

Abstract Body:

Target enrichment systems, such as hybridization capture using the Twist Exome 2.0 panel, increase sample throughput by focusing on genomic regions of interest. Further, recent advances in automation and sequencing output have made it possible for laboratories to test hundreds or even thousands of samples per day. As the number of samples grows, however, so does the likelihood of an accidental sample swap. In some environments, such mistakes can be costly, and have a significant impact on drug development or research decisions. It is therefore important to develop methods that ensure the identity of samples can be accurately linked to their cognate results. Sample swaps can occur at any point along the route from collection to sequencing. At Twist, we developed a solution to ensure sample identity starting from an early step in the workflow. Here, an aliquot is taken directly from a blood collection tube and as little as **2 µl of whole blood can be directly amplified** in a multiplex PCR reaction. This simplifies the workflow, stakes sample identity before processing begins, and eliminates another source of sample swapping. The included primer pool and single-tube polymerase mix target a panel of SNPs, described by Pengelly, et al. and by The European Society of Human Genetics (ESHG) EuroGentest committee, that are useful for sample tracking and identification in human samples. Additionally, several loci, including AMELX/Y, are included for sex determination. The multiplexed product can then be barcoded and readied for sequencing using one of the Twist library preparation kits and the Twist 10 bp Unique Dual-Indexed (UDI) system. To confirm sample identities, the Sample ID panel SNPs are compared to the matched loci in the test samples. The Twist Sample ID kit may be used directly with the Twist Exome 2.0 panel. Alternatively, a sample ID target enrichment panel containing the targets of interest may be blended into your custom hybrid capture panel. Here we demonstrate the application of the workflow on a combination of different sample conditions: sample purity (whole blood vs purified genomic DNA), blood collection tube preservative (K2EDTA and Streck cfDNA), and sex (female and male). Based on population segments with the lowest measured minor allele frequencies (MAFs), we calculate the probability of encountering the same SNP profile on a 96-well plate is approximately 1 in 70,000, with probabilities for other populations commonly calculated to be at 1 in 950,000. With its direct-from-blood capability and power of discrimination, the Sample ID kit provides high confidence that the right results are matched to the right samples.

Omics Technologies Posters - Thursday

PB2980. Establishing a baseline transcriptomic profile of human eccrine sweat glands via single-cell RNA-sequencing with validation by 3D imaging

Authors:

A. Eastman, G. Rosson, N. Kim, G. Cutting, N. Sharma; Johns Hopkins, Baltimore, MD

Abstract Body:

Eccrine sweat glands (ESGs) are essential for human thermoregulation. While several genetic diseases are known to have ESG-related phenotypes, further knowledge of molecular processes involved in sweat production are required to elucidate etiologies. The immense atlases of transcriptomic information generated by single-cell RNA-sequencing (scRNA-seq) are based on tissue dissociated *en bloc*, which does not well capture cells from microstructures within tissues. Thus, only a minor fraction of skin scRNA-seq datasets is comprised of ESG cells. Consequently, no published scRNA-seq datasets currently contain all known ESG cell types. Therefore, we have performed scRNA-seq on micro-dissected ESGs to identify novel marker genes for ESG cell types and pathways implicated in ESG-related diseases. Individual ESGs were micro-dissected from skin and processed for scRNA-seq or fixation and optical clearing for immunofluorescent protein labeling (IF) and 3D imaging. For scRNA-seq, glands were enzymatically dissociated, 3' 10X cDNA library preparation was used, NovaSeq was used to sequence, and Seurat was used for analysis. The CLARITY protocol was followed for fixation and optical clearing, proteins of interest were labeled by IF, and a multi-photon microscope was used for 3D imaging. For scRNA-seq, we captured approximately 7,300 cells and used dimensionality reduction and clustering in Seurat to successfully separate them into all expected eccrine sweat gland cell types - clear cells, dark cells, myoepithelial cells, and ductal cells - as well as fibroblasts, pericytes, endothelial cells, and immune cells based on variable expression of published marker genes. Interestingly, several genes we show to be highly expressed in ESG dark cells are in the arachidonic acid catabolism pathway. This suggests that an arachidonic acid-based mechanism may trigger sialomucin release, which influences ESG lumen pH. Our optimized 3D imaging technique has allowed us to visualize ESG proteins - including *ACTA2*, *CFTR*, and multiple keratins - within the native geometry of the tissue, demonstrating its utility as a validation measure.

While previously published skin scRNA-seq datasets have captured 0, 1, or 2 ESG cell types, our technique has allowed us to identify all 4 major cell types. Enriching for microstructures in tissues throughout the body will greatly add to the level of detail of transcriptomic atlases. IF and 3D imaging of optically cleared ESGs allows for the validation of novel marker genes found in our scRNA-seq data, and for the establishment of the spatial organization of gene products.

Omics Technologies Posters - Wednesday

PB2981. Establishing best practice for structural variant discovery with long read sequencing in the Gabriella Miller Kids First Pediatric Research Program using Sentieon's haplotype-resolved variant evaluation tool

Authors:

Z. Li¹, M. Ahsan², H. Chen¹, D. Freed¹, K. Wang², Y. Zhu²; ¹Sentieon Inc., San Jose, CA, ²Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

As a NIH common fund project and one of the largest childhood cancer cohort programs, the Gabriella Miller Kids First (GMFK) Pediatric Research Program has sequenced 48,000 genomes representing over 20,000 patients with 44 childhood cancer and birth defects cohorts in the past 15 years. To take advantage of recent accuracy and throughput improvements in long read sequencing platforms, GMFK has initiated long reads pilot projects to enable sensitive and accurate discovery of genetic structural variation (SV) underlying childhood cancers and structural birth defects.

A key objective of the pilot program is to establish a production long read data processing pipeline that can reproducibly deliver high-quality data for cohort research. However, evaluation and qualification of long read SV pipelines has been particularly challenging due to limited truth sets and a lack of accurate evaluation tools. Additionally, popular SV evaluation tools perform a pairwise comparison of SVs, which results in the mischaracterization of more complex rearrangements, especially in tandem repeat regions.

As haplotype-resolved genome assemblies are becoming feasible, the development of better evaluation tools that can perform a faithful comparison with base-resolution has become critical.

Here, we present hap-eval, a new open-source haplotype-resolved SV evaluation tool. Instead of comparing each pair of calls, SV calls within a cluster are first assembled into haplotypes based on available genotype and phase information. The assembled haplotypes for the truth set and calls are then comprehensively compared, and the best-matching haplotypes are evaluated.

We used this tool to thoroughly benchmark and evaluate different SV discovery pipelines for both PacBio HiFi and Oxford Nanopore sequencing platforms. We have evaluated different long-read SV callers in combination with different aligners, and compared with SV truthsets for the HG002 sample developed by the Genome in a Bottle consortium. Platform-specific SVs callers were also benchmarked. Evaluation with haplotype-resolved SV callset on NA12940 were also performed. The haplotype-based comparison implemented in hap-eval is able to properly assemble and evaluate clusters of distinct SV calls providing a more accurate benchmark of SV discovery tools relative to earlier evaluation tools. Stratified analysis was performed for different genomic regions and SV lengths. We were also able to compare SV calls from different pipelines, which is essential in developing ensemble-based approach for SV discovery with further improved accuracy.

Omics Technologies Posters - Thursday

PB2982. Estimating and testing cell-type-specific gene co-expression from single-cell data: A robust and efficient method that mitigates technical confounding.

Authors:

C. Su¹, Z. Xu¹, X. Shan¹, B. Cai¹, J. Zhang², H. Zhao¹; ¹Dept. of Biostatistics, Yale Univ., New Haven, CT, ²Dept. of Management Sci., Univ. of Miami, Coral Gables, FL

Abstract Body:

Gene co-expression networks encode the functional organization of genes, and the single cell RNA-seq technology enables understanding such networks at the individual cell type level. However, sparse UMI counts from single cell data are measured with strong technical variations across cells, posing unique challenges to co-expression analysis. In this presentation, we first demonstrate that most existing co-expression estimation methods fail to address the confounding due to heterogeneous sequencing depths, resulting in falsely inferred co-expressions. For example, for a pair of independently simulated genes (5,000 cells, 100 simulation runs), at the statistical significance level of 0.05, Pearson correlations on log transformed and scaled data had an inflated type I error of 0.99 (SD=0.01), while state-of-the-art methods, such as locCSN and BZINB, also had inflated estimates of 0.66 (0.03) and 0.51 (0.01). In addition, at a fixed correlation strength, correlation estimates from these methods spuriously varied with mean expression levels (i.e., a mean-correlation relationship). To address the above limitations, we propose a novel and general bivariate expression-measurement model that explicitly accounts for the heterogeneity in sequencing depths. We also propose a new metric on gene co-expressions based on the true underlying expressions, which separates technical variations from biological ones and is robust to technical artifacts and variations in mean expression levels. To efficiently estimate large co-expression networks, we propose a fast method-of-moment estimator and an asymptotic test for co-expression identification. With simulated gene pairs, we show that our method successfully removed unwanted variation with nominal type I error control regardless of the expression level and achieved high power to infer co-expressed gene pairs. In large network simulations, our method achieved the highest AUC and its estimates were not confounded by gene expression levels (Pearson's $r=-0.00$, $p=0.98$), while the estimates from other methods were notably confounded by gene expression levels, such as Pearson correlations on log normalized data ($r=0.92$, $p<2.2e-16$) and SpQn ($r=0.68$, $p<2.2e-16$). Finally, we applied our method to single-nucleus RNA-seq data on Alzheimer's disease patients, and uncovered microglia-specific co-expressions among genes differentially expressed in microglia in diseased individuals. Further clustering analysis based on inferred co-expression patterns identified critical biological pathways involved in Alzheimer's disease, such as immune response, that were not discovered by other methods.

Omics Technologies Posters - Wednesday

PB2983. Evaluating deep learning for predicting epigenomic profiles

Authors:

Z. Tang; Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract Body:

Deep learning has been successful at predicting epigenomic profiles from DNA sequences. Most approaches frame this task as a binary classification relying on peak callers to define functional activity. Recently, quantitative models have emerged to directly predict the experimental coverage values as a regression. As new models continue to emerge with different architectures and training configurations, a major bottleneck is forming due to the lack of ability to fairly assess the novelty of proposed models and their utility for downstream biological discovery. Here we introduce a unified evaluation framework and use it to compare various binary and quantitative models trained to predict chromatin accessibility data. We highlight various modeling choices that affect generalization performance, including a downstream application of predicting variant effects. In addition, we introduce a robustness metric that can be used to enhance model selection and improve variant effect predictions. Our empirical study largely supports that quantitative modeling of epigenomic profiles leads to better generalizability and interpretability.

Omics Technologies Posters - Thursday

PB2984. Evaluation of cell type annotation for peripheral blood mononuclear cells using single-cell RNA versus a deconvolution approach with bulk RNA sequencing.

Authors:

X. Liu, T. M. Norden-Krichmar; Univ. of California, Irvine, Irvine, CA

Abstract Body:

Background: Deconvolution methods have been widely used to computationally estimate cell type composition in bulk RNA-seq data, in order to reveal cell-type-specific gene expression without conducting single-cell RNA sequencing (scRNA-seq). However, direct comparison of deconvolution methods is challenging because bulk RNA-seq samples are often collected from different participants than the scRNA-seq samples. The goal of this study was to compare and evaluate cell types of peripheral blood mononuclear cells (PBMCs) from the same participants, as determined from scRNA-seq data versus cell types inferred by deconvolution from bulk RNA-seq data. **Methods:** Biospecimens from an IRB-approved study by the Southern California Alcoholic Hepatitis Consortium (SCAHC) were collected at baseline with consent by the participants from alcohol-associated hepatitis (AH, n=3) and healthy controls (CT, n=2). ScRNA-seq was performed using 10x Genomics Chromium Single Cell technology and Illumina sequencing. Sequence data was mapped to the human genome (hg19) and integrated using cellranger 6.0.2 version. We then performed downstream analysis using Seurat (version 4.0.1). Bulk-RNA data was aligned and mapped to the human genome (hg19) using Bowtie2 release 2.3.4.1 and Tophat2 release 2.1.1. Deconvolution was performed using Absolute Immune Signal (ABIS) with 29 human immune cell types for PBMC transcriptomic data. **Results:** Using the ABIS deconvolution approach, we identified 17 cell types from the bulk RNA-seq data, including 8 out of 9 cell types identified by Seurat cell annotation of scRNA-seq data. Natural-killer T cells were the only scRNA-seq cell type that was not inferred, due to their absence from the reference dataset in the ABIS method. Percentages of CD8+ T cells, CD14+ monocytes, and CD16+ monocytes were consistent between the deconvolution and scRNA-seq results. In addition, both ABIS and scRNA-seq showed an increased percentage of monocytes in AH vs. CT. ABIS deconvolution identified very little naïve CD4+ T cells and natural-killer cells, whereas ABIS categorized a large percentage of terminal status of T cells, such as gamma-delta T cells, mucosal-associated invariant T (MAIT) cells, and memory CD4+ T cells. **Conclusion:** This exploratory study assessed the performance of deconvoluted bulk RNA-seq against scRNA-seq data using samples of PBMCs from the same participants, enabling direct comparison of these two methods. Our results showed that the robustness of the deconvolution method is dependent upon the reference dataset selected, and therefore, the deconvoluted results require careful interpretation.

Omics Technologies Posters - Wednesday

PB2985. Evaluation of single nuclei RNA sequencing in brain tissue using Pre-templated Instant Partitions (PIPseq)

Authors:

R. Meltzer, K. Kugler, S. Pandey, A. May-Zhang, A. George; Fluent BioSci., Watertown, MA

Abstract Body:

Single nuclei RNA sequencing (snRNA-seq) is an essential method for transcriptional characterization of cells when viable cell scRNA-seq is not an option due to fragile, difficult, or frozen cell samples. PIPseq is a novel, single cell sequencing technology capable of instantly partitioning, lysing, and capturing mRNA from extracted nuclei. PIPseq has benefits over existing single cell methods by allowing researchers to capture and instantly partition their nuclei of interest without the use of microfluidics, and is intrinsically scalable from hundred to hundreds of thousands captured nuclei in a single sample. Here, we extracted nuclei from various mouse tissues using optimized nuclei isolation methods for each tissue. We performed snRNA-seq as well as scRNA-seq on each tissue in order to compare the nuclei transcripts to the whole cell transcripts in each tissue type. For neuronal tissue, we explored two different nuclei isolation techniques and analyzed the effect of each method on obtained transcripts and differentially expressed genes. In summary, these experiments allowed us to assess the similarities and differences between fresh, whole cells and frozen, single nuclei after single-cell/nuclei sequencing. This study emphasizes the importance of understanding how input material affects data quality and the biological interpretations that are derived from these preparations- especially when access to one sample type or the other is limited.

PB2986. Evercode™ Whole Transcriptome Single-Cell RNA-Seq with Focal Barcoding Enables Single-Cell Transcriptomes Coupled with Gene or Vector-Enriched Readouts

Authors:

J. Pangallo, L. Kenyon, A. Sova, R. Koehler, C. Roco, A. Rosenberg; Parse BioSci.s, Seattle, WA

Abstract Body:

A limitation of single-cell RNA sequencing is the inability to detect every expressed gene in a given cell without exhaustive sequencing, which can be cost prohibitive due to the sequencing depth required per cell. This is problematic for applications such as single cell CRISPR screens where it is essential to detect the guide RNA (gRNA) in every cell in order to associate a transcriptome-wide perturbation effect. To address this we demonstrate an approach, known as “Focal Barcoding”, that enables enrichment and highly sensitive detection of individual genes or transgenes in single cell experiments. This allows dissection of complex pathways and biological mechanisms associated with one or more specific markers and is completely compatible with Parse’s current suite of Evercode™ single-cell RNA sequencing kits that enable profiling of up to one million cells. By enriching a target of interest, focal barcoding dramatically reduces the sequencing needed to robustly detect that target across different cells. We demonstrate that enriched genes or transgenes of variable expression levels, some of which are only detected in a small percentage of cells, can be detected in > 90% of cells after using focal barcoding (even when sequenced at shallow depth). We will present this proof of principle data and discuss additional applications that will be enabled by Evercode™ focal barcoding, such as single cell CRISPR perturbation experiments.

PB2987. Exome sequencing reanalysis complemented with combined multi-omics approach reached to 60% diagnostic yield in previously undiagnosed rare disease cohort

Authors:

K. Ounap^{1,2}, K. Oja^{1,2}, K. Reinson^{1,2}, K. Muru^{1,2}, T. Reimand^{1,2}, M. H. Wojcik^{3,4}, I. A. Osei-Owusu⁴, G. Michelotti⁵, A. O'Donnell-Luria^{3,4}, S. Pajusalu^{1,2}; ¹Univ. of Tartu, Tartu, Estonia, ²Dept. of Clinical Genetics, Genetics and Personalized Med. Clinic, Tartu Univ. Hosp., Tartu, Estonia, ³Boston Children's Hosp., Boston, MA, ⁴Broad Inst. of MIT and Harvard, Cambridge, MA, ⁵615 Davis Drive, Suite 100, Metabolon, Morrisville, NC

Abstract Body:

Rare diseases have heterogeneous underlying etiologies, and despite an application of different genomic analyses in clinical setting, only 30-50% of cases will receive a precise etiological diagnosis. In this study, we reanalyzed exome sequencing (ES) data in unsolved Estonian families from 2013-2019. In reanalysis negative cases, we carried out trio genome (GS), RNA sequencing, and/or untargeted metabolome analysis for the identification of new Mendelian disorders. We enrolled 154 individuals in whom single or trio ES was performed in clinical setting, but did not result in a confirmed diagnosis. Chromosomal microarray analysis, metabolic tests and fragile X syndrome testing in males are also regularly performed as part of the clinical workflow. The final study group consisted of 116 individuals; in all of them reanalysis of ES data was performed using the seqr platform, in collaboration with the Broad Institute Center for Mendelian Genomics. Among cases that remained negative after ES reanalysis, trio/quad GS was performed in 56 families, RNA sequencing in 49 individuals, and untargeted metabolome analysis in 35 individuals. We identified the disease cause in 70 (60%) individuals, of which 35 involved gene variant(s) or copy number variation in a previously known gene and 32 involved a novel gene. All novel gene variants were submitted to the Matchmaker Exchange. Among novel gene findings, 18 of them are published as a part of international collaboration (*RORA*, *OGT*, *H3F3B*, *RAB11A*, *POU3F3*, *CYFIP2*, *HIST1H1E*, *JAG2*, *POLRMT*, *TET3*, etc.). Reanalysis of ES data showed highest diagnostic efficacy - 49 (70%), among them 25 known and 24 novel genes. GS and RNA sequencing alone or in combination reached diagnostic efficacy of 16 (23%), 10 known and 6 novel genes. Metabolome data added special input in at least two cases (2 novel genes). Importantly, in one case, somatic known gene variant was identified and in two patients acquired etiology was confirmed after extensive diagnostic odyssey. Using this combined approach, our diagnostic yield increased by at least twofold. In the clinical setting in Estonia, the diagnostic yield of ES is 29% (Pajusalu et al., 2018). With this study, an additional 60% of previously unsolved cases received a genetic diagnosis with the total diagnostic yield reaching to approximately 70%. Our results highlight the importance of regular reanalysis of ES data as 70% of cases were solved by reanalysis. The added detection rate of GS and/or RNA sequencing is similar to previously published studies. Funding: Estonian Research Council grants PRG471, PUT355, and PSG774.

PB2988. Exome technology innovations advancing personalized medicine.

Authors:

K. Walker, J. Hu, Q. Meng, Q. Wang, X. Liu, Y. Dai, D. Pasham, M. Kaur, H. Shen, G. Weissenberger, S. Bhamidipati, K. Kottapalli, Z. Momin, G. Metcalf, H. Dinh, Y. Han, J. Santibanez, H. Doddapaneni, R. A. Gibbs, D. M. Muzny; Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX

Abstract Body:

Oligonucleotide capture-based DNA sequencing technologies have been a driving force for clinical diagnostics, novel disease gene discovery and identification of low frequency alleles in common disease and cancer. Advancement of exome sequencing in the clinical diagnostic arena has required technical innovations to ensure optimal DNA sequence coverage of clinically relevant genes, while maintaining overall high-quality, together with optimal speed and cost. To improve upon our previous generation of exome-sequencing reagents and methods, we generated a new exome capture design (HGSC-ClinExD) that targets 36.8Mb GENCODE and RefSeq coding regions on the HG38 reference sequence, utilizing TWIST capture technology. In addition to targeting gene coding regions, we incorporated clinically relevant non-CDS regions such as ClinVar pathogenic or likely pathogenic sites, COSMIC coding point mutations, pharmacogenomic sites, *TERT* promoter and key cardiovascular PRS sites. Exome sequencing performance using this new design was assessed utilizing 470 KAPA HiFi libraries from control, research consented and de-identified clinical samples. A subset of 210 samples with known pathogenic and benign variants (SNVs, Indel, CNVs) in genes with a range of genomic context (i.e., *PMS2*, *GBA*) were used to establish sensitivity, specificity, and reproducibility for clinical validation. Libraries were pooled (10-plex) for capture overnight at 70°C and sequenced as 70-plex in one lane of the Illumina NovaSeq S4 flowcell. This capture and sequencing format resulted in an average 12 Gbs of raw data generated for individual samples and >99% of the total targeted bases sequenced to a minimum depth of 20-fold with 65% of the reads mapping to target regions. Titration analyses showed that with only 5Gbs of data (40X average coverage) this design will achieve >95% of the target bases at 20X coverage, allowing for increased plexing of up to 130 samples per Illumina NovaSeq S4 lane and significantly decreasing sequencing costs. A survey of low coverage bases (<20X coverage) showed that the majority (53%) are in regions of <10bp encompassing a full range GC content. These results, along with the clinical validation data, demonstrate that the HGSC-ClinExD design has unprecedented utility for variant determination, novel gene discovery, deep somatic sequencing and orthogonal validation. Incorporation of the reagent in routine applications in both clinical and research settings enables comprehensive inclusion of clinical targets and general cost effectiveness, without loss of performance.

Omics Technologies Posters - Wednesday

PB2989. Extensive differential cell type-specific gene expression and regulation by sex in human skeletal muscle.

Authors:

S. Hanks¹, D. Ciotlos¹, A. Varshney¹, M. R. Erdos², N. Manickam¹, A. U. Jackson¹, J. Okamoto¹, H. M. Stringham¹, P. Orchard¹, N. Narisu², L. Bonnycastle², M. D. Sweeney¹, M. Laakso³, J. Tuomilehto⁴, T. A. Lakka³, K. L. Mohlke⁵, M. Boehnke¹, H. Koistinen⁴, F. S. Collins², S. C. J. Parker¹, L. J. Scott¹; ¹Univ. of Michigan, Ann Arbor, MI, ²NHGRI/NIH, Bethesda, MD, ³Univ. of Eastern Finland, Kuopio, Finland, ⁴Finnish Inst. for Hlth.and Welfare, Helsinki, Finland, ⁵Univ. of North Carolina, Chapel Hill, NC

Abstract Body:

Human skeletal muscle exhibits sex differences in its size, composition, and physiology that may contribute to disparities in muscle-related diseases such as type 2 diabetes, obesity, and osteoporosis. Here, we quantify sex differences in cell type composition, cell type specific gene expression and chromatin accessibility, and miRNA abundances to better understand biological variation in this tissue. We profiled single nucleus-resolution gene expression (snRNA-seq, n=287) and chromatin accessibility (snATAC-seq, n=287), as well as bulk miRNA expression (miRNA-seq, n=290), in vastus lateralis skeletal muscle biopsied from Finnish individuals. We jointly clustered snATAC-seq and snRNA-seq nuclei into 13 cell types, including 3 main muscle fiber types (Type 1, 2A and 2X). We tested for sex differences in cell type composition using a negative binomial model, and found being female was associated with more non-nerve neuronal ($p=2 \times 10^{-6}$) and Type 1 slow twitch oxidative fiber nuclei ($p=2 \times 10^{-5}$) and fewer Type 2X fast twitch glycolytic fiber nuclei ($p=3 \times 10^{-12}$). We tested for sex differences in gene expression and found that 11-15% of genes showed significant differences by sex in the Type 1, 2A and 2X fiber types (FDR<5%). Gene set enrichment analyses showed that genes in mitochondrial activity and energy metabolism pathways were more highly expressed in males than females in all three fiber types. Similarly, we found that 13-32% of ATAC-seq peaks were differentially accessible (DA) by sex in the muscle fiber types. We tested for enrichment of autosome DA peaks in muscle chromatin states and found the strongest enrichment the active enhancers (1.4-3.0 fold for sex differences ($p < 1 \times 10^{-100}$)). We then tested for an enrichment of DA peaks in promoters (<1 kb from TSS) of differentially expressed genes. The odds of differential expression by sex increased 2.4-3.4X ($p < 1 \times 10^{-25}$) for each additional DA promoter ATAC-seq peak in the same direction, indicating potential sex differences in transcriptional regulation. We next tested for sex differences in miRNA expression levels in bulk muscle as miRNAs regulate gene expression post-transcriptionally. We found that 359/1,049 (34%) miRNAs are differentially expressed by sex, indicating potential differences by sex in post-transcriptional regulation. Overall, we found extensive differences in gene expression by sex at the cell type level and potential evidence of sex-based regulation at both the transcriptional and post-transcriptional levels. These findings may help uncover the mechanisms of sex differences in muscle physiology and disease.

Omics Technologies Posters - Thursday

PB2990. Extracellular protein monitoring in the ResolveOME genomic and transcriptomic dual workflow to uncover cancer pathology mechanisms in single cells

Authors:

T. Morozova¹, V. Weigman¹, J. Blackinton¹, J. Croteau², A. Fernandes², K. Taylor², M. Fabani³, J. West¹, G. Harton¹, J. Zawistowski¹; ¹BioSkryb Genomics, Durham, NC, ²BioLegend Inc, San Diego, CA, ³Singular Genomics Systems, San Diego, CA

Abstract Body:

Cancer is a disease of remarkable cell heterogeneity and is driven by complex, interconnected omic tiers. Single cell research has become an instrumental method in interrogating these multiple levels, as the bulk sequencing does not have enough resolution to reveal the true heterogeneity of the samples. The ResolveOME workflow aids understanding of cell-to-cell heterogeneity by providing unified genomics and transcriptomic information—including assessment of genome-wide single nucleotide variation, copy number changes, regulatory variants, splice isoform variation and cell state changes from the same single cell. Here, we have adapted the existing ResolveOME genomic/transcriptomic workflow to include the detection of cell-surface protein expression using the TotalSeqTM-A Human T-cell, B-cell, Natural Killer (TBNK) panel (BioLegend) of antibody-conjugated oligonucleotides. Primary peripheral blood mononuclear cells (PBMCs) were processed using the ResolveOME workflow which unifies template-switching single-cell RNAseq chemistry and Primary Template-directed Amplification (PTA) for whole genome amplification (WGA). We incorporated the TotalSeqTM-A antibody-oligo cocktail into this workflow, whereby both cellular mRNAs and antibody-derived oligos specifically bound to PBMC antigens anneal to oligo dT primers, followed by template switch-based reverse transcription. This resulted in the creation of first-strand cDNA molecules and antibody-derived tag molecules that could be affinity purified and pre-amplified following whole genome amplification by PTA. Separate protein+RNA and DNA fractions are processed as distinct library preparations at the end of the workflow. Sequencing was performed with the novel G4 Sequencing Platform from Singular Genomics. Using this strategy with PBMC cells, we detected all nine barcode IDs corresponding to the specific antibodies in the TotalSeqTM-A panel. The total number of detected barcodes varied between antibodies as well as between single cells, whereby CD19, CD3, CD4, CD16 and CD56 showed the most significant variation between individual single cells. We are extending these analyses to other cellular systems as well as to primary cancer cells, using antibody-conjugated antibody panels tailored to the application. Our study has devised a method for simultaneous detection of three omic tiers: whole genomic and transcriptomic signatures coupled to the assessment of defined protein panels at the individual cell level, empowering insights into the interplay between the three tiers not possible in isolation.

PB2991. faiGP: an evolutionary approach to discover governing equations in high-dimensional genomic data

Authors:

S. Razavi¹, E. Gamazon²; ¹vanderbilt Univ. Med. center, nashville, TN, ²VUMC Clare Hall, Univ. of Cambridge, Nashville, TN

Abstract Body:

Here, we develop an integrative approach incorporating a convolutional variational autoencoder (for dimensionality reduction to reduce the search space), a bayesian multilabel classifier (for posterior inference and generation of the prior to guide the search), and a genetic programmer (for evolution of programs towards optimal fitness), to extract governing equations from data. We demonstrate an application of the framework in a theoretical account of ligand-receptor interactions with immediate relevance to transcription factor binding to regulatory DNA sequence. We propose a model of ligand-receptor binding kinetics that is generated from Hill dose-response experimental observations, providing a transcription-factor-mediated model of gene expression. Finally, the development of a model of transcription factor regulatory range with high fidelity to the original data, as an application, suggests the framework can facilitate discovery of governing equations in high-dimensional genomic data.

Omics Technologies Posters - Thursday

PB2992. Fast and gentle microfluidic cell sorting upstream of single cell transcriptomics

Authors:

M. Ciarlo¹, E. Rodriguez-Mesa², R. Barhouma², V. Tran³, A. Gadkari³, J. Musmacker³; ¹Miltenyi Biotec, San Diego, CA, ²Miltenyi Biotec, Santa Barbara, CA, ³Parse BioSci.s, Seattle, WA

Abstract Body:

While single-cell RNA sequencing (scRNA-seq) has become a widely used technique across many disciplines over the last decade, the high cost of sequencing, time-consuming cell preparation protocols, and extensive data analysis requirements have posed challenges to mainstream adoption. One way to reduce the cost and save time is to isolate the cell type of interest before performing scRNA-seq using cell-sorting techniques such as jet-in-air/droplet sorters or MACS® Magnetic Cell Sorting Technology. The challenge is that any upstream manipulation of the cells can lead to RNA degradation and perturbations in the transcriptome as well as the generation of cellular debris and/or dead cells which will negatively affect the quality of the transcriptomic data. Therefore, it is imperative to minimize sample preparation time and handle the cells as gently as possible. Jet-in-air/droplet sorters expose the cells to harsh conditions, such as high pressure, long fluidics pathways, electrostatic charges, and lengthy processing times. While the MACS Cell Separation Portfolio provides gentle, fast, and low parameter cell separation, the technology is not always sufficient for the isolation of specific cell types. This study demonstrates a multiparameter, fast, and gentle workflow for cell sorting with downstream scRNA-seq. In this example, the MACSQuant® Tyto® Cell Sorter, a microfluidic cartridge and microchip-based sorting technology, isolates B cells, CD16+ natural killer (NK) cells, and regulatory T cells (Tregs) from human peripheral blood as well as neurons, astrocytes and microglia from dissociated adult mouse brain. With this sorting technique, highly pure populations of distinct cell subtypes are obtained quickly while still maintaining high cell viability. Sorted cells are then analyzed via scRNA-seq using Evercode whole transcriptome technology allowing the profiling of single-cell whole transcriptomes from a bulk-sorted sample on any NGS device — eliminating the need for a droplet-based sequencing instrument. Sorted and unsorted samples were compared by looking at the number of reads obtained per cell as well as clustering of the data. This analysis showed a high number of reads per cell as well as distinct cell clusters of the sorted populations that overlaid directly on the clusters from the unsorted sample demonstrating that this method of sorting had no significant effect on the cell's transcriptome. This approachable and time-efficient process of combining microfluidic cell sorting with single-cell transcriptomics can be easily applied to other cell and tissues types and used in a broad range of applications.

Omics Technologies Posters - Wednesday

PB2993. FastRNA: an efficient exact solution for PCA of single-cell RNA sequencing data based on a batch-accounting count model

Authors:

B. Han, H. Lee; Seoul Natl. Univ. Coll. of Med., Seoul, Korea, Republic of

Abstract Body:

[Background] The analysis of single cell RNA sequencing (scRNA-seq) data almost always begins with the generation of the low dimensional embedding of the data by principal component analysis (PCA). Because PCA requires normally distributed data, researchers have traditionally applied a log-normal transformation to the count data of scRNA-seq. However, log-normalization can induce an artificial bias to the data. Studies have shown that the log-normalization can exaggerate the effects of the small counts. As a result, the final clustering can be in low quality in terms of the resolution. **[Challenge]** To address this bias, recent studies have developed methods that directly assume a count model. In these methods, a Poisson or negative binomial distribution is assumed for the observed count, and then normally-distributed residuals of the counts are calculated. The most popular method is scTransform (Genome Biology 2019), and a more recent method is the analytic Pearson residual (Genome Biology 2021). These methods were superior to naïve normalization in both theoretical and practical perspectives. However, they are extremely slow for large datasets, often taking more than several years of computation time. For this reason, for large datasets, naïve normalization is still being widely used. **[Solution]** Here we present FastRNA, an efficient exact solution for PCA of scRNA-seq data based on a full count model accounting for both batches and cell size factors. We assume the same general count model as previous methods, but we obtain the exact solution using two orders of magnitude less time and three orders of magnitude less memory than other methods. This achievement results from our unique algebraic strategy that utilizes several key observations, such as (A) that the PCA of the count residual matrix is equivalent to the PCA of the covariance of that matrix, (B) that the latter covariance matrix can be decomposed into a sum of sparse matrices, and (C) that the batch-wise count summation can serve as a sufficient statistic for calculation of batch-corrected residuals. These unique algebraic ideas, as a combination, work seamlessly together to completely remove the need for storing the actual residual matrix in memory. Importantly, our solution does not use an approximation but provides an exact solution without any sacrifice of the precision. Generating a batch-accounted PC of an atlas-scale dataset with 2 million cells takes less than 1 minute and 1GB memory using our method. By allowing the analysis of the largest data inside an ordinary laptop environment, we believe that FastRNA can revolutionize scRNA-seq analysis.

Omics Technologies Posters - Thursday

PB2994. FedExosome: mitochondrial DNA & microRNA profiling of neuronal-derived packages in Alzheimer's disease

Authors:

C. Hall, I. Garlotte, K. Subasinghe, R. Barber, N. Phillips; UNTHSC, Fort Worth, TX

Abstract Body:

Background: Alzheimer's disease (AD) is a complex neurodegenerative disorder characterized by impaired memory, diminished cognitive abilities, and accumulation of amyloid beta plaques and hyperphosphorylated tau tangles in the brain. AD progression is insidious, with the earliest clinical symptoms appearing decades after key neuropathological changes have occurred. Accurate diagnosis during the transitional period between disease onset and clinical manifestation could provide critical insight into AD pathogenesis and enable development of effective therapeutic strategies to prevent irreversible neuronal death. Evidence suggests that early alterations in the AD brain (oxidative stress, neuroinflammation, aberrant gene expression) can propagate to local and distal cells through the biological packages secreted by neurons. These neuronal-derived exosomes (NDEs) can cross the blood-brain barrier and are thus capable of mediating systemic inflammation in response to CNS-sourced stress through their mitochondrial DNA (mtDNA) and microRNA (miRNA) cargo. Circulating NDEs may serve as an easily accessible, early indicator of the forthcoming neuropathological changes in the AD brain. This study aims to develop a high-throughput workflow for profiling mtDNA and miRNA in plasma NDEs. **Methods:** Human plasma samples (500 μ L) were processed in duplicate using a two-step method involving (1) precipitation of total exosomes with ExoQuick (SBI) and (2) immunocapture of NDEs with a biotinylated antibody against the well-established neuronal surface marker, CD171. Intact NDEs were characterized via nanoparticle tracking analysis and flow cytometry. DNA was then extracted with the DNeasy blood & tissue kit (Qiagen) and mtDNA load was estimated using real-time qPCR. RNA was extracted with the EVeryRNA (SBI) and miRNeasy (Qiagen) purification systems and prepared for sequencing on the Illumina NextSeq 550 using the QIAseq miRNA library kit (Qiagen). **Results:** The protocol modifications implemented in this project were compared based on particle size, distribution, and purity as well as absolute mtDNA load and spike-in normalized miRNA read counts. These data not only demonstrate the feasibility of profiling the mtDNA and miRNA from 500 μ L of plasma NDEs but have also resulted in a high-throughput workflow for processing patient samples. **Conclusion:** This work represents the first successful attempt to simultaneously quantify the mtDNA and sequence the miRNAs in the relatively small subpopulation of plasma exosomes that originate from neurons. Future studies will harness the protocol developed herein to assess the biomarker potential of NDEs in AD.

Omics Technologies Posters - Wednesday

PB2995*. Fixing falsely duplicated and collapsed regions of the GRCh38 reference genome

Authors:

S. Behera¹, J. LeFaive², P. Orchard³, M. Mahmoud¹, J. Farek¹, D. Soto⁴, A. Smith³, M. Dennis⁴, J. Zook⁵, F. Sedlazeck¹; ¹Baylor Coll. of Med., Houston, TX, ²Univ. of Michigan Sch. of Publ. Hlth., Ann Arbor, MI, ³Univ. of Michigan, Ann Arbor, MI, ⁴Univ. of California Davis, Davis, CA, ⁵Natl. Inst. of Standards and Technology, Gaithersburg, MD

Abstract Body:

The GRCh38 reference is the current standard in human genomics research. However, the current version of GRCh38 (p.13) contains a number of errors including 1.2 Mbp of falsely duplicated and 8.04 Mbp of collapsed (e.g., missing copies of segmental duplication) regions. This impact variant calls for 33 protein-coding genes, including 12 with medical relevance such as *KCNE1*, *CBS*, and *MAP2K3*. We generated a modified GRCh38 reference to correct these errors by masking the falsely duplicated regions and adding decoy sequences of falsely collapsed regions. To avoid re-analyzing data for the entire genome, we developed an efficient tool, FixItFelix, that extracts sequences from impacted regions of an existing BAM/CRAM and then remaps to the modified GRCh38 within 5~8 minutes. We evaluated the performance of our approach using the HG002 sample with the GIAB challenging medically relevant gene (CMRG) benchmark set and demonstrated improved accuracy of variant calling with the modified GRCh38. For falsely duplicated regions, a perfect recall score (1.0) with a precision of 0.96 was achieved for both SNV and indel call (0.007 and 0 respectively for GRCh38). For the falsely collapsed regions, remapping produced mainly improved precision by removing false variants caused by mismapped reads. Expanding our benchmark to genes not included in the CMRG set using variant calls from dipcall of phased HG002 assemblies, we also validated improved performance in these genes using the modified reference. Similar improvements were observed for SNV callings in exon regions when using the modified reference with HG002 whole exome and RNA sequencing data. Expanding our analysis beyond HG002, we used eight samples of different ancestries from the T2T Diversity panel— generating dipcall-based benchmark sets— and observed improvements in variant calling. To explore the impact of this new reference beyond variant calling, we performed cis-eQTL analysis using 449 lymphoblastoid cell line RNA-Seq datasets from the 1000 Genomes Project using either GRCh38 or the modified GRCh38 and showed that GRCh38 shows several apparently artifactual eQTL signals in the falsely duplicated regions. We applied FixItFelix to sequence data of 4,174 publicly available samples and showed that the mapping qualities for the erroneous regions were consistent with the evaluations for HG002. In summary, we present a modified GRCh38 reference that corrects errors while maintaining the same coordinates allowing us to leverage the extensive existing annotations of GRCh38, along with an efficient remapping approach that enables quick and efficient re-analysis of genomes to gain improved insights from existing data.

Omics Technologies Posters - Thursday

PB2996. Functional characterisation of the amyotrophic lateral sclerosis risk locus *GPX3/TNIP1*

Sch., Boston, MA, ¹⁶Dept. of Computer Sci., Univ. of California Los Angeles, Los Angeles, CA, ¹⁷Queensland Brain Inst., The Univ. of Queensland, Brisbane, Australia

Abstract Body:

Background: Amyotrophic lateral sclerosis (ALS) is a complex, late-onset, neurodegenerative disease with a genetic contribution to disease liability. Genome-wide association studies (GWAS) have identified ten risk loci to date, including the *TNIP1/GPX3* locus on chromosome five. Given association analysis data alone cannot determine the most plausible risk gene for this locus, we undertook a comprehensive suite of in silico, in vivo and in vitro studies to address this. **Methods:** The Functional Mapping and Annotation (FUMA) pipeline and five tools (conditional and joint analysis (GCTA-COJO), Stratified Linkage Disequilibrium Score Regression (S-LDSC), Polygenic Priority Scoring (PoPS), Summary-based Mendelian Randomisation (SMR-HEIDI) and transcriptome-wide association study (TWAS) analyses) were used to perform bioinformatic integration of GWAS data ($N_{\text{cases}} = 20,806$, $N_{\text{controls}} = 59,804$) with ‘omics reference datasets including the blood (eQTLgen consortium $N = 31,684$) and brain ($N = 2,581$). This was followed up by specific expression studies in ALS case-control cohorts (microarray $N_{\text{total}} = 942$, protein $N_{\text{total}} = 300$) and gene knockdown (KD) studies of human neuronal iPSC cells and zebrafish-morpholinos (MO). **Results:** SMR analyses implicated both *TNIP1* and *GPX3* ($p < 1.15 \times 10^{-6}$), but there was no simple SNP/expression relationship. Integrating multiple datasets using PoPS supported *GPX3* but not *TNIP1*. In vivo expression analyses from blood in ALS cases identified that lower *GPX3* expression correlated with a more progressed disease (ALS functional rating score, $p = 5.5 \times 10^{-3}$, adjusted $R^2 = 0.042$, $B_{\text{effect}} = 27.4 \pm 13.3$ ng/ml/ALSFRS unit) with microarray and protein data suggesting lower expression with risk allele (recessive model $p = 0.06$, $p = 0.02$ respectively). Validation in vivo indicated *gpx3* KD caused significant motor deficits in zebrafish-MO (mean difference vs. control \pm 95% CI, vs. control, swim distance = 112 ± 28 mm, time = 1.29 ± 0.59 s, speed = 32.0 ± 2.53 mm/s, respectively, p for all < 0.0001), which were rescued with *gpx3* expression, with no phenotype identified with *tnip1* KD or *gpx3* overexpression. **Conclusions:** These results support *GPX3* as a lead ALS risk gene in this locus, with more data needed to confirm/reject a role for *TNIP1*. This has implications for understanding disease mechanisms (*GPX3* acts in the same pathway as *SOD1*, a well-established ALS-associated gene) and identifying new therapeutic approaches. Few previous examples of in-depth

investigations of risk loci in ALS exist and a similar approach could be applied to investigate future expected GWAS findings.

Abstract Body:

Gene regulatory network (GRN) inference has been a major topic in the field of computational biology and bioinformatics. Constructing GRNs is crucial to understanding regulatory relationships between transcription factors (TFs) and their target genes under different biological conditions. Previous GRN inference methods mainly use transcriptomic data, and many of them have been proposed to analyze RNA sequencing (RNA-seq) data. Popular methods such as GENIE3 and SCENIC that rely on regression trees have shown success in GRN inference using bulk RNA-seq and single-cell RNA-seq (scRNA-seq) data, respectively.

Although inferring GRNs from transcriptomic data has been widely adopted, it has been shown that even the top methods' performance was moderate. This may result from the inherent shortcomings to the assumption that regulatory interactions can be fully extracted from expression patterns. However, gene regulation does not only involve the expression of necessary TFs, but also other factors such as the accessibility of important chromatin regions (promoters and enhancers) around the transcription starting (TSS) site of a gene. In recent years, the emergence of new sequencing technologies has enabled the measurement of expression levels by scRNA-seq and chromatin accessibility by scATAC-seq at the same time. Such co-assayed data provide new opportunities for us to infer more accurate GRNs.

In our presentation, we will introduce a new framework for GRN inference using single-cell multiome ATAC-seq and RNA-seq data. We first collect ATAC peaks within 500 kb around the TSS of a target gene, and pair TFs with candidate ATAC peaks by applying FIMO, a TF binding site analysis tool. Next, we run GENIE3, a random forest algorithm, to build a model between TF-ATAC pairs and the target gene using the multiome data. Last, the weight for each TF is calculated as the summation of the importance scores of all TF-ATAC pairs that involve the TF. We analyze a single-cell multiome data from a healthy donor's blood sample and benchmark the performance of our framework with the method that is based on expression data only using GRNs from existing databases (DoRothEA, TRRUST and RegNetwork) as the ground truth. We show that our model infers GRN with higher precision and AUPRC values. We also extend our approach by considering the strength of TF binding on an ATAC peak, which can further improve GRN inference. Overall, our proposed method can effectively use the ATAC data for more accurate GRN inference.

PB2998. Generating long-range sequencing information without long-read sequencing

Authors:

Z. Chen, L. Pham, V. Mikhaylova, T-C. Wu, G. Mo, P. Chang, Y. Xia, C. Heberling, I. Bassets, Y. Wang; Universal Sequencing Technology Corp, Carlsbad, CA

Abstract Body:

Long-range sequencing information is required for de novo assembly, haplotype phasing and structural variation detection. Current long-read sequencing technologies can provide valuable long-range information but at high cost or low accuracy and require large amount of DNA input. How can we use highly accurate and relatively low-cost short reads to generate long-range sequencing data? We achieve it by using TELL-SeqTM linked read technology, which enables a short-read second-generation sequencer to generate over 100 kb long-range sequencing information with as little as 0.1 ng input material. In a PCR tube, millions of clonally barcoded beads are used to uniquely barcode long DNA molecules and generate sequencing-ready library in 3 hours. Using TELL-LinkTM assembler with these barcoded linked reads produced by a short read sequencer, we successfully assembled many microbes into one scaffold at high accuracy with 0.1 - 0.5ng input DNA. Other sizes of genomes ranging from megabases to gigabases were able to be de novo sequenced with 0.5ng to 5ng genomic DNA input. In addition, TELL-Seq reads were used for scaffolding of other long read sequencing assemblies and resulted in significantly improved assembly for various samples, such as, insects, marine organisms and humans. TELL-Seq reads also provide excellent haplotype phasing capability. We constructed whole genome sequencing linked read libraries using 5ng high molecular weight genomic DNA from GM12878 and GM24385 cells and sequenced them on a NovaSeq system. Analyzing TELL-Seq reads with TELL-SortTM phasing tool, we phased NA12878 and NA24385 human genomes into megabase long phased blocks with N50 phased block size up to 15Mb long. A notable example was that entire 4Mb Major Histocompatibility Complex (MHC) locus was phased into one phase block. Besides whole genome scale phasing, we demonstrate excellent phasing results on long-range PCR amplicons and enriched genomic regions ranging from 2kb to 200kb using linked reads. Furthermore, for the very first time we show that TELL-Seq is capable to generate average 40kb long-range sequencing information from FFPE samples and provide the first “long-read” approach to investigate this widely used clinical sample type.

PB2999. Generative Adversarial Networks Create High-Quality Synthetic Prostate Cancer Magnetic Resonance Images.

Authors:

B. Ledesma¹, I. Xu¹, D. Van Booven¹, S. Goberdhan², S. Punnen¹, A. Mahne², R. Stoyanova¹, H. Arora¹; ¹Univ. of Miami, Miami, FL, ²Univ. of Central Florida, Orlando, FL

Abstract Body:

Introduction. The recent integration of open-source data to machine learning models, especially in the medical field, has opened new doors to studying disease progression and/or regression. However, one limitation of the medical data for machine learning approaches is the insufficient quantity and quality of data for a particular medical condition. In this context, synthetic data augmentation by using generative adversarial networks (GAN), could potentially generate high-quality data that preserve clinical variability. **Methods.** A GAN pipeline to curate synthetic prostate cancer magnetic resonant images (MRIs) was conducted. A total of 139 T2-weighted prostate images from public sources were used in an unsupervised GAN called SinGAN, to create synthetic prostate MRI images from a single image. Synthetic images with a high-level segmentation boundary of the prostate were filtered and used in the quality control assessment by a different machine learning segmentation pipeline. To assess final quality, participating scientists with varying levels of experience (more than 10 years, 1 year, or no experience) to work with MRI images were asked to study 60 MRI images and evaluate if they were conventional or synthetic images. **Results.** The most experienced group correctly identified conventional vs synthetic images with 67% accuracy, the group with 1 year of experience correctly identified the images with 58% accuracy, and the group with no prior experience reached 50% accuracy. Nearly half (47%) of the synthetic images were mistakenly evaluated as conventional images. Interestingly, the blinded quality assessment by a board-certified radiologist to differentiate conventional and synthetic images was not significantly different in the context of the mean quality of synthetic and conventional images. **Conclusion.** SinGAN model creates MRI images that are similar enough to the acquired MR images to be indistinguishable in some cases. This study shows promise that high-quality synthetic images from MRI can be generated using GAN. Such an AI model may contribute significantly to various clinical applications which involve supervised machine learning approach.

PB3001*. Genetics guided approach to infer unobserved covariates in functional genomics data

Authors:

R. Yamamoto¹, M. Thompson¹, N. Zaitlen²; ¹Univ. of California, Los Angeles, Los Angeles, CA, ²UCLA, Los Angeles, CA

Abstract Body:

High dimensional datasets used in functional genomics studies are often confounded by technical and environmental variation that occur during high-throughput experiments. These unobserved confounders bias the results of analysis significantly. Therefore, it is common practice to use methods to estimate these covariates and account for such effects in analysis. Since these variations are not directly observed, most commonly used methods, such as PEER and SVA, aim to predict covariates that explain the largest proportion of variability for the data and regard them as confounding. However, the extent to which these predicted confounders affect actual biological variations is not well understood. In fact, some studies suggest that using covariates carelessly from these methods could remove signals of interest. In this study, we revisit the problem of hidden confounder prediction and propose a new approach to estimate covariates while maximizing the genetically derived variability. We formulate this approach in the context of eQTL detection studies. Our neural net-based model takes in the matrix of gene expression and known covariates and transforms them into a set of hidden covariates. Our loss function takes in predicted hidden covariates and we aim to maximize the absolute value of t-statistics for a subset of eQTLs that are known to have strong associations. Once the training reaches convergence, we use predicted hidden covariates to discover eQTLs that are not included during the training. We first show through simulations that our method outperforms PEER, state of art hidden covariates predictor. Our model yields more than two fold increase in the number of eQTL discovered compared to when using PEER (246 new eQTL discovered vs 89 new eQTL discovered using PEER across simulations). Our predicted hidden covariates also explain more variance for true hidden covariates than PEER factors (14% increase in R^2 ($H_{true} \sim H_{pred}$) overall). Applied to the GTEx consortium, we also observe a significant improvement in t-statistics of eQTLs compared to previous approaches. Together, we show that our novel approach to estimate hidden covariates provides a valuable resource to improve functional genomics studies.

PB3002. *Genetics of Cardiovascular diseases: Mathematical Modeling & Development of a Predicting Simulator Prediction of the heart attack, the treatment to prescribe and the risk of secondary complications*

Authors:

H. Hassani Idrissi¹, H. AKODAD², R. HABBAL³, S. NADIFI¹; ¹Univ. Hassan II Sch. of Med. and Pharmacy casablanca Morocco, Casablanca, Morocco, ²CHU Hassan II, Fes, Morocco, Fes, Morocco, ³CHU Ibnou Rochd, Casablanca, Morocco, Casablanca, Morocco

Abstract Body:

Objective: Cardiovascular diseases are among the leading causes of death worldwide, affecting both the costs of medical and healthcare services, as well as the quality of patients' life. Since the majority of these pathologies are the result of an occlusive thrombosis, the therapeutic strategy adopted is essentially based on the prescription of an antithrombotic agent. However, inter-individual variability has -for long- been observed in these diseases, in terms of response to treatment: patients fail to derive the same degree of benefit from the prescribed dose, and side effects are observed in many of them. Therefore, our pharmacogenomics study aims -not only- to identify the clinical and genetic factors modulating the response of CVD patients to treatment, but also tries to suggest a solution to improve the quality of care and treatment, and life expectancy of these patients. **Methodology:** To do so, the clinical data of our patients were collected after obtaining signed consents. We have -then-used- - **Reverse transcription RT-qPCR analysis** (objective: quantification of mRNA copies), - **Sequencing (DNA:** identification of eight novel mutations), - **PCR-RFLP** (genotyping of patients for SNPs that are already known) - **Molecular Modeling** using bioinformatics tools (protein: study of the effect of the identified novel mutations on the protein's function and structure), to identify the genetic factors that would be responsible for the resistance to treatment, the development of secondary complications, and predisposition to the disease. **Important results obtained** Based on these identified clinical and genetic risk factors, we have developed, through a Mathematical Modeling approach, mathematical models (equations) that we have integrated into a Digital Simulator, the first-of-its-kind, in terms of Medical Decision Support Systems (MDSS), in the form of a digital platform (smartphone application and website). We made sure that the latter is easy to access and manipulate by the treating physician, and highly sensitive and specific in terms of predictions. The ultimate aim of our study was to help predict the patient's behavior towards the therapeutic molecule before its administration, the risk of developing secondary effects, in addition to that of developing the heart attack among normal subjects (genetic counseling). It is also good to mention that the analyzed pathology (cardiovascular diseases) was just an example and that the followed approach can easily be used to predict the same events for any other pathology such as cancer.

Omics Technologies Posters - Wednesday

PB3003. Genome-wide prediction of chromatin profiles from gene expression

Authors:

J. Fu¹, S. Sabri¹, J. Ernst²; ¹Univ. of California, Los Angeles, Los Angeles, CA, ²UCLA, Los Angeles, CA

Abstract Body:

High-throughput sequencing based methods for chromatin profiling have been developed to map epigenetic modifications such as histone methylation and acetylation. Large compendia of these maps have been accumulated and used for a range of biological questions including analyzing the contribution of non-coding genetic variants to disease. However, mapping such modifications in the context of limited number of cells or at the single cell level remains challenging. In some cases it is easier to acquire gene expression data. This motivates the development of computational methods that can impute maps chromatin marks by integrating compendia of chromatin and gene expression data into new cell types with only gene expression data available. Here we present a regression based method that makes predictions based on integrating features defined based on both expression data of nearby genes within the cell type and the relationship of chromatin mark signal at the target position with gene expression across cell types. We applied and evaluated the method using a compendia of paired bulk RNA-seq and H3K27ac data in human and mouse. We compare this method against other related methods. We also demonstrate the potential application of this method in the deconvolution of bulk chromatin profiles into cell type specific chromatin profiles in the presence of single cell RNA-seq data.

Omics Technologies Posters - Thursday

PB3004*. *Genome-wide prediction of pathogenic gain- and loss-of-function variants from ensemble learning of diverse feature set*

Authors:

Y. Itan¹, A. Schlessinger¹, **D. Stein**¹, C. Bayrak¹, y. wu¹, P. Stenson², D. Cooper³; ¹Icahn Sch. of Med. at Mount Sinai, New York, NY, ²Cardiff Univ., Cardiff, United Kingdom, ³Cardiff Univ, Cardiff, Wales, United Kingdom

Abstract Body:

Gain-of-function (GOF) variants yield increased or novel protein function while loss-of-function (LOF) variants yield diminished protein function. GOF and LOF variants can result in markedly varying phenotypes even when occurring in the same gene. Experimental approaches for identifying GOF and LOF are slow and costly, and computational tools cannot accurately discriminate between GOF and LOF variants. We developed LoGoFunc, the first computational genome-wide GOF and LOF classifier. LoGoFunc is an ensemble machine learning method for predicting pathogenic GOF, pathogenic LOF and neutral variants, trained on 672 protein, gene, variant, and network annotations describing diverse biological characteristics. We analyzed features in terms of protein structure and function, splice disruption, and phenotypic associations, revealing previously unreported relationships between various biological phenomena and variant functional outcomes. For example, GOF and LOF variants demonstrate contrasting enrichments in protein structural and functional regions, and LOF variants are more likely to disrupt canonical splicing as indicated by splicing-related features employed by the model. Furthermore, by performing phenome-wide association studies (PheWAS), we identified strong associations between relevant phenotypes and high-confidence predicted GOF and LOF variants. LoGoFunc performs well on an independent test set of GOF and LOF variants, and we provide precomputed genome-wide GOF and LOF predictions for 71,322,505 missense variants.

Inc., Montreal, QC, Canada, ⁹Fulcrum Genomics, Boulder, CO, ¹⁰Berlin Inst. of Hlth.(BIH) at Charité – Univ.smedizin Berlin, Berlin, Germany, ¹¹Univ. of Gothenburg, Gothenburg, Sweden, ¹²Sahlgrenska Univ. Hosp., Gothenburg, Sweden, ¹³King's Coll. London, London, United Kingdom

Abstract Body:

Metabolic processes can influence disease risk and provide therapeutic targets, yet their genetic determinants and role in human diseases are not well understood. Here, we conducted a series of large genome-wide association studies of metabolites, including 1,091 blood metabolites and 309 metabolite ratios in 8,299 individuals from the Canadian Longitudinal Study on Aging. We identified associations for 690 metabolites across 248 loci; and associations for 143 metabolite ratios arising from 69 loci. Integrating metabolite-gene and gene expression information identified 94 effector genes for 109 metabolites and 48 metabolite ratios. We used Mendelian Randomization (MR) to estimate the causal effect of selected metabolites and metabolite ratios on 12 traits and diseases influenced predominately by three mechanisms: aging, metabolism and immune response. MR identified 22 metabolites and 20 metabolite ratios for these 12 outcomes, which included orotate for estimated bone mineral density (eBMD), alpha-hydroxyisovalerate for body mass index and ergothioneine for two immune-related traits: inflammatory bowel disease and asthma. Since increased orotate was associated with lower eBMD in MR studies, we measured its level in a separate nested case-control cohort study for osteoporotic fracture and demonstrated that, as predicted by MR, increased orotate was associated with increased incident hip fractures. This study provides a valuable resource describing the genetic architecture of metabolites and delivers insights into their role in common disease, thereby offering opportunities for therapeutic targets.

Omics Technologies Posters - Thursday

PB3006. Genotyping known disease-associated short tandem repeats in 7,000 Project MinE genomes reveals their relation to ALS and assists in disease-association analysis of unknown short tandem repeats.

Authors:

J. van Vugt¹, R. Zwamborn¹, E. Dolzhenko², Project MinE Sequencing Consortium, M. A. Eberle², J. H. Veldink¹; ¹UMC Utrecht Brain Ctr., Utrecht, Netherlands, ²Illumina Inc., San Diego, CA

Abstract Body:

Short tandem repeats (STRs) are causal to many neurodegenerative disorders such as the *C9ORF72* repeat expansion in amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Some STRs that are causal to a disease are also a risk factor for another disease. For example, the *ATXN2* repeat expansion is causal to spinocerebellar ataxia 2 and a risk factor for ALS. To see whether more disease associated STRs are a risk factor for ALS, we have analyzed ~40 known STRs in 7,000 whole genomes of Project MinE. STRs were genotyped with ExpansionHunter (EH), because of the high genotyping accuracy and ability to genotype consecutive STRs. This genotyping accuracy was validated with PCR and Sanger sequencing of 5,680 samples in three STRs, which revealed concordance with the wet lab results of 98.3%. Though EH genotyping accuracy is very high, it is limited by the fragment length, read length and read depth, and can be obstructed by motif changes, motif interruptions, indels and multiallelic genotypes. We therefore created a workflow with a manual and automated part to assess the STR genotyping, based on the results of EH, REViewer and ExpansionHunterDeNovo (EHdenovo). The manual part entails visual inspection of 6,500 read pileup plots, which allows for identification of genotyping errors and, if possible, correcting these. The automated part involves the analysis of STR parameters from EH and REViewer, for example fragment length limitation and allelic read depth, and identification of STR motif changes with EHdenovo. Combining the automated and manual workflows allowed for complete STR genotype assessment. With EHdenovo we identified motif changes in *BEANI*, *DABI*, *DMPK*, *FXN*, and *RFC1* of which some motifs have not been reported before. The pathogenic and premutation frequencies of the disease associated STRs in Project MinE genomes were compared to that described in literature. Some misdiagnoses were resolved (i.e. Kennedy's disease), which supports the importance of genetic screening upon disease diagnosis. The ALS association analysis was performed by comparing the repeat sizes between 5271 cases and 1756 controls. The only STRs that revealed a significant effect with ALS after multiple testing correction were *C9ORF72* and *ATXN2*, which are known ALS associated STRs. Notably, the repeat expansion in *Huntingtin (HTT)* was not ALS associated (5 cases and 1 control with 40 or more repeats). More than 37 thousand unknown STRs were analyzed in Project MinE using the automated workflow and more will follow. The read pileup plots of potential ALS associated STRs were visually inspected to complete the genotype assessment and validate the authenticity of the ALS association.

Omics Technologies Posters - Wednesday

PB3007*. GestaltMatcher supports classification of ultra-rare disorders and delineation of novel syndromes by facial phenotype descriptors

Authors:

T-C. Hsieh¹, A. Bar-Haim², S. Moosa³, K. W. Gripp⁴, H. Lesmann⁵, J-T. Pantel¹, N. Fleischer², A. Hustinx¹, B. Javanmardi¹, L. Averdunk⁶, M. M. C. Chui⁷, C. C. Y. Mak⁷, B. H. Y. Chung⁷, F. Distelmaier⁶, P. Krawitz¹; ¹Inst. for Genomic Statistics and Bioinformatics, Univ. Hosp. of Bonn, Bonn, Germany, ²FDNA Inc., Boston, MA, ³Div. of Molecular Biology and Human Genetics, Stellenbosch Univ. and Med. Genetics, Tygerberg, South Africa, ⁴DuPont Hosp, Wilmington, DE, ⁵Inst. of Human Genetics, Univ. Bonn, Bonn, Germany, ⁶Dept. of Gen. Pediatrics, Neonatology and Pediatric Cardiology, Med. Faculty, Univ. Hosp., Heinrich-Heine-Univ., Düsseldorf, Germany, ⁷The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract Body:

Introduction: Many monogenic disorders cause a characteristic facial gestalt. Next-generation phenotyping (NGP) can support physicians in recognizing these patterns by associating facial phenotypes with the underlying syndrome through training on thousands of patient photographs. However, this supervised approach means that diagnoses are only possible if the disorder was part of the training set, which often excludes ultra-rare disorders due to a lack of data. To improve recognition of ultra-rare and novel disorders, we developed GestaltMatcher, an encoder for portraits that is based on a deep convolutional neural network. GestaltMatcher goes beyond existing NGP tools by supporting not only classification of known disorders but cluster analysis of any photograph. By this means, GestaltMatcher can be used to lump and split phenotypes.

Methods: We compiled a dataset consisting of 17,560 patients diagnosed with 1,115 different rare disorders. For each individual, a frontal photo and the molecularly confirmed diagnosis were available. A deep convolutional neural network was trained on patients' frontal photos and can be used to encode photos to facial phenotype descriptors. By this means, a photo is positioned in the Clinical Face Phenotype Space (CFPS), in which distances between images define syndromic similarity. We presented two cohorts for the lump and splitter analysis: Cohort-1 consisted of five patients with disease-causing mutations in *Gene-X*, and Cohort-2 contained 33 patients with the disease-causing mutations in *Gene-Y*.

Results: Within the CFPS, the patients with a similar phenotype were located in close proximity. Ranking syndromes by distance showed that patients could be matched to others with the same molecular diagnosis even when the disorder was not included in the training set. With cluster analysis in the CFPS, we demonstrated how GestaltMatcher can lump *Gene-X* into the phenotypic series of Rothmund-Thomson syndrome and split *Gene-Y* into two phenotypes. On the molecular level, the pathogenic mutations of *Gene-Y* are subgrouped into two different exons differing in NMD. Moreover, as a tool for matching patients of unknown cause, GestaltMatcher could be seen as the analogon to GeneMatcher on the phenotypic level, that not only accelerates the clinical diagnosis of patients with ultra-rare disorders but also enables the delineation of new phenotypes.

Conclusions: GestaltMatcher opens the door to extend the coverage of syndromes recognized by NGP tools and to further enable exploration of unknown phenotype-genotype associations.

Omics Technologies Posters - Thursday

PB3008*. GTAGMe-seq reveals the genome-wide long-range coordinated cis-regulatory elements at the single-molecule level

Authors:

Y. Liu¹, H. Fu¹, H. Zheng¹, L. Muglia², L. Wang¹; ¹Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH, ²Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract Body:

Cis-regulatory elements (CREs), such as promoters and enhancers, play instrumental roles in regulating mammalian gene expression. Sets of transcription factors (TFs) bring together multiple CREs, which can be up to megabases away, to initiate and maintain the expression of their target genes. How distal CREs coordinate together to regulate the downstream target genes' expression is one of the central questions in gene regulation. Detection and quantification of the binding events that co-occur at distal CREs require the ability to measure TFs-DNA interaction at the single-molecule level with awareness of spatial proximity. Here, we report a method, GTAGMe-seq, to simultaneously capture the genetic variants, DNA methylation, GpC methyltransferase footprints, and chromosome conformation changes from a single DNA molecule, together with transcriptome in the same assay. To benchmark the performance, we applied GTAGMe-seq to the IMR-90 and GM12878 cell lines and found the high concordances with the state-of-art mono-omics assays across all the molecular measurements at the same cell types. We found that the genomic regions linearly separated but positioned in proximity in three-dimensional topology showed coordinated chromatin accessibility at CREs. We further identified three groups of CREs with different long-range allele-specific activities (FDR<0.05): Group 1 (n=2,149) showed concordant allele-specific activities in both local (with heterozygous SNPs nearby) and distal regions (>20kb distant to linked SNPs but in spatial proximity). Group 2 (n=3,285) showed allele-specific activities only in local but not in distal linked regions. Group 3 (n=2,963) showed allele-specific activities only in distal but not in local regions. In genome-wide association studies (GWAS), the local imbalanced CREs activities linked with the risk or non-risk alleles are often utilized to prioritize the potential causal SNPs within the same linkage disequilibrium blocks. The long-range allele-specific activities in CREs from Groups 1 and 3 may suggest that the switching of risk and non-risk alleles can also be correlated with the activities of distant CREs but in spatial proximity. In inflammatory bowel diseases, we observed the overlap of Group 3 regions (B-lymphoblastoid cell) with three significant GWAS loci, which are all annotated as heterochromatin regions locally but with imbalance chromatin accessibility at linearly distal and spatial proximal regions. Thus, GTAGMe-seq here provides an interesting approach to linking non-coding genetic variants with the distal CREs' activities in spatial proximity at the same DNA molecules.

Omics Technologies Posters - Wednesday

PB3009. HD-Seq: A novel method for high accuracy sequencing.

Authors:

S. Shore, A. King, E. A. LaMarca, K. Gouin III, R. Schultzaberger, T. Looney, D. Witters, M. M. Fabani, E. N. Glezer; Singular Genomics, San Diego, CA

Abstract Body:

Background Next generation sequencing (NGS) has enabled rapid progress in cancer diagnostics. However, challenges remain around detection of somatic variants at allele frequencies similar or below the error rate of on-market DNA sequencers (typically $\sim 10^{-3}$) when using standard library preparation methodologies. Here, we introduce HD-Seq, a novel library preparation and sequencing method that allows for efficient and high accuracy sequencing, achieving error rates in the range of $\sim 10^{-5}$ - 10^{-6} . The HD-Seq method relies on the physical linkage of original dsDNA templates in a sample, a connection that is maintained throughout library preparation, clustering and sequencing. By requiring consensus between the sequences of the linked strands, errors present in one of the original strands or introduced during amplification are readily identified and eliminated. In addition, error correction efficiency is maximized by guaranteeing that complementary strands of each molecule are represented in the sequence output. **Methods** Library preparation for the HD-Seq method is similar to library preparation for standard libraries, except for use of two custom adapters and a purification. Typically, 50 ng of fragmented gDNA (150 bp mean size, Covaris) is end-repaired and A-tailed (Quantabio SparQ DNA library prep kit), ligated to Singular Genomics adapters, and purified. Libraries are then amplified with 10 cycles of PCR and purified followed by optional capture based enrichment. Paired end 2x150 bp sequencing occurs on the Singular Genomics G4 platform followed by consensus error correction. Briefly, paired reads are aligned to each other and non-overlapping portions of the read pair are trimmed. Discordant basecalls between R1 and R2 are assumed to reflect library preparation or sequencing errors and are masked (called 'N'). **Results** The typical mismatch rate observed in single pass (non-consensus) sequencing is approximately 10^{-3} . The HD-Seq method enables $\gt;100$ -fold lower error rates by building a consensus sequence from linked strands. Prior to HD-Seq correction, Read 1 and Read 2 from a representative HD-Seq experiment (Salmonella gDNA input) show mean accuracies of 99.76% and 99.82% , respectively. When reads are combined to build a consensus sequence, the accuracy increases to 99.9991% . **Conclusions** The HD-Seq approach is a novel library preparation and sequencing method that relies on linking the original paired strands in a dsDNA fragment. DNA errors affecting one of the two strands can be easily identified during sequencing of the corresponding linked strands. Through consensus sequencing, the HD-Seq technique enables accuracies of $\gt;Q50$.

Omics Technologies Posters - Thursday

PB3010. High accuracy Sequencing By Binding (SBB) improves human germline variant calling

Authors:

D. Nasko, C. Kingsley, N. Pezeshkian, W. Rowell; Pacific BioSci.s, Menlo Park, CA

Abstract Body:

PacBio Sequencing By Binding (SBB) is a short-read sequencing technology that provides a >10X increase in read accuracy relative to Sequencing By Synthesis (SBS). This new level of read accuracy brings opportunities to improve variant detection, but requires germline variant callers that take full advantage of the higher accuracy. Here we compare variant calling with SBB and SBS reads and develop an error model that is specific to SBB reads using the highly controlled and characterized Genome in a Bottle samples from the National Institute of Standards & Technology (NIST).

PCR-free libraries were prepared for the reference samples HG001, HG002, HG003, HG004, and HG005 and sequenced to 30-fold depth each on the PacBio SBB sequencing technology. Reads were first mapped to the GRCh38 human reference genome and variants were called using GATK HaplotypeCaller and DeepVariant with its SBS model (DeepVariant-SBS). The SBB data was also used to train SBB-specific models for both DeepVariant (DeepVariant-SBB) and Sentieon DNAscope.

With GATK Haplotype Caller and DeepVariant-SBS, the SBB callsets had higher precision but lower recall than SBS callsets for both SNVs and indels. In comparison, DeepVariant-SBB and Sentieon DNAscope trained on SBB data improve both precision and recall for SBB. This demonstrates that improved accuracy of SBB short reads translates into improved accuracy for variant calling, opening new applications in human genomics.

Omics Technologies Posters - Wednesday

PB3011. High throughput single-cell epigenomic profiling through split-pool combinatorial barcoding.

Authors:

Z. Sayar, A. Sova, R. Koehler, C. Roco, A. Rosenberg; Parse BioSci.s, SEATTLE, WA

Abstract Body:

Understanding the chromatin dynamics which regulate gene expression and cellular differentiation can elucidate mechanisms responsible for key biological processes. Current methods for profiling the open chromatin landscape of single cells require highly specialized equipment to compartmentalize individual cells and are expensive and limited in throughput. Here, we demonstrate an approach for high-throughput profiling of chromatin accessibility in single cells which integrates an Assay for Transposase-Accessible Chromatin-sequencing (ATAC-seq) with split-pool combinatorial barcoding. Our approach produces chromatin fragments of comparable quality and quantity to existing platforms, while offering the ability to scale up to hundreds of thousands of cells and dozens of samples in a single experiment. Furthermore, the workflow uses only common laboratory equipment, and allows for samples collected and fixed across different time points to be processed in the same experiment. To demonstrate the utility of this platform, we profiled fixed single nuclei isolated from multiple cell lines and mouse brain tissue. Our assay consistently produced high unique fragment counts per cell, enabling the identification of active gene regulatory networks associated with different cell types. Our resulting data yielded high transcription start site enrichment scores, while maintaining low mitochondrial fragment counts and low doublet rates across multiple species. Overall, our approach provides a flexible and accessible option for scalable single cell profiling of accessible chromatin.

Omics Technologies Posters - Thursday

PB3012. High throughput workflow for human whole genome sequencing using PacBio HiFi.

Authors:

J. Rocha¹, J. Burke¹, R. Fedak¹, D. Kilburn¹, E. B. Iglesias², D. Laubscher², B. Ottenwalder², S. Dee¹, H. Ferrao¹, K. Liu¹; ¹PacBio, MP, CA, ²Hamilton, Bonaduz, Switzerland

Abstract Body:

Improved throughput and cost of long-read sequencing, driven by recent technological advances, has opened the door for investigation of human whole genomes across progressively larger populations. To support the rapidly growing capabilities of long-read sequencing, high throughput sample and library preparation solutions are necessary. While short-read sequencing workflows are well established, long-read sequencing workflows for handling of high molecular weight (HMW) DNA are not widely available. We present a fully automated 96 well plate-based high throughput HMW DNA extraction, shearing, size selection, and library preparation workflow for processing human whole blood samples for PacBio HiFi sequencing. First, HMW DNA extraction is performed utilizing Nanobind magnetic disk technology on the fully automated Hamilton NIMBUS Presto. Nanobind disks feature micro- and nanostructured silica wrinkles to shield bound DNA from damage during extraction. This method is capable of generating ~6 µg of DNA on average per 200 µL blood sample on a 96 well plate in only 2.5 hours. Alternatively, the stand-alone Thermo Fisher KingFisher instruments provide a semi-automated option with comparable metrics. After extraction, size selection is performed to reduce small DNA from HMW samples. Here a high throughput version of Short Read Eliminator (SRE) technology is used. Size selection can also be achieved through magnetic bead-based methods instead. Prior to library preparation, HMW DNA is sheared down to 15-20 kb using an automated 96 well plate-based platform. Finally, automated PacBio library and loading preparation is performed on the fully automated Hamilton NGS STAR. The methods presented utilize standard configurations of commercially available Hamilton instruments and can easily be incorporated into existing workflows. Data is presented using human whole blood for a workflow which can prepare 96 samples from blood to library ready for loading in ~10 hours. A single SMRTcell typically generates ~10-12X coverage of high quality sequence data sufficient for analysis including phasing, 5mC, and variant calling. However, the protocols can be readily adapted to support a variety of other sample types including cultured cells, bacteria, and tissue.

Omics Technologies Posters - Wednesday

PB3013. High-throughput CRISPR Inhibition Screen to Improve Interpretation of Noncoding Variants in Developmental Epileptic Encephalopathies

Authors:

E. Almanza Fuerte; St Jude Children s Res. Hosp., Memphis, TN

Abstract Body:

Developmental and epileptic encephalopathies (DEEs) are a heterogeneous group of disorders characterized by severe, early-onset epilepsies, cognitive/developmental disabilities, and movement disorders. *De novo* mutations in coding regions are the most common cause for DEEs, identified by next-generation sequencing, however, these mutations only account for ~ 50% of DEE cases. We postulate the remaining undiagnosed cases may arise from mutations in the noncoding region that influence gene expression. Thus, a better understanding of the noncoding genome can help prioritize and interpret pathogenic variants. We are performing a high-throughput CRISPR-inhibition (CRISPRi) screen to identify non-coding regions and variants that regulate the expression of DEE-associated and neurodevelopmental genes. CRISPRi relies on catalytically deactivated Cas9 protein (dCas9), which is unable to cut DNA. dCas9 is linked to a repressive KRAB domain to bind to targeted DNA regions and provide steric hindrance, preventing the transcription of target genes. We identified 400 candidate genes for our full-scale CRISPRi screen. For each gene, we have identified regions of interest in noncoding regions surrounding (+/- 5kb) each candidate gene, including promoters, enhancers, putative enhancers, poison exons, and highly conserved regions. We designed multiple sgRNA for each candidate region, targeting both sense and antisense strands of DNA. We will leverage single-cell RNA sequencing to determine the consequences of CRISPRi perturbation. We will utilize a multiplex approach to introduce sgRNA into the cells, providing an unbiased and high-throughput approach to link regulatory regions to associated genes. We have completed our pilot screen targeting 20 DEE genes, including *CHD2*, *SCN1A*, and *SCN2A*. In total, we are targeting 20 promoter regions, 364 enhancer and putative enhancer regions and 151 highly conserved regions based on GERP score, with 3807 sgRNA. We included 25 positive control sgRNA against TSS of both DEE and non-DEE genes and 415 non-targeting controls. Currently, we are analyzing results from our pilot screen to identify differential gene expression corresponding to sgRNA influence. We will utilize data from this proof-of-concept screen to optimize the full-scale screen. Our high throughput CRISPRi screen will identify noncoding regions and variants that regulate the expression of 400 DEE-associated and neurodevelopmental genes. These findings will provide insights into variants identified by whole-genome sequencing in patients in uncovering underlying disease-causing mutations.

Omics Technologies Posters - Thursday

PB3014. High-throughput metabolomics enabling discovery of tens of thousands of small molecule biomarkers that link genetics and disease

Authors:

T. Long; Sapient, San Diego, CA

Abstract Body:

Metabolomics, or the measure of circulating small molecule factors, has the potential to transform our understanding of human disease as well as to uncover new biomarkers of drug response, target engagement, and disease risk even years in advance of disease onset. Small molecule biomarkers read out both genetic variations and exposures stemming from diet, lifestyle, and the environment, including the internal organs and the microbiome, and how these exposures interact with genetics to influence disease. Mapping small molecule biomarkers provides complementary information relative to genomics and can also be an intermediary to connect genetics to disease. Herein we describe a next generation, high-throughput rapid liquid chromatography-mass spectrometry (rLC-MS) system capable of capturing and measuring more than 11,000 circulating small molecule biomarkers - including thousands of uncharacterized factors - in a human biosample. This nontargeted platform was applied in population-level studies to mine genetic information on small molecule biomarkers via genome-wide association studies (GWAS) and identify biomarkers that are sensitive to changes in gene functions and that may be causal to disease development.

Biosamples from over 18,000 individuals across diverse populations were assayed using rLC-MS and matched with genotype data from the same cohort. Biocomputational integration of these two data-rich sources enabled the discovery of specific biomarkers that read out changes in gene function of disease-associated variants. Across the genome, we find tens of thousands of small molecule biomarkers that reach genome-wide thresholds of association with genetic variants. We also find that over 90% of the approximately 20,000 genes have genetic variants in the transcribed regions associated with one or more small molecule biomarker(s).

These findings emphasize the importance of nontargeted small molecule biomarker discovery as a complementary approach to genomics. Using rLC-MS technologies to probe the still largely unexplored non-genetic landscape of disease, we can leverage the discoveries in integrative analyses that elucidate links between genetics, environment/exposures, and disease. Performing these analyses at population scale provides the statistical power to identify robust, specific biomarkers across diverse individuals.

Omics Technologies Posters - Wednesday

PB3015. High-throughput RNA isoform sequencing using programmable cDNA concatenation.

Authors:

A. AlKhafaji¹, J. T. Smith¹, K. V. Garimella¹, M. Babadi¹, V. Popic¹, M. Sade-Feldman¹, M. Gatzem¹, S. sarkizova¹, M. A. Schwartz¹, E. Blaum¹, A. Day¹, M. Costello¹, T. Bowers¹, S. Gabriel¹, E. Banks¹, A. Philippakis¹, G. M. Boland², P. C. Blainey¹, N. Hacohen¹; ¹Broad Inst., Cambridge, MA, ²Div. of Surgical Oncology, Massachusetts Gen. Hosp., Harvard Med. Sch., Boston, MA

Abstract Body:

Alternative splicing is a core biological process that enables profound and essential diversification of gene function. Short-read RNA sequencing approaches fail to resolve RNA isoforms and therefore primarily enable gene expression measurements - an isoform unaware representation of the transcriptome. Conversely, full-length RNA sequencing using long-read technologies are able to capture complete transcript isoforms, but their utility is deeply constrained due to throughput limitations. Here, we introduce MAS-ISO-seq, a technique for programmably concatenating cDNAs into single molecules optimal for long-read sequencing, boosting the throughput >15 fold to nearly 40 million cDNA reads per run on the Sequel IIe sequencer. We validated unambiguous isoform assignment with MAS-ISO-seq using a synthetic RNA isoform library and applied this approach to single-cell RNA sequencing of tumor-infiltrating T cells. Results demonstrated a >40 fold boosted discovery of differentially spliced genes and robust cell clustering, as well as canonical PTPRC splicing patterns across T cell subpopulations and the concerted expression of the associated hnRNPLL splicing factor. High-throughput full-length cDNA sequencing will drive discovery of novel isoforms, bringing to light this rich genetic feature and make transcript isoform expression analysis the new standard in transcriptomics.

Omics Technologies Posters - Thursday

PB3016. High-throughput RNA sequencing directly from cell lysates enables reproducible phenotypic profiling for CRISPR treatment phenotyping and cell response screening applications

Authors:

A. O'Hara, M. Stephens, E. Louie, L. Turner, I. DeVito, C. Mozdierz, H. Latif, G. Zhou; Azenta, South Plainfield, NJ

Abstract Body:

Gene editing has the potential to revolutionize genetic approaches to personalized medicine and enable a new era of gene-based therapeutic treatment options for heretofore untreatable diseases. Recent advancements in targeted gene editing and genome editing techniques allow for highly-specific, targeted DNA modifications to genes of interest. This includes the CRISPR/Cas9 system, which can be used for gene knockout, gene mutagenesis and gain-of-function gene knock-in approaches to engineer cell lines and potential therapeutics. Downstream discovery of CRISPR editing effects relies heavily on high-throughput screening assays for measurement of phenotypic responses which can range from very targeted assays to wide-ranging unbiased approaches. Standard whole transcriptome RNA-seq is a preferred method for unbiased measurement of phenotypic responses but is often overlooked due to limited scalability and high sample screening costs. To address these challenges, we have developed a high-throughput gene expression (HT-GEx) assay that combines a variety of strategies to enable a low-cost and high-throughput alternative to standard RNA-seq. First, a simplified workflow removes upstream RNA isolation steps and tags transcripts directly from cell lysate. This is achieved by incorporating both a sample barcode and a unique molecular index (UMI) during the reverse transcription reaction. Next, we leverage a 3' end counting approach to enable a reduction in sequencing depth coverage (i.e. sample cost) without compromising gene detection sensitivity. With these key advances, a high-plex and high-throughput screening assay is achievable at a reduced cost by removing the need to purify RNA, tagging transcripts early in the workflow to allow pooling of samples and reducing sequencing depth. We have combined these high-throughput and cost-saving strategies and present results which confirm HT-GEx offers results on par with standard RNA-seq. Gene detection sensitivity based on number of genes detected per millions of reads is highly similar, with gene detection sensitivity saturated at approximately 2 million reads. Additionally, the number of genes detected between replicates for RNA samples and lysate samples demonstrate strong linear correlation, implying highly reproducible results. Thus, high-throughput gene expression is an ideal method for phenotypic screening and has applications in CRISPR edited cell lines following stand-alone or combined compound treatments.

Omics Technologies Posters - Wednesday

PB3017. High-Throughput Sample Processing workflow for rapid Vaginal microbiota profiling of women's health samples.

Authors:

J. Kelvekar, E. Zeringer, A. Cheng; ThermoFisher Scientific, Austin, TX

Abstract Body:

Vaginal microbiota is composed of a dynamically convoluted microecosystem that fluctuates throughout woman's life. For a healthy woman, the vaginal microbiota is highly influenced by Lactobacillus species which produce various antimicrobial compounds and helps to keep pathogenic bacteria in check. Conversely, Bacterial Vaginosis (BV), affecting up to 30% of women around the world and leads to increased risk for sexually transmitted diseases, HIV, and premature birth, is characterized by a sharp reduction in Lactobacillus species leading to an overgrowth of anaerobic bacteria with the potential for pathogenesis. However, despite the high importance of the vaginal microecosystem, there is a lack of knowledge regarding its function and how it helps in protecting the female reproductive system. This leads to a lack of development of an effective clinical treatment to improve women's health. The traditional techniques for vaginal microbiota identification, such as complex culture preparation, specialized microscopy and sequencing often take days or weeks and can have sensitivity limitations. To enable advancement of vaginal microbiota research, Thermo Fisher Scientific launched a robust detection workflow using the MagMax™ DNA Multi-sample Ultra Kit on the KingFisher Flex instrument together with the TaqMan OpenArray Vaginal Microbiota Comprehensive Plate. This is a simple end-to-end workflow that includes, nucleic acid extraction, purification and interrogation of 34 microbial targets with prokaryotic 16S rRNA and human RNase P gene targets as process controls. The vaginal microbiota profiling workflow is compatible with several sample collection and storage systems, including the HOLOGIC™ ThinPrep™ Pap Test, the BD SurePath™ Liquid-Based Pap Test, the Copan Diagnostics ESwab™ Specimen Collection and Transport System, and Thermo Scientific™ MicroTest™ M4RT kits and allows processing of up to 96 samples in less than 8 hours and enables simple and efficient sample processing with a rapid turnaround.

Omics Technologies Posters - Wednesday

PB3018*. High-throughput targeted enrichment for long read third-generation sequencing: A flexible, scalable, and cost-efficient method achieving similar throughput as for short read NGS.

Authors:

T. Steiert¹, J. Fuss¹, S. Juzenas¹, M. Wittig¹, M. Hoepfner¹, M. Vollstedt¹, G. Varkalaite², H. ElAbd¹, C. Brockmann³, S. Goerg³, C. Gassner⁴, M. Forster¹, A. Franke¹; ¹Inst. of Clinical Molecular Biology, Christian-Albrechts Univ. and Univ. Med. Ctr. Schleswig-Holstein, Kiel, Germany, ²Inst. for Digestive Res., Lithuanian Univ. of Hlth.Sci., Kaunas, Lithuania, ³Inst. of Transfusion Med., Univ. Med. Ctr. of Schleswig-Holstein, Kiel, Germany, ⁴Inst. of Translational Med., Private Univ. in the Principality of Liechtenstein, Triesen, Liechtenstein

Abstract Body:

Hybridization-based targeted enrichment is a widely used and well-established technique in high-throughput second-generation short read sequencing. Despite the high potential to genetically resolve highly repetitive and variable genomic sequences by, for example PacBio third-generation sequencing, targeted enrichment for long fragments has not yet established the same high-throughput due to currently existing complex workflows and technological dependencies. We here describe a flexible, scalable, and cost-efficient targeted enrichment protocol for fragment sizes of >7 kb. For demonstration purposes we developed a custom blood group panel of challenging loci. Test results achieved >65% on-target rate, good coverage (142.7x) and sufficient coverage evenness for both non-paralogous and paralogous targets, and sufficient non-duplicate read counts (83.5%) per sample for a highly multiplexed enrichment pool of 16 samples. We genotyped the blood groups of nine patients employing highly accurate phased assemblies at an allelic resolution that match reference blood group allele calls determined by SNP array and NGS genotyping. Seven Genome-in-a-Bottle reference samples achieved high recall (96%) and precision (99%) rates. Mendelian error rates were 0.04% and 0.13% for the included Ashkenazim and Han Chinese trios, respectively. In summary, we provide a protocol and first example for accurate targeted long read sequencing that can be used at similar high-throughput fashion as for short read NGS.

Omics Technologies Posters - Thursday

PB3019. Horizon - an ultrarapid platform for NICU/PICU whole genome clinical pathogenicity prediction

Authors:

G. Salih^{1,2}, M. Woodbury-Smith³, P. Rahman⁴, W. Kuebler⁵, A. Ahmad¹, H. Akter⁶, B. Berdiev¹, A. Islam⁶, N. Nassir¹, M. Uddin^{1,7}; ¹Mohammed Bin Rashid Univ. of Med. and Hlth.Sci., Dubai, United Arab Emirates, ²Vrije Univ.it Amsterdam, Amsterdam, Netherlands, ³Newcastle Univ., Jesmond, Newcastle upon Tyne, United Kingdom, ⁴Mem. Univ., St. John's, NL, Canada, ⁵Charité - Univ.smedizin Berlin, Berlin, Germany, ⁶NeuroGen Hlth.care Ltd., Dhaka, Bangladesh, ⁷GenomeArc Inc., Toronto, ON, Canada

Abstract Body:

The fast adaptation of whole genome sequencing technologies in the clinic provides major advantages in identifying clinically actionable variants. However, the functional interpretation of the identified variants poses a challenge in terms of accuracy and efficiency, especially in neonatal and pediatric intensive care units (NICU/PICU) where molecular diagnosis and clinical decision often need to be made very quickly. We developed an ultrarapid analytics, Horizon, an automated machine learning integrated platform, to predict pathogenicity of genetic variants (single nucleotide variants (SNV), indels, and structural variants (SVs)) from whole exome/genome mapped .vcf or .bed files. The platform implements i) a functional prediction module for mutations, ii) multiple machine learning modules, iii) large parallel processing and indexing strategies, and, iv) integration with multiple largescale proprietary highly accurate human annotated clinical genomic and pharmacogenomic databases. We have conducted run-time validation experiments on whole exome (64K variants) and whole genome (4 million variants) .vcf files for functional annotation and pathogenicity predictions according to American College of Medical Genetics (ACMG) guidelines. Using a small quad core server station, the computation time was 5 and 65 minutes to process entire exome and whole genome .vcf data, respectively. A patient with genome wide structural variants can be processed within 60 seconds. We are currently using population scale clinical genomic datasets to validate sensitivity and specificity of Horizon's pathogenicity prediction module. Using a cohort of 4,864 pediatric genetic disease patients (including NICU/PICU), the validation analysis will compare each patient's Horizon predicted pathogenicity with pre-assigned pathogenicity by multiple ACMG board certified clinical geneticists. Our initial results indicate that Horizon's ultrarapid implementation of functional annotation and pathogenicity prediction can be extremely useful for timely diagnosis and to make clinical intervention related decision of NICU/PICU patients.

Omics Technologies Posters - Wednesday

PB3020*. Human cytomegalovirus infection extensively re-organizes the human genome at human disease risk loci

Authors:

M. Weirauch¹, S. Khund¹, S. Parameswaran¹, M. J. Beucler², M. Freeman², O. Donmez¹, A. von Handorf¹, L. E. Edsall³, K. Kaufman⁴, B. Zhao⁵, J. B. Harley⁶, W. Miller², L. C. Kottyan⁷; ¹Cincinnati Children's Hosp., Cincinnati, OH, ²Univ. of Cincinnati Coll. of Med., Cincinnati, OH, ³Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH, ⁴Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH, ⁵Harvard Univ., Cambridge, MA, ⁶US Dept. of VA, Cincinnati, OH, ⁷Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract Body:

Human infection with Cytomegalovirus (CMV) has been linked to several human disorders. However, the underlying mechanisms remain poorly elucidated. Here, using RNA-seq, ATAC-seq, ChIP-seq and Hi-ChIP-seq, we show that CMV extensively re-organizes the human genome upon infection of both fibroblast and epithelial cell lines. Comparison between uninfected and infected cells using RNA-seq and ATAC-seq data indicates thousands of differentially expressed genes and tens of thousands of human genomic regions with differential chromatin accessibility. Transcription factor binding site motif enrichment analysis reveals enrichment for CTCF and TEAD1 sites in the newly opened and closed chromatin of infected cells, respectively. ChIP-seq experiments confirm strong differential binding in infected vs uninfected cells of CTCF and TEAD1 at these sites. We confirm that the extensive loss of TEAD1 binding leads to inactivation of the Hippo pathway in infected cells. Regions of differential chromatin accessibility are highly enriched for genetic variants associated with diverse human diseases and phenotypes including several autoimmune diseases, end stage coagulation, and dysregulation of lipid metabolism. Our approach and data provide new avenues to dissect the mechanisms operating in host-pathogen interactions and characterize their effects on disease phenotypes.

Omics Technologies Posters - Thursday

PB3021*. Human microglia transcriptional changes associated with progression and development of Alzheimer's Disease.

Authors:

R. Kosoy¹, J. Bendl², S. Kleopoulos², Y. Ma¹, V. Haroutunian^{2,3}, D. Bennett⁴, J. Fullard², G. Hoffman¹, P. Roussos^{1,3}; ¹Icahn Sch. of Med. at Mount Sinai, New York, NY, ²Icahn Sch. of Med. at Mount Sinai, New York City, NY, ³James J. Peters VA Med. Ctr., Bronx, NY, ⁴Rush Univ. Med. Ctr., Chicago, IL

Abstract Body:

Microglia are resident macrophages of the brain with a range of functions, including immune surveillance, neuronal maintenance and synaptic remodeling. While microglia have been implicated in the etiology of Alzheimer's Disease, the relevance of animal model-based investigations is not clear and the contribution of microglia to disease progression in human patient samples is poorly understood. Importantly, we have very limited insights into the cellular and molecular processes of microglia in early versus advanced states of the disease, which is critical for developing appropriate therapeutic interventions. Here we present a transcriptional landscape associated with AD progression measures in primary microglia derived from 189 human postmortem brains, representing people with both healthy aging (61 individuals) and those with a range of neurodegenerative phenotypes (including 79 patients with AD). In addition to the short read RNAseq data generated in all of these patients, we also generated long-read IsoSeq data in 20 samples to identify the microglia specific transcripts, allowing us to query the expression patterns for transcribed entities beyond those present in the standard gene reference resources. We derived transcriptional changes associated with various AD relevant measures reflecting neurodegeneration, tau neurofibrillary tangles and dementia. Additionally, we utilized co-expression network approaches to describe biological structures intrinsic to human microglia, highlighting the diversity of biological processes associated with disease etiology and different AD phenotypes. We identify a molecular signature associated with disease severity allowing for identification of patient subtypes with different relationships between the objectively measured underlying neurodegeneration and the clinical manifestation of AD phenotypes. In particular, we observe pronounced indices of transcriptional dysregulation of immune functionality in microglia associated with AD progression. Furthermore, we observe independent patterns of biological functional annotations associated with AD etiology and progression, suggesting that the molecular and cellular processes leading to disease development are principally different from the processes relevant to disease progression and homeostatic maintenance. Finally, we identify a number of microglial key driver genes with most relevance to AD associated signatures and biological functions for further exploration of their suitability as therapeutic targets.

Omics Technologies Posters - Wednesday

PB3022. Identification of FZD3 and SEMA3A as potentially secreted proteins involved in proliferative sickle cell retinopathy.

Authors:

A. Lima Camargo, V. de Haidar e Bertozzo, S. da Silva Costa, J. Nicolielo Pereira de Castro, T. Adalton Rosa Rodrigues, P. Rodrigues Souza Cruz, M. Gonçalves Monteiro Viturino, M. C. Ozelo, F. Ferreira Costa, M. Barbosa Melo; UNICAMP, Campinas, Brazil

Abstract Body:

Background: Retinal alterations are the most important ocular morbidity in sickle cell diseases. They occur due to vaso-occlusion of the ocular microvasculature, which leads to hypoxia, ischemia, and neovascularization. Proliferative sickle cell retinopathy (PSCR) is the most severe form of retinopathy, leading to retinal detachment and visual loss, affecting 10 to 20% of the affected eyes. Endothelial Colony Forming Cells (ECFCs) are recruited into ischemic or damaged outer retina and play an important role during vascular repair and revascularization of ischemic retinopathies. **Aim:** To evaluate the differential gene expression profile and predict potentially secreted proteins (PSPs) in ECFCs from patients with HbSS genotypes with and without PSCR. **Methods:** RNA-seq data analysis comparing ECFCs from patients with PSCR (N=3) versus without PSCR (N=2) was performed with the Deseq2 package in R. *PANTHER* database was used for gene ontology (GO) analysis. Differentially expressed genes (DEGs) were combined for retina tissue-specific genes dataset by *Genotype-Tissue Expression (GTEx)*. DEGs obtained from GO terms and GTEx were compared to *The Human Protein Atlas* secretome database to identify PSPs. *miRWalk* 3.0 tool was used to evaluate predicted regulatory miRNAs. **Results:** The ECFCs expression profile revealed 501 DEGs. GO analysis demonstrated 129 DEGs related with angiogenesis, cell adhesion, MAP kinase activity, and PI3K signaling, pathways involved in PSCR. Among them, we highlight the overexpression of Frizzled Class Receptor 3 (*FZD3*), and underexpression of Semaphorin 3A (*SEMA3A*) which are PSPs also expressed in the retina. In the PSPs-miRNA network, the following edges were observed: *FZD3* with miR-20b-5p; *SEMA3A* with miR-15b-5p, microRNAs also expressed in the retina. Studies suggest that *SEMA3A* and Vascular endothelial growth factor (VEGF) have antagonistic effects on EC growth and survival. *VEGF* plays an important role during angiogenesis, and was overexpressed in our DEGs, unlike *SEMA3A*. High expression of *FZD3* and *VEGF* in EC has been associated with deregulation of the Wnt pathway. Interestingly, Wnt pathway ligands and receptors, such as *FZD3*, are key regulators of ocular angiogenesis in vascular eye diseases. Moreover, miR-20b-5p and miR-15b-5p were reported to be underexpressed and overexpressed, respectively, in the pathophysiology of diabetic retinopathy. **Conclusions:** We identified *SEMA3A* and *FZD3* as PSPs in ECFCs that may have essential roles in angiogenic processes and are also regulated by miRNAs. This data may contribute to a better understanding of the mechanisms involved in PSCR and indicate novel biomarkers of disease.

Omics Technologies Posters - Thursday

PB3023. Identification of novel long non-coding RNA with distinct expression patterns in different multiple myeloma subtypes.

Authors:

M. Bauer, D. Elsayed, C. Wardell, F. van Rhee, D. Ussery, C. Ashby, F. Zhan; Univ. of Arkansas for Med. Sci., Little Rock, AR

Abstract Body:

The biological role of long non-coding RNAs (lncRNAs) in multiple myeloma (MM) has recently been receiving more attention as we learn more of their vital role in all cellular functions. Despite advancement in therapies, a significant variation in survival with symptomatic MM still exists, indicating an enormous genomic heterogeneity and complexity of the disease. While lncRNAs do not carry information about proteins recent studies suggest that they regulate several molecular mechanisms, such as, supporting cellular homeostasis and regulation of gene expression. LncRNA expression is highly cellular specific and the list of discovered lncRNAs continues to grow.

In this study we explore the expression of novel lncRNA in different molecular subtypes of MM and examine their contribution to patient prognosis. The RNA-seq data of 643 newly diagnosed MM samples was analyzed to discover novel lncRNAs. We identified 8,556 potentially novel lncRNA transcripts. We used a number of bioinformatic approaches to infer their function and role in MM. Which included, looking for correlated expression with nearby protein coding genes and their pathways. We also compared k-mer content with known lncRNA to infer possible similar function. We then assessed significance through survival analysis.

We identified 1,264 novel lncRNA transcripts with significant differential expression between the different molecular subtypes of multiple myeloma. Hierarchical clustering defined 9 clusters of novel lncRNAs associated with different subtypes. Using nearby protein coding genes with significant expression correlation, we observed overlapping enriched pathways between clusters as well as unique pathways distinct to specific MM groups. The pathway, Signaling by BMP was the topmost significant enriched pathways for cluster 1 and 9 in which lncRNAs were highly expressed in MM defined by t(14;16) and t(14;20). K-mer content comparison with known lncRNA identified novel lncRNAs with similarity to HELLP associated long non-coding RNA (*HELLPAR*), *AC003984.1* and PDGFA Divergent Transcript (*PDGFA-DT / HRAT92*). These 3 known lncRNAs have been previously implicated in other diseases and may provide clues to the function of the novel lncRNAs. Lastly we did a survival analysis and identified 108 novel lncRNAs associated with significant overall survival when expressed.

The results of our study reveal that the noncoding portion of the genome is still largely unexplored and the potential role of lncRNAs in cellular maintenance and survival in MM. Disruption of these key molecules may have a big impact on disease progression and outcome and provide novel potential therapeutic targets.

Omics Technologies Posters - Wednesday

PB3024. Identifying high-confidence de novo mutations in somatic and germline cells through duplex sequencing of diverse tissue types.

Authors:

S. Lulla¹, J. Kunisaki², L. Hiatt¹, A. Quinlan³; ¹Univ. of Utah, Salt Lake City, UT, ²Univ. of Utah Sch. of Med., Salt Lake City, UT, ³Univ of Utah, Salt Lake City, UT

Abstract Body:

Identification of de novo mutations (DNMs) and the rate at which they accumulate have applications in research and clinical work, especially related to cancer and genetic disease risk. Several research efforts have used whole-genome sequencing (WGS) technologies to analyze DNMs. However, WGS has an error rate on the order of 10^{-3} , which presents challenges when distinguishing low-frequency mutations (signal) from sequencing artifacts (noise) in bulk tissue samples. TwinStrand Duplex Sequencing overcomes the limitations associated with WGS by reducing error rates to the order of 10^{-8} through exclusive reporting of variants that occur on complementary DNA strands, allowing more accurate quantification of DNM rates. Here, we present a computational workflow to quality control and examine DNMs detected with TwinStrand Duplex Sequencing across bulk somatic and germline tissue samples.

To determine general reliability of duplex sequencing data, we compare our observed mutation spectra to those expected from previous studies. We then further refine the data to high-confidence variant calls through several filtering strategies. Mutations that occur at frequencies of roughly 0.5 and 1 are considered heterozygous and homozygous inherited mutations respectively and are removed from analysis to isolate DNMs. Non-clonal variants that occur in more than one matched tissue sample or across multiple donors are likely to be artifacts and suggest error-prone loci. Variants with high no-call rates and homopolymer INDELs that occur adjacent homopolymers in the reference genome are also considered artifacts. Reasons for filtering are annotated for each variant, and variants are additionally annotated with information about mutation consequence and pathogenicity using ClinVar data. The workflow has been documented in a GitHub repository and used in a pilot study of longitudinal bulk sperm sample DNM rates.

We anticipate applying the pipeline to bulk sperm to measure germline mutation rates in the context of infertility. We also aim to apply the pipeline to somatic cells including blood, prostate, skin, and testicular tissue, as well as cancerous, pre-cancerous, and noncancerous colon. We will use these tissue data to evaluate mutagenic etiologies.

Omics Technologies Posters - Thursday

PB3025*. Illuminating Dark Proteins using Reactome Pathways

Authors:

L. Matthews¹, G. Wu², R. Haw³, T. Brunson², N. Sanati², S. Shorser³, D. Beavers², P. Conley², L. Stein³, P. D'Eustachio¹; ¹NYU Langone Med. Ctr., New York, NY, ²Oregon Hlth.& Sci. Univ., Portland, OR, ³OICR, Toronto, ON, Canada

Abstract Body:

Diseases are often the consequence of proteins or protein complexes that are non-functional or that function improperly. An active area of research has focused on the identification of molecules that can interact with defective proteins and restore their function. While 22% percent of human proteins are estimated to be druggable, less than fifteen percent are targeted by FDA-approved drugs, and the vast majority of untargeted proteins are understudied or so-called "dark" proteins. Elucidation of the function of these dark proteins, particularly those in commonly drug-targeted protein families, may offer therapeutic opportunities for many diseases. Reactome is the most comprehensive, open-access pathway knowledgebase covering 2585 pathways and including 14246 reactions, 11088 proteins, 13984 complexes, and 1093 drugs. Placing dark proteins in the context of Reactome pathways provides a framework of reference for these proteins facilitating the generation of hypotheses for experimental biologists to develop targeted experiments, unravel the potential functions of these proteins, and then design drugs to manipulate them. To this end, we have trained a random forest with 106 protein/gene pairwise features collected from multiple resources to predict functional interactions between dark proteins and proteins annotated in Reactome and then developed three scores to measure the interactions between dark proteins and Reactome pathways based on enrichment analysis and fuzzy logic simulations. Literature evidence via manual checking and systematic NLP-based analysis support predicted interacting pathways for dark proteins. To visualize dark proteins in the context of Reactome pathways, we have also developed a new website, idg.reactome.org, by extending the Reactome web application with new features illustrating these proteins together with tissue-specific protein and gene expression levels and drug interactions.

Omics Technologies Posters - Wednesday

PB3026. Improved data quality for renal cell carcinoma samples with HIVE scRNAseq integrated storage.

Authors:

E. Sergison, L. Wasson, T. Gierahn, J. Flanigan; Honeycomb Biotechnologies, Waltham, MA

Abstract Body:

Honeycomb Biotechnologies offers a new solution for single-cell technology: HIVE scRNAseq. The HIVE is a portable, handheld, single-use device that enables gentle capture, RNA stabilization without fixation, and easy processing for the analysis of single-cell samples without specialized instrumentation. The HIVE uses an array of 65,000 picowells that are preloaded with uniquely barcoded 3' transcript capture beads to quickly capture single cells. Once loaded, the Cell Preservation Solution is added to stabilize RNA and lock in molecular signals. Cell-loaded HIVEs can be shipped or stored until ready for Honeycomb's simplified and scalable HIVE processing and library preparation workflow. Quality control metrics (genes, transcripts, % mitochondrial reads), marker gene expression, and cell-type proportions are not significantly different between freshly processed cells and cells stored in the HIVE device for up to 9 months at -20°C.

Here, we demonstrate robust capture and profiling of cells isolated from a renal cell carcinoma biopsy. Freshly dissociated cells were either loaded directly into the HIVE (pre-cryo) and stored for ~3 weeks or cryopreserved for ~3 weeks prior to loading into the HIVE (post-cryo). Beads with captured transcripts were extracted from the HIVEs, and the remaining HIVE library preparation steps were conducted in a 96-well plate format. HIVE scRNAseq libraries were sequenced on an Illumina NovaSeq 6000 and count matrix files were generated using BeeNet, Honeycomb's software specifically designed for HIVE scRNAseq libraries. Seurat was used for downstream analysis. We provide data demonstrating the increased viability and quality of single-cell RNAseq data generated using the HIVE scRNAseq Solution with integrated storage compared to data generated from samples stored using cryopreservation. The HIVE propels forward clinical research using blood, bone marrow, fine needle aspirates, and other minimally invasive biopsies in the context of infectious diseases, blood cancers, allergy/asthma, and autoimmune diseases and inflammation. Stable HIVE storage enables longitudinal studies, time-courses, sporadic or end-of-day samples, collection sites with centralized processing, and multi-site collaborations. Honeycomb aims to expand single-cell opportunities across basic, translational, and clinical research throughout the world.

PB3027. Improved detection of functionally relevant aberrant splicing using the intronic Jaccard index

Authors:

C. Mertes, I. Scheller, K. Lutz, V. Yepez, J. Gagneur; Technical Univ. of Munich, Garching, Germany

Abstract Body:

Detection of aberrantly spliced genes from RNA-seq data is an important step of RNA-seq based diagnostics of rare diseases. We have recently developed FRASER¹, a denoising autoencoder-based method that outperformed alternative approaches for the detection of aberrant splicing on precision-recall analyses. When systematically investigating FRASER results on 303 rare disease samples² and 16,213 GTEx v8 samples, we noticed however that many of the detected events captured aberrant weak and cryptic splice site usage that did not result in substantial major isoform change.

Here, we introduce the intronic Jaccard Index, a new intron excision metric that combines alternative donor, alternative acceptor, and intron retention signal into a single value. The intronic Jaccard index captures variations in major isoform usage more closely than other split-read based metrics while retaining the advantage of being annotation-agnostic. As with FRASER, we modeled this ratio using a beta-binomial based denoising autoencoder thereby controlling for potential confounding sources of variations. Compared to FRASER, using a single metric also reduces the multiple testing burden and speeds up the fitting procedure. In addition, we implemented a goodness-of-fit metric, which we use to filter out false positives caused by model misspecification. Collectively, we call this new approach FRASER2.

On the rare disease dataset, FRASER2 considerably reduced the number of splicing outliers (by 25% - 75% per sample) for a mild loss of sensitivity (only 2 out of 24 pathogenic splicing cases not recovered with default cutoffs). Moreover, in GTEx, FRASER2 splicing outliers were 5 times more enriched for rare splice affecting variants. Including the goodness of fit metric further reduced the number of false positive calls. Also, outliers called using the intronic Jaccard index are less sensitive to sequencing depth. By introducing a new splicing metric, the intronic Jaccard index, FRASER2 is able to maintain the sensitivity of FRASER while providing more functionally relevant outlier calls. Omics Technologies Posters - Thursday

PB3028. Improved sequence mapping using a complete reference genome and lift-over

Authors:

N-C. Chen¹, L. Paulin², F. Sedlazeck^{3,4}, S. Koren⁵, A. Phillippy⁶, B. Langmead¹; ¹Johns Hopkins Univ., Baltimore, MD, ²Baylor Coll. of Med., Huston, TX, ³Baylor Coll. Med., Houston, TX, ⁴Rice Univ., Houston, TX, ⁵Natl. Human Genome Res. Inst., NIH, Bethesda, MD, ⁶NIH/NHGRI, Bethesda, MD

Abstract Body:

Complete, telomere-to-telomere genome assemblies promise improved analyses and the discovery of new variants, but many essential genomic resources remain associated with older reference genomes. Thus, there is a need to translate genomic features and read alignments between references. Here we describe a new method called levioSAM2 that accounts for reference changes and performs fast and accurate lift-over between assemblies using a whole-genome map. In addition to enabling the use of multiple references, we demonstrate that aligning reads to a high-quality reference (e.g. T2T-CHM13) and lifting to an older reference (e.g. GRCh38) actually improves the accuracy of the resulting variant calls on the old reference. By leveraging the quality improvements of T2T-CHM13, levioSAM2 reduces small-variant calling errors by 11.4-39.5% compared to GRC-based mapping using real Illumina datasets. LevioSAM2 also improves long-read-based structural variant calling and reduces errors from 3.8-11.8% for a PacBio HiFi dataset. Performance is especially improved for a set of complex medically-relevant genes, where the GRC references are lower quality. The software is available at <https://github.com/milkschen/leviosam2> under the MIT license.

PB3029*. Improving gene detection sensitivity from clinically relevant low input and FFPE RNA samples utilizing a rapid whole transcriptome library prep workflow.

Authors:

T. Sanders¹, L. French², J. Walker¹, C. Ross¹, T. Harrison¹, K. Reed¹, R. Wadsworth², B. Kudlow¹, J. Pavlica¹; ¹Watchmaker Genomics, Boulder, CO, ²Watchmaker Genomics, Cape Town, South Africa

Abstract Body:

mRNA-seq is a powerful tool for transcriptome profiling. However, it does not detect long noncoding RNAs, which are valuable disease biomarkers, and it is not amenable to certain clinically relevant sample types, such as blood and FFPE. Whole transcriptome sequencing (WTS), which specifically depletes uninformative overabundant transcripts, preserves noncoding species and is compatible across a wide range of sample types and qualities. As WTS becomes more broadly applied in the clinical and translational space, there is an increasing demand for solutions that alleviate the laborious library preparation bottleneck while also meeting increasingly stringent sensitivity requirements. To address this need, we undertook a complex development effort combining enzyme engineering and streamlined WTS library preparation workflow design and optimization.

Traditional RNA depletion workflows are lengthy, complicated, and difficult to automate - requiring long incubations and reagent additions at elevated temperatures. To streamline the protocols and improve depletion efficiency and specificity, we developed algorithms to computationally design novel depletion probes. To improve sensitivity, we leveraged an engineered reverse transcriptase to maximize conversion and tailored buffers throughout the workflow to further enhance performance. Cleanup steps were reduced to minimize sample loss, and a novel de-crosslinking step was integrated to improve FFPE performance.

With RNA extracted from whole blood and multiple FFPE blocks, we compared our solution to commercially available kits using inputs ranging from 1 to 500 ng. We observed a significant increase in sensitivity with low input and FFPE samples in comparison to other workflows, as indicated by an increase in the number of unique genes detected and more reads supporting a given gene call. Further, Watchmaker libraries showed excellent inter-input correlation, reproducibility, and improved sequencing economy with fewer bases wasted due to lack of alignment or mapping to rRNA regions.

This highly automatable and rapid solution generates libraries in under 5 hours and improves on the data quality currently attainable with existing commercial kits - making more clinically relevant samples addressable with higher success rates.

PB3030. Improving sensitivity of combinatorial barcoding-based single cell sequencing.

Authors:

S. Schroeder, G. S. Kim, V. Tran, P. Matulich, J. Pangallo, A. Sova, A. Gadkari, L. Kenyon, E. Papalexi, Z. Sayar, A. Sapre, R. Koehler, A. Rosenberg, C. Roco; Parse BioSci.s, Seattle, WA

Abstract Body:

While adoption of single cell sequencing has grown rapidly over recent years, microfluidic based approaches remain costly and the need to isolate individual cells in droplets limits throughput. These limitations can be overcome by using combinatorial barcoding to label individual cells in single cell experiments. This approach uses fixed cells or nuclei as starting material and generates single cell transcriptional profiles through a series of split-pool barcoding steps that uniquely label individual cells without any need for costly microfluidic instruments. Furthermore, the ability to use fixed cells and nuclei provides flexibility and consistency in single cell RNA-seq experiments, as samples can be frozen and stored for up to 6 months, then processed in a single reaction, eliminating potential batch effects. With both droplet and combinatorial based scRNA-seq, a key consideration is the number of RNA molecules that can be detected per cell. Over the last several years there have been considerable improvements in the sensitivity of both droplet and combinatorial based single cell sequencing. This added sensitivity makes it possible to detect lowly expressed genes that may be critical in pathway analysis or distinguishing cell types and cell states. However, many samples and cell types have inherently low RNA content due to cell size and transcriptional activity and would benefit from further improvements in sensitivity. Here we demonstrate that by using an updated and optimized chemistry, we are able to dramatically improve the number of genes detected per cell in single cell experiments using Parse's Evercode™ single cell products. We observe consistent improvement in transcript and gene detection across cells and nuclei from a variety of different sample types tested, including mouse brain nuclei and human PBMCs. In PBMC samples we see an approximate two-fold improvement in transcripts detected per cell. We anticipate these improvements will enable researchers to uncover underlying biology that was previously obscured with lower sensitivity single cell RNA-seq.

Omics Technologies Posters - Wednesday

PB3031. Imputing functionally impactful *CYP2A6* structural variants from SNP array data.

Authors:

A. W. R. Langlois^{1,2}, M. Chenoweth^{1,2}, C. Lerman³, N. L. Nollen⁴, L. S. Cox⁴, J. S. Ahluwalia⁵, R. F. Tyndale^{1,2,6}; ¹Dept. of Pharmacology & Toxicology, Univ. of Toronto, Toronto, ON, Canada, ²Campbell Family Mental Hlth.Res. Inst., CAMH, Toronto, ON, Canada, ³Norris Comprehensive Cancer Ctr., Univ. of Southern California, Los Angeles, CA, ⁴Dept. of Population Hlth., Univ. of Kansas Sch. of Med., Kansas City, KS, ⁵Dept.s of Behavioral and Social Sci. and Med., Brown Univ., Providence, RI, ⁶Dept. of Psychiatry, Univ. of Toronto, Toronto, ON, Canada

Abstract Body:

CYP2A6 is the primary nicotine-metabolizing enzyme, responsible for ~90% of nicotine inactivation. Faster CYP2A6 activity is associated with greater smoking, poorer smoking cessation outcomes and higher lung cancer risk. The *CYP2A6* gene is polymorphic, with known functional variants including structural variants (SV) such as a gene deletion (*CYP2A6*4*), a gene duplication (*CYP2A6*1x2*), and hybrids with the highly homologous *CYP2A7* pseudogene (*CYP2A6*12*, *CYP2A6*34*). Compared to single nucleotide polymorphisms (SNP), which comprise the other functional *CYP2A6* variants, SVs are also functionally impactful but challenging to genotype due to their complex genetic architecture. Work in the major histocompatibility complex region found that SVs are associated with SNP haplotypes using SNP array data (Sekar et al. 2016). Our aim was to develop a reference panel for imputation of *CYP2A6* SVs from SNP array data.

European- (EUR; n=935) and African-ancestry (AFR; n=964) individuals from smoking cessation clinical trials were genotyped for SNPs on an Illumina array and for *CYP2A6* SVs using Taqman copy number assays. SV diplotype and SNP array (with the region affected by SVs excluded) data were integrated and phased using Beagle 5.2 (as in Sekar et al. (2016)); ancestry-specific panels were generated. Leave-one-out cross-validation was used. Briefly, a target sample was set, and a panel was created using all other samples. SV diplotype was imputed for the target; this was repeated for all samples. Accuracy was measured by comparing imputed calls to known SV diplotypes.

In AFR, diplotypes (i.e. the presence or absence of SVs for both alleles) were accurately imputed in 97% of all individuals (932/964), while among those with SVs 67% were identified (11/11 *CYP2A6*12*, 27/44 **4*, 1/2 novel hybrid SV, 2/2 **34*, and 16/26 **1x2* alleles).

In EUR, diplotypes were accurately imputed in 98% of all individuals (912/935), while among those with SVs 76% were identified (41/42 *CYP2A6*12*, 2/6 **4*, 9/10 novel hybrid SV, and 4/16 **1x2* alleles). False positive (FP) rates were low in both ancestry groups (<1% overall).

Our data confirm that *CYP2A6* SVs are associated with identifiable SNP haplotypes. Over 70% of SV alleles were positively identified with very low FP rates; panel expansion could improve this rate. Use of this reference panel could simplify SV genotyping for prediction of CYP2A6 activity, particularly for clinical use of weighted genetic risk scores. The method could also be applied widely to other genes with SVs. While external validation of the panel is necessary, array imputation may be useful for predicting *CYP2A6* SVs in large biobanks and clinical trials.

Omics Technologies Posters - Thursday

PB3032. Imputing the whole metagenomic shotgun sequencing data using the 16s amplicon sequencing data

Authors:

S. Jang, B. Han; Seoul Natl. Univ. Coll. of Med., Seoul, Korea, Republic of

Abstract Body:

The importance of the human microbiome is emerging to analyze various diseases current days. There are two methods for profiling the microbiome: 16s rRNA gene sequencing (16s sequencing) and whole-genome shotgun sequencing (WGS). Although the cost of NGS has become much cheaper than before, 16s sequencing is still widely used to identify the profile of microorganisms since it is much cheaper than WGS. Unlike 16s rRNA sequencing, WGS can read all metagenomic DNA, not specific DNA. Therefore, WGS has multiple advantages compared to the 16s sequencing including higher taxonomic profiling resolution and functional profiling analysis. Our study provides a method that can use machine learning to impute the WGS profiled count data from 16s profiled count data. It is quite challenging that profiled data has lots of zero inflation. Our approach can help studies characterize and quantify accurate genus and species levels of microbiome profile cost-effectively without WGS.

Sch. of Med., Atlanta, GA, ¹²The Henry M Jackson Fndn., Bethesda, MD, ¹³USUHS - TAGC, Bethesda, MD, ¹⁴Case Western Reserve Univ, Cleveland, OH, ¹⁵Univ. of miami, Miami, FL

Abstract Body:

Alzheimer disease (AD) is a multifactorial neurodegenerative disease that affects 6.5 million Americans. The *APOEε4* allele is the strongest genetic risk factor and is reported to lead to mitochondrial dysfunction (MTD). The AD risk is lower when the allele is carried on an African local ancestry (ALA) compared to European local ancestry (ELA). Since two thirds of AD patients are female, we sought to get a deeper understanding of ancestry-specific gender alterations in carriers of the strongest genetic risk factor, *APOEε4*. Single nuclei RNA sequencing (snRNA-seq) the frontal cortex (Brodmann area 9) in 17 homozygous AD *APOEε4/4* carriers of ALA (N=7, 4 females) and ELA (N=10, 7 females) was used to identify ancestry gender-based alterations and the specific MTD landscape of *APOEε4/4* carriers. The snRNA-seq was performed using 10X Chromium system. We found that the astrocyte clusters with high expression of *APOEε4*, also had the highest levels of mitochondrial (MT) markers. Next, we analyzed the 35 MTD processes in the MitoXplorer database (MX) and identified higher MTD alteration in cell types with the highest *APOEε4* expression, namely microglia, endothelial cells, and L2/3 layer excitatory neurons. When analyzing gender differences, all *APOEε4*/MT cell types, except one microglial subtype, showed lower MTD ratios in female *APOEε4* ALA carriers compared to *APOEε4* ELA. This ratio was inverted in males. The increase in MTD in males points to an overload of MTD leading to MT stress and oxidation that is associated with worsening AD pathology. The MX processes showing the greatest differences in both sexes were apoptosis, amino acid metabolism, calcium signaling, and MT dynamics. The expression of MT encoded genes linked to oxidative phosphorylation was decreased in females with *APOEε4* ALA compared to *APOEε4* ELA and increased in male samples of ALA compared to ELA. In conclusion, we observed specific mitochondrial processes significantly altered in the cell types which showed the highest expression of *APOEε4*, but differing in direction and degree by both sex and ancestry. This suggests further studies of the *APOEε4* effect on mitochondrial dysfunction are warranted and highlights the importance of considering sex and ancestry in the pathological mechanisms of AD.

Omics Technologies Posters - Thursday

PB3034. Increasing throughput and decreasing cost for single-cell profiling using combinatorial indexing

Authors:

M. Nakamoto, P. Boyd, N. Pacheco, J. Thomas, D. Pokholok, L. Lin, F. Schlesigner, T. Guettouche, F. Steemers; ScaleBio, San Diego, CA

Abstract Body:

The ability to examine populations at the single-cell level has led to novel advances across many fields, but despite the increasing number of systems available the cell throughput of single-cell experiments has not scaled as rapidly due to high costs and complex workflows. Studies that require hundreds of thousands of cells or more, such as those involving screens, rare cell populations, or large patient cohorts, can be prohibitively expensive.

To address this, we increase the throughput of on-market systems by adding upstream combinatorial indexing technology using the ScaleBio ATACseq pre-indexing kit. In this workflow nuclei from up to 24 samples are distributed across 24 wells of a provided plate for barcoded tagmentation, introducing an additional cell-based index to each molecule. Nuclei are then pooled and can be superloaded onto existing single-cell capture systems. Despite loading of 100,000 nuclei per channel the additional tagmentation barcode creates a low effective doublet rate, enabling recovery of the majority of multiplet nuclei for downstream analysis.

We demonstrate this technology first using a human/mouse barnyard experiment in which human and mouse cell lines were mixed prior to loading onto the tagmentation plate. Nuclei were then pooled and 100,000 nuclei were loaded onto a single lane of a droplet system. Analysis of these data show effective recovery of nuclei across multiple sites and users (~55-60%) with low effective doublet rates (<5%). Barnyard analysis using ATACseq data shows clean distinction of human and mouse populations with no decrease in sensitivity or increase in background with increasing nuclei per droplet. We next tested this technology with PBMCs with a similar loading rate of 100,000 nuclei per channel. We observed high barcode and mapping rates, high recovery of both fresh and frozen PBMCs, and after QC filtering and clustering we show successful identification of the major PBMC subsets using ATACseq data. Taken together these data show that the ScaleBio ATACseq pre-indexing kit can massively increase throughput of on-market systems while decreasing cost, enabling single-cell analysis for even the most high-throughput needs.

Omics Technologies Posters - Wednesday

PB3035. In-depth analysis and comparison of different whole genome methylation sequencing library preparations with low DNA input

Authors:

Z. Sun¹, S. Behati¹, P. Wang², A. Bhagwate¹, V. Wang¹, S. McDonough¹, W. Taylor¹, J. Cunningham¹, J. Kisiel¹; ¹Mayo Clinic, Rochester, MN, ²Mayo Clinic, Scottsdale, AZ

Abstract Body:

Background. Whole genome methylation sequencing (WGMS) is an unbiased and comprehensive way to measure the modification of cytosines in the genome. The most common approach is through bisulfite treatment which converts an unmethylated cytosine to uracil (thymine). However, the harsh treatment leads to DNA loss and artifacts. A recent enzymatic methyl-seq (EM-seq) overcomes these limitations and is becoming a popular alternative. WGMS can also theoretically be used for single nucleotide or structural variant detection; however, limited data are available on variant calling accuracy from WGMS data. **Materials and methods.** NA12878 was sequenced by EM-seq, QIAseq Methyl Library Kit (QIA-seq), Swift Accel-NGS Methyl-Seq (Swift-seq) and WGS with 25ng input (additional replicates of 25ng and 10ng for EM-seq). Traditional quality metrics (read alignment, genomic coverage, CpG capture, conversion rate, and etc), DNA methylation measurement, SNP call accuracy using Genome in a Bottle (GIAB) as reference and copy number calls using several benchmarks were compared. Two data processing pipelines, Bismark and SAAP-BS, and two methylation data specific variant callers BisSNP and BSSNPER were used to compare the analytical variability. CNVpytor was used to call copy number variation (CNV). **Results.** EM-seq demonstrated the best performance in almost all measurements. It had the highest mapping rate, number of CpGs captured at 5X, and the lowest duplication rate. QIA-seq had the highest conversion rate (0.999) but the highest duplication rate and lowest CpGs at 5X, particularly from Bismark processed data. Swift-seq performance was between EM-seq and QIA-seq. For the commonly detected CpGs within a processing pipeline, the highest correlation was between EM-seq and Swift-seq and followed by EM-seq replicates. Across processing pipelines, the data from the same library always clustered together and had correlation coefficient greater than 0.97. In SNP detection, EM-seq could reach a recall of 0.83, precision of 1, and F1 score 0.9 in which only the recall was inferior to WGS (0.98). Both Swift and QIAseq had low recalls and F1 scores although precision was high for the genomic positions with coverage. The recalls for CNVs in all libraries including the WGS were below 20% while an EM-seq library performed as well as the WGS. **Conclusions.** EM-seq demonstrates the best performance in CpG capture, genomic coverage evenness and DNA methylation measurement. It provides almost similar information for SNP and CNV to WGS. Poor CNV performance for all libraries is mostly due to lack of a gold standard of a truth set and remains challenging in genomics research (not unique to WGMS).

Omics Technologies Posters - Thursday

PB3036. Individualized cellular ancestry: efficient reconstruction of cell lineage trees

Authors:

Y. Jang¹, L. Fasching², T. Bae¹, L. Tomasini², J. Schreiner², A. Szekely², T. Fernandez², J. Leckman², F. Vaccarino², A. Abyzov¹; ¹Mayo Clinic, Rochester, MN, ²Yale Univ., New Haven, CT

Abstract Body:

Mosaic mutations can be used to track cell ancestries and reconstruct high resolution lineage trees starting from the very first cell divisions of the zygote. However, this approach requires sampling and analyzing the genomes of multiple cells, which can be redundant in lineage representation, limiting the scalability of the approach. We describe a strategy for cost- and time-efficient lineage reconstruction using clonal induced pluripotent stem cell (iPSC) lines from human skin fibroblasts. The approach leverages shallow sequencing coverage to assess the clonality of the lines, clusters redundant lines and sums their coverage to accurately discover mutations in the corresponding lineages. Only a fraction of lines needs to be sequenced to high coverage. We show that using shallow-sequenced 72 iPSC lines from a living individual, this strategy can recapitulate and extend a lineage tree generated using high coverage data. We discuss and propose an optimal experimental design for reconstructing lineage trees.

Omics Technologies Posters - Wednesday

PB3037. Induced pluripotent stem cells (iPSCs) for functional genetic screen applications.

Authors:

N. Isachenko, D. Hu, A. Chenchik, D. Tedesco; Cellecta, Inc., Mountain View, CA

Abstract Body:

Induced pluripotent stem cells (iPSCs) are widely used for disease modeling, drug discovery, and cell therapy development. However, iPSCs are difficult to engineer with an efficient CRISPR/Cas9 system for functional genetic screens. We used WTC11 human iPS cells to generate functionally validated lentiviral transduced Cas9 lines, characterized by high gene-editing activity and sustained potential to differentiate. Flow cytometry was used to check for the expression of the pluripotency markers Oct3/4, TRA1-60, and SSEA-4 in the iPS-Cas9 cells, and their actual pluripotency was then confirmed by testing the ability to differentiate into the three germ layers: ectoderm, mesoderm, and endoderm. Furthermore, genome-wide transcriptome analysis was performed to confirm the expression of germ-layer specific markers in the differentiated cells. Sustained Cas9 activity was confirmed in the differentiated cells. This study provides proof-of-principle that patient-derived iPSCs can be used to enable CRISPR/Cas9 functional genetic screening technology in reconstituted patient-specific tissues/disease models.

Omics Technologies Posters - Thursday

PB3038. Infection with SARS-CoV-2 leads to variant-specific changes in gene expression in airway cell lines and primary cell cultures.

Authors:

A. Rustagi¹, D. T. Bravo¹, M. Leong¹, A. Beck¹, T. Cormier², J. V. Nayak¹, C. A. Blish¹; ¹Stanford Univ., Stanford, CA, ²Parse BioSci.s, Seattle, WA

Abstract Body:

Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) has caused a global pandemic of illness, disability, and death unmatched since the flu epidemic of 1918. People infected with SARS-CoV-2 exhibit symptoms ranging from asymptomatic to mild airway infections through to severe impacts on lung function and possibly death. The virus spreads through aerosols and droplets exhaled by infected individuals that, in turn, come into contact with mucous membrane tissues of uninfected individuals. The virus can infect a range of cell and tissue types within the human body primarily by using the Spike (S) protein on its surface to bind to angiotensin-converting enzyme 2 (ACE2) displayed on cell surfaces. Once the virus releases its RNA and proteins into the cell cytoplasm, the cell begins to copy and translate the viral genome and assemble new viral particles, which ultimately escape the cell and propagate the infection within the body and between individuals. Questions remain about the impacts of viral infection on host gene expression in different cell types, including the induction of innate immune genes. To investigate these questions, we cultured a human lung epithelial cell line (A549-ACE2) as well as primary cultures of nasal tissues from healthy donors. We induced the primary cell cultures to differentiate into cultured nasal cells and then infected both the epithelial cell line and the cultured differentiated nasal cells with various strains of SARS-CoV-2 virus. We used the Parse Biosciences Evercode™ Whole Transcriptome RNA-sequencing kit to investigate gene expression in these infected cells. We identified the cells present in the differentiated nasal cultures using canonical cell markers and examined changes in gene expression. Our current research focuses on the impacts of SARS-CoV-2 infection on the human transcriptome in hopes of better understanding the biology of disease progression and immune response.

Omics Technologies Posters - Wednesday

PB3039. Inference of menopausal status from female reproductive tissue gene expression signatures

Authors:

E. Theusch; Univ. of California, San Francisco, Oakland, CA

Abstract Body:

Unfortunately, the extensive endocrine changes that accompany menopause result in physiological changes throughout the body that can negatively influence women's health. One major barrier to uncovering the mechanisms of these changes is the lack of menopausal status information in many existing datasets, including most human tissue gene expression datasets. Due to the responsiveness of reproductive tissues to female sex hormones and the correlations of ovarian follicle-produced and female sex hormone-regulated genes with age that we observed in our initial studies of uterus and ovary data, we sought to infer women's menopausal status using female reproductive tissue gene expression data. Since GTEx (Genotype-Tissue Expression) includes many tissues contributed by each donor, this can then be applied to other tissues for downstream analyses. To extract a strong menopause-related signal from library size-adjusted and variance-stabilized gene expression data, we used PEER (probabilistic estimation of expression residuals) to infer "hidden factors" that corresponded to unmeasured covariates, while including known covariates. Importantly, we withheld age as a covariate since it is strongly correlated to menopause status, our unmeasured variable of interest. In the uterus, hidden factor 2 (HF2) showed the greatest correlation with age, and, importantly, this relationship was not linear but had an inflection point around age 51, the average age of menopause, supporting the likelihood that it is a proxy for menopause status. 96% (72/75) of uterus tissue samples with $HF2 < 0$ were collected from women under 54 years old (inferred premenopausal), and 95% (64/67) of samples with $HF2 > 0$ were from women over 48 years old (inferred postmenopausal), demonstrating the high consistency of menopausal status inferences based on the $HF2 = 0$ threshold and age. We further validated uterus HF2 as a viable menopausal status marker by cross referencing with pathology notes recorded during ovarian tissue collection from many of the same donors. 96% (27/28) of donors for which ova, follicles, and/or corpora lutea were noted in the ovaries had uterus $HF2 < 0$. Furthermore, 92% (11/12) of donors with ovaries noted to be atrophic had uterus $HF2 > 0$. Interestingly, ovaries that were noted to have a postmenopausal appearance had a wide range of uterus HF2 values, potentially reflecting that ovarian changes precede gene expression changes in the uterus. Future extension of premenopausal versus postmenopausal gene expression comparisons to non-reproductive tissues could provide molecular-level insights about the changes in health and disease risk that women experience post-menopause.

Omics Technologies Posters - Thursday

PB3040. Insights from HLA transcriptome analysis of a cohort from the Qatar Genome Program

Authors:

A. Fadda, H. Naeem, B. Lo, Y. Mokrab; Sidra Med., Doha, Qatar

Abstract Body:

The Human Leucocyte Antigen (HLA) is an essential player in the immune system, controlled by a set of genes on chromosome 6 in the human genome. This set of genes expresses proteins presented on the cell surface, for the main role of presenting foreign antigens for targeted destruction. Hence, an array of diseases has been associated with HLA, such as cancer, autoimmune diseases, and transplant rejection. HLA genes are highly polymorphic for the purpose of fine tuning the immune response, with thousands of alleles documented so far. There is evidence that in addition to allelic identity, expression levels contribute to disease status as well: around 50% of reported loci in the GWAS catalogue are in intronic and regulatory regions of HLA genes. Therefore, we aimed to study the transcriptomics of 13 class I & II genes and their association with phenotype. Through Qatar Biobank and the Qatar Genome Program, around 2000 Qatari samples have genomic and RNAseq data, demographic, biochemical, proteomic, and medication data, and various questionnaires, providing a very rich database of over 2000 phenotypic parameters per subject. We used a specialized analysis pipeline to infer the HLA haplotype from the genomic data of each subject, then used a personalized reference to quantify the per-allele expression from the RNAseq data. We have ~ 400 alleles in total for the 13 genes, with HLA-B, -A, -DRB1 having the most alleles respectively. One-way-ANOVA shows allele-specific expression. Alleles' expression per gene were summed up to create gene-level expression. Our results show that, apart from HLA-G, class I genes show higher expression, with HLA-C being the most abundant, followed by HLA-B, -A, -E, and -F. Surprisingly, association testing between individual gene expression and phenotypic data was not significant (with correction for multiple testing), with few exceptions including thrombosis, chest pain, stroke, angina, asthma, and hemorrhoids. To evaluate non-gene-specific HLA expression, RNAseq data were quantified against the entire MHC region. This total-HLA expression was tested for associations with the phenotypic data. The most striking association was with gender, with females having slightly higher total HLA expression level than males. In conclusion, our dataset is unique in its richness and the ethnicity of its subjects, and the analysis will result in more distinctive findings.

PB3041. Insights into Molecular Pathways Associated with Juvenile Myositis through Single-Cell Transcriptome Profiling

Authors:

C. Kao, H. Qu, J. Garifallou, R. Pellegrino di Silva, H. Hakonarson; Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

Inflammatory myopathies (IM)-including dermatomyositis (DM), polymyositis (PM), and inclusion body myositis (IBM)-are a group of rare autoimmune diseases most often characterized by chronic muscle inflammation leading to progressive skeletal muscle weakness and loss of function, where cutaneous involvement may be present (in DM) and systemic problems occur in severe cases. IM presentation is heterogenous, where amyopathic forms (without apparent muscle involvement) can manifest. Juvenile-onset IMs are generally considered distinct but closely related clinical entities from their adult-onset forms. The etiology of IM is unknown, although there is a clear genetic/heritable component. Steroids and other immunomodulatory agents have been transformative, but some cases remain difficult to treat/manage. We are collecting a biobank of samples from families with juvenile IM cases, with the aim of using "omics" technologies to find potentially informative biomarkers to guide use of existing and possibly new therapies. One of the technical challenges posed with blood sample collection is that it may not always be practical to process and harvest cells immediately, since the collection site may not have the necessary equipment, tools, and staff, where instead unprocessed blood may need to be shipped first, which then introduces a delay of ~2-3 days between collection and processing. The impact on single-cell gene expression signatures of peripheral blood mononuclear cells (PBMC) upon prolonged storage prior to processing has not been examined, thus we collected blood from healthy volunteers into EDTA-coated tubes and isolated (and froze down) PBMCs immediately or stored the blood at 4°C for 24, 36, or 48 h prior to PBMC isolation (and freezing). The samples were then analyzed following single-cell transcriptional profiling using the 10x Genomics Chromium platform and sequencing via Illumina NovaSeq (i.e. single-cell RNASeq, or scRNASeq). The impact of prolonged delays in processing on the transcriptome signatures of PBMCs was assessed, and a "delay" signature was identified which was used as a means for correcting and filtering out genes most sensitive to delays in sample processing. We then analyzed the scRNASeq dataset derived from PBMCs collected from juvenile IM subjects which had experienced processing delays and evaluated the differential expression signature to healthy controls before and after filtering/correction for the delay signature. The impact on type I IFN and mTOR pathway signature was also examined.

Ctr., Cincinnati, OH, ¹⁶Dept. of Pediatric Surgery, Columbia Univ. Med. Ctr., New York, NY

Abstract Body:

Congenital diaphragmatic hernia (CDH) is a life-threatening birth defect characterized by incomplete development of the diaphragm that is often accompanied by other congenital anomalies. Although rare *de novo* and inherited coding variants identified from exome and genome sequencing contribute to about 20% of CDH patients and have identified a number of candidate risk genes, the genetic causes of most CDH cases remain unexplained. Here, we performed RNA sequencing (RNA-seq) of diaphragm cells of 153 CDH cases to investigate the utility of RNA-seq in genetic analysis. All cases were previously exome or whole genome sequenced. Forty-nine cases (28.8%) have putative pathogenic *de novo* variants. We normalized the expression level across samples to remove technical batch effects, and then quantified cis- and trans-effects of putative pathogenic variants to confirm their functional role at the cellular level. We confirmed that most genes with likely gene disrupting variants have nonsense mediated decay (NMD) that affects expression levels for that gene. We performed an annotation-free algorithm able to detect splice sites *de novo* to identify aberrant splicing events by testing for differential splicing in each subject against the others. We found functional effects of three important RNA processing genes, *HNRNPC*, *ALYREF* and *CSTF2*. The sample from the carrier of a *HNRNPC* deleterious missense variant has the highest global rate of intron retention among all samples. Additionally, *GATA4* and *GATA6*, key transcription factors in developing heart and diaphragm, have extremely low expression levels in ~10% CDH subjects, all without known deleterious variants in *GATA4* or *GATA6*. The samples with low *GATA4* expression have low expression of genes potentially regulated by *GATA4*. In conclusion, we demonstrated that RNA-seq data of patient tissues can confirm the functional impact of putative pathogenic variants at the cellular levels and that *GATA4* and *GATA6* regulatory networks are a potential convergent pathway in CDH.

Omics Technologies Posters - Wednesday

PB3043. Integrated Proteotranscriptomics Analysis of Breast Cancer using Variational Autoencoders to Prioritize Pathogenic Genes

Authors:

J. Jhee¹, M-Y. Song², B. G. Kim³, H. Shin^{4,5}, S. Lee¹; ¹Ctr. for KIURI Bio-Artificial intelligence, Ajou Univ. Sch. of Med., Suwon, Korea, Republic of, ²Div. of Cardiology, Dept. of Internal Med., Kyung Hee Univ. Hosp., Kyung Hee Univ., Seoul, Korea, Republic of, ³Dept. of Brain Sci. and Neurology, Ajou Univ. Sch. of Med., Suwon, Korea, Republic of, ⁴Dept. of Industrial Engineering, Ajou Univ., Suwon-si, Korea, Republic of, ⁵Dept. of Artificial Intelligence, Ajou Univ., Suwon, Korea, Republic of

Abstract Body:

Because cancer phenotypes with high heterogeneity are controlled by diverse mechanisms following multiple points in the Central Dogma, various deep learning approaches have been applied to identify biomarkers that have representative characteristics of integrated multi-points omics data. To overcome the imbalance which multi-omics data generally have a characteristic that has high dimensions compared with relatively few patient samples, many researches applied variational autoencoder (VAE) that is known to have strength in handling high dimensional data with few samples for its innate generative modeling process. This study develops methods to prioritize key breast cancer regulator genes based on a unified representation applying the compressed features learned through VAE using proteotranscriptomic data of identical 105 breast cancer patients from TCGA and CPTAC. We computed encoding weighted scores (EWS) which deduced each lower-dimensional encoding feature with VAE using pre-processed omics data, and conducted survival analysis using Cox hazard model with the survival period and EWS to select significant encoding features (SEF). The SEF were decoded through VAE, and we computed the p-value per each gene based on decoding weight score, and calculated the accuracy using breast cancer-related genes from the knowledgebase. Survival analysis results show that each PT, P and RNA data contains 12.9%, 12% and 19.3% of significant encoding features, respectively. To verify the effect of the unified representation, we compared accuracy measurements, significant encoding features which belong to proteotranscriptomic data represented not only represent the highest accuracy of 0.98 at significance level of 0.01 but also showed an increasing trend of accuracy as decreasing significance level. Based on the results, we can conclude that our methods based on VAE to prioritize cancer-associated gene set showed remarkable performance at integrated multi-omics than mono-omics data.

PB3045. Integrating Knowledge in Breast Cancer Subtyping Deep Learning Classifiers

Authors:

J. Davidson, M. Kressman, J. Tang, H. Lakshman Kumar, N. Zarate, L. Garabedian, B. Aduaka, C. Janssens, P. Kim, P. Anderson; Cal Poly, SLO, San Luis Obispo, CA

Abstract Body:

The large amounts of data present in biomedical research provides an incredible opportunity for precision medicine, and also a complicated question on how to use that data in a biologically and diagnostically meaningful way. Deep learning neural networks have been utilized to improve precise diagnostics and treatment options in many cancer fields, but often fail due to issues with reproducibility, underspecification and subtle adjustment to certain parameter combinations which may perform poorly when the test distribution differs from the training distribution. We seek to address these complications by embedding prior knowledge from the biological research literature. We hypothesize that embedding domain specific knowledge into classifiers can boost predictive models and increase their functional utility. To test this hypothesis, we focus first on breast cancer due to the wealth of knowledge available, especially related to subtype biomarkers and genetic signatures. Here we will present our work translating clinical and genetic data into graph knowledge which is then embedded into our modified neural network classifier. We embed this prior knowledge into the loss function and can easily test the impact of various levels of clinical data (mutation rate, patient metadata, tumor gene expression, etc) obtained from the METABRIC study. Our results show that our approaches reduce variability in our deep learning architecture and increase consistency. We demonstrate the specificity of these knowledge integrations to the outcomes of biomarkers identified through pathway enrichment studies. In general, our novel model can apply to a broad range of biomedical questions to access machine learning classifiers with improved biological confidence that the results are meaningful and reproducible.

Omics Technologies Posters - Thursday

PB3046. Integrating multiple human toxicogenomics datasets for drug repositioning

Authors:

M. Leclercq; Université Laval, Québec, QC, Canada

Abstract Body:

Introduction: A few publicly available toxicogenomics databases exist, which include many molecules exposed on various human cell lines from multiple tissues, with different time and dose expositions, generated from different technologies. By integrating such data we aim to identify molecules providing the same transcriptomics effect (molecular repositioning) in various human cells by automated learning. However, to perform such a task, the cell lines must present equivalent transcriptomic profiles after an exposition to a same molecule, at equivalent dose and time. Here, we evaluated different approaches to integrate such data and expose the identified groups of molecules presenting consistent transcriptomic profiles across datasets. We integrated experiments from various platforms, including L1000 from Connectivity Map, microarray data from Open TG-GATEs and RNA-seq from local datasets. Methods and results: The tested approaches to integrate the datasets included computation of differential expression (e.g. DeSeq2, GeoDE), data transformations and standardisation, and batch effect correction methods using various approaches (e.g. Combat, Harmony). We also tested deep learning algorithms (e.g. variational auto-encoders, domain adversarial neural networks) to integrate the data together. We succeeded in integrating microarray experiments and RNAseq, but L1000 was mitigated. Some molecules demonstrated a better integration than others. We finally used unsupervised learning to find molecules having the same corrected transcriptomic profiles. Integrating these data allowed us to evaluate the consistency of the impact of tested molecules on the various tested cell lines through gene signatures. Conclusions: Integration of toxicogenomics databases is very challenging, mostly due to the heterogeneity of the data, multiple batch effect sources, and experimental and biological variations. Many attempts to correct batch effects by the state of the art methods demonstrated a mitigated success to group together equivalent experiments. However deep learning showed promising results to handle batch effects and we were able to propose closely related molecules based on their impact on transcriptomic profiles in various cell lines.

Omics Technologies Posters - Wednesday

PB3047. Integration of single nucleus and bulk adipose RNA-seq reveals distinct adipocyte subtypes for obesity and insulin resistance.

Authors:

M. Alvarez¹, E. Rahmani², Z. Chen¹, O. Avram¹, B. van der Kolk³, K. Mohlke⁴, K. Pietiläinen³, E. Halperin¹, M. Laakso⁵, P. Pajukanta¹; ¹Univ. of California, Los Angeles, Los Angeles, CA, ²Univ. of California, Berkeley, Berkeley, CA, ³Univ. of Helsinki, Helsinki, Finland, ⁴Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ⁵Univ. of Eastern Finland, Kuopio, Finland

Abstract Body:

Obesity predisposes to cardiovascular disease and type 2 diabetes. Several transcriptomic studies have characterized adipose tissue (AT) gene expression changes across cardiometabolic conditions. However, AT consists of a heterogeneous assembly of cell-types confounding bulk tissue analyses. Thus, we sought to map transcriptomic changes associated with cardiometabolic traits at cell-type resolution, and performed one of the largest single-nucleus RNA sequencing (snRNA-seq) of subcutaneous adipose biopsies to date from 111 individuals across 4 cohorts, resulting in 104,669 nuclei. Additionally, we integrated bulk subcutaneous AT RNA-seq of 335 participants from the METSIM cohort, of which 84 overlapped with the snRNA-seq samples. First, we searched for cell-type composition changes across metabolic phenotypes by using negative binomial regression and snRNA cell-type counts. We found that adipocyte and AT-resident myeloid cell-type proportions were negatively and positively correlated, respectively, with obesity, insulin resistance, and serum lipid levels. To validate these changes in the 335 bulk AT samples, we estimated cell-type proportions using Bisque and observed the same directions of correlations with traits. To search for subcell-type associations, we performed cell-type-specific differential expression (DE) in adipocytes, stromal, endothelial, and myeloid cells using snRNA-seq-derived pseudo-bulk. Among these tissue-resident cell-types, adipocytes demonstrated the highest number of DE genes, with 127 and 105 significant (FDR<0.05) for BMI and Matsuda index, respectively. Interestingly, extracellular matrix pathway genes were significantly up-regulated in obese and insulin resistant individuals' adipocyte nuclei, while their lipid genes such as *FADS3* were down-regulated. We validated these results by performing DE analysis in the 335 bulk AT METSIM samples after regressing out estimated cell-type proportions. We found that 112 (93%) and 86 (90%) overlapping snRNA adipocyte DE genes for BMI and Matsuda index showed the same directional effect in the bulk AT data, indicating that single-cell level references can help retrieve biological signals in larger bulk RNA-seq sets. Finally, canonical correlation analysis (CCA) between snRNA adipocyte and bulk AT expression showed that the first canonical vector recapitulated the observed single-cell-level adipocyte differences between the obese and insulin resistant individuals. Overall, our integrative transcriptomic approach revealed that obese and insulin resistant individuals' adipocyte subtypes differ from those of metabolically healthy individuals.

Omics Technologies Posters - Thursday

PB3048*. Integrative computational analysis of long-read transcriptomes identifies alternatively spliced poison exons in iPSC-derived brain organoids

Authors:

M. Broad, J. Hong, K-M. Lamar, J. Calhoun, G. Carvill; Northwestern Univ., Chicago, IL

Abstract Body:

Poison exons (PEs) are naturally occurring, evolutionarily conserved alternative exons that regulate the expression of genes by introducing a premature truncation codon (PTC), signaling nonsense-mediated decay (NMD) to degrade the transcript. Computational mapping and deep RNA-sequencing of the human and mouse cortex have revealed that ~33% of all alternatively spliced cassette exons are predicted to involve PEs. Additionally, PEs are cell type and tissue-specific, emphasizing their role in regulating gene expression spatially. For example, the PE of *SCN1A* is included in the mature mRNA transcript in neural progenitor cells (NPCs) and degraded by NMD. However, in mature neurons, the PE is skipped, as the full-length sodium channel is required for normal neuronal electrophysiological function. Pathogenetic variants in genes like *SCN1A* and *FLNA* can cause dysregulated PE splicing during neurodevelopment and are associated with neurodevelopmental disorders (NDDs) like epilepsy and autism spectrum disorder. Although PEs are integral in transcriptional regulation and proper neurodevelopment, little is known about the locations of PEs in the genome. Therefore, we have developed a computational analysis pipeline to annotate and identify alternatively spliced isoforms that include PEs in the human genome with a particular emphasis on neurodevelopment. We achieved this using whole transcriptome long-read sequencing of brain organoids generated from healthy female- and male-derived iPSCs at multiple time points. The brain organoids were either untreated as control or treated with the drug cycloheximide (CHX) treatment. CHX inhibits global protein translation and increases the abundance of PE-containing isoforms, thus increasing the likelihood of detection. We have previously successfully identified increased inclusion of PEs in known NDD-associated genes, including *SCN8A*, *SCN1A*, and *CHD2*. This experimental paradigm will identify PEs in human neurodevelopment that can be used to interpret variants from genome sequencing in individuals with NDDs. Ultimately, we will create a computational resource of PEs that the scientific community can use to identify therapeutic targets and create effective therapies to treat individuals suffering from severe NDDs.

Omics Technologies Posters - Wednesday

PB3049. Integrative single-nucleus multi-omics across 287 skeletal muscle biopsies reveals context-specific e/caQTL and extensive caQTL-GWAS colocalization

Authors:

S. Parker¹, A. Varshney¹, N. Manickam², M. Erdos³, P. Orchard², A. Jackson², N. Narisu⁴, H. Stringham², M. Laakso⁵, J. Tuomilehto⁶, T. Lakka⁷, K. Mohlke⁸, M. Boehnke², H. Koistinen⁶, F. Collins⁹, L. Scott¹⁰; ¹Univ MICHIGAN, Ann Arbor, MI, ²Univ. of Michigan, Ann Arbor, MI, ³NHGRI/NIH, Bethesda, MD, ⁴NIH, Bethesda, MD, ⁵Inst. of Clinical Med., Kuopio, Finland, ⁶Finnish Inst. for Hlth. and Welfare, Helsinki, Finland, ⁷Univ. of Eastern Finland, Kuopio, Finland, ⁸Univ North Carolina, Chapel Hill, NC, ⁹NHGRI, NIH, Bethesda, MD, ¹⁰Univ Michigan, Ann Arbor, MI

Abstract Body:

Skeletal muscle is the largest organ by weight (>40%) and is relevant for several polygenic phenotypes including type 2 diabetes (T2D) and related metabolic traits. Identifying genetic mechanisms underlying these traits requires pinpointing the set of causal variants, the target genes these variants regulate, and the specific cell populations in which they function. Here, we generated single nucleus chromatin (snATAC) and transcription (snRNA) profiles across 287 frozen human skeletal muscle biopsies. We integrated 414,982 nuclei across the modalities with LIGER and identified 13 cell types, ranging in abundance from 35% (type 1 fiber) to <1% (adipocyte) of all nuclei. We integrated genotypes and identified expression and chromatin accessibility quantitative trait loci (e/caQTL) in the five most abundant cell types (type 1, type 2a, type 2x, mesenchymal stem cell, endothelial). We identified 6,844 eQTL (250kb from TSS) and 100,928 caQTL (10kb from peak) at 5% FDR, ranging from shared to cell type-specific, and fine-mapped 268 eQTL and 4,502 caQTL signals to a single causal variant (95% credible set). We identified 1,637 eQTL-caQTL colocalizations (coloc5 posterior probability $H_4 > 0.5$); 977 (58%) were unique to one cell type. We performed heritability enrichments, colocalization, and chain-of-causality inferences of cell-specific e/caQTL with fine-mapped signals from UKBB, T2D, and related metabolic trait genome-wide association studies (GWAS). For all GWAS, we observed more colocalizations with caQTL compared to eQTL. For example, for waist-to-hip ratio (WHR) adjusted for BMI, 246 GWAS signals had caQTL colocalizations, with 86 (35%) detectable in only one cell type, highlighting the importance of sn-caQTL maps for GWAS functional studies. We identified multiple three-way GWAS-eQTL-caQTL colocalizations. One example is at a WHR adjusted for BMI GWAS signal, eQTL for SEMA3C, and a 20kb upstream intergenic caQTL peak, with strong evidence for chromatin accessibility being causal on gene expression (MR Steiger $P=0.00002$). Notably, SEMA3C is associated with exercise induced improvements of metabolism. These results inform the causal chain of molecular events that influence the complex genetic regulatory architecture of skeletal muscle at high-resolution epigenomic, transcriptomic, and cell state scales.

Omics Technologies Posters - Thursday

PB3050. Integrative single-nucleus multi-omics analysis identified candidate regulatory elements and variants and their target genes in Alzheimer's disease brains

Authors:

O. Chiba-Falek, D. Gingerich, J. Gamache, J. Barrera, M. Garrett, A. Ashley-Koch, G. Crawford; Duke Univ., Durham, NC

Abstract Body:

The genetic architecture of late-onset Alzheimer's disease (LOAD) is yet to be fully explored. While genome wide association studies (GWAS) discovered numerous LOAD-associated loci, the causal variants and their target genes remain largely unknown. Our overarching goal is to advance our understanding of the genetic underpinning LOAD. Here we applied a pipeline for systematic interrogation of regulatory elements and variants underlying gene dysregulation in LOAD in a cell-subtype resolution. We conducted a single-nucleus (sn)multi-omics study in *parallel* on the 10X Genomics platform using 24 frozen brain tissues, 12 normal and 12 LOAD. The *parallel* snRNA-seq and snATAC-seq collected from the same nuclei samples and at the same time were used in multimodal analysis to profile in gene expression and chromatin accessibility. The 202,223 snRNA-seq and 79,771 snATAC-seq nuclei were grouped into 33 and 26 clusters, respectively. We identified cell subtype specific LOAD-associated differential expressed genes (DEGs; total of 5,910 in all clusters), differential accessible peaks (DAPs; total 82,742) and *cis* co-accessibility networks (CCANs; 25,020) in LOAD. The *parallel* experimental design facilitated the performance of multi-omics integrative analysis and the following analyses focused on 309 LOAD CCANs, where at least one peak overlapped the promoter/intron 1 of a LOAD DEG and contained >1 DAPs. Transcription factor (TF) enrichment analysis identified 2-93 enriched motifs in 9 of the cell subtypes, out of which 1-10 TFs were LOAD DEGs in the corresponding cell subtype. Several TFs including, ZNF135, SP1 and JUN, were enriched in multiple cell subtypes. A subset of 12 CCANs in 7 cell subtypes overlap with known LOAD-GWAS regions that contain 47 (~10% of the total CCAN peaks) LOAD-associated candidate *cis* regulatory elements (cCRE) linked to 16 LOAD DEGs. Finally, we catalogue 35 putative functional SNPs within cell subtype-specific LOAD cCREs that disrupt TF motifs. Several examples including, SNPs within cCRE linked to *MYO1E*, *CUTA* and *RPS15* genes that affect the binding of TFs in the corresponding cell clusters of the microglia, excitatory neuron, and oligodendrocytes, respectively. To our knowledge this study represents the most comprehensive integrative single-cell genomics study in LOAD. We provide new insights into the interactions between the genome, epigenome, and transcriptome in LOAD brains in an unprecedented cell-subtype specific resolution. In summary, our findings enhance the translation of LOAD-genetic risk into mechanistic understanding of causation.

Omics Technologies Posters - Thursday

PB3052. Investigating somatic mutation rates and signatures across the length of the colon with duplex sequencing

Authors:

L. Hiatt^{1,2}, J. Kunisaki^{1,2}, S. Lulla², X. Nie³, Y. Guo³, J. Ramsay³, J. Horns¹, J. Baldwin-Brown⁴, J. Guo⁵, N. Phadnis⁴, T. Jenkins¹, K. Aston¹, J. Hotaling¹, A. Quinlan²; ¹Univ. of Utah Sch. of Med., Salt Lake City, UT, ²Univ. of Utah Dept. of Human Genetics, Salt Lake City, UT, ³Univ. of Utah Dept. of Oncological Sci., Salt Lake City, UT, ⁴Univ. of Utah Sch. of Biological Sci., Salt Lake City, UT, ⁵Chinese Academy of Sci. Inst. of Zoology, Beijing, China

Abstract Body:

Somatic mosaicism refers to the accumulation of mutations in non-germline cells throughout an organism's lifetime. Somatic mutations exist in healthy tissues but play a central role in disease pathogenesis, from developmental syndromes to cancer. In the colon, somatic mosaicism is a causative factor in colorectal cancer (CRC) and has been proposed to contribute to inflammatory bowel disease (IBD). These diseases cause significant mortality and morbidity: CRC is the 2nd leading cause of US cancer death, and IBD affects one in 200 individuals of European ancestry. These diseases have well-established regional presentations, with distinct pathologies along the length of the colon, such as "right" and "left" CRC and differently-clustered subtypes of IBD. However, the genetic etiologies underlying these region-specific pathologies are unknown.

Recent experimental and computational advances have made it possible to investigate the somatic mosaicism of healthy organs and somatic evolution to disease. However, we still lack a detailed characterization of healthy colon and how mutagenic processes may contribute to pathogenesis. To investigate the mutational landscape of healthy colon, we will apply duplex sequencing to biopsies across the length of cadaver-sourced colons. Duplex sequencing reduces error rates from 10⁻³ to <10⁻⁹, allowing exceptionally accurate mutation detection and measurement of mutation clonality. By extracting mutational signatures, we will determine whether there are endogenous or exogenous processes that may be enriched in specific parts of the organ. We will also evaluate mutation rate gradients as they may vary across the colon. Investigating these processes will provide insight into regional pathologies and their genetic etiologies and guide future clinical strategies for disease prevention, screening, and management. We are currently collecting cadavers via the Utah-based organization DonorConnect and establishing a computational workflow to quantify and interrogate region-specific mutational landscapes in the colon. We expect to present preliminary data based on a pilot study on a subset of acquired colons that have undergone duplex sequencing.

Omics Technologies Posters - Wednesday

PB3053. ioSearch: A tool for searching disease-associated interacting omics.

Authors:

S. Das, D. Srivastava; St. Jude Children's Res. Hosp., Memphis, TN

Abstract Body:

Biomarkers are important predictors of disease onset/progression and hence play a vital role in the prediction of patient survival and/or response to therapy. But the key challenge in finding biomarkers for complex diseases is, decoding the intricate interplay of multiple omics data. Although information from multiple omics data intuitively provides substantial information on the disease compared to a single source of data, it is difficult to analyse such correlated information from multiple omics together due to the differences in the data structure emerging from different assays, less sample size than the number of features under study etc. On one hand, translation deregulation has been held responsible for disruption in the normal mechanisms of individuals while it is also well-known that aberrations in genes disrupt downstream protein formation. Thus, intuitively studying the alteration in protein may provide substantial insight into disease progression, when integrated with the transcriptomic data. But most analytical procedures are unable to integrate subject-specific multi-omics data for a disease outcome because of the high dimensionality and diversity in the nature of multi-omics data. We propose an algorithm ioSearch, to identify novel omics signatures that may differentiate between two subtypes or groups, in a single data integration framework. Our method is based on principal components that select important transcriptomic and proteomic features associated with disease and explores the inter-relation of the most informative features using a multivariate model, to identify disease-associated multi-omics biomarkers. Simulation results show that our method is powerful with a controlled type I error rate. On application of ioSearch to the protein and gene expression data of nearly 800 breast cancer patients from TCGA database, we identified a list of genes and proteins most of which are reported to have interacting functional implications across independent experimental studies.

Omics Technologies Posters - Thursday

PB3054. Is single nucleus ATAC-seq accessibility a qualitative or quantitative trait?

Authors:

Z. Miao¹, J. Kim²; ¹Univ. of Pennsylvania, Philadelphia, PA, ²Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Single nucleus ATAC sequencing (snATAC-seq) is a technique that detects open chromatin for each individual cell. While it is a key assay for gene regulation analysis, existing computational methods for snATAC-seq show a fundamental inconsistency in how data is quantified. Most computational pipelines binarize the data while others retain quantitative information. By analyzing several public datasets, we show that even with sparse single cell data, quantitative counts are correlated with functional outputs such as different levels of gene expression. Thus, the quantitative counts are informative for estimating a cell's regulatory state, which calls for consistent treatment. By investigating the possible molecular events associated with snATAC-seq assays, we propose a new Paired-Insertion-Counting (PIC) as a uniform method for snATAC-seq feature characterization. PIC has theoretical and practical advantages over existing snATAC-seq feature counting methods and is conservative. In addition, we derive the distribution of PIC counts taking into account the experimental protocols (i.e., Tn5 insertions and amplification), which can be used to derive a model-based quantification for snATAC-seq data.

Omics Technologies Posters - Wednesday

PB3055. IsoMiGA: Combining long and short read RNA-seq in human microglia reveals novel isoforms and splicing events and insight into Alzheimer's disease

Authors:

E. Brophy¹, J. Humphrey², R. Kosoy³, B. Zeng¹, E. Coccia⁴, D. Mattei¹, A. Ravi⁵, A. G. Efthymiou⁴, B. Muller¹, G. J. Snijders², C-F. Tsai⁶, S. P. Kleopoulos¹, T. Liu⁷, G. E. Hoffman⁴, A. Goate⁴, L. de Witte¹, J. F. Fullard¹, P. Roussos⁴, T. Raj⁴; ¹Mount Sinai, New York, NY, ²Mount Sinai Sch. of Med., New York, NY, ³Mount Sinai Sch. Of Med., New York, NY, ⁴Icahn Sch. of Med. at Mount Sinai, New York, NY, ⁵Icahn Sch. of Med., Mount Sinai, New York, NY, ⁶Pacific Northwest Natl. Lab., Richland, WA, ⁷Rutgers Univ, Piscataway, NJ

Abstract Body:

Genome-wide association studies in Alzheimer's disease (AD) have identified multiple non-coding genetic loci nearby, or within, genes expressed in myeloid cells of the innate immune system. Microglia are the primary myeloid cell type in the brain and are therefore of high interest for the genetics of AD. We recently generated the Microglia Genomic Atlas (MiGA), a genetic and transcriptomic resource comprising 255 primary human microglia samples from 100 human donors. We found several AD-associated risk variants that act through either expression or mRNA splicing of specific genes in microglia. While we localized the expression-altering variants to microglia-specific enhancers, due to the limitations of short-read RNA-seq, it is more challenging to dissect how these variants alter splicing. Here we use long-read RNA-seq (IsoSeq; Pacific Biosciences) data to create a microglia-specific isoform reference, isoMiGA, to identify novel transcripts and give insight into genetic associations between AD risk and splicing. isoMiGA is constructed from 30 IsoSeq libraries from microglia purified from 27 post-mortem donors for a total number of 89 million long reads. We used the isoMiGA reference to impute isoform expression in 474 short read RNA-seq post-mortem microglia samples from 310 human donors from 3 different independent multi-ancestry cohorts. Additionally, we performed short-read RNA-seq on 3 iPSC-derived microglia lines stimulated with either lipopolysaccharide or interferon-gamma. After filtering, isoMiGA contained a total of 81,170 transcripts, of which 51% are novel compared to GENCODE v38. Interestingly, we identified 1,973 novel fusion transcripts that we explored further. A fusion transcript contains sequences from two or more neighboring genes spliced together by an unknown mechanism. Using microglia-specific ATAC-seq data, we see that 81% of the fusion transcripts have an overlapping transcription start site. 1,877 fusion transcripts have an open reading frame, of which 911 would potentially produce a protein product. We validated multiple fusion transcripts using RT-PCR to verify gene-spanning junctions and observed an overlap in fusion transcripts with those found in the human frontal cortex. We observed that multiple fusion genes and other novel genes were differentially expressed and/or differentially spliced in response to pro-inflammatory stimulation. Overall, long read sequencing of microglia enables the identification of novel isoforms and a deeper understanding of cellular and disease biology.

PB3056. Large-scale single-cell RNA-sequencing in Japanese identified biological and host genetic involvement of innate immune cells in COVID-19 severity.

Authors:

R. Edahiro¹, Y. Shirai¹, Y. Takeshima², S. Sakakibara², Y. Yamaguchi¹, T. Murakami¹, T. Morita¹, Y. Kato¹, Y-C. Liu², D. Motooka², Y. Naito², A. Takuwa², F. Sugihara², K. Tanaka², J. Wing², K. Sonehara¹, Japan COVID-19 Task Force, H. Namkoong³, H. Tanaka³, H. Lee⁴, K. Fukunaga³, H. Hirata¹, Y. Takeda¹, D. Okuzaki², A. Kumanogoh¹, Y. Okada^{1,5,6,7}; ¹Osaka Univ. Graduate Sch. of Med., Osaka, Japan, ²Osaka Univ., Osaka, Japan, ³Keio Univ. Sch. of Med., Tokyo, Japan, ⁴Keio Univ. Sch. of Med., Tokyo, Japan, ⁵Osaka Univ., Immunology Frontier Res. Ctr. (WPI-IFReC), Osaka, Japan, ⁶RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, ⁷the Univ. of Tokyo, Graduate Sch. of Med., Tokyo, Japan

Abstract Body:

While multiple studies have highlighted dysregulation of complex networks of peripheral blood immune responses in COVID-19 using single-cell RNA-sequencing (scRNA-seq) analysis, the immune response of the host to SARS-CoV-2 still remains unclear. COVID-19 GWAS have demonstrated the influence of human genetic background on pathogenesis of COVID-19. However, functional analysis has mostly focused on the variant at *LZTFL1* on 3p21 which showed the strongest severity association in Europeans but conferred a rare frequency of the risk allele in East Asian. We analyzed single-cell transcriptome and T/B cell receptor of over 600,000 peripheral blood mononuclear cells from 53 COVID-19 patients and 51 healthy controls of Japanese ancestry with host genetics data. Differential abundance analysis revealed that the proportion of non-classical monocytes (ncMono) decreased in COVID-19 patients, especially in severe COVID-19. RNA velocity analysis identified the downregulation of the cell transition from classical monocytes to ncMono in COVID-19 patients. We observed the downregulation of *CXCL10*, which is IFN- γ induced gene and reported to be involved in COVID-19 severity by proteomics analysis, in ncMono of severe COVID-19, and the depletion of *CXCL10/CXCR3* interaction between ncMono and plasmacytoid dendritic cells (pDC) or activated T cells despite IFN- γ signal from activated T cells. Cell-cell communication analysis inferred that the cellular interactions involving ncMono and pDC were reduced in severe COVID-19 compared to moderate COVID-19. Clonal expansions of B cell receptor were most evident in plasmablasts of severe COVID-19. The putative disease genes identified by the GWAS for severe phenotypes (i.e., hospitalized COVID-19 and very severe COVID-19) showed cell type-specific expressions in monocytes and dendritic cells, whereas no cell type was enriched in the self-reported infection GWAS. Context and cell type-specific expression quantitative trait loci (eQTL) effects of COVID-19-associated risk variants preferably enriched in monocytes of COVID-19 patients (e.g., *IFNAR2*). In summary, our data linked innate immune cells dysfunction, especially ncMono, with severe COVID-19 and demonstrated the enrichment of host genetic risk in innate immune cells, indicating biological and host genetic critical involvement of innate immune cells in COVID-19 severity.

Omics Technologies Posters - Wednesday

PB3057. Learning nonlinear causal relations in complex biological systems using a deep-learning approach and knockoff statistics

Authors:

H. Park¹, Z. Fan¹, K. Kernan¹, P. Benos¹, S. Canna², J. Carcillo¹, S. Kim¹; ¹Univ. of Pittsburgh, Pittsburgh, PA, ²Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Learning the causal structure helps identify risk factors, disease mechanisms, and candidate therapeutics of complex diseases for future evaluation. Although the complex diseases would render variable interactions highly nonlinear, most bioinformatic methods of causal inference cannot identify the nonlinear relationships and estimate their effect size. To address this limitation and enable a more realistic causal structure learning, we developed the first method that learns both linear and nonlinear causal relations and estimates the effect size, causal Directed Acyclic Graphs using deep-learning VArIable SElection (DAG-deepVASE). DAG-deepVASE formulizes a variable selection problem for causal learning and solves this problem using a deep-learning approach with knockoff statistics. We further demonstrated that it consistently outperforms existing methods in identifying known and new causal relations in the following simulation and biological data. First, in simulation data of various sample size (200 to 1000), number of variables (50 to 3000), and different nonlinearity degree (complete- or partial-nonlinear simulation), DAG-deepVASE identifies 97% of true causalities without false positives, while the other methods could identify less than half of true nonlinear causalities with several false positives. Second, using serum cytokine data of 404 children with sepsis, DAG-deepVASE identifies 98 linear and 117 nonlinear associations. Although existing methods could identify the linear associations, the nonlinear associations were discovered only by DAG-deepVASE. By incorporating the linear and nonlinear causal relations, DAG-deepVASE could rediscover complex causal relations validated in sophisticated experimental models, including a beneficial one from interferon-gamma to tumor necrosis factor-alpha mediated by lipopolysaccharide. Third, using a data set of 214 nutrient intakes, 87 gastrointestinal bacteria genera and body-mass index collected from 90 healthy volunteers, DAG-deepVASE identified not only validated but also novel causal interactions by estimating the nonlinear effect size. Fourth, using the gene expression and clinical variables of the TCGA breast cancer data, DAG-deepVASE enables to understand complex biological interactions not only within genes and clinical features separately, but also across genes and clinical features. Altogether, DAG-deepVASE discovers the complex pathobiological interactions involving both linear and nonlinear causal relations, which is not possible using other methods.

Omics Technologies Posters - Thursday

PB3058. Leveraging a multi-omics Parkinson's Disease dataset to understand the role of mitochondrial transcriptional control in the aetiology of Parkinson's Disease.

Authors:

A. Fairbrother^{1,2}, A. Gil Martinez¹, M. Ryten¹, A. Hodgkinson²; ¹UCL Great Ormond Street Inst. of Child Hlth., London, United Kingdom, ²Kings Coll. London, London, United Kingdom

Abstract Body:

Mitochondrial (MT) dysfunction is known to contribute to the pathogenesis of an array of neurodegenerative diseases, including sporadic Parkinson's Disease (PD) for which the causal genetics remain largely unknown. Mutations in the nuclear-encoded mitophagy genes PINK1 and PRKN are important causes of autosomal recessive PD, which is strong evidence for the involvement of nuclear-mediated MT dysfunction in PD aetiology and underscores the importance of nuclear-MT interaction for normal cellular function. We aim to understand whether nuclear genetic variation is associated with variance of MT transcriptional processes (*trans*-QTLs), and whether these are disease-specific. We focus on two types of MT phenotype related to MT function: gene expression of 15 genes and RNA methylation at 15 independent sites. MT RNA methylation events are known to promote RNA stability and affect the activity of mito-ribosomes and cleavage enzymes. Thus, they are essential to MT function, and to our knowledge, have not previously been implicated in neurodegenerative disease. We leverage the case-control AMP-PD consortium dataset, consisting of multi-omic data from the blood of 1483 PD patients and 965 healthy controls. In total, we identify 56 *trans*-eQTLs (expression QTLs) and *trans*-meQTLs (methylation QTLs). We replicate 42.2% of associations in an independent dataset. We identify *cis*-eQTLs known to regulate several important genes in general MT transcriptional processes, including the nuclear-encoded MT RNase *MRPP3*, and *FASTKD4*, which are involved in MT mRNA processing and regulation of MT mRNA stability. Interestingly, 27% (15/56) of our significant associations represent interaction effects where genetic regulation of MT transcription is significantly different between PD cases and controls (FDR<0.05), pointing to formation of novel control mechanisms in the disease state. Three of our peak genetic variants overlap with those from a recent PD GWAS meta-analysis (P<0.05), which is more than expected by chance (P=0.016752), implicating MT processes in the causal biology of disease. Genes linked to these variants include *GPR155*, a G-protein receptor involved in cognition and *MAGII*, encoding a cellular component of the pre-synapse, *WIPF1*, involved in actin cytoskeleton organisation. We also highlight *ARPP21* (associated with MT methylation in cases), a cAMP-regulated phosphoprotein enriched in basal ganglia. In summary, we observe differences in nuclear genetic regulation of the MT transcriptome between PD cases and controls, pointing to a role for MT-nuclear co-ordination in the pathogenesis of sporadic PD.

Omics Technologies Posters - Wednesday

PB3059. Linking GWAS risk variants to disease genes by epigenomic mapping and prediction of functional enhancer-promoter interactions.

Authors:

Y. Guo, G. Ramaswami, G. Xiang, L. Chen, B. Matthews, J. Weinstein, B. Akerberg, Y. Liu, D. Bumcrot; CAMP4 Therapeutics, Cambridge, MA

Abstract Body:

Genome wide association studies (GWAS) have identified thousands of noncoding loci associated with human diseases and complex traits. These loci are strongly enriched in gene regulatory elements such as enhancers. Identifying the genes regulated by these enhancers promises to further reveal disease mechanisms. However, it remains a major challenge to link functional enhancers to their target genes. We developed enhancer-promoter interaction characterization (EPIC), a machine learning model for predicting functional enhancer-promoter (E-P) pairs. EPIC integrates epigenomic data such as HiC/HiChIP, ChIP-seq, and ATAC-seq, and uses CRISPRi-based enhancer perturbation screening data in K562 cells to train a random forest model to score E-P pairs. The features in the EPIC model include genomic distances, chromatin interaction frequencies of E-P pairs, biochemical activities of enhancers and promoters, and interactions among these features. We compared EPIC with the ABC model (Fulco et al., 2019), one of the best performing published methods, for predicting functional E-P interactions. In hold-out testing, EPIC (AUPR=0.611, AUROC=0.919) outperforms the ABC model (AUPR=0.451, AUROC=0.885) and the difference is statistically significant ($P = 7.6e-11$, Delong's test on ROC curve). We generated epigenomic data in human primary hepatocytes and discovered about 30,000 E-P interactions using EPIC. We compared EPIC with the ABC model in discovering target genes of a set of "gold-standard" curated GWAS loci of liver-related diseases and traits (Mountjoy et al., 2021). We find that EPIC (AUPRC=0.643, AUROC=0.879) is more accurate than the ABC model (AUPRC=0.337, AUROC=0.877) in distinguishing causal genes from neighboring genes. In addition, the EPIC scores significantly associate with the liver eQTL status of the E-P pairs ($P < 2.2e-16$). These results demonstrate the functional relevance of the E-P pairs discovered by EPIC. We further expanded our analysis to discover liver-related GWAS loci-gene pairs and conducted in silico mutagenesis analysis based on the Enformer model (Avsec et al., 2021) to predict the effect of enhancer deletions on gene expression.

In summary, EPIC enables accurate cell-type-specific prediction of functional E-P interactions using epigenomic data. It outperforms an established method in predicting E-P interactions and in linking GWAS loci to causal genes in a new cell type. Applying EPIC to diverse human cell types may help discover disease-causing genes and enable development of novel therapeutics that target enhancers of disease-related genes.

Omics Technologies Posters - Thursday

PB3060. Long read transcriptomes identify features not found with very deep short read sequencing

Authors:

T. Salas-Morris, N. Prasad, B. Umylny; Discovery Life Sci., Huntsville, AL

Abstract Body:

The limited capacity of long-read sequencing technologies has significantly limited researchers' ability to efficiently apply long read sequencing data in drug development. Discovery Life Sciences (Discovery) has addressed this challenge by building a service laboratory that utilizes over 20 Sequel IIe devices from Pacific Biosciences (PacBio) and incorporates liquid handling and robotics to optimize efficiency, cost, and accuracy of large-scale, long-read sequencing projects. To demonstrate the ability of this offering to discover novel isoforms that cannot be detected using established short read RNA-Seq technologies, Discovery partnered with researchers to analyze 12 human tumor samples using between 1 and 5 SMRT Cells per sample (3-18 million reads). When compared to short read sequencing results of the same samples, the data shows that even with only 3 million reads, long read technology can identify validated isoforms missed by very deep short read sequencing. Analysis by quality control and annotation tools further shows that not only are the isoforms identified by short read sequencing much shorter, but they also are much more likely to be false positives, making analysis of the short read transcriptomes more difficult.

Omics Technologies Posters - Wednesday

PB3061. Long-amplicon variant-robust genome capture of SARS-CoV-2 using molecular inversion probes.

Authors:

E. Boyden, A. Patel, J. Vieira, J. Amaral, G. Porreca, P. Saunders; Molecular Loop BioSci.s, Inc., Woburn, MA

Abstract Body:

Combating pandemics such as COVID-19 requires routine and systematic complete viral sequencing of positive samples to identify and track emergent variant strains. The PCR-based ARTIC assay is effective but prone to amplification dropouts when new mutations arise, which has required multiple primer revisions. We previously developed an alternative short-read sequencing assay that uses tiled molecular inversion probes (MIPs) for high redundancy (7.5X mean tiling depth), which improves coverage uniformity and insures against amplification and mutation dropouts, thereby facilitating superior genome completion rates across a broad range of Ct values. However, short-read NGS assays may show reduced sensitivity to modestly sized indels and be unable to phase distant variants. Sequencers by Pacific Biosciences and Oxford Nanopore Technologies can generate reads that are several hundred to thousands of bases long, with more power to identify indels and phase variants, but capitalizing on these advantages requires sufficiently long library molecules, which is not a common feature of published MIP assays. To establish that our highly scalable and easily automatable chemistry can produce templates that are optimal for long-read sequencing, we designed panels of MIPs to capture 99.5% of the SARS-CoV-2 Wuhan-Hu-1 genome in overlapping elements of either 675 or 1215 bp, with mean tiling depths of 22.5X or 40.5X respectively, and evaluated their performance on synthetic RNA from multiple strains using either a single-day or overnight workflow. The results demonstrate that a) our MIP-based SARS-CoV-2 genome capture assays are sensitive, specific, and robust, even for mutation-rich strains such as Omicron BA.1, and b) MIPs can capture much larger elements than commonly reported, which will improve their utility for long-read sequencing platforms.

Omics Technologies Posters - Thursday

PB3062. Long-read capture with Twist target enrichment system

Authors:

T. Han, H. Corbitt, L. Arbiza, E. Toro, C. C. Locklear; Twist BioSci., South San Francisco, CA

Abstract Body:

Targeted resequencing allows for high-resolution characterization of gene regions at a scale and cost that is more accessible than whole genome sequencing. While long-read PacBio HiFi sequencing has been shown to accurately and comprehensively interrogate complex clinically actionable loci, studies have been primarily focused on single genes using PCR amplicon-based methods. Here we describe a method to leverage Twist Bioscience target enrichment workflow for gene panels sequenced with HiFi reads. We designed gene panels of various target sizes, ranging from 0.2-20 Mb. Our long-read hybrid capture protocol starts with 200-1000 ng of fragmented gDNA that were sheared using mechanical fragmentation. After end-repair and dA-tailing, truncated Y-shaped adapters were ligated to adapted gDNA. A pair of 10-bp unique dual indices (UDIs) for sample barcoding were added during PCR. Multiple samples can be pooled for an overnight hybridization. The post-capture libraries then undergo SMRTbell library preparation and sequencing on PacBio Sequel II. Depending on target size, up to 400 samples may be multiplexed and sequenced in one SMRT Cell with HiFi read length of 5-10 kb. We demonstrate that this method efficiently enables comprehensive coverage of gene targets using Coriell samples run with multiple gene panels of varying sizes, which include complex regions like *CYP2D6*, *HLA*, *SMN1*, and *LPA*. This long-read hybrid capture protocol can be utilized with Twist custom or fixed gene panels to efficiently capture genes of interest using long-read sequencing. Optional secondary panels (spike-ins) can also be easily added during hybridization for additional content. The demonstrated method allows for scalable and cost-efficient hybrid capture with long read lengths, minimizing coverage bias, and maximizing accuracy to fully capture all variant types. This includes structural variation and haplotype phasing information which are inaccessible to short-read and Sanger sequencing.

Omics Technologies Posters - Wednesday

PB3063. Long-read isoform sequencing reveals aberrant splicing of *PSEN2*, but not *PSEN1*, in individuals with sporadic Alzheimer's disease.

Authors:

P. Valdmanis¹, K. Gudsnuk¹, C. D. Keene¹, T. D. Bird¹, S. Jayadev¹, M. M. Course^{1,2}; ¹Univ of Washington, Seattle, WA, ²Colorado Coll., Colorado Springs, CO

Abstract Body:

Alzheimer's disease (AD) is a common neurodegenerative disease, characterized by dementia and premature death. Early-onset familial AD is caused in part by pathogenic variants in presenilin 1 (*PSEN1*) and presenilin 2 (*PSEN2*). Sporadic AD is much more frequently observed than familial AD and shares the same hallmarks of pathology including amyloid beta aggregates and tau neurofibrillary tangles, without pathogenic variants in these genes. We hypothesized that improper RNA splicing of *PSEN1* and/or *PSEN2* could generate aberrant transcripts that act mechanistically in a manner similar to pathogenic variants in these genes and provide a direct connection between sporadic and familial AD. Currently available RNA-seq data of *PSEN1* and *PSEN2* is limited to short reads that are fragments of complete transcripts, which may not readily reveal pathogenic isoforms. We utilized a probe-based pull-down strategy and leveraged PacBio isoform sequencing (Iso-Seq) to characterize thousands of complete *PSEN1* and *PSEN2* transcripts in the prefrontal cortex of individuals with sporadic AD, familial AD (carrying *PSEN1* and *PSEN2* variants), and controls. While *PSEN1* splicing patterns were consistent between sporadic AD, familial AD and controls, our results reveal alternative splicing patterns of *PSEN2* specific to sporadic AD. Alternative splicing events include a human-specific cryptic exon present in intron 9 of *PSEN2* and a 77bp intron retention product prior to exon 6 that are both significantly elevated in sporadic AD samples, alongside a significantly lower percentage of canonical full-length *PSEN2* transcripts versus familial AD samples and controls. Both alternatively spliced products are predicted to generate a prematurely truncated PSEN2 protein and were corroborated in an independent cerebellum RNA-seq dataset. In addition, we observed far fewer full-length transcripts carrying pathogenic alleles versus wild-type alleles in *PSEN2* variant carriers. Finally, we identified frequent RNA editing at Alu elements present in an extended 3'UTR in *PSEN2*. Overall, this work expands the understanding of *PSEN1* and *PSEN2* variants in AD, shows that transcript differences in *PSEN2* play a role in sporadic AD, and point to novel therapeutic strategies for AD.

Omics Technologies Posters - Thursday

PB3064*. Long-read RNASeq in human brains aligned to T2T CHM13 complete human genome reveals new gene bodies and new transcripts, exons, & exon junctions in known genes.

Authors:

B. Aguzzoli Heberle¹, J. Brandon¹, K. A. Nations¹, M. Page¹, M. E. Wadsworth¹, D. W. Dickson², P. T. Nelson¹, J. B. Miller¹, J. Fryer², M. T. W. Ebbert¹; ¹Univ. of Kentucky, Lexington, KY, ²Mayo Clinic, Jacksonville, FL

Abstract Body:

Background: RNASeq experiments are generally performed using short-read sequencing technologies that collapse all RNA isoforms for a given gene into a single expression measurement—a **major oversimplification of the underlying biology**. A critical next step in biology research will be to determine the distinct roles individual RNA & protein isoforms play across tissue and cell types. Long-read technologies can sequence entire RNA molecules, allowing researchers to accurately quantify expression for the complete set of RNA isoform species, including new RNA isoforms. Long-read sequencing is especially well suited to discovering novel transcripts when aligning to the first complete telomere-to-telomere (T2T) human reference genome (CHM13). Here, we identify entirely new gene bodies, RNA transcripts/isoforms, exons, and exon junctions in human brain tissue. We also identified major differences between CHM13 and GRCh38 based on gene annotations and RNASeq results.

Methods: We sequenced pre-frontal cortex tissue from five post-mortem human brain samples using Oxford Nanopore Technologies long-read sequencing (cDNA). Data were basecalled using Guppy, reads were aligned to the CHM13 human reference genome using minimap2, and transcripts were assembled and quantified using Bambu.

Results: Among other findings, we discovered 146 new, high-confidence gene bodies expressed in all five samples with 5+ reads in each sample, including 16 with 2+ isoforms. We also found 428 new RNA isoforms in known gene bodies, where 44 are from medically-relevant genes. In total, we discovered 1185 new exons and 668 new exon junctions. *We also identified thousands of non-genic regions with high RNA expression throughout the completed genome, and hundreds of the genes discovered by the T2T consortium had high expression in our samples.* Lastly, we found that 43 genes were transposed to different chromosomes between the GRCh38 and the CHM13 assemblies, and hundreds of additional genes were found to be duplicated on other chromosomes between the assemblies.

Conclusions: Our results suggest long reads combined with the completed CHM13 human reference genome has the potential to reveal exciting new biology relevant to human health and disease, including new gene bodies and RNA isoforms that are overlooked with standard approaches. These methods can provide a more complete picture of the transcriptomic landscape across all tissue and cell types, with potential for clinically-relevant discoveries. We also highlight key gene transpositions and duplications that could affect linkage disequilibrium blocks when aligning samples to the CHM13 reference genome.

Omics Technologies Posters - Wednesday

PB3065. LongReadSum: A fast and flexible quality control tool for long-read sequencing data.

Authors:

J. Perdomo, M. U. Ahsan, Q. Liu, L. Fang, K. Wang; Raymond G. Perelman Ctr. for Cellular and Molecular Therapeutics, Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

Recent advances in long-read sequencing technologies have generated reads tens to thousands of kilobases long with high accuracy. These long reads have a broad range of applications in genomics, including but not limited to uncovering previously missed genetic causes of human diseases, detecting variants in difficult-to-map regions, assembling repetitive regions of the human, and identifying novel splicing isoforms. Prior to analyzing long read data, quality control (QC) checks are needed to ensure that the raw data from sequencers do not contain substantial errors and biases and to understand the basic characteristics of the sequencing run. While short-read sequencing technologies have well-established QC tools such as FastQC, there have been several challenges in implementing QC frameworks for long reads. First, long read data can be generated by different types of sequencing technologies (such as PacBio and Oxford Nanopore) with unique data formats, and the currently available QC tools usually only support one specific sequencing platform or only support some data formats. Second, long read data can be orders of magnitude larger than short reads (for example, a single flowcell on the Nanopore platform can generate 5TB of signal data), and thus it remains imperative to develop a tool that enables fast, high-throughput, and comprehensive QC summary statistics of reads. LongReadSum is a tool that addresses these challenges: It supports the four main data format types used across sequencing technologies (FASTA, FASTQ, FAST5, unaligned BAM, and aligned BAM) and can generate a comprehensive summary of different aspects of sequencing data in a timely manner by executing programs in a flexible multi-threaded C++ framework. Outputs are compiled into both a static and a dynamic HTML report customizable to the user's needs which contains basic statistics such as the total number of reads, base pairs, maximum, mean, and median read length, percent guanine-cytosine (GC) content, and the N50. The report also includes histogram plots of read length, base quality across reads, and average base quality per read. In addition, for Nanopore reads, we include platform-specific QC measures such as sequencing throughput by time. These statistics provide a comprehensive overview of all major aspects of read quality, enabling the identification of significant errors that may preclude downstream analyses. In conclusion, LongReadSum is a computational tool for fast, comprehensive, and high throughput long read QC with support for all major sequencer data types, and it can be adapted to custom long-read sequencing pipelines.

Omics Technologies Posters - Thursday

PB3066*. Low cost, noninvasive RNA-sequencing to enable massive scaling of transcriptome studies.

Authors:

M. Martorella^{1,2}, S. Kasela², R. Garcia-Flores^{1,2}, K. Buschur¹, P. Hoffman², A. Gokden², A. Vasileva², S. Castel², T. Lappalainen^{3,2}; ¹Columbia Univ., New York, NY, ²New York Genome Ctr., New York, NY, ³KTH Royal Inst. of Technology, Stockholm, Sweden

Abstract Body:

Transcriptomic studies disentangle functional mechanisms of gene expression regulation, however, many applications are limited by invasiveness and cost of sample collection and processing, or, by disease-relevancy of samples collected. Optimizing RNA-sequencing of noninvasive biospecimens facilitates discovery by scalable access to other cell types.

304 noninvasive samples (hair follicles, buccal swabs, saliva, and urine cell pellets) collected from 19 individuals over four time points were processed using a reduced-cost, in-house TSO and tagmentation reaction, SMART-seq, and Illumina TruSeq commercial kits. We found low-input methods performed best, but samples passing QC showed comparable metrics and high replication regardless of preparation. Urine and hair follicles provided high-quality data equivalent to cell line RNA, while saliva samples showed a high percent of unmapped reads and typically failed QC. Remapping unmapped reads across all tissues showed microbial signatures characteristic to each, and saliva may be more valuable in microbiome study designs. Tissue was the main driver of gene expression variability across all samples, and sample donor contributed most within a tissue, indicating capture of biological differences rather than technical factors. Cell type deconvolution showed hair, buccal, and urine samples primarily captured epithelial cells, whereas saliva contained neutrophils. Across collections, cell type proportions in hair remained constant while cell quantities fluctuated in other tissues depending on the donor. To identify invasive tissue proxies, we compared noninvasive tissues to GTEx. By PCA, hair clustered with skin, buccal and urine bore similarity to a multitude of tissues, and saliva fell adjacent to whole blood. This clustering appeared to reflect shared cell type composition. We replicated GTEx eQTLs in our data, and saw hair captured cis-regulatory mechanisms present in most tissues, with skin performing highest, and urine best replicated eQTLs found in kidney cortex.

To assess common and rare disease applications, we analyzed gene expression using OpenTargets and OMIM. Hair follicles and buccal swabs showed enrichment for eczema and psoriasis genes, while urine additionally captured kidney disease genes. For Mendelian disease, clustering by median OMIM gene expression with GTEx recapitulated prior proxy observations.

Our findings support noninvasive sampling as a promising approach for scalable, cost-efficient, and disease-relevant transcriptome analyses. This may have value for large-scale cohort studies, longitudinal designs, and sampling from vulnerable populations.

Omics Technologies Posters - Wednesday

PB3067. Low-pass whole genome sequencing as a cost-effective and improved alternative to genotyping arrays

Authors:

P. Zhang, H. Ling, J. Paschall, B. Marosy, J. Gearhart, K. Doheny; Johns Hopkins Univ., Baltimore, MD

Abstract Body:

As the cost of sequencing continues to drop, low-pass whole genome sequencing (lpWGS) has become a potential alternative for SNP arrays in genome-wide association studies. The emergence of both new reference panels derived from large-scale diverse deep WGS data and more computationally efficient algorithms designed for imputation and phasing of lpWGS is now making lpWGS a viable alternative. Here we designed and analyzed an experiment to evaluate aspects of practical implementation including: library preparation methodology, impact across ancestry groups, DNA source, lpWGS coverage levels, imputation algorithm, and imputation reference. We created a validation ‘truth’ dataset by deep sequencing 92 samples with diverse ancestry background (down sampled coverage to 28X). The lpWGS ‘test’ dataset (~ 1X) was generated using a cost-effective library prep (plexWell LP384 from seqWell) for the same set of 92 samples. For cost-comparison modeling, we mimicked NovaSeq6000 run conditions of 768 samples in a 2 x 150 bp S4 flowcell. We used a recent imputation method designed for lpWGS, GLIMPSE, to perform imputation based on the 1000 Genomes (1KG) deep sequencing reference panel (NYGC). The SNP array ‘test’ dataset was *in silico* array data derived by extracting the illumina Global Screening Array (GSA, 654K variants) genotypes from the deep WGS validation dataset, and then performing imputation with the TOPMed reference panel. We evaluated both sensitivity and concordance of each method by comparing all imputed sites that exist in the validation dataset, as well as sites passed different QC filters (R-square from TOPMed imputation, INFO and GP from GLIMPSE imputation). When compared to the validation dataset for autosomal chromosomes for the 92 samples, our results showed that lpWGS recalled more non-reference variants than array (average sensitivity, 89.7% vs 84.1%). After applying filters, lpWGS has improved concordance over array and the gain is more prominent for non-European ancestry, the average precision for non-reference calls are 0.982 vs 0.922 for African, 0.981 vs 0.915 for Asian, and 0.982 vs 0.924 for European. When binned by minor allele frequency, we observed more gain for less common variants (e.g. MAF <10%). In addition, we were able to use lpWGS data to perform the necessary array-based quality checks of contamination (for 5% mixture or higher), genetic ethnicity by principal component analysis (PCA), and relatedness using identical by descent (IBD). Our study demonstrates the feasibility of using lpWGS as a cost-effective and more population agnostic alternative for array-based approaches using publicly accessible resources.

Omics Technologies Posters - Thursday

PB3068. Machine learning approach embedding an alternative splicing as a strategy for a multi omics integration

Authors:

Y. Lee¹, S. Han², J. Lee³, h. aycheh⁴; ¹Seoul Natl. Univ., Seoul, Korea, Republic of, ²Univ. of Utah, Salt Lake City, UT, ³Yonsei Univ., Seoul, Korea, Republic of, ⁴Univ. of Utah Asia campus, Incheon, Korea, Republic of

Abstract Body:

While individual analysis of omics datasets is valuable for identifying omic-phenotype associations, analyses using only one data type are not sufficient to fully elucidate complex diseases because such diseases are the end point of events cumulating with multiple variations through multi-omics biology. To better understand the genetic architecture of complex diseases, a relevant strategy for integrating multi-omics data (i.e. genomics and transcriptomics) is needed. In this study, we seek to develop a machine learning that can integrate genetic variants and expression based on a molecular mechanism - alternative splicing (AS). AS acts as a bridging mechanism connecting genetics to phenotype, passing genetic information encoded in DNA sequences into protein via mRNA sequences. Most of all AS is a key regulatory mechanism of gene expression. We developed a machine learning model that encompass a genetic regulatory elements of gene expression as feature variables sch as exon length, intro length, splice site, distance between genetic variants and exons, splicing regulatory elements, and splicing factor that bridge a exon-level expression and genetic variant. Among these features, intron length, splicing regulatory elements, and the distance were the highest contribution in the model. This study will summarize an evaluation of prediction power of various supervised machine learning classifier and will provide a feasibility of multi-omics integration strategy that incorporate a molecular mechanism into machine learning approach.

Omics Technologies Posters - Wednesday

PB3069. Major cell-types in imbalanced multiomic single-nuclei datasets impact statistical modeling of links between regulatory sequences & genes.

Authors:

F. Leblanc^{1,2}, G. Lettre^{1,2}; ¹Université de Montréal, Montreal, QC, Canada, ²Montreal Heart Inst., Montreal, QC, Canada

Abstract Body:
