The coronavirus disease 2019 (COVID-19), caused by the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), manifests through a broad spectrum of symptoms and symptom severity; many who were infected remained asymptomatic and in those who developed symptoms, the disease ranged from mild cold like symptoms to severe illness and death. Age, sex, and presence of comorbidities such as cardiovascular disease, diabetes, hypertension, and obesity have been the major risk factors for severe COVID-19. However, a large portion of this heterogeneity in disease susceptibility and severity of illness remains poorly understood. SARS-CoV-2 infects humans through the angiotensin converting enzyme (ACE2) receptor, enriched in nasal epithelial cells, and then spread to the ACE2-expressing cells in the distal lung. A growing body of evidence suggests that alveolar epithelial cell type 2 (AT2), which constitute 10-15% of all alveolar cells and are critical for alveolar homeostasis, are the primary targets of SARS-CoV-2 infection. Damage to AT2s was reported to be positively correlated with poor prognosis in COVID-19 patients. Modeling SARS-CoV-2 infection in-vitro, in well characterized, highly uniform, (r^2 at 95% CI = 0.89 ± 0.03), induced pluripotent stem cell (iPSC) derived AT2s from ten participants of our Mexican American Family Study, showed interindividual variability in SARS-CoV-2 infection susceptibility and in cellular viral load. To understand the underlying mechanistic of the AT2's capacity to regulate SARS-CoV-2 infection and cellular viral load, we performed a systematic characterization of pre- and post- SARS-CoV-2 challenged AT2's transcriptomes. The expression of 760 genes in pre-infection AT2s showed statistically significant (FDR corrected p -value ≤ 0.05 ; r^2 absolute ≥ 0.64) correlation with infection susceptibility and cellular viral load. 307 of these genes, whose expression was negatively correlated, showed significant enrichment (Fisher's exact test p -value ≤ 0.001) in cytokine-mediated signaling pathways, positive regulation of interferon-beta production, positive regulation of the inflammatory response, type I interferon signaling pathway, and MDA-5 signaling pathway gene ontology (GO) terms and included innate immunity genes *IFIH1*, *OAS1*, *OAS3*, *DHX58*, *IRF7*, *ADAM8*, *NMI*, *ADAR*, and *GBP6*, whose expression also significantly upregulated (One way ANOVA, FDR corrected p -value range 5.69×10^{-21} to 8.04×10^{-11}) in post SARS-CoV-2 challenged AT2s. Our results strongly suggest that activated pre-infection innate immunity regulates susceptibility to SARS-CoV-2 infection and post infection cellular viral load in AT2s.

Complex Traits Posters - Wednesday

PB1595*. Prioritization of causal genes at Parkinson's disease associated loci using machine learning.

Authors:

E. Yu^{1,2}, R. Lariviere^{1,2}, R. Thomas^{1,2}, K. Senkevich^{1,2}, E. Fon^{1,2}, Z. Gan-Or^{1,2}; ¹McGill Univ., Montreal, QC, Canada, ²Montreal Neurological Inst.-Hosp. (The Neuro), Montreal, QC, Canada

Abstract Body:

In the most recent Parkinson's disease (PD) genome-wide association study (GWAS), 90 independent genetic variants within 78 loci were reported to be associated with the disease. Because most of these variants have unknown functional evidence, we faced a challenge to uncover the potential mechanism and identify causal genes. Previous studies trained machine learning models to predict causal genes from multiomic data. However, these methods lacked tissue and cell-type specific data that is relevant for each disease. In this study, we leveraged genomic datasets from dopaminergic neurons with other publicly available brain tissue quantitative trait loci (QTL) to train a model specific for Parkinson's disease. We trained a machine learning model to predict PD associated genes from GWAS loci. To train our model, we combined transcriptomic, epigenomic data including single-cell multiomic data by FOUNDIN-PD, dopaminergic neuron expression QTL (eQTL), GTEx brain tissues eQTL, enhance-promoter interactions. To select specific gene candidates, PD variants were fine mapped using echolocator to exclude passenger variants. Variant level information was transformed to a gene-feature matrix. We used loci which contained known PD genes (*GBA*, *GCH1*, *LRRK2*, *MAPT*, *SNCA*, *TMEM175*, *VPS13C*) for cross-validation by labeling the known PD genes as positive and other genes 1Mb upstream and downstream as negative. Across all 78 loci, we nominated the genes with high statistical evidence associated with PD such as *IP6K2*, *BIN3*, *IGSF9B*, *TMEM163* and others. Most of these genes are not extensively studied in PD. This study prioritizes multiple candidate genes at PD GWAS loci for functional studies and therapeutic targets for drug development. We used a comprehensive approach including PD relevant datasets from dopaminergic neurons to improve the accuracy of our model.

PB1596*. Prioritizing genes and gene programs for disease by integrating genetic and perturbation data

Authors:

K. Dey¹, K. Jagadeesh², K. Geiger-Schuller³, B. Eraslan³, W. Zhou⁴, W. Bi⁵, Z. Zhao⁵, C. Frangieh⁶, E. Weeks², X. Jin⁷, R. Xavier², S. Lee⁸, H. Finucane⁴, A. Regev³, A. Price¹; ¹Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, ²Broad Inst. of MIT and Harvard, Cambridge, MA, ³Genentech, South San Francisco, CA, ⁴Massachusetts Gen. Hosp., Boston, MA, ⁵Univ. of Michigan, Ann Arbor, MI, ⁶Dana-Farber Cancer Inst., Boston, MA, ⁷Scripps Res., San Diego, CA, ⁸Seoul Natl. Univ., Seoul, Korea, Democratic People's Republic of

Abstract Body:

GWAS have identified thousands of disease-associated variants, but identifying genes and gene programs that impact disease remains challenging. Here, we propose a new method, PolyGene, that assigns a disease score to each gene by integrating GWAS summary statistics, gene-level annotations, and gene-gene interactions to prioritize genes with functional relationships to disease GWAS genes. We applied PolyGene to 28 diseases/traits (mean $N=270K$) and evaluated gene score enrichments for gold-standard gene-disease pairs based on approved drug targets, Mendelian genes and CRISPR-implicated genes. PolyGene attained higher gene score enrichments than other methods (e.g. mean excess enrichment 5.01x higher than MAGMA, $P=8e-32$). For a subset of 7 well-powered UK Biobank blood cell traits, incorporating gene-based association statistics from WES data (PolyGene-S) produced a small but statistically significant further improvement (1.14x, $P=3e-04$ vs. PolyGene). We used PolyGene to evaluate the informativeness for 18 autoimmune diseases and blood cell traits of small gene programs constructed from Perturb-seq data in bone marrow dendritic cells, defined by the top 500 genes with downstream effects on gene expression of knocking out (or knocking down) a target gene. We analyzed 1,030 gene perturbation programs constructed from Perturb-seq of E3 ligase genes and their interacting partners (Geiger-Schuller*, Eraslan* et al. in preparation). We observed higher enrichment for immune-related blood cell traits than RBC/platelet-related traits (5.3x, $P<1e-50$), consistent with the immune function of dendritic cells; PolyGene attained higher gene score enrichments than other methods (e.g. 3.4x vs. MAGMA, $P=2e-12$). The *NFKB1* and *CUL3* gene programs were enriched across all autoimmune diseases (1.5x, $P=2e-06$ and 1.7x, $P=4e-12$), and the *CHFR* gene program was specifically enriched for type 1 diabetes (1.4x, $P=3e-06$). Notably, gene-level PolyGene scores of target genes were significantly correlated with gene score enrichments of their perturbation programs (mean $r=0.23$, $P=4e-05$). We also used PolyGene to evaluate the informativeness for autism of perturbation programs for 35 *de novo* autism risk variant genes in 5 brain cell types, derived from in-vivo Perturb-seq data (Jin et al. 2020 Science). The perturbation programs in astroglia and microglia attained the highest enrichments for autism (mean of 2.4x, $P=5e-07$ vs. mean of 1.2x, $P=3e-04$ in other cell types), consistent with the known role of these two cell types in autism. In conclusion, PolyGene is a powerful approach for prioritizing genes and gene programs for disease to produce biological insights.

Complex Traits Posters - Thursday

PB1598. Profiling the neurobiology underlying brain structure in living human subjects.

Authors:

A. Lund, The Living Brain Project Team; Icahn Sch. of Med., New York, NY

Abstract Body:

While large genome-wide association studies have shown that the structure of the brain is at least partially controlled by genetic variation, the relationship between molecular neurobiology and brain structure has yet to be thoroughly characterized. Many studies have investigated the relationship between molecular neurobiology and neuroimaging, but, due to the uncommon occurrence of profiling of living brains, few have been able to do so in a living population. The Living Brain Project (LBP) was designed to overcome this limitation of human brain research by obtaining samples from the dorsolateral prefrontal cortex (dlPFC) in a large cohort of living subjects undergoing deep brain stimulation. Leveraging clinical multimodal neuroimaging performed on the subjects at the time of surgery and molecular profiling generated from their dlPFC biopsies, we look at 171 living individuals for which we have both neuroimaging and RNAseq data. Using this resource, we provide what is, to our knowledge, the most extensive characterization of the molecular profiles of brain structure. Using differential expression, we identify genes whose levels of expression associate with imaging metrics of the brain in the dlPFC including cortical thickness, volume and area. This analysis significantly contributes to the body of work that attempt to generate a complete picture of the molecular properties that play a role in brain anatomy.

Complex Traits Posters - Wednesday

PB1599. PRS-PheWAS of psychiatric/ behavioral traits to disentangle clinical heterogeneity in Substance Use Disorders.

Ribasés^{1,2,3,4}; ¹Psychiatric Genetics Unit, Group of Psychiatry, Mental Hlth.and Addiction, Vall d'Hebron Res. Inst. (VHIR), Barcelona, Spain, ²Dept. of Mental Hlth., Hosp. Univ.ri Vall d'Hebron, Barcelona, Spain., Barcelona, Spain, ³BioMed. Network Res. Ctr. on Mental Hlth.(CIBERSAM), Madrid, Spain., Barcelona, Spain, ⁴Dept. of Genetics, Microbiol., and Statistics, Faculty of Biology, Univ.t de Barcelona, Barcelona, Spain., Barcelona, Spain, ⁵Addiction and Dual Diagnosis Unit, Dept. of Psychiatry, Hosp. Univ.ri Vall d'Hebron, Barcelona, Spain, Barcelona, Spain

Abstract Body:

Substance Use Disorders (SUDs) are known to be highly polygenic, and many genetic risk factors have been identified by genome-wide association studies (GWASs). Phenome-wide association studies (PheWAS) have been designed to explore how the genomic profile associates with a range of phenotypes. Individuals with SUD suffer from psychiatric comorbidity, resulting in higher clinical severity, and genetic effects are to a substantial extent pleiotropic across psychiatric diseases. Here, we perform an integrated polygenic risk score (PRS)-PheWAS to explore the association between the genetic liability for 10 psychiatric and behavioral traits with the clinical phenome of SUD, to explain the **clinical heterogeneity** seen in SUD patients. We genotyped 1427 SUD patients, whom underwent deep phenotyping, and selected 41 clinical phenotypes related to: (a) lifetime substance use, (b) psychiatric comorbidity, and (c) sociodemographic and health features. We selected 10 pre-existing GWASs from psychiatric and related traits and constructed PRSs in the SUD cohort, using PRSs, to test their association with the clinical phenotypes. We performed logarithmic transformations and used appropriate regression models depending on the nature of the data. We also used available data on lifetime personal abuse (physical, sexual or emotional) to test for a potential abuse by PRS interaction. We observed that PRS constructed from anxiety, depression, schizophrenia and bipolar disorder, were nominally associated ($P < 0.05$) with phenotypes including, psychiatric family history, number of ambulatory treatments, age at onset of consumption and multiple psychiatric conditions, as well as lower educational level and less employment. Similarly, PRSs constructed from educational attainment and well-being showed a negative association with criminal record, substance use family history and lifetime DSM-IV disorder, among others. Our results also showed that PRSs for depression, schizophrenia and suicide attempt seemed to modulate the effect of lifetime personal abuse on phenotypes related to number of therapeutic interventions, psychiatric family history and mental health problems. We observed that the clinical heterogeneity of SUD can be explained, at least in part, by genetic signatures related to other comorbid disorders and traits. Moreover, the presence of genetic risk variants underlying psychiatric conditions in SUD patients can be indicative of higher clinical severity and comorbidity rates, and unfavorable social status. Despite our limited sample size, we are able to show promising preliminary results that should be further investigated in bigger studies.

Complex Traits Posters - Wednesday

PB1600*. Quantification of race, ethnicity, and genetic ancestry disparities in anti-hypertensive drug efficacy in the All of Us Research Program

Authors:

S. Goleva¹, J. Keaton², D. Schlueter³, T. Cassini⁴, H. Mo⁵, A. Williams⁶, T. Ferrara⁶, O. Stubblefield³, C. Zeng⁶, J. Dai⁶, J. Denny⁷; ¹NIH, Bethesda, MD, ²Med. Genomics and Med. Genetics, Clarksburg, MD, ³Natl. Human Genome Res. Inst., Bethesda, MD, ⁴NIH, Chevy Chase, MD, ⁵NHGRI, Bethesda, MD, ⁶NIH, Bethesda, MD, ⁷NIH, Kensington, MD

Abstract Body:

Hispanic ethnicities and non-White races have been, and continue to be, underrepresented in clinical trials. Pharmacokinetic and pharmacogenetic differences in race, ethnicity, and genetic ancestry remain understudied despite evidence that they affect drug efficacy. Essential hypertension affects 47% of Americans, and several mechanisms can contribute to its development, each of which drugs can target. We developed a generalizable method to determine systemic race, ethnicity, and genetic ancestry disparities in common anti-hypertensive drug efficacy. The NIH All of Us Research Program (AoU) is a longitudinal cohort of 194,420 participants with electronic healthcare record (EHR) data, drug exposures, and self-reported demographics, 98,640 of which have whole genomes sequenced. We used a self-controlled case study design to determine the efficacy of common anti-hypertensive medication using the reduction in systolic blood pressure (SBP) values after medication (delta SBP). We analyzed 16 antihypertensive medications present in AoU, each of which over 500 participants used for >28 days. We predicted African, Admixed American, European, East Asian, South Asian, and Middle Eastern genetic ancestry using genetic principal components analysis. Linear regressions were used to determine whether delta SBP for each medication was significantly different in each race, ethnicity, or genetic ancestry compared to non-Hispanic White participants after adjusting for covariates. We were able to determine the most effective hypertensive drugs within each demographic (e.g. chlorthalidone in Black participants). We were also able to determine drugs which have the most variable effectiveness based on race/ethnicity (e.g. labetalol delta SBP = -3.73 ± 0.76 mmHg in White, -7.87 ± 4.56 mmHg in Asian, -9.01 ± 0.96 mmHg in Black, and -12.07 ± 1.64 mmHg in Hispanic participants). 14 out of 16 anti-hypertensive drugs were less effective in Black and 8 out of 16 were less effective in Hispanic, compared to non-Hispanic White, participants after Bonferroni correction. This provides support for the further need to increase racial- and ethnic-minority representation in clinical research. Results using genetic ancestry data closely mirrored those using race/ethnicity. The diuretic chlorthalidone was most effective at reducing SBP in African ancestry participants (delta SBP = -10.32 mmHg, SE = 1.2). This warrants further examination of underlying genetic variants that may contribute to the pharmacogenomic predictors of drug outcomes in future studies. Together, this data demonstrates the potential of real-world evidence to guide medication therapy selection.

Complex Traits Posters - Wednesday

PB1601. Quantifying differential multiple sclerosis risk via polygenic risk scores in African American and Hispanic cohorts.

Authors:

A. Hernandez¹, M. Davis²; ¹Brigham Young Univ., Provo, UT, ²Brigham Young Univ, Provo, UT

Abstract Body:

Polygenic risk scores (PRSs) have been used as a method to learn about disease risk due to genetics. However, the majority of PRSs have been developed using Genome-Wide Association Studies (GWASs) that overrepresent individuals of European ancestry and underrepresent diverse populations such as individuals of African or Latin ancestry. This suggests that PRSs have limited generalizability to diverse populations, which poses medical concerns and could contribute to health disparities. Previous research has found that autoimmune diseases collectively exhibit ethnic disparities, such as Multiple Sclerosis (MS) which shows that non-Hispanic black patients with MS died at an earlier age and have an increasing mortality trend in comparison to white patients with MS. Calculating accurate PRSs for MS can help accommodate ethnic minorities and contribute to closing existing gaps in health care. We acquired de-identified electronic health records (EHRs) from Vanderbilt University Medical Center BioVU that were genotyped on the Illumina MEGAex platform. The software program *Tractor* was used to facilitate the inclusion of admixed individuals and generate ancestry-specific effect size estimates and boost GWAS power. Using *Tractor*, we replicated the 200 previously identified variants for increased MS risk among Hispanic and African Americans by Beecham, A H et al. as well as the variants rs12373588, rs1335532, and rs4821544 which we previously identified to have statistically significant associations with later age of onset in African Americans. We then calculated PRSs using the formula $PRS_j = \sum^N S_i * G_{ij} / P * M_j$ for African American and Hispanic populations using the software program PLINK. We will analyze the efficiency of the PRSs calculated by conducting a linear regression.

Complex Traits Posters - Thursday

PB1602. Quantifying mitochondrial dysfunction at biobank scale using insights from rare disease

Unit in Donor Hlth. and Genomics, Univ. of Cambridge, Cambridge, United Kingdom, ¹¹Hlth. Data Res. UK Cambridge, Wellcome Genome Campus and Univ. of Cambridge, Cambridge, United Kingdom

Abstract Body:

Mitochondrial dysfunction, defined as a decline in energy production via oxidative phosphorylation (OXPHOS), has been linked to many common diseases of aging, including type 2 diabetes (T2D) and cardiovascular disease. Though often called a “hallmark” of aging, the etiology of age-related OXPHOS dysfunction is poorly defined. Human genetics provides a natural approach to study OXPHOS dysfunction and could contextualize genetic associations with age-related disease. However, classical measures of OXPHOS dysfunction, such as OXPHOS activity assays and histochemical stains of biopsy material, are low-throughput and impractical to perform at biobank scale.

Here, we created a new measure of OXPHOS dysfunction we call “MitoScore,” defined using plasma metabolite profiles from patients with mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS), a monogenic OXPHOS disease. Using a cohort of 134 patients and healthy controls, we trained an elastic net model for disease status. The resultant linear model, with non-zero contributions from 8 metabolites, produced scores well-correlated to disease severity measures in held-out samples (e.g., $r=0.42$ for urine heteroplasmy) with better performance than any single included metabolite.

We then assessed if MitoScore generalizes to other OXPHOS diseases. In a Leigh syndrome cohort ($N=18$), MitoScore produced perfect case-control separation ($AUC=1$). In a distinct cohort with diverse inborn errors of metabolism ($N\sim 230$), MitoScore highlighted patients with lesions in OXPHOS genes over those with other severe genetic diseases ($AUC=0.8$).

After validation in 3 independent cohorts, we performed a GWAS of MitoScore computed in UK Biobank (UKB; $N\sim 80,000$). We identified 15 genome-wide significant associated loci, 86% of which showed concordant effect sizes in INTERVAL ($N\sim 12,000$). Several nominated genes are biochemically linked to the NADH/NAD⁺ ratio, which often rises with OXPHOS impairment due to a reduced respiratory chain capacity to oxidize NADH. Genetic correlations with MitoScore highlighted T2D-related traits, including T2D ($r_g=0.34$) and sex hormone-binding globulin ($r_g=-0.26$), which is notable as elevated NADH/NAD⁺ has recently been linked to insulin resistance.

We expect that MitoScore will be useful in many contexts. For rare disease, MitoScore may be useful in aiding diagnosis (e.g., interpreting variants of uncertain significance) and monitoring disease progression and treatment response. In the general population, we anticipate using MitoScore-associated loci as a genetic instrument to test the causal link between OXPHOS dysfunction and age-related disease.

Complex Traits Posters - Thursday

PB1604. Rare copy number variants in *CACNA1H* implicated in essential tremor.

Authors:

M. Medeiros^{1,2}, C. Liao^{1,2}, D. Spiegelman^{1,2}, P. A. Dion^{1,2}, G. A. Rouleau^{1,2}; ¹McGill, Montreal, QC, Canada, ²Montreal Neurological Inst., Montreal, QC, Canada

Abstract Body:

Background: Essential tremor (ET) is a neurological condition and the most common movement disorder in the world, affecting approximately 5% of the population by the age of 65¹. ET leads to significant impairment and diminished quality of life due to tremors occurring in the hands during voluntary motion (action tremors)¹. Despite ET having an overall heritability of between 45-90%, only a limited number of associated genomic loci have been identified². In the past, linkage disequilibrium, sequencing, and genome-wide association studies were done to identify candidate ET genes; however, copy number variants (CNVs) have been studied less extensively in ET³. Here we leveraged a large ET cohort of 2,133 cases and 10,336 controls to identify genomic deletions or duplications of genes (CNVs) associated with ET.

Methods: The sample cohort was limited to those with European ancestry inferred through PCA. CNVs were called from SNP array data using the program PennCNV and annotated for functional consequence and population frequency using gnomAD. Only rare CNVs (gnomAD frequency less than 1%) intersecting protein coding regions of the genome were tested. The enrichment of CNVs per gene between cases and controls was investigated using Fisher's exact test, and only the candidate genes that passed Bonferroni correction were considered.

Results: Following quality control, 3,516 CNVs across 1,638 genes were tested across 1,365 cases and 9,585 controls. Of the genes tested, 17 were significantly different between cases and controls. One of these genes, the Calcium Voltage-Gated Channel Subunit Alpha 1H (*CACNA1H*), was overlapped by 18 unique CNVs. Genomic duplications overlapping *CACNA1H* were exclusively observed in ET cases and were not observed in any controls ($p = 7.1 \times 10^{-9}$). Approximately 1.3% of the cases in our cohort carried a rare CNV spanning the protein-coding regions of *CACNA1H*.

Discussion: Previously, different calcium channel subunits (*CACNA1G*, *CACNA1C*, *CACNA1A*) have been implicated in ET³. The observation of duplications of the *CACNA1H* gene implicates this gene as a risk factor for ET, supplements the involvement of calcium channels in ET and adds to the involvement of *CACNA* genes in ET pathology.

Med. Ctr., Amsterdam, Netherlands

Abstract Body:

Recent studies have found that duplications or deletions of DNA fragments, known as copy number variants (CNVs), may play a role in missing heritability for complex human diseases. In that sense, we conducted a scan for CNVs in the GR@ACE/DEGESCO dementia dataset of Spanish population (n=20,080 individuals using Axiom 815K Spanish biobank array (Thermo Fisher)). We ran CNV calling algorithms from PennCNV software to obtain high-confidence calls for CNVs. After extensive quality control (QC) for individuals (sex discrepancies, excess of heterozygosity, high missingness, familiar relations and population outliers were excluded), CNVs (>50kb and nSNPs>10 were included), removing spurious CNVs in telomeric/centromeric regions, gene QC (ANOVA comparisons between DNA origin source evaluated in controls), 8,275 controls and 7,818 dementia cases were selected for following analysis. Global burden analyses revealed highly significant differences between dementia cases and controls (dem/ctrl) in CNV rate ($p < 2.2e-16$, $mean_{ctrl-dem} = 6.31-5.23$), distribution of deletions or duplications (both $p < 2.2e-16$; duplications $mean_{ctrl-dem} = 2.22-2.42$; deletions $mean_{ctrl-dem} = 4.10-2.81$), but not in number of genes affected by CNVs ($p = 0.1085$). We also observed a nominal deletion-gene-affected association by genes related to nervous system development pathway or intellectual disability such as *VPS13B* (nine cases affected), *PKP3* ($Freq_{ctrl-dem} = 0.30-0.45\%$) and *FBRSL1* ($Freq_{ctrl-dem} = 0.27-0.47\%$). The current study did not detect significant differences in CNVs that affect known Alzheimer's disease (AD) loci identified by recent genome-wide association studies ($p = 0.128$). Nevertheless, we found three

ASHG 2022 Annual Meeting Poster Abstracts

important AD genes with CNVs potentially associated to dementia. Specifically, we detected *MAPT* protective deletions ($\text{Freq}_{\text{ctrl-dem}} 0.16\text{-}0.01\%$), *ABCA7* risk deletions ($\text{Freq}_{\text{ctrl-dem}} 0.05\text{-}0.14\%$) and *APP* CNVs detected in five dementia cases (0.064%). Because the technology used in our study has limitations in detecting small CNVs, future studies must carefully assess the presence of smaller CNVs and their relationship with dementia.

Complex Traits Posters - Thursday

PB1606. Rare *Plasmodium falciparum* coronin gene mutations following ACT treatment of malaria in South Western Nigeria

Authors:

O. Ajibaye¹, I. C. Nwankwo¹, Y. A. Olukosi¹, O. V. Adaramoye², C. Nnam¹, E. Oriero³, M. Oboh³, B. A. Iwalokun¹, A. Amambua-Ngwa³; ¹Nigerian Inst. of Med. Res., Lagos, Nigeria, ²Coll. of Med., Univ. of Lagos, Lagos, Nigeria, ³Med. Res. Council, The Gambia, Fajara, Banjul, Gambia

Abstract Body:

Plasmodium falciparum Non-*Pfkelch13* protein variants have been implicated in Artemisinin (ART) resistance, but not in Africa. The specific genetic markers driving in vivo reduced ART efficacy among African *P. falciparum* populations are currently unclear. Here we investigated SNPs in *Plasmodium falciparum* actin-binding protein (Pfcoronin) associated with in vivo reduced sensitivity to ART in Nigeria.

Seven isolates showing parasitaemia after Day 3 in a 28-day therapeutic efficacy study of artemether-lumefantrine among 51 volunteers in Lagos, Nigeria were investigated. Molecular diagnosis was done by conventional and real-time PCR amplification of Pf18S rRNA gene, var acidic terminal sequence, telomere-associated repetitive elements-2 and coupled conventional and real-time Pf18S rRNA PCR. High resolution melting (HRM) and 12 neutral *P. falciparum* microsatellite loci genotyping were analyzed to confirm recrudescence in comparison with *msp2* genotyping. We genotyped drug resistance targets (DHFR_51, DHFR_59, DHFR_108, DHFR_164, MDR1_86, MDR1_184, DHPS_581 and DHPS_613) and sequenced *PfCoronin* and *PfKelch13* bi-directionally to investigate presence and association of SNPs with ART insensitivity.

The Real-Time PCR methods equally detected *P. falciparum* infections. A total of 7 (26.92%) cases were either early treatment failure (ETF), late parasitological failure (LPF) or late clinical failure (LCF), and 18 (73.08%) showed adequate clinical and parasitological response (ACPR). Only one sample was confirmed as recrudescence by microsatellites and HRM analysis out of the four identified as recrudescence infections by *msp2* genotyping. Presence of the drug resistance-associated haplotypes, pfdhfr/pfdhps/pfmdr1 (108T/N/51I/164L/59R/581G/86Y/184F) was observed in two samples. Expected heterozygosity (*He*), allelic diversity, for each of the microsatellite loci from pre- and post-drug administration, revealed no significant difference in *He*, ($P = 0.19$, Mann-Whitney test). Analysis of the allele sizes and frequency per locus implicated one isolate as recrudescence. LD measured as a standardized association index *IAS* between multiple *P. falciparum* loci revealed significant LD ($IAS = 0.2865$, $P = 0.02$, Monte Carlo simulation). Genetic analysis identified 7 new Pfcoronin single nucleotide variants (V55L, V67E, I68G, K69G, L77I, D154Y and E200Q) and the P76S earlier reported. None of the ART resistance-associated mutations earlier reported in *pfkelch-13* and Pfcoronin was observed. Pfcoronin mutations here reported are important for investigations on mechanisms of non-*keclh13* markers of emerging African ART resistance phenotypes.

Complex Traits Posters - Wednesday

PB1607. Rare protein-truncating DNA variants in APOB or PCSK9, low-density lipoprotein cholesterol, and risk of coronary artery disease.

Authors:

J. Dron^{1,2}, TOPMed Lipids Working Group; ¹Massachusetts Gen. Hosp., Boston, MA, ²Broad Inst. of MIT and Harvard, Cambridge, MA

Abstract Body:

Introduction: Protein-truncating variants (PTVs) in either apolipoprotein B (*APOB*) or proprotein convertase subtilisin/kexin type 9 (*PCSK9*) are associated with significantly lower low-density lipoprotein (LDL) cholesterol concentrations. Using data from prospective cohort studies, we quantified the relationship between PTVs in *APOB* and *PCSK9*, LDL cholesterol concentrations and protection against coronary heart disease (CHD).

Methods: We considered participants in five prospective cohorts from the NHLBI Trans-Omics for Precision Medicine (TOPMed) program and the UK Biobank. PTVs were defined as nonsense, frameshift, and splice-site variants disrupting *APOB* or *PCSK9*. The impact of PTVs on LDL cholesterol levels was assessed using linear regression, and the hazard ratio (HR) for CHD between PTV carriers and non-carriers was estimated using a Cox proportional hazard model. Models were adjusted for age, sex and the first five principal components of ancestry. Age-dependent probabilities for cumulative incidence of CHD in carriers and non-carriers were determined by summing all events by age at most recent follow-up. The cumulative incidence of CHD by age 75 years between carriers and non-carriers was assessed using a standardized Cox proportional hazard model, adjusted for sex and the first five principal components of ancestry.

Results: From the NHLBI cohorts (N=19,073; 44.4% male; mean [SD] age of 52 [17] years; 67.0% white, 23.9% Black), PTVs were identified in 139 (0.7%) participants and were associated with a 49 mg/dL (95% CI 43-56) reduction in LDL cholesterol. Over a median follow-up of 21.5 years, incident CHD was observed in 12 carriers (8.6%) versus 3,029 non-carriers (16.0%), corresponding to an HR of 0.51 (95% CI 0.28-0.89). From the UK Biobank (N=190,464; 45.0% male; mean [SD] age of 58 [8] years; 93.9% white, 1.6% Black), a PTV was identified in 662 (0.4%) participants and were associated with a 45 mg/dL (95% CI 42-47) reduction in LDL cholesterol. By age 75, estimated cumulative exposure to LDL cholesterol was 31.6% lower in carriers, and the estimated CHD risk was 3.7% (95% CI 2.0%-5.3%) in carriers compared to 7.0% (95% CI 6.9%-7.2%) in non-carriers, corresponding to an HR of 0.51 (95% CI 0.32-0.81).

Conclusion: Results of this large-scale genetic association study confirm and extend prior cross-sectional analyses in identifying that a PTV in either *APOB* or *PCSK9*—owing to significantly decreased exposure to LDL cholesterol—is associated with a 49% reduction in risk of CHD.

Complex Traits Posters - Thursday

PB1608*. Rare protein-truncating variants in *ZNF518A* are associated with shorter female reproductive lifespan

Authors:

S. Shekari^{1,2}, S. Stankovic³, E. J. Gardner³, N. D. L. Owens¹, G. Hawkes¹, K. A. Kentistou³, A. Azad⁴, R. N. Beaumont¹, F. R. Day³, Y. Zhao³, A. R. Wood¹, K. Ong³, C. N. Wright¹, E. R. Hoffmann⁴, K. S. Ruth¹, J. R. B. Perry³, A. Murray¹; ¹Univ. of Exeter Med. Sch., Exeter, United Kingdom, ²Univ. of Queensland Publ. Hlth.Sch., Brisbane, Australia, ³MRC Epidemiology Unit, Wellcome–MRC Inst. of Metabolic Sci., Univ. of Cambridge, Cambridge, United Kingdom, ⁴DNRF Ctr. for Chromosome Stability, Dept. of Cellular and Molecular Med., Faculty of Hlth.and Med. Sci., Univ. of Copenhagen, Copenhagen, Denmark

Abstract Body:

Female reproductive lifespan is characterised by declining ovarian reserve, but the underlying mechanism is poorly understood. At 6 months gestation, there are around 6 to 7 million non-renewable oocytes in the fetal ovary, which are lost by apoptosis throughout life until menopause, when ovarian reserve reaches around 1 thousand oocytes. Reproductive longevity varies due to environmental and genetic factors that affect the size of the initial oocyte pool and the rate of follicle loss.

We assessed the role of rare (MAF<0.1%) protein-coding variants on ovarian function in data from 104,733 females of European ancestry in the UK Biobank using gene burden association tests. We identified protein-truncating variants in Zinc Finger Protein 518A (*ZNF518A*) associated with both earlier age at natural menopause (effect size 5.61 years, $P=1.2 \times 10^{-10}$) and later puberty timing in girls (effect on menarche timing, 0.42 years, $P=9.8 \times 10^{-4}$). The effect on menopause timing is larger than for any previously reported gene or variant. *ZNF518A* has not been previously implicated in ovarian ageing and its function is unknown. *ZNF518A* was highly expressed in human fetal primordial germ cells as well as primary and secondary oocytes during folliculogenesis. By integrating ChIP-Seq data from ENCODE, we determined that *ZNF518A* has >18,000 binding sites in the genome, many occurring in regulatory regions for genes expressed in the human fetal ovary. Common GWAS variants associated with age at natural menopause were also enriched in the binding sites of *ZNF518A*.

Our results suggest that *ZNF518A* is involved in establishing initial ovarian reserve during fetal life and may regulate many genes that are important for ovarian development. Heterozygous protein-truncating variants in *ZNF518A* are a risk factor for primary ovarian insufficiency (POI; menopause before 40 years), with 12% of carriers having POI.

Complex Traits Posters - Wednesday

PB1609*. Rare variant genetic architecture of mitochondrial DNA copy number from 415,422 exomes.

Authors:

V. Pillalamarri^{1,2,3}, W. Shi¹, C. Say⁴, S. Yang¹, J. Lane⁵, E. Guallar⁶, N. Pankratz⁵, D. Arking¹; ¹McKusick-Nathans Dept. of Genetic Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ²Predoctoral Program in Human Genetics, Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ³Maryland Genetics Epidemiology and Med. Training Program, Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, ⁴Johns Hopkins Univ. Dept. of Biology, Baltimore, MD, ⁵Dept. of Lab. Med. and Pathology, Univ. of Minnesota Med. Sch., Minneapolis, MN, ⁶Dept.s of Epidemiology and Med., and Welch Ctr. for Prevention, Epidemiology and Clinical Res., Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD

Abstract Body:

A portion of interindividual variation in the number of mitochondrial genome copies (mtDNA-CN) reflects mitochondrial function and has recently been shown to have a heritable component. We hypothesized that nuclear loci would harbor rare, functional variants that could influence variation in mtDNA-CN. We examined 415,422 exomes of self-reported White ancestry individuals from the UK Biobank with a median age of 58, and tested the impact of rare variants, both at the level of single variants and through aggregate variant-set mixed model association tests, on mtDNA-CN adjusted for cell counts and covariates including genome-wide independent common variants. A survey across nine variant sets chosen to cover coding sequence and loss-of-function mutations at multiple minor allele frequency thresholds identified 14 genes at experiment-wide significance and three genes at marginal significance. These included associations at known mitochondrial DNA depletion syndrome genes (mtDNA helicase *TWNK*, $p=5.7 \times 10^{-29}$; mitochondrial transcription factor *TFAM*, $p=4.3 \times 10^{-13}$; mtDNA maintenance exonuclease *MGME1*, $p=1.3 \times 10^{-6}$). Novel gene associations included the tyrosine kinase *JAK2* ($p=7.1 \times 10^{-17}$) mutated in myeloproliferative disease, the ATP-dependent protease *CLPX* ($p=9.9 \times 10^{-9}$) involved with mitochondrial proteome quality, and the mitochondrial adenylate kinase *AK2* ($p=5.3 \times 10^{-8}$) involved with hematopoiesis. The most significant association was a missense variant in *SAMHD1* ($p=4.2 \times 10^{-28}$), found on a rare, 1.2 Mb shared ancestral haplotype on chromosome 20. *SAMHD1* is a cytoplasmic host restriction factor involved with viral defense response and the mitochondrial nucleotide salvage pathway, and the missense mutation falls within a critical region of Aicardi-Goutieres syndrome 5 associated with childhood encephalopathy and a chronic inflammatory response. Using leave-one-out analysis, we identified an additional three independent variants driving the *SAMHD1* signal and observed a linear dose-response relationship between the genetic association with mtDNA-CN and genetic association with breast cancer risk across the four conditionally independent, uncorrelated variants at the *SAMHD1* locus (inverse-variance weighted Mendelian randomization causal estimate = 1.6, SE = 0.3, $p=5.5 \times 10^{-8}$), supporting a mechanistic link. Rare variants were enriched in Mendelian mtDNA depletion syndrome loci, and these variants further implicated core processes in mtDNA replication, nucleoid structure formation, and maintenance. Together, these data indicate strong-effect mutations from the nuclear genome contribute to the genetic architecture of mtDNA-CN.

Complex Traits Posters - Thursday

PB1610. Rare variants in ADAMTS13 lead to COVID-19 autosomal dominant disorder, conditioned by SARS CoV-2 infection, sex, and age.

Abstract Body:

We have modeled COVID-19 using a machine learning approach and Whole Exome Sequencing (WES). As an extreme end of this polygenic model, we have identified a Mendelian form of X-linked recessive COVID-19 affecting males, due to rare variants in TLR7. We report here another extreme Mendelian form due to ADAMTS13, affecting mainly females (in the non-reproductive phase of life) and young males. WES analysis of 2,988 SARS-CoV-2 infected subjects was performed and the post-Mendelian model was applied. The ADAMTS13 activity was measured by TECHNOZYM® ADAMTS-13 Assay. Segregation analysis within families was performed. We found an association between ADAMTS13 ultra-rare variants (Minor Allele Frequency < 0.001) and severity in female patients (OR=3.32; 95% CI 1.34 to 8.18; p-value= 4.9x10⁻³). One of several heterozygous ADAMTS13 ultra-rare variants was identified in 124 SARS-CoV-2 infected patients (4.2%), including 49 females and 75 males. Most subjects (106 - 85.5%) had severe COVID-19 disease requiring hospitalization with signs of hyperinflammation, higher D-dimer, and a tendency to platelet consumption. The remaining not-hospitalized 18 subjects (14.5%) were either females between 18 and 50 years (14 subjects) or males over 50 years of age, likely due to the protective role of estrogens, which increase ADAMTS13 transcript. Among the hospitalized patients, there were also 3 female children younger than 10 months. In all cases in which fresh blood was available a reduction of ADAMTS13 activity was demonstrated (p-value = 0.017 at Wilcoxon test). Segregation analysis was available in 2 families: i) a 66-year-old female who required oxygen support transmitted the mutation to the 34-year-old son who required CPAP treatment; ii) a 73-year-old female treated by oxygen support transmitted the mutation to the 40-year-old daughter who was oligosymptomatic likely due to the young age; her sister 76-year-old without the mutation was asymptomatic during infection. Here, we show that carriers of Thrombotic Thrombocytopenic Purpura, (a well-known severe autosomal recessive disorder in which carriers are reported asymptomatic), have a micro-thrombotic form of COVID-19, which segregates in families as an autosomal dominant disorder, conditioned by SARS-CoV-2 infection, sex, and age.

Complex Traits Posters - Wednesday

PB1611. Rare variation in ADHD and related diagnoses in the Mass General Brigham Biobank

Authors:

F. Satterstrom¹, M. J. Daly²; ¹Broad Inst., Cambridge, MA, ²Massachusetts Gen. Hosp., Boston, MA

Abstract Body:

Attention-deficit/hyperactivity disorder (ADHD) is estimated to affect more than 5% of children, making it a potentially important context for sequencing studies. In a Danish cohort, individuals with an ADHD diagnosis had a greater burden of constrained rare protein-truncating variants than controls, similar to individuals with an autism diagnosis (Satterstrom et al., 2019, *Nature Neuroscience* 22:1961-1965). We seek to follow up on this finding by examining ADHD and related psychiatric diagnoses in the biobank of the Mass General Brigham hospital system in Boston, MA, which contains the exome sequences of 49,593 unrelated individuals after sample-level quality control.

The biobank contains 2,743 individuals with an ADHD diagnosis, and we have compared their rates of constrained (i.e. the lowest decile of LOEUF) ultra-rare (i.e. gnomad non-neuro frequency $<1e-5$ and occurring only once in the biobank) protein-truncating variants to the ~30,000 individuals in the biobank without a psychiatric diagnosis. In a preliminary analysis stratified by predicted population (based on PCA), the case enrichment of these variants is greater than 10%. We plan to identify the genes harboring these variants and identify those occurring more often in cases than controls.

In addition, the biobank contains 2,004 samples with a diagnosis of schizophrenia or schizoaffective/psychotic disorder and 2,218 samples with a diagnosis of bipolar disorder (in addition to smaller numbers of autism and intellectual disability cases), enabling within-biobank comparison of these diagnoses to ADHD. We also plan to leverage the data from recent large-scale sequencing efforts from the Autism Sequencing Consortium and the Schizophrenia Exome Sequencing Meta-Analysis consortium to compare risk genes across these disorders and ADHD. From these data we will seek to identify genetic factors contributing to risk for psychiatric disorders in general as well as factors contributing to risk for specific diagnoses.

Complex Traits Posters - Thursday

PB1612. Rare-Inherited variations in Sensory genes increased burden of Autism Spectrum Disorders: A Whole Exome Sequencing study of Indian families

Authors:

A. Siddappa Niranjana Murthy, S. Valiya Parambath, S. Durbagula, A. Korlimarla, N. Kumar Gowda, A. Mysore Vishweshwaraiah; St John's Res. Inst., Bengaluru, India

Abstract Body:

De novo Mutations (DNMs) and rare inherited variations have long been implicated as the strongest contributors to risk for Autism Spectrum Disorders (ASD). Since DNMs do not account for all incidences of ASDs, it is suspected that rare inherited variations add formidable pressure toward disease manifestation. Considering that inherited variations might provide important clues on the subtle yet common behavioral dysfunctions that accumulate over generations to produce phenotypic effects in offspring, we performed the first trio Whole Exome Sequencing (WES) of 14 Indian ASD simplex families with male probands on the Illumina platform at 100X coverage. Data was processed in BWA, GATK, VarScan, and VEP. Genes were prioritized based on their evolutionary conservation, haploinsufficiency, and mutation intolerance scores and further subjected to gene-set enrichment analysis, brain-tissue expression, and protein-protein interaction analysis using the tool IPA. Of the total 539 ASD behaviors genes, 149 genes (27.6%) were enriched for core ASD behaviors- social-interaction and restricted repetitive behaviors (RRB) and 200 genes (37%) for associated ASD behaviors including language, speech, communication, learning, cognition, intelligence, emotions, and moods. Unexpectedly, inherited genes were significantly enriched for sensory perception of mechanical stimulus ($p \leq 1.27E-07$), and hereditary hearing loss ($p \leq 9.78E-06$). A total of 116 sensory genes were found carrying inherited variations. Each child carried mutations in an average of 9 sensory genes that were equally transmitted maternally and paternally; hearing and tactile sensation genes were most prevalent. Notably, 74% of these sensory genes displayed neuronal functions and 70% were directly linked to ASD core and/or associated behaviors. 62% of RRB genes had sensory functions indicating a strong interplay between them. The majority of the prenatally upregulated sensory genes produced core ASD behaviors ($p \leq 0.048$). Our cohort carried inherited variations in well-established ASD genes *CNTNAP2*, *GABRB3*, *SPAST*, *EP300*, *CHD7*, *HIVEP2*, *DLG2*, *CNTN5* as well as novel genes *APC*, *WFS1*, *KIF1B*, *ESR1*, *HGS*, *JAK2* producing sensory dysfunctions. Supporting evidence from a previous study on individuals with sensory dysfunctions without ASD found increased mutations in ASD genes. Thereby, we suspect that underlying, undiagnosed sensory dysfunctions in parents might collectively increase the risk for ASD in offspring. Sensory functions of ASD genes must be studied for a better understanding of the role of sensory dysfunctions in ASD manifestations.

Complex Traits Posters - Wednesday

PB1613. Relationship between the gut microbiome and depression in individuals with post traumatic stress disorder

Authors:

C. Finnicum¹, J. L. Scholl², C. Davis¹, S. Viet¹, P. L. Jason¹, L. A. Baugh², E. A. Ehli³; ¹Avera McKennan Hosp. & Univ. Hlth.Ctr., Sioux Falls, SD, ²Univ. of South Dakota, Vermillion, SD, ³Avera Inst. for Human Genetics, Sioux Falls, SD

Abstract Body:

The gut microbiome is a large collection of microbial inhabitants, living within the human GI system. The gut microbiome is known to be involved in various human traits and diseases, including links to mental health disorders such as post-traumatic stress disorder (PTSD) and depression. We sought to further understand how the gut microbiome is related to depression, particularly in individuals with PTSD. DNA was extracted from stool samples collected from PTSD-associated participants (N = 16) and was used for 16S rRNA profiling to survey the bacterial composition of the gut microbiome. Our preliminary analyses, comparing the gut microbiomes of individuals with PTSD and varying degrees of depression (minimal, mild, moderate, severe), identified a single significant *genus*, *Dialister* ($p < 1 \times 10^{-5}$) after controlling for multiple testing. This *genus* was particularly enriched in the PTSD-associated individuals with moderate depression, while markedly depleted in the PTSD-associated individuals with severe depression. No significant enrichment of taxa was observed at the species or phylum levels. Furthermore, no significant associations were observed with the alpha diversity, although a trend towards a lower alpha diversity with higher severity of depression was observed. Active enrollment is planned and underway, which will aid in further increasing the statistical power of the study.

Complex Traits Posters - Thursday

PB1614. Results from largest GWAS in Gastroparesis point to macrophage polarization etiology

Authors:

S. Smieszek; Vanda Pharmaceuticals, Washington, DC

Abstract Body:

Gastroparesis is a serious medical condition characterized by delayed gastric emptying and symptoms of nausea, vomiting, bloating, fullness after meals, and abdominal pain. An innate immune dysregulation and injury to the interstitial cells of Cajal and other components of the enteric nervous system is likely central to the pathogenesis of gastroparesis. Thus far, little is known about the underlying genetic risk factors for gastroparesis. We have done a genome-wide association study comparing idiopathic and diabetic cases with controls as well as contrasting idiopathic versus diabetic cases.

The samples were obtained from patients with idiopathic and diabetic gastroparesis enrolled in 2 clinical trials of gastroparesis (VP-VLY-686-2301 VP-VLY-686-3301). The dataset consisted of 1215 WGS samples from screened subjects. Subjects included male and female adults age 18-70 with a diagnosis of diabetic or idiopathic gastroparesis.

We report a novel genetic association of SLC15A4 locus with idiopathic gastroparesis. This signal is driven by multiple variants with top missense variant SLC15A4:NM145648:exon2:c.T716C:p.V239A, rs33990080. Altogether, among EUR (PCA defined) cohort we report 69 carriers out of 214 versus controls 165 out of 896 (MAF: cases 0.18; MAF: controls 0.09) and OR: 1.9 (p-value logistic model 10^{-9}). The significant effect persists when idiopathic cases are compared with diabetic cases as the MAF of diabetic cases (0.10) is comparable to that of population controls (0.09). The variant is a strong SLC15A4 eQTL across multiple tissues reported in GTEx.

Solute carrier family 15 (SLC15) A4 is a lysosome-resident amino acid/oligopeptide transporter that is preferentially expressed in immune cells. It is required for TLR7/9-dependent type I interferon production and plays a critical role in the pathogenesis of lupus and colitis. SLC15A4 was shown to mediate M1-prone metabolic shifts in macrophages and guards immune cells from metabolic stress. Previous reports have shown that when the anti-inflammatory M2 macrophages are switched to pro-inflammatory M1 macrophages, delayed GE was evident in animal models. The variant is associated with severe nausea. We also differentiate idiopathic from diabetic gastroparesis with an established diabetes genetic risk score (p-value<0.0004).

Current genetic findings suggest that a mechanism directly connected to macrophage polarization may be implicated in a subset of idiopathic gastroparesis patients. The GWAS picture that is emerging implicates novel loci implicated in the pathophysiology of gastroparesis differentiating those of diabetic versus idiopathic etiology.

Complex Traits Posters - Wednesday

PB1615. *RGS3* and *ILIRAPL1* missense variants implicate defective neurotransmission in early-onset inherited schizophrenias

Authors:

A. Kanwal¹, J. Pardo², S. Naz³; ¹Sch. of Biological Sci., Univ. of the Punjab, Lahore, Pakistan, ²Minneapolis VA Hlth.Care System, minneapolis, MN, ³Sch. of Biological Sci., Univ. of the Punjab, lahore, Pakistan

Abstract Body:

Schizophrenia is a clinically and genetically heterogeneous complex disorder characterized by hallucinations, disorganized behavior, delusions, and negative symptoms. Despite identification of hundreds of susceptibility loci associated with schizophrenia, monogenic causes remain largely undiscovered. We designed a family study to identify inherited rare gene variants for schizophrenia. Two consanguineous families each with two patients affected by severe treatment-resistant schizophrenia were recruited. Structured clinical evaluations supported the diagnosis in the four patients. Whole-exome sequencing was performed for all participants. Data analyses identified few variants segregating with schizophrenia of which only two were likely pathogenic. The homozygous c.649C>T, p.(Arg217Cys) variant in *RGS3* and a hemizygous c.700A>G, p.(Thr234Ala) variant in *ILIRAPL1*, were the most likely causes of phenotype in patients of families PSYAK2 and PSYAK3, respectively. The two variants were rare in all publicly available databases (gnomAD allele frequency = 0.00004692 and 0.000005491, respectively) and absent from the DNA of at least 400 ethnically matched controls. Amino acids affected by these variants were conserved among different orthologs. *RGS3* is involved in the G-protein signaling pathway and was previously implicated in modulating sensory behavior in *C. elegans*. *ILIRAPL1* plays a known role in synapse formation and modulation. Variants of *ILIRAPL1* have been described to cause non-syndromic X-linked intellectual disability with or without behavioral defects in humans. Our work suggests that these missense variants are involved in causing schizophrenias. Cellular assays and variant-specific functional studies will elucidate the pathophysiology relevant to schizophrenias and will motivate translation to novel, personalized therapeutics. Our work is funded by NIMH, NIH USA, 1R21MH120692-01A1

Complex Traits Posters - Thursday

PB1616. Risk factors involved in Congenital Diaphragmatic Hernia, a case-control study in Bogotá and Cali, Colombia.

Authors:

C. Acevedo Castaño¹, G. Villamil Patiño¹, M. Uribe Gaviria¹, S. A. Suarez Gomez¹, L. A. Quintero Riaño¹, L. J. T. Rincon Abreo¹, M. S. Parra Artunduaga¹, S. C. Bernal Bejarano¹, K. Sarmiento¹, I. M. Zarante¹, P. Hurtado², J. A. Holguín³; ¹Pontificia Univ. Javeriana, Bogotá, Colombia, ²Pontificia Univ. Javeriana, Cali, Colombia, ³Secretaria de Salud Pública de Cali, Cali, Colombia

Abstract Body:

The aim of the study was to determine, classify, quantify and qualify the possible risk factors involved in the development of congenital diaphragmatic hernia (CDH), through the analysis and comparison of sociodemographic, clinical and anthropometric variables; related to the mother, the newborn and the pregnancy that could possibly be involved, as well as to determine the degree of association between these variables. In order to expand the knowledge of the practitioner and thus facilitate the identification of the disease and generate a prompt diagnosis. **Materials and Methods** A descriptive retrospective study of cases and controls was carried out, with patients registered in the Surveillance and Follow-up Program for Congenital Defects of Bogotá and Santiago de Cali (PVSACB-C) with 51 and 3 Hospitals, respectively, between 2001-2018. With 546,123 births reported between these periods. A sample of 83 cases and 332 controls was selected with a ratio between cases and controls of 1:4, respectively. In our data analysis results CDH is significantly associated with maternal age (MA) >35 years, low birth weight, male sex, primigravid mother, socioeconomic status, cesarean delivery, weight for gestational age (WGA) (OR 1.95, 4.6, 1.75, 2.90, 6.17, 3.59, 8.28), (CI 1.04-3.67, 2.64-8.01, 1.08-2.86, 2.59-14.7, 1.91-6.73, 4.78-14.35) respectively; negatively with maternal BMI greater than 25 (OR 0.39 (0.16-0.96)) and was not associated with gestational age < 35 weeks, alcohol consumption of illicit substances during pregnancy, parental consanguinity (OR 0.99, 1.34, 9.04, 1.53), (CI 0.42-2.35, 0.49-3.68, 0.8-101.66, 0.94-2.48) respectively, among others. It was identified that of those born with HD (n = 83), 91.5% were born at term, 59% had a birth weight greater than 2,500 g, 71.3% were the mother's first birth, 27.7% of the children were classified as polymalformed since they had one or more additional malformations to HD and 7.2% were included within some syndrome. In conclusion, despite the lack of etiological knowledge and given the high prevalence of this disease, the data obtained in this study provide useful information to identify and learn more about CDH, as well as its associated anomalies, in order to achieve a prompt diagnosis.

Complex Traits Posters - Wednesday

PB1617*. Risk factors that affect performance of polygenic risk scores across diverse cohorts

Authors:

D. Hui, M. D. Ritchie; Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Polygenic risk score (PRS) performance varies across datasets, which prevailing evidence suggests is mostly due to ancestry differences. However, differences in personal or environmental covariates may also affect PRS performance. Little is known why select covariates do so and assessing myriad environmental exposures is infeasible; covariate-specific effects are also notorious for poor replicability in human genetics studies. To explore risk factors affecting PRS, we analyzed the effects of covariate stratification and interaction on PRS for body mass index (BMI) across four cohorts of European (EUR) and African (AFR) ancestry - UK Biobank (UKBB), Penn Medicine Biobank (PMBB), eMERGE, and GERA. We assessed 62 covariates for R^2 differences, stratifying on binary covariates and quintiles for continuous covariates. With UKBB EUR as discovery, 18 covariates had significant differences in R^2 among groups, including age, sex, alcohol, physical activity, Townsend index, diet, lipids, blood pressure, and A1c. Relative R^2 s between worst and best performing physical activity, alcohol intake, and HDL quintiles were 71%, 61%, and 56%, respectively, comparable to differences due to ancestry. PRS R^2 of bottom age quintile PMBB AFR individuals ($R^2 = .058$, mean = 28) was higher than top age quintile PMBB ($R^2 = .051$, mean = 78) and eMERGE ($R^2 = .047$, mean = 82) EUR individuals. Main covariate effects on BMI and max R^2 differences across quintiles had .56 correlation, suggesting PRS R^2 increases for individuals with higher BMI-associated covariates (i.e., most at-risk). This result may also reduce search for PRS-interacting covariates as outcome-associated covariates are often known. Next, we modeled PRS-covariate interaction terms and observed replicable interactions with age, sex, lipids, and blood pressure. Magnitude of main and interaction effects had .43 correlation, suggesting BMI-associated covariates excessively alter PRS effects. Unlike published reports, smoking and education interactions were insignificant, supported by their small main effects on BMI. R^2 increases when including interaction terms were small (max increase .0024). Given PRS-covariate dependence evidence, we assessed R^2 gains using machine learning models (neural networks) versus L1-regularized linear regression. Relative cross-validated R^2 increased up to 67% (mean 25%) across cohorts with age and sex as covariates, and up to 16% (mean 7%) with all available covariates. These results suggest covariate-specific effects can affect PRS comparably to ancestry, covariates affect PRS proportionately to their outcome association, and machine learning models improve PRS prediction.

Complex Traits Posters - Thursday

PB1618. RNA editing regulates interferon induction and host immune response in SARS-CoV-2 infection

Authors:

M. Huang¹, A. Mark², K. Vera¹, C. Meydan³, J. Foox³, D. Butler³, C. Mozsary³, A. Saravia-Butler⁴, A. Beheshti^{4,5}, C. Mason³, Q. Jiang⁶, K. Fisch^{1,2}; ¹Dept. of Obstetrics, Gynecology & Reproductive Sci., Univ. of California, San Diego, La Jolla, CA, ²Ctr. for Computational Biology & Bioinformatics, Univ. of California, San Diego, La Jolla, CA, ³Dept. of Physiology and Biophysics, Weill Cornell Med., New York, NY, ⁴KBR, NASA Ames Res. Ctr., Moffett Field, CA, ⁵Broad Inst. of MIT and Harvard, Cambridge, MA, ⁶Div. of Regenerative Med., Univ. of California, San Diego, La Jolla, CA

Abstract Body:

Viruses enhance the RNA editing function of *ADARI* in the host and emerging data points to a role of *ADARI*-mediated A-to-I editing in the inflammatory response associated with severe COVID-19 disease. Understanding the relationships between the SARS-CoV-2 induced cytokine storm, disease severity, and clinical outcomes is key to developing effective treatments and prognostic biomarkers for COVID-19 infection.

Human whole transcriptome data from nasopharyngeal swabs was obtained from 208 SARS-CoV-2 positive, 82 positive for other viral illness (OVI) and 411 SARS-CoV-2 negative patients. We performed RNA editing analysis to obtain A-to-I editing events present in at least 5% of samples, differential editing (DE) at each site using a log likelihood ratio test, enrichment analysis using clusterProfiler, cellular deconvolution with XCell, and interrogated *ADARI* expression within immune cell types in SARS-CoV-2 infected nasopharyngeal swabs with the BROAD Single Cell Portal. Validation was performed by activating CD8 and CD4 naive T cells with CD3/28 beads. *ADARI* expression and IL2 level was quantified by flow cytometry and RT-qPCR, and knockdown of *ADARI* was performed using lentiviral vectors in CD8 and CD4 T-cells followed by analysis of apoptosis (Annexin V), cell cycle (Ki67), and IL2 production using flow cytometry.

Overall editing levels ($p = 0.0026$) and variant allele frequencies ($p = 6.2E-6$) were higher in SARS-CoV-2 positive patients than negative patients. RNA editing levels increased with decreasing viral load ($p = 2.4E-5$). We identified DE sites ($\text{padj} < 0.05$) in SARS-CoV-2 vs None: 1,466; OVI vs None: 1,031; SARS-CoV-2 vs OVI: 1,139; SARS-CoV-2 High vs Low Viral Load: 734. DE in SARS-CoV-2 vs None were enriched in 23 pathways including interferon signaling ($\text{padj} = 6.6E-8$) and antiviral mechanisms by interferon stimulated genes ($\text{padj} = 0.00021$) in High vs Low Viral Loads. Interferon responsive cytotoxic CD8 T-cells highly express *ADARI* at single cell resolution and cellular deconvolution revealed significantly higher enrichment for CD8+ naive T-cells in OVI and None relative to high viral load ($p = 0.015$ and 0.00016 , respectively). We observed a striking increase in *ADARI* levels within 48 hrs (>2.5 fold) by quantifying the *ADARI* protein and mRNA levels in CD3/38-activated CD4 and CD8 T cells. Finally, lentiviral directed *ADARI* knockdown in naive CD4 cells followed by CD3/28 activation revealed that *ADARI* knockdown leads to accelerated T-cell proliferation coupled with necroptosis and overproduction of IL2. This study highlights the importance of *ADARI* activation in T-cell homeostasis with relevance to SARS-CoV-2 infection.

PB1619. RNASeq in nasal epithelium from African ancestry subjects in the CAAPA consortium reveal *IL4* and *TGFBI* as upstream regulators of differentially expressed networks for asthma

Authors:

B. Szczesny¹, K. Kammers², M. P. Boorgula³, M. Taub⁴, M. Campbell³, R. Johnson⁵, I. Ruczinski⁶, S. Chavan³, C. Figueiredo⁷, C. N. Rotimi⁸, R. C. Landis⁹, H. Watson⁹, N. N. Hansel¹⁰, I. V. Yang¹¹, C. O. Olopade¹², C. Ober¹³, A. H. Liu¹⁴, E. Kenny¹⁵, K. C. Barnes¹⁶, R. A. Mathias², CAAPA Consortium; ¹Johns Hopkins Univ., Baltimore, MD, ²Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ³Univ. of Colorado, Denver, CO, ⁴Johns Hopkins, Baltimore, MD, ⁵Univ. of Colorado Anschutz Med. Campus, Aurora, CO, ⁶Johns Hopkins Univ., Dept. of Biostatistics, Bloomberg Sch. of Publ. Hlth., Baltimore, MD, ⁷Univ. of Bahia, Salvador, Brazil, ⁸Natl. Human Genome Ctr., Howard Univ. Coll. of Med., Washington, DC, ⁹The Univ. of the West Indies, Queen Elizabeth Hosp., Bridgetown, Barbados, ¹⁰Johns Hopkins Sch. of Med., Baltimore, MD, ¹¹Univ. of Colorado, Aurora, CO, ¹²Univ. of Chicago Med., Chicago, IL, ¹³Dept. of Human Genetics, Univ. of Chicago, Chicago, IL, ¹⁴Children's Hosp. Colorado, Aurora, CO, ¹⁵Icahn Sch. of Med. at Mt Sinai, New York, NY, ¹⁶Univ. of Colorado, Anschutz Sch. of Med., Aurora, CO

Abstract Body:

Asthma, a complex chronic lung disease affecting the airways, has striking disparities across racial and ethnic groups. The second phase of the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA) aims to understand genomic signatures of asthma and asthma severity in populations of African descent.

RNASeq data was generated from nasal epithelium in subjects recruited from 7 sites (Baltimore, Washington DC, Chicago, Denver, Brazil, Barbados, and Nigeria). Analysis was limited to active asthmatics (N=253, 8-80 years of age) determined using a respiratory health questionnaire and the Composite Asthma Severity Index, and never-asthmatic controls (N=283, 8-75 years of age). Pre-alignment quality control, adapter trimming, and alignment of reads to GRCh38 were performed using FastQC and Picard tools, BBDUK, and HISAT2, respectively. Raw counts were generated by CoCo, mean normalized counts were generated by DESeq2, and 21,831 advanced to differential analysis in LIMMA and edgeR. Linear models were fit to the normalized expression data adjusting for relevant covariates.

At a q-value<0.05, we found 389 differentially expressed genes (DEGs). The top 10 DEGs included *FNI*, *POR*, *VSIG4*, *SUSD4*, *PTCHD4*, *HS3ST4*, *PPP1R9A*, *SPTBNI*, *SNTG2*, and *RHEX*. Several of these have been previously implicated and/or have biological relevance for asthma: *SNTG2* (q-value= 1e-4) is the target of multiple miRNAs related to asthma. *SUSD4* (q-value=1e-6) plays a role in cell-to-cell adhesion and has been shown to harbor complement inhibitory activity; it has similar homology to *CD46* which has a known regulatory role in T cell activation. *PPP1R9A* expression (q-value=7e-5) was previously determined to be influenced by IL-13 in mouse lung, and IL-13 is documented to contribute to asthma pathogenesis. *SPTBNI* (q-value=1e-4) plays a key role in mediating TGF-beta signaling. The most significant differentially expressed gene, *FNI* (q-value=3e-9), was downregulated in asthmatics. *FNI* encodes fibronectin, which plays a key role in airway remodeling. Ingenuity Pathway Analysis reveals several networks with upstream regulators highly relevant for asthma; the top 5 of these include two genes: *IL4* (p=7.4e-10) and *TGFBI* (p=6.8e-8), and two drugs: dexamethasone (p=4.3e-10) and fluticasone propionate (p=6.8e-8).

Our analyses reveal that many genes with known and plausible mechanistic roles in asthma are differentially expressed in nasal epithelium of asthmatics of African ancestry in CAAPA. Ongoing work

ASHG 2022 Annual Meeting Poster Abstracts

includes testing for networks related to asthma and asthma severity, and integration with eQTLs and methylation data in the nasal epithelium of these same subjects.

Complex Traits Posters - Thursday

PB1620. Role of amino acids in COVID-19 virulence and pathogenicity : an observational study

Authors:

H. Singh; CHC, Pilkhuwa, Hapur, Hapur, India

Abstract Body:

Role of amino acids in Covid 19 virulence & pathogenicity Virus machinery is dependent on host body for their activation & survival. The multiplication within the host body requires a suitable environment rich in specific Amino acids (AA) like arginine to be more specific. The alteration in host nitrogen balance, protein & lipid metabolism, and catabolic effects make the host body vulnerable to viral infection due to altering AA concentration. Currently, AA restriction diet is been advised in cancer patients to sustain cancer progression & proved to be successful. AAs are mediators of metabolic cross-talk between host & pathogen. Methodology The study comprises 28 COVID 19 patients including 12 new variants (UK strain). All the patients were informed & taken consent before taking a small drop of blood from finger pulp, on filter papers. After that, liquid base chromatography was performed to titer the AA profile of blood spots i.e. alanine, arginine, citrulline, glycine, leucine, valine, methionine, ornithine, phenylalanine, tyrosine & proline. Symptoms of the patients were noted & later, the correlation was attempted between AAs & symptoms to understand & the virulence & pathogenicity of COVID-19. All the patients were included under the act of ethics. Result We observed arginine being the main highlight of the study, which was raised to 100 $\mu\text{MOL/L}$ in one patient J6 (Jaipur, India patient 6), whose symptoms were aggressive in comparison to other patients. Also, leucine & valine values were also significantly increased to 450 & 352 $\mu\text{MOL/L}$ respectively. Patient J5 showed increased arginine value up to 64 $\mu\text{MOL/L}$, which was near to maximum limit. That patient J5 showed symptoms like loss of smell & taste for 7 days including 2/3 days severe body ache. All the United Kingdom (UK) variants of COVID-19 patients were asymptomatic & their arginine value was noted to be very low in comparison to other patients. Conclusion- we hypothesized that arginine plays a major role in the pathogenicity & virulence of Coronavirus. The body microenvironment of AAs in body may decide the outcome of infections. So, the diet should be considered important along with focusing on hygiene, wearing masks, & medication

Complex Traits Posters - Wednesday

PB1621. SARS-CoV-2 sequencing: A comparison of high-throughput methods.

Authors:

R. Olasso¹, Z. Gerber¹, C. Daviaud¹, D. Delafoy¹, F. sandron¹, E. Alidjinou², J. Mercier¹, S. Gerber³, V. Meyer¹, A. Boland¹, L. Bocket², J. Deleuze¹; ¹CEA - CNRGH, Evry, France, ²CHU de Lille, Lille, France, ³MNHN - CNRS, Paris, France

Abstract Body:

Introduction: The COVID-19 pandemic continues to threaten public health and burden healthcare systems worldwide. Whole SARS-CoV-2 genome sequencing has become essential for epidemiological monitoring and identification of new variants, which could represent a risk of increased transmissibility, virulence, or resistance to vaccines or treatment. In this study, we assess the performance of various target enrichment methods for whole SARS-CoV-2 sequencing.

Methods: We applied three target enrichment methods - two multiplex amplification methods and one hybridization capture - to the same set of nasopharyngeal patient samples (N = 93) in high-throughput mode. SARS-CoV-2 genome was obtained using short-read next-generation sequencing.

Results: All three methods provided excellent breadth of coverage of SARS-CoV-2 genome (above 99%), albeit with vastly different sequencing depth (5-fold difference) and uniformity of coverage (20% difference in coefficient of variation). Poor local coverage has negative impact on variant calling in the concerned region, leading to an occasional allele drop-out (1.2% SNPs affected for one method).

Conclusion: We discuss the performance of each target enrichment method and their potential for scaling up, in order to promote prospective programs of large-scale genomic surveillance of SARS-CoV-2 worldwide. Genomic surveillance will be crucial to overcoming the ongoing pandemic of COVID-19, despite its successive waves and continually emerging variants.

Funding: LabEx GENMED (grant number ANR-10-LABX-0013).

PB1622. Screening of variant rs11190870 nearby *LBXI* gene for association with Adolescent Idiopathic Scoliosis in the population of North India

Authors:

H. Singh¹, S. Kowra¹, M. Gupta², P. Bhau¹, T. Chalotra¹, R. Manotra¹, N. Gupta³, G. Gupta⁴, A. Pandita⁵, M. Bhat⁶, R. Sharma⁶, S. Pandita⁷, V. Singh¹, E. Rai¹, B. Garg², S. Sharma¹; ¹Shri Mata Vaishno Devi Univ., Katra, India, Jammu, India, ²All India Inst. of Med. Sci., New Delhi, India, ³District Hosp. Poonch, Jammu and Kashmir, Poonch, India, ⁴Dept. of Radiology, Shri Mata Vaishno Devi Narayana Superspeciality Hosp., Jammu, India, ⁵Accidental Hosp., Chowki Choura, Jammu, India, ⁶Government Med. Coll., Jammu, India, ⁷Radiology section, Chest Disease Hosp., Bakshi Nagar, Jammu, India

Abstract Body:

Adolescent idiopathic scoliosis (AIS) is the most common spinal deformity of adolescent individuals accompanied with the lateral curvature and twisting of spine with Cobb angle of $\geq 10^\circ$. Our recently published epidemiological study, where 9500 post adolescent children were screened, has shown uniquely low incidence (0.61%) of AIS in northwest India. Globally, genetic predisposition to AIS has been studied extensively. However, any such study in Indian populations is yet lacking. The present study is the first of the kind that has been carried out to evaluate variant rs11190870 nearby *LBXI* gene, reported to be associated with AIS in literature, in North Indian population. In addition to samples collected during population screening, samples from special care hospitals and clinics have been collected to increase the patient sample size from the region, in this SMVDU Institutional Ethical Review Board approved study. A total of 95 AIS cases and 282 healthy controls were screened in this pilot case control association study for AIS from North India. The genotyping was carried out using TaqMan Allele discrimination assay on Mx3005p Real-time PCR System. The genotypes distributions, in cases (CC - 0.141, CT - 0.353 and TT - 0.506) and controls (CC - 0.136, CT - 0.398, TT - 0.466) separately as well as in total samples, were found to be following Hardy Weinberg Equilibrium. The allele frequencies distribution in cases were T = 0.682 and C = 0.318 and in controls T = 0.665 and C = 0.335, respectively and the variant was not found associated with the AIS in the population. Interestingly, similar allele frequencies were noted in healthy public datasets for other Indian populations. However, in contrast to other global populations in literature, where T allele has been noted in lower frequencies in controls than AIS cases. Similar distribution of alleles in cases and controls resulted in non-association of the variant in screened population. This is an interesting finding and worth reporting timely. *LBXI* is a candidate gene for AIS and rs11190870 is nearby variant reported as part of haplotype providing susceptibility to AIS. Present study highlights need for screening of other SNPs across the gene to elucidate if haplotypic differences exist w.r.t Indian populations. Also, study in an increased sample size would be ideal to increase the confidence in the findings. This study provides an insight in the genetics of AIS in an Indian population group. It also highlights the possibility of the potential haplotypic differences or genetic heterogeneity and lays a foundation for carrying out a genome wide association study in Indian population for better understanding of AIS, a task we are pursuing.

Complex Traits Posters - Wednesday

PB1623*. Secretoglobin family 1D member 2 (SCGB1D2) protein inhibits growth of *Borrelia burgdorferi* and affects susceptibility to Lyme disease

Authors:

S. Strausz^{1,2}, G. Blacker², S. Galloway², H. Paige^{2,3}, S. Jones¹, E. C. Sanders^{2,3}, N. Sinnott-Armstrong², FinnGen, I. L. Weissman², M. Daly¹, T. Aivelo¹, M. C. Tal^{2,3}, H. M. Ollila^{1,4,5,6}; ¹Univ. of Helsinki, Helsinki, Finland, ²Stanford Univ., Stanford, CA, ³Dept. of Biological Engineering, Massachusetts Inst. of Technology, Cambridge, MA, ⁴Broad Inst. of MIT and Harvard, Cambridge, MA, ⁵Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA, ⁶Anesthesia, Critical Care, and Pain Med., Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA

Abstract Body:

Lyme disease is a tick-borne disease caused by bacteria of the genus *Borrelia*. The disease can initially manifest as an erythema migrans rash and, if able to evade the host immune defenses, can progress into a secondary stage chronic disease with debilitating physical or neurological manifestations. The host factors that modulate susceptibility for Lyme disease have remained mostly unknown. Here we show a novel host defense mechanism against Lyme disease in humans. Using epidemiological and genetic data from FinnGen, we identify a common missense variant at the gene encoding for Secretoglobin family 1D member 2 (SCGB1D2) protein that increases the susceptibility for Lyme disease. The genetic variant changes proline at position 53 to leucine and is predicted as deleterious. Consequently, we validate the dysfunction of this protein variant using live *Borrelia burgdorferi* (Bb). Recombinant reference SCGB1D2 protein inhibits the growth of Bb twice as effectively as the recombinant SCGB1D2 P53L deleterious missense variant. Together, these data suggest that SCGB1D2 is a host defense factor present in the skin, sweat, and other secretions which protects against Bb infection. This finding provides a novel therapeutic avenue for drug development to prevent and treat Lyme disease.

Complex Traits Posters - Thursday

PB1624. Self-reported and device-based physical activity and risk of Alzheimer's disease and related dementias: a Mendelian randomization study.

Authors:

McKnight Brain Inst., Tucson, AZ, ¹⁰Dept.s of Psychology and Psychiatry, NeuroSci. and Physiological Sci. Interdisciplinary Programs, BIO5 Inst., and Evelyn F. McKnight Brain Inst., Univ. of Arizona, Tucson, AZ, ¹¹Dept. of Epidemiology and Biostatistics, Mel and Enid Zuckerman Coll. of Publ. Hlth., Univ. of Arizona, Tucson, AZ

Abstract Body:

Background: Current observational studies suggest that physical activity may have a protective role in Alzheimer's disease and related dementias (ADD). However, these may be prone to residual confounding, bias, and reverse causation. Mendelian randomization (MR) is an alternative approach that may avoid these limitations in order to better assess the causal role of physical activity in ADD. **Aim:** We conducted Mendelian randomization analyses to examine whether genetically-predicted levels of physical activity (PA) are associated with ADD. **Methods:** We used GWAS of three self-reported measures ($n_{\max}=377,234$): moderate-to-vigorous physical activity (MVPA), vigorous physical activity (VPA), and strenuous sports or exercises (SSOE), along with two accelerometry-based measures ($n_{\max}=91,084$): acceleration average (AAv) and fraction of accelerations >425 mg (AF). We used the most recent GWAS of ADD that included 111,326 cases and 677,633 controls from the European Alzheimer's & Dementia Biobank. (EADB) We used a p-value threshold of $p < 5 \times 10^{-7}$ to identify genetic instruments for each PA phenotype. We primarily assessed MR associations using the inverse-variance weighted (IVW) method and conducted multiple sensitivity analyses. **Results:** We found positive trends in the estimates for MVPA (0.12, 95% CI: -0.10, 0.34), and AF (0.13, 95%CI: -0.64,0.89), with ADD outcome. We found negative trends in the estimates for VPA (-0.17, 95% CI: -0.99, 0.65), SSOE (-0.29, 95% CI: -0.77, 0.20), and AAv (-0.02, 95% CI: -0.05, 0.02), with ADD outcome. However, none of these IVW estimates were statistically significant. Our sensitivity analyses also did not reveal any evidence of associations between genetically-predicted PA phenotypes and the risk of ADD. **Conclusion:** We leveraged both self-reported and objective measures of PA, and the largest ADD GWAS to date in our Mendelian randomization analyses. However, we did not find any evidence to support that the genetic propensity for different types of physical activity is associated with the risk of Alzheimer's disease and related dementias. The lack of evidence for a causal effect may be explained by the absence of a true causal effect, or by the limitations of the MR approach.

Complex Traits Posters - Wednesday

PB1625. Sequencing-based genome-wide association study of triglycerides in East Africans.

Authors:

K. Meeks, A. Bentley, M. Gouveia, A. Doumatey, D. Shriner, G. Chen, L. Lei, J. Zhou, A. Adeyemo, C. Rotimi; NIH, Bethesda, MD

Abstract Body:

Despite dramatically different environmental exposures, studies consistently show that West African ancestry populations in Africa and in the diaspora have substantially lower triglyceride (TG) levels compared with European ancestry populations. In contrast, East Africans (EA) experience disproportionately high TG levels. The reasons for the high TG levels in EA are unclear, although there is evidence that suggests a population-specific genetic architecture for TG. We performed whole-genome sequencing (WGS) on a subset of 199 unrelated Kenyans from the Africa America Diabetes Mellitus (AADM) study using an extreme phenotype sampling strategy: 99 samples with the highest TG levels (mean = 363 mg/dl) and 100 with the lowest TG levels (mean = 70 mg/dl). Participants were aged 37-80 years and were not on lipid-lowering medication. The groups were matched on age, sex (52-54% women), and ethnic group (60-64% Kalenjin). WGS was performed on the Illumina NovaSeq 6000 platform and variant calling was done using GATK best practices guidelines. After filtering based on variant quality score recalibration, missingness (> 50%), minor allele count (< 3), and Hardy Weinberg Equilibrium (< 1×10^{-6}), 15.9 million variants remained for analysis. Common variants (MAF > 5%) were analyzed using a mixed linear model in GENESIS with adjustment for body mass index. We identified 10 loci with P-value < 5×10^{-6} . Half of the variants best representing these loci had a higher frequency in the high-TG group (*NEDD9*, *SERPINA13P*, *LOC107985969*, *PPP1R3A*, *AC020551.1*) and the other half had a higher frequency in the low-TG group (*REL*, *VPS13C*, *DOK6*, *FRMD4A*, *TMEM170A*). Gene-based burden testing of variants with MAF \leq 5% revealed *TMEM170A* as the gene set with the lowest P-value (1.5×10^{-5}). Next, we identified rs1291962476 (*LOC105377067*) and rs369751109 (*TUBGCP5*) as having a frequency of > 8% in the low and high TG group, respectively, and being monomorphic in the other. Annotation showed that one of the common loci (*REL*) was found only in people of African descent. The *REL* gene encodes a protein involved in the regulation of apoptosis, inflammation, immune response, and oncogenic processes. Two common variants were eQTLs for their annotated gene (*VPS13C*, *TMEM170A*). *TMEM170A* is involved in endoplasmic reticulum and nuclear envelope organization. In summary, these first genome-wide sequencing analyses in East Africans identified candidate loci that may play a role in the high TG levels in this population. The loci identified will be further investigated through association studies in a larger cohort of Africans and functional studies.

Complex Traits Posters - Thursday

PB1626. Serum osteopontin levels in Mexican patients with systemic lupus erythematosus with lupus nephritis and molecular interaction review

Authors:

A. Rivera-Cameras^{1,2}, M. P. Gallegos Arreola², M. C. Morán Moguel³, M. Salazar Páramo⁴, M. Alcaraz López⁵, J. F. Topete Reyes⁵, L. Bobadilla Morales⁶, I. Cuero Quezada^{1,6}, I. P. Dávalos Rodríguez^{1,2}; ¹Doctorado en Genética Humana, CUCS, UDG., Guadalajara, Mexico, ²División de Genética, CIBO, IMSS., Guadalajara, Mexico, ³Departamento de Disciplinas Filosófico-Methodológicas e Instrumentales, CUCS, UDG, Guadalajara, Mexico, ⁴Departamento de Fisiología, CUCS, UDG, Guadalajara, Mexico, ⁵Hosp. Gen. de Zona 46, Inst. Mexicano del Seguro Social, Guadalajara, Mexico, ⁶Centro de Registro e Investigación de Anomalías Congénitas (CRIAC), Servicio de Unidad de Genética y Citogenética, División Pediátrica, Hosp. Civil Dr. Juan I. Menchaca de Guadalajara, Guadalajara, Mexico

Abstract Body:

Introduction: Osteopontin (OPN) is encoded by the *SPP1* gene, it is a glycoposphoprotein, which acts as a cytokine. OPN overexpression has been associated with a predisposition to systemic lupus erythematosus (SLE) and a poor prognosis. OPN is known to mediate polyclonal B-cell activation, promote T follicular helper cells (TFH) and enhance antinuclear antibody production, where OPN's role in lupus nephritis (LN) is central to tissue damage. **Objectives:** Compare the serum levels of OPN in Mexican patients with SLE, without LN and with LN and analyze the protein-protein molecular interaction networks of OPN. **Materials and methods:** The study included forty-three patients (18-82 years) affected by SLE, 17 with LN and 26 without LN. OPN serum levels were quantified using the ELISA technique (Invitrogen Osteopontin/SPP1 Human ELISA Kit). Version 11.5 of the STRING database was used for the prediction of functional interactions of the OPN protein. **Results:** Serum OPN levels in patients with SLE without LN was 185.92 ± 259.86 pg/mL ($p=.0001$), and 311.08 ± 498.40 pg/mL in patients with SLE and LN ($p=0.121$), in the reference group was 72.59 ± 77.62 pg/mL ($p=0.002$). Additionally, were analyzed involved pathways that play a relevant role in renal tissue damage, finding interaction nodes and protein networks in relation to the OPN that could explain a final impact on LN. The pathways involved were selected based on relevance: fibronectin, integrin, protease, and collagen binding, as well as extracellular matrix binding. **Conclusions:** These results indicate that serum OPN levels were associated with patients with LES and LN, however we considered increase N sample. The molecular interaction of OPN was observed in the participation of fibronectin in glomerular injury is based on the internalization of IgG mediated by fibronectin, so this node of interaction is a fundamental piece, in turn the role of macrophages is mediated by the nodes of interaction of the binding to integrin and protease, correlating with the infiltration of diffuse macrophages in the kidneys developing LN.

Complex Traits Posters - Wednesday

PB1627. Serum proteomic signatures predicting unintentional weight loss in patients with chronic obstructive pulmonary disease

Authors:

J. Chiles¹, A. C. Wilson¹, A. Rocco¹, H. B. Rossiter², R. Casaburi², E. A. Regan³, R. Bowler³, C. P. Hersh⁴, M-L. N. McDonald¹; ¹Univ. of Alabama at Birmingham, Birmingham, AL, ²The Lundquist Inst., Los Angeles, CA, ³Natl. Jewish Hlth., Denver, CO, ⁴Brigham and Women's Hosp., Boston, MA

Abstract Body:

RATIONALE: Unintentional weight loss in patients with chronic obstructive pulmonary disease (COPD) is associated with increased mortality and morbidity. There are limited therapeutic options for patients once unintentional weight loss occurs. Populations with weight loss have been extensively characterized; however, there have been no studies of molecular risk factors that may precede the manifestation of weight loss in patients with COPD. Our goal was to identify proteomic predictors of unintended weight loss. **METHODS:** Data from 971 participants with COPD from the COPDGene study were analyzed: 842 controls who never reported unintentional weight loss and 129 cases who developed unintentional weight loss in the 5 years between visits 2 and 3. COPD was diagnosed using post-bronchodilator lung function. Serum was collected at visit 2 and used to generate proteomic data with SomaScan v4.0 (SomaLogic, Boulder, CO), which measures 4,776 human proteins. Linear regression models were built to test the association of each peptide with future unintentional weight loss while including age, sex, smoking status, and body mass index as covariates with false-discovery rate (FDR) correction. Gene-set enrichment analyses were conducted using peptides with an unadjusted p-value < 0.05. **RESULTS:** Age, sex, race, and baseline body-mass index were not different between groups, but participants reporting unintentional weight loss lost significantly more weight ($p < 0.001$). No single peptide met the FDR significance threshold, but 300 single peptides had an unadjusted p-value < 0.05. The top single peptides associated with future unintentional weight loss, each with FDR adjusted p-value of 0.15, were serum amyloid A1 (1.32 fold greater in cases), serum amyloid A2 (1.22 greater), complement factor 9 (1.08 greater), and C-reactive protein (1.34 greater); all are markers of inflammation. Gene set enrichment analysis of the up-regulated nominally significant peptides showed enrichment for eight pathways, including apoptosis (FDR $p = 0.018$). Down-regulated nominally significant peptides showed enrichment for 16 pathways, including adipogenesis (FDR $p < 0.001$). **DISCUSSION:** This study is the first to investigate peptide biomarkers that predict the development of unintentional weight loss in patients with COPD. Although no single peptide met significance criteria for association with future unintentional weight loss, there are patterns of increased inflammation and apoptosis with decreased adipogenesis. These are consistent with proposed mechanisms of unintentional weight loss in COPD. Further protein quantitative trait loci (pQTL) analyses are planned.

Complex Traits Posters - Thursday

PB1628. Sex dependent transcriptional changes in response to stress in patients with myalgic encephalomyelitis/chronic fatigue syndrome.

Authors:

J. Gamer¹, D. Van Booven², A. Joseph¹, M. Perez¹, O. Zarnowski¹, N. Klimas¹, E. Oltra³, L. Nathanson¹; ¹Dr. Kiran C. Patel Coll. of Osteopathic Med., Nova Southeastern Univ., Fort Lauderdale, FL, ²Univ Miami Miller Sch Med, Miami, FL, ³Catholic Univ. of Valencia, Valencia, Spain

Abstract Body:

Background The underlying mechanisms associated with the onset and progression of Myalgic Encephalomyelitis/Chronic Fatigue Syndrome (ME/CFS), a condition characterized by symptoms such as debilitating fatigue or easy fatigability, memory problems, muscle and joint pain, gastrointestinal issues, neurological problems, and hormonal imbalance remains unclear. **Objectives.** The main objectives of this research proposal are to evaluate 1) sex differences in circulating immune cells' gene expression in ME/CFS patients, 2) sex differences in ME/CFS patients in response to stress modeled by exercise challenge, and 3) the need to consider sex differences in diagnosis and treatment of ME/CFS. **Methods.** We evaluated differential gene (DG) expression (fold change > 1.5 in either direction, FDR < 0.1) by RNA-seq in circulating lymphocytes of 20 ME/CFS female patients, 14 ME/CFS male patients and 40 sex-, age- and BMI-matched healthy controls (HC) at T0 (baseline), T1 (exercise, maximal exertion) and T2 (4 hours of recovery after T1). After removing genes from sex chromosomes, analysis was done separately in men and women between ME/CFS patients and HC at each time point and in response to exercise (between time points for each group). **Results.** At baseline we found 20 DG between ME/CFS patients and HC in females and 160 DG in males. The largest difference in response to exercise in men and women with ME/CFS was between T2 and T1 time points. At these time points 395 DG were the same in men and women, 167 DG were only in men, and 174 only in women. Functional analysis revealed that at baseline in males with ME/CFS the most affected were regulation of leukocyte activation (-log₁₀(P)=6.99) and regulation of cell adhesion (-log₁₀(P)=5.26) compared to HC, while regulation of viral process (-log₁₀(P)=5.57) and cellular response to hypoxia (-log₁₀(P)=4.12) were the most affected in females with ME/CFS compared to HC. **Conclusion.** Identification of sex-specific biomarkers and therapeutic targets of ME/CFS can provide insight into sex-specific disease onset and progression, which will lead to optimal therapeutic intervention for such challenging disease.

Complex Traits Posters - Wednesday

PB1629*. Sex-specific analysis of rare variant associations with quantitative traits in the UK Biobank.

Authors:

R. Hoffing, A. Deaton, A. M. Holleman, L. Krohn, P. J. LoGerfo, P. Nioi, M. E. Plekan, C. Willis, L. Ward; Alnylam Pharmaceuticals, Cambridge, MA

Abstract Body:

Genetic variation can manifest differently between sexes and lead to substantial changes in health outcomes. Most genome-wide studies aggregate data by sex, which can mask meaningful and novel associations and exacerbate health disparities between the sexes. In this study, we perform a sex-stratified analysis of 100 quantitative traits in the UK Biobank across 363,661 exomes. We use burden tests to aggregate rare high-confidence predicted loss-of-function (pLOF) and damaging missense variants and test their association with these 100 traits. We elucidate several novel sex-specific associations, including *PREB* pLOF which associates with decreased apolipoprotein B in men ($P = 2.3 \times 10^{-6}$, -0.55 SD decrease). Additionally, we show several other novel associations including *WNT5B* pLOF + damaging missense with increased heel bone mineral density in women ($P = 8.9 \times 10^{-7}$, 0.28 SD increase), *MEN1* pLOF + damaging missense with increased calcium in women ($P = 1.9 \times 10^{-7}$, 0.40 SD increase), and *PDE3B* pLOF with decreased LDL cholesterol in women ($P = 5.2 \times 10^{-7}$, -0.21 SD decrease). These findings show instances of genetic loci with sexually dimorphic effects on complex traits and highlight potential new therapeutic strategies for diseases such as osteoporosis and cardiovascular disease with disparate effects across sexes.

Complex Traits Posters - Thursday

PB1630. Sex-specific and multiomic integration to enhance accuracy of peripheral blood biomarkers of major depressive disorder

Authors:

A. Delahaye-Duriez^{1,2}, A. MOKHTARI¹, E. Ibrahim³, A. Gloaguen⁴, D. P. Cohen¹, M. Derouin¹, I. Yalcin⁵, C. Marie-Claire⁶, B. Etain⁶, R. Belzeaux³, P-E. Lutz⁵; ¹NeuroDiderot UMR1141 INSERM Université Paris Cité, Paris, France, ²UFR SMBH, Université Sorbonne Paris Nord, Bobigny, France, ³Inst. of NeuroSci. of la Timone, Université Aix-Marseille, Marseilles, France, ⁴Inst. François Jacob, CNRGH - CEA, Université Paris-Saclay, Evry-Courcouronnes, France, ⁵Inst. des NeuroSci.s Cellulaires et Intégratives, UPR 3212, CNRS, Université de Strasbourg, Strasbourg, France, ⁶UMR-S1144 INSERM Université Paris Cité, Paris, France

Abstract Body:

Background/Objectives: Major depressive disorder (MDD also known as major depression or depression) is a psychiatric disorder that affects mood, behavior, and overall health, with a reduced life expectancy. Women are nearly twice as likely as men to be diagnosed with MDD. Clinical heterogeneity of MDD and the implication of multiple environmental risk factors contribute to the difficulty in identifying reliable biomarkers for diagnostic and therapeutic purposes. Here, we implemented a multi-omic integrative framework, designed to extract peripheral blood molecular signatures of MDD, and to evaluate the added-value of combining several types of omics data when classifying patients and controls. **Methods:** We analyzed transcriptomic (RNA-sequencing) and epigenomic processes (microRNA-sequencing and DNA methylation arrays) in blood samples from a well-characterized cohort of individuals with MDD (n=80), and healthy controls (n=89). We combined several strategies: first, we applied gene co-expression network and annotation enrichment analyses; second, we used supervised machine learning methods for matrix reduction; finally, we prioritized a subset of features (individual protein-coding genes, micro-RNAs, and methylation probes) that maximize the accuracy of the clustering of MDD patient and healthy controls. The performance of each combination of omics data and feature selection approach is evaluated through a 5 fold cross validation (CV) approach. **Results:** Gene co-expression network analyses identified gene modules that significantly associate with SNPs implicated in the risk for MDD in previous studies, and also show significant enrichment for differentially expressed genes, differential DNA methylation, and regulation by differentially expressed micro-RNAs. The joint dimension reduction approach allowed the identification of features that achieve good clustering of cases and controls (best accuracy=0.81). In both the pooled and male only cohort, the clustering based on the combination of mRNA and DNAm outperformed the single omic based approaches. While in the female mRNA based feature selection slightly outperformed the mRNA DNAm combination. **Conclusion:** Our analyses show a sex dependent biological signal of MDD that is important to consider when seeking to identify MDD biomarkers. These results also provide support for the hypothesis that, compared to single omics, integration of multi-omic datasets have the potential to significantly improve patient clustering, with implication for the development of MDD biomarkers.

Complex Traits Posters - Wednesday

PB1631. Sex-Specific associations of gene expression in brain with Alzheimer's disease pathology and cognitive performance.

Authors:

M. Clifton¹, M. Seto¹, R. F. Buckley^{2,3,4}, K. A. Gifford¹, A. L. Jefferson¹, P. L. De Jager^{5,6}, D. A. Bennett⁷, L. L. Barnes⁷, J. A. Schneider⁷, T. J. Hohman^{1,8}, L. Dumitrescu^{1,8}; ¹Vanderbilt Memory and Alzheimer's Ctr., Vanderbilt Univ. Med. Ctr., Nashville, TN, ²Dept. of Neurology, Massachusetts Gen. Hosp./Harvard Med. Sch., Boston, MA, ³Ctr. for Alzheimer's Res. and Treatment, Dept. of Neurology, Brigham and Women's Hosp./Harvard Med. Sch., Boston, MA, ⁴Melbourne Sch. of Psychological Sci., Univ. of Melbourne, Melbourne, Australia, ⁵Ctr. for Translational & Computational Neuroimmunology, Dept. of Neurology, Columbia Univ. Med. Ctr., New York, NY, ⁶Cell Circuits Program, Broad Inst., Cambridge, MA, ⁷Rush Alzheimer's Disease Ctr., Rush Univ. Med. Ctr., Chicago, IL, ⁸Vanderbilt Genetics Inst., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract Body:

Alzheimer's disease (AD) disproportionately affects women, who make up two-thirds of all prevalent AD. While sex differences in AD neuropathology, the response to pathology, and the genetic predictors of clinical AD have been well described, sex differences in the brain transcriptomic signatures of AD phenotypes have not been fully characterized. We leveraged bulk RNA-sequence data from three brain regions (dorsolateral prefrontal cortex [DLPFC], posterior cingulate cortex [PCC], and caudate nucleus) from 2201 samples and 994 participants from the Religious Orders Study and Rush Memory and Aging Project (35% male; mean age at death 87.6 years). Sex-stratified and sex-interaction (int) regression models assessed sex-specific transcript associations with amyloid and tau burden, along with global cognition. Age at death, latency to death, and post-mortem interval were included as covariates. Sex-specific genes were defined as related to a trait in one sex (FDR-corrected $p < 0.05$) but not in the other sex and that showed evidence of a sex-modifying effect (int $p < 0.05$). Of the more than 20,000 significant autosomal gene expression associations with the three AD endophenotypes, 9% were sex-specific. Given the larger sample size, it was unsurprising that we observed more female-specific (8%) compared to male-specific (1%) effects. A number of genes showed particularly strong effects among females, including *BDNF-ASI* with tau tangles in the PCC ($P_{\text{men}}=0.93$, $P_{\text{women}}=3.03 \times 10^{-7}$, $P_{\text{int}}=7.25 \times 10^{-4}$), *LRIG3* with amyloid in the DLPFC ($P_{\text{men}}=0.11$, $P_{\text{women}}=6.99 \times 10^{-11}$, $P_{\text{int}}=0.012$), and *TMX4* in multiple tissues with cognition ($P_{\text{men}}=0.89$, $P_{\text{women}}=1.4 \times 10^{-3}$, $P_{\text{int}}=0.04$), tangles ($P_{\text{men}}=0.30$, $P_{\text{women}}=2.4 \times 10^{-3}$, $P_{\text{int}}=0.01$), and amyloid ($P_{\text{men}}=0.57$, $P_{\text{women}}=3.7 \times 10^{-3}$, $P_{\text{int}}=0.02$). Additionally, 17 genes showed male-specific associations with at least two traits including *HIP1R* ($P_{\text{men}}=5.7 \times 10^{-5}$, $P_{\text{women}}=0.07$, $P_{\text{int}}=0.03$), *CD83* ($P_{\text{men}}=8.4 \times 10^{-4}$, $P_{\text{women}}=0.45$, $P_{\text{int}}=0.04$), and *ZFH4-ASI* ($P_{\text{men}}=1.2 \times 10^{-3}$, $P_{\text{women}}=0.45$, $P_{\text{int}}=1.4 \times 10^{-3}$). Similar sex-specific patterns with AD were observed in independent AMP-AD cohorts for *LRIG3*, *BDNF-ASI*, and *ZFH4-ASI* (<https://agora.adknowledgeportal.org/>). A formal replication analysis is forthcoming, as is an examination of X chromosome genes. Our results highlight sex-specific transcriptomic associations with AD phenotypes, including genes along protein misfolding and neurotrophic signaling among females and macrophage markers among males. These findings highlight the exciting potential of precision medicine approaches that consider sex-specific biological pathways to select new targets for mechanistic evaluation.

Complex Traits Posters - Thursday

PB1632. Sex-specific genetic loci linked to early and late onset type 2 diabetes.

Authors:

Mendoza-Tenorio¹, L. Martínez-Juárez⁴, J. Lomelín-Gascón⁴, A. Montoya⁴, J. Ortega-Montiel⁴, R. Tapia-Conyer^{4,1}; ¹Univ. Natl. Autónoma de México, México, Mexico, ²Natl. Inst. of Genomic Med., México, Mexico, ³Univ. de Guadalajara, México, Mexico, ⁴Fundación Carlos Slim, México, Mexico, ⁵Laboratorio Huella Génica, México, Mexico

Abstract Body:

PurposeTo investigate the effect of sex and age on the timing of a type 2 diabetes (T2D) diagnosis and the influence T2D-related genes, parental history of T2D, and obesity have on T2D development.**Methods**In total, 1012 T2D cases and 1008 healthy subjects were selected from the Diabetes in Mexico Study database. Participants were stratified by sex and age at T2D diagnosis (early, ≤ 45 years; late, ≥ 46 years). The percentage contribution (R^2) of 71 SNPs located in T2D-related genes, parental history of diabetes, and obesity (body mass index [BMI] and waist-hip ratio [WHR]) on T2D development was calculated using univariate and multivariate logistic regression models.**Results** T2D-related genes influenced T2D development greatest in males who were diagnosed early ($R^2 = 23.5\%$; females diagnosed early, $R^2 = 13.5\%$; males and females diagnosed late, $R^2 = 11.9\%$ and $R^2 = 7.3\%$, respectively). With an early diagnosis, insulin production genes were more influential in males (76.0% of R^2) whilst peripheral insulin resistance genes were more influential in females (52.3% of R^2). With a late diagnosis, insulin production genes from the chromosome region 11p15.5 notably influenced males while peripheral insulin resistance and inflammation genes notably influenced females. Influence of parental history was higher among those diagnosed early (males, 19.9%; females, 17.5%) versus late ($\leq 6.4\%$). Unilateral maternal T2D history was more influential than paternal T2D history. BMI influenced T2D development for all, while WHR exclusively influenced males.**Conclusions** The influence of T2D-related genes, maternal T2D history, and fat distribution on T2D development was greater in males than females.

Complex Traits Posters - Wednesday

Ctr., Washington Univ., St. Louis, MO, ²⁶Hope Ctr. for Neurologic Diseases, Washington Univ., St. Louis, MO, ²⁷Dept. of Genetics, Washington Univ. Sch. of Med., St. Louis, MO

Abstract Body:

Nearly two-thirds of Americans with Alzheimer's disease (AD) are women, yet the role of sex-specific genetic drivers of AD or AD neuropathology has not been well-characterized. Amyloid positron emission tomographic (PET) imaging allows for *in vivo* detection of amyloid plaques in the brain, a neuropathological feature of AD. While amyloid PET levels have been leveraged as AD biomarkers in previous GWAS, sex-stratified models have not been incorporated. Hence, we analyzed sex-specific genetic associations with amyloid PET measured in 4,871 non-Hispanic white participants from seven cohorts of aging and AD ($N_{\text{men}}=2,137$, $N_{\text{women}}=2,734$, $\text{Age}_{\text{both sexes}}$: mean=72.37 years, SD=6.66). Amyloid PET was harmonized by applying a gaussian mixture model using modified nonlinear distributional mapping. We then performed sex-stratified and sex-interaction GWAS within each dataset and meta-analyzed. Covariates included age and the first five principal components for the sex-stratified GWAS and sex additionally for the sex-interaction GWAS. Outside of the expected association within the *APOE* locus, we identified a novel locus on chromosome 6 (index SNP rs544047, closest gene: *ROSI*, MAF=0.41) that was significantly associated with amyloid PET in men ($\beta=-0.17$, $p_{\text{men}}=3.86 \times 10^{-8}$) but not women ($\beta=-0.01$, $p_{\text{women}}=0.59$; $\text{pint}=2.45 \times 10^{-5}$). This top variant at the locus is an eQTL for *VGLL2* in

adipose tissue (GTEx, $p=2.2 \times 10^{-5}$) and *FAM26F* in blood (eQTLgen, $p=4.53 \times 10^{-10}$) and a methylation QTL in prefrontal cortex for *ROSI* (Brain xQTLServe, $\beta=-0.26$, $p=4.96 \times 10^{-10}$). *ROSI* encodes a receptor tyrosine kinase involved in chromosomal rearrangements, and some *ROSI* fusions were found in gliomas. Interestingly, *ROSI* rearrangement in cancer has shown evidence of a sex bias, and *ROSI* is downregulated in the AD brain, making it a fascinating sex-specific candidate gene. In our previous sex-agnostic GWAS we identified a genome-wide locus in *RBFox1*. Here, we observed nominal evidence that the association may be driven by females (rs56081887; $\beta_{\text{men}}=0.07$, $p_{\text{men}}=0.21$; $\beta_{\text{women}}=0.20$, $p_{\text{women}}=7.96 \times 10^{-6}$), though sex-interaction was not significant ($p_{\text{int}}=0.11$). In validation analyses, higher expression of both *ROSI* and *RBFox1* in prefrontal cortex was associated with lower amyloid plaque burden in women ($p=1.64 \times 10^{-4}$; $p=2.34 \times 10^{-4}$) but not men ($p=0.80$, $p_{\text{int}}=1.57 \times 10^{-2}$; $p=0.56$, $p_{\text{int}}=0.14$) at autopsy. Our results highlight the utility of sex-aware genome-wide analysis for identifying novel sex-specific genetic contributors to disease and the critical need for larger sample sizes to explore sex-specific genetic effects. Future work will seek replication of the novel male-specific *ROSI* locus.

Complex Traits Posters - Thursday

Abstract Body:

Two-thirds of clinical Alzheimer's disease (AD) cases are women compared to men, and women have more AD neuropathology at autopsy. Additionally, AD biomarker-positive women have steeper cognitive decline compared to AD biomarker-positive men. Sex-specific genetic factors may contribute to these observed sex differences, yet large-scale sex-aware genomic studies on late-life cognition are lacking. Thus, we sought to identify sex-specific genetic drivers of memory performance. Leveraging psychometric techniques, we harmonized item-level cognitive data into a continuous memory composite score that was scaled across four cohorts of cognitive aging ($N_{\text{men}}=9,618$, $N_{\text{women}}=13,199$, $\text{Age}_{\text{Both Sexes}}$:

mean=75 years). We performed sex-stratified and sex-interaction GWAS on baseline and longitudinal memory performance in non-Hispanic white (NHW; $N_{\text{total}}=20,205$) and in non-Hispanic black (NHB; $N_{\text{total}}=2,612$) participants. GWAS results were meta-analyzed both within and across each ancestry group. Among NHW men, we identified a locus on chromosome 18 associated with baseline memory performance (rs2590395; $P_{\text{men}}=2.15 \times 10^{-8}$, $P_{\text{women}}=0.65$, $P_{\text{sex-interaction}}=8.10 \times 10^{-7}$). The top variant in the locus, rs2590395, was an eQTL for *SERPINB2* and *SERPIN10* in blood (eQTLGen) and was a methylation QTL (xQTLServe) at two sites just downstream of the locus. Interestingly, our group previously identified a genome-wide significant *SERPIN* locus, *SERPINB1*, on chromosome 6, that was associated with CSF A β 42 burden among women. Among NHB participants, we did not identify any genome-wide significant loci, and no variants in linkage disequilibrium with the significant NHW male locus were significant in NHB men (rs2590395; $P_{\text{men}}=0.42$). In the Trans-Ancestry meta-analysis, among women, we identified two loci associated with longitudinal memory performance. First, we identified a chromosome 20 locus (rs2427384; $P_{\text{men}}=0.75$, $P_{\text{women}}=3.09 \times 10^{-8}$, $P_{\text{sex-interaction}}=4.33 \times 10^{-4}$), whereby the top variant, rs2427384, was an eQTL in the hippocampus for *LAMA5* (BrainSeq), a gene encoding extracellular matrix glycoproteins. Second, we observed an association at a known AD locus, *BINI*, that was genome-wide significant among women, but not among men (rs6733839; $P_{\text{men}}=7.60 \times 10^{-5}$, $P_{\text{women}}=3.29 \times 10^{-8}$) with no evidence for a true sex-specific effect ($P_{\text{sex-interaction}}=0.51$). Overall, our results highlight many promising sex-specific genetic predictors and candidate genes that may contribute to sex differences in late-life cognition. We are excited to follow-up on these results, including the opportunity to incorporate additional cognitive domains into our genetic analyses.

Complex Traits Posters - Thursday

PB1636. Sex-specific risk scores for coronary artery disease using machine learning models.

Authors:

Q. Ye¹, S. Gagliano Taliun²; ¹Montreal Heart Inst., Montreal, QC, Canada, ²Montréal Heart Inst./Université de Montréal, Montreal, QC, Canada

Abstract Body:

Coronary artery disease (CAD) affects millions of adults worldwide, and it affects women differently than men. Predicting CAD risk in a sex-specific manner using non-genetic and genetic factors is of great importance to moving towards personalized medicine and to improving human health. In recent years, polygenic risk scores for CAD built on linear models using genetic variants combined with phenotypic features as covariates have been proposed, and the area under the receiver operating characteristic curve (AUC) has reached 0.80. Here, we trained and compared two linear models (logistic regression (LR) and elastic net (EN)) and two non-linear models (support vector classifier (SVC) with non-linear kernels and multi-layer perceptron (MLP)) to predict CAD risk in the European-ancestry subset of the UK Biobank dataset (N cases = 14,740 with 22.30% female, and N controls= 299,580 with 55.25% female). We trained models in three sex categories (both sexes, female-only and male-only) considering various phenotypic feature sets and published polygenic scores. AUC was used to measure model performance. The highest AUCs for LR, EN, SVC, and MLP were 0.81, 0.79, 0.83 and 0.83, respectively with both sexes modeled together. The highest values were 0.76, 0.75, 0.79, and 0.78 on the female only dataset and 0.76, 0.75, 0.79, and 0.79 on the male only dataset. There was no significant decrease in AUC when a model was trained on the dataset with one sex and then tested on the opposite sex. We concluded that the non-linear models (SVC and MLP) achieved the highest AUCs, and both may out-perform linear models (LR and EN). Machine learning models can serve as an important tool for building risk scores for CAD.

Complex Traits Posters - Wednesday

PB1637. Sex-stratified meta-analysis of age-related cognitive decline across neurocognitive domains

Authors:

V. Acharya¹, K-H. Fan¹, B. Snitz², M. Ganguli³, S. Dekosky⁴, O. Lopez², E. Feingold¹, M. Kamboh¹; ¹Dept. of Human Genetics, Univ. of Pittsburgh Sch. of Publ. Hlth., Pittsburgh, PA, ²Dept. of Neurology, Sch. of Med., Univ. of Pittsburgh, Pittsburgh, PA, ³Dept. of Epidemiology, Univ. of Pittsburgh, Pittsburgh, PA, ⁴Dept. of Neurology, Coll. of Med., Univ. of Florida, Gainesville, FL

Abstract Body:

Cognitive aging is a huge public health concern due to increased elderly population worldwide. Age is the largest risk factor for cognitive decline in older adults. Increasing evidence suggests that cognitive decline across several cognitive domains exhibits sex-specific effects. Despite these sex-related differences, there is limited understanding of sex-specific genetic architectures of cognitive aging. To identify genetic variants involved in cognitive decline in males and females, we performed sex-stratified meta-analysis on 1499 males and 1569 females, ranging in age from 65 to 95 years and free of dementia at baseline, from three different prospective cohorts: Ginkgo Evaluation of Memory Study (GEMS), Monongahela-Youghiogheny Healthy Aging Team (MYHAT) and Monongahela Valley Independent Elders Survey (MoVIES). Longitudinal follow-up with cognitive evaluations ranged from 6 to 12 years. We calculated z scores across five cognitive domains: attention, memory, executive function, language, and visuospatial function, as well as global cognitive function score that was derived by averaging the performance across all tests within the five cognitive domains. Inter-individual domain-specific slopes over time were then generated by fitting a linear mixed effect model. We identified a genome-wide significant (GWS) locus for memory decline in males near *MIR1269A* on chromosome 4 ($p=2.94E-08$), a region which has previously been implicated with education attainment. We also observed a sub-threshold GWS locus for attentional decline in females near *GALR1* and *LINC01029* on chromosome 18 ($p=8.08E-08$). In addition, we identified multiple suggestive loci in males or females for the following domains: 4 loci for decline of attention in females (p from $p=3.41E-07$ to $p=9.71E-07$); 2 loci for decline of memory in females (p from $5.37E-07$ to $7E-07$); one locus for global cognitive function decline in females ($p=6.26E-07$); 2 loci for decline of memory in males (p from $4.22E-07$ to $8.21E-07$); 2 loci for decline of language in males (p from $1.22E-07$ to $8.96E-07$); 2 loci for global cognitive function decline in males (p from $9.46E-07$ to $9.89E-07$) and one locus for decline of visuospatial function in males ($p=2.35E-07$). The latter locus (*JAZF1*) has previously been implicated with Alzheimer's disease risk. These novel, exploratory data expand the landscape of the genetics of neurocognition and offer sex-specific findings of cognitive aging across the neurocognitive domains.

Complex Traits Posters - Thursday

PB1638. *SHANK3* domain specific functional characterization of a spectrum of neurodevelopmental disorders phenotypes.

Authors:

N. Kosaji¹, S. Al Shaibani¹, N. Nassir¹, B. Ashraf¹, A. Ahmed¹, M. Uddin^{1,2}; ¹MBRU (Mohammed bin Rashid Univ. of Med. and Hlth.Sci.s), Dubai, United Arab Emirates, ²GenomeArc (Cellular Intelligence (Ci) Lab, GenomeArc Inc.), Toronto, ON, Canada

Abstract Body:

Autism spectrum disorder (ASD) is a multifaceted neuropsychiatric condition characterized by impairments in social interaction, communication, and behavior. Previous experimental research and clinical studies established a correlation between *SHANK* protein impairment and the onset of neurodevelopmental disorders (NDD), particularly autism. *SHANK* proteins function as master organizers of the postsynaptic density, owing to their ability to form multimeric complexes with postsynaptic receptors, signaling molecules and cytoskeletal proteins. From this gene family, *SHANK3*, an excitatory synapse scaffolding protein, was found to be primarily involved in NDD pathogenesis. To explore those interactions, our research aimed to identify the most frequent *SHANK* mutations to mimic their pathophysiology using *in vitro* models with CRISPR/Cas9 technology. Furthermore, deducing distributional trends provides valuable insight into the mutations' characteristics, vital for understanding gene interactions and disease pathogenesis. In our study, we conducted a comprehensive meta-analysis of *SHANK* mutations in NDD cases by constructing a mutation database from published genomic studies on *SHANK* genes. For stratification analysis, we collected *SHANK* mutation clinical phenotypes to identify variable trends. The mutations were categorized into ASD, Asperger's syndrome, Schizophrenia, undiagnosed cases of intellectual disability, and others including ADHD, Phelan Mcdermid, and Rhett's Syndrome. Initially we congregated 1482 cases across 433 *SHANK* mutations. We then filtered the data for exonic and splice junction variants and investigated their pathogenicity following ACMG guidelines. After quality control, 297 proband cases across 211 distinct mutations were retained. Our analysis identified trends in mutation distribution across gender, type, location, pathogenicity, and disease. Our findings show that *SHANK* mutations predominantly affect males and are primarily involved in ASD amongst other NDDs. Additionally, the majority of *SHANK1/2* mutations are paternally inherited while *SHANK3* mutations are mostly *de novo*. Interestingly, the bulk of reported pathogenic *SHANK* mutations are in *SHANK3*. Since the results suggested the particular involvement of *SHANK3* into the pathogenesis of NDDs, we intend on exploring this phenotypic heterogeneity by CRISPR/Cas9 induced recurrent mutations within different *SHANK3* domains to model pluripotent stem cell differentiated knockout neurons. This model system will enable us to quantify morphological and molecular domain specific phenotypes that contribute into the pathophysiology of NDDs.

Complex Traits Posters - Wednesday

PB1639. Shared genetic basis informs the roles of polyunsaturated fatty acids in brain disorders

Authors:

H. Xu¹, Y. Sun¹, M. Francis², K. Ye^{1,2}; ¹Dept. of Genetics, Univ. of Georgia, Athens, GA, ²Inst. of Bioinformatics, Univ. of Georgia, Athens, GA

Abstract Body:

Polyunsaturated fatty acids (PUFAs) are associated with brain disorders, such as major depression (MDD) and Attention-Deficit Hyper-activity Disorder (ADHD). Supplementation of omega-3 PUFAs was also suggested to reduce psychotic symptoms, such as anxiety and anorexia. However, most previous findings were based on observational associations. Here, we systematically investigate the shared genetic basis between PUFAs and brain disorders, aiming to illuminate their interacting mechanisms. We will perform three major analyses using genome-wide association study summary statistics of 11 PUFA traits (n=114,999) and 20 brain disorders (n=9,725~762,917). First, we performed genetic correlation analysis with LDSC. We confirmed a previous observation that there are positive genetic correlations across most brain disorders. Among PUFA traits, there are strong correlations between PUFA, omega-6, linoleic acid (LA), omega-3, docosahexaenoic acid (DHA), and the percentage of omega-3 in total fatty acids (omega-3%), with the strongest correlation between LA and omega-6 ($r_g=0.95$, $P < 4.55 \times 10^{-3}$). Notably, for total PUFAs, omega-6, and LA, there are negative correlations between their absolute measurements and their relative percentages in total fatty acids. With pairwise analysis between PUFA traits and brain disorders, we identified a large number of significant correlations. Six PUFA phenotypes (PUFA%, omega-6%, LA%, omega-3%, DHA% and DHA) were negatively correlated with substance use disorders (opioid dependence: $r_g=-0.4\sim-0.23$; $P < 0.05$; alcohol dependence: $r_g=-0.3\sim-0.18$, $P < 0.05$; cannabis use disorder: $r_g=-0.27\sim-0.20$, $P < 0.001$), followed by ADHD ($r_g=-0.34\sim-0.23$, $P < 2.27 \times 10^{-4}$), Post Traumatic Stress Disorder ($r_g=-0.32\sim-0.16$, $P < 0.05$), anxiety ($r_g=-0.23\sim-0.22$, $P < 0.05$), insomnia ($r_g=-0.20\sim-0.11$, $P < 0.05$), MDD ($r_g=-0.19\sim-0.1$, $P < 0.05$) and neuroticism ($r_g=-0.14\sim-0.08$, $P < 0.05$). In addition, these six PUFA phenotypes were positively correlated with compulsive behaviors (obsessive-compulsive disorder: $r_g=0.14\sim0.3$, $P < 0.05$; anorexia nervosa: $r_g=0.17\sim0.28$, $P < 2.27 \times 10^{-4}$), followed by schizophrenia and alcohol consumption. The moderate to strong genetic correlations indicate a shared genetic basis between PUFAs and brain disorders. We are in the process of estimating the numbers of shared and unique causal variants using MiXeR. Moreover, we will apply colocalization analysis to pinpoint specific shared genes. This study will improve our understanding of the roles of PUFAs in brain disorders and inform their interacting biological pathways.

Complex Traits Posters - Wednesday

PB1641. Shriners Children's international program on the genetics of rare pediatric disorders

Authors:

K. Shazand¹, A. Gustafson¹, A. Quitadamo¹, X. Liu², V. Bijanki³, M. Lalande⁴; ¹Shriners Children's Genomics Inst., Tampa, FL, ²Univ. of South Florida, Tampa, FL, ³Shriners Children's St. Louis, St. Louis, MO, ⁴Shriners Hosp. for Children, Tampa, FL

Abstract Body:

The Shriners Children's recently initiated an ambitious large-scale research program, namely the Shriners Precision Medicine and Genomics (SPMG) program. The aim of SPMG is to build a comprehensive genetic database of over 5,000 trios (patients and their biologic parents) by Whole Genome Sequencing (WGS) by short and long read platforms. This work aims to first characterize the etiology of these disorders based on a statistically solid approach, and use this knowledge to improve patients' lives with highly specific diagnostic tools, more reliable treatment protocols and better therapeutic approaches. The pediatric disorders that we treat at our hospitals and clinics are neurologic, musculoskeletal and orthopedic, as well as burns and cleft lip and palate. In the last 2 years, we were able to get all 22 Shriners centers onboard for patient recruitment and accumulate over 4,000 samples of highly diverse ethnic descents, of which ~3,000 are sequenced. Due to its higher prevalence (3%), the adolescent idiopathic scoliosis (AIS) cohort reached a considerable number, allowing identification of some of the genes and pathways potentially involved in the onset and development of AIS during the embryonic and perinatal phases. We are developing animal models to functionally validate and isolate the most clinically relevant ones. The most recent results will be reported at the conference. In addition, the study of several other disorders such as cerebral palsy, arthrogryposis multiplex congenital, toe walking and pain management of burns have been ongoing in parallel and exciting developments are underway. Altogether, these projects have been successful in delivering some of the underlying genetic structure of the disorders under study and should contribute to the collective efforts in supporting patients across the world.

Complex Traits Posters - Thursday

PB1642. Significant heritability enrichment for Schizophrenia located in single neuron electrophysiology genes.

Authors:

X. Li, H. Hu, N. Johansen, L. Walker, G. Quon; Univ. of California, Davis, Davis, CA

Abstract Body:

The impact of psychiatric GWAS variants on cellular phenotypes such as single neuron electrophysiology (ephys) is unknown. We leveraged single neuron Patch-seq data (matched RNAseq and patch-clamping) to perform a genome-wide search for genes whose expression levels are correlated with different quantitative measurements of single neuron ephys in interneurons.

Globally, we identified 30 ephys features that can be robustly predicted (Spearman $\rho > 0.5$) from gene expression across mouse interneurons. Surprisingly, models trained on individual classes of interneurons (Sst, Pvalb, Lamp5, Vip) were highly cell type specific: models trained on one cell type but tested on another typically yielded a drop in 72% on average, suggesting distinct sets of ephys genes are responsible for control of the same ephys feature across different interneuron types. Unexpectedly, we found that of the genes predictive of ephys, ion channels only constitute a small fraction (average $< 4.3\%$) of them. Instead, we found significantly overrepresentation of adhesion molecules with known roles modulating ion channel activity, suggesting more indirect influence on ephys properties of neurons. We also found novel functional diversity among cell adhesion molecules such as Kirrel3 and Cxadr, in which individual adhesion genes established different ephys properties in different interneurons, despite similar expression levels across interneurons. This potential for cell adhesion function switching is previously unappreciated but was prevalent in our analysis.

To quantify the heritability of psychiatric diseases with respect to neuron ephys, we performed partitioned heritability analysis of different ephys gene sets and found the first action potential dV/dt genes explained significant heritability specifically for Schizophrenia (permuted $P < 0.001$). Co-localization analysis found four genes whose expression is likely modulated by SCZ GWAS variants, and are ephys genes: RGS6, STK4, TCTN1 and RBM26. Co-expression partners of these genes were significantly different between SCZ cases versus controls, suggesting changes in function between cases and controls. Further evidence gathered from epigenetic and chromatin accessibility data highly support two potential SCZ causal variants that may affect Sst neuron ephys. Overall, our work demonstrates a potential role of single neuron electrophysiology in mediating the genetic risk of psychiatric disorders.

Complex Traits Posters - Wednesday

PB1643. Single cell patch-seq in understanding the regenerative ability of cortical spinal motor neurons

Authors:

H. Kim, J. M. Saikia, A. Moore, E. Ha, K. Cervantes, D. Lusk, B. Zheng; Univ. OF CALIFORNIA, SAN DIEGO, San Diego, CA

Abstract Body:

Spinal cord injury (SCI) is a severe condition that results in loss of function in mobility. The corticospinal tract (CST) is a clinically important target for functional recovery after SCI. Multiple molecular pathways including the Pten/mTOR signaling pathway have been revealed to regulate axon regeneration and sprouting from the CST. However, among diverse populations of CST neurons, only a subset regenerates axons following molecular intervention and the number of regenerating neurons declines with age. Here, we have performed single cells RNA-seq using Patch-seq after retrograde tracer injection in animals with Pten/mTOR pathway modification. Through differential gene expression and pathway / network analyses, we identified known and new potential regulators of CST regeneration and found that regenerating transcriptomes differentially map to previously defined neuronal clusters based on single cell seq data.

Complex Traits Posters - Thursday

PB1644. Single nucleotide variants genotyping of IL-6, IL-1 β , TNF- α genes promoter region and its protein levels associated to inflammatory response in obstructive sleep apnea and periodontal disease

Authors:

F. Sir-Mendoza¹, M. Rey¹, F. Gonzalez², L. Otero³; ¹Univ. Natl. de Colombia, Bogotá, Colombia, ²Univ. de Cartagena, Cartagena, Colombia, ³Pontificia Univ. Javeriana, Bogotá, Colombia

Abstract Body:

We aimed to determine single nucleotide variants (SNVs) in the promoter region of *IL-1 β* (c.-511 C>T, c.-31 T>C) and *TNF- α* (c.-308 G>A) gene, and the protein level of these proinflammatory cytokines in saliva of individuals with Obstructive Sleep Apnea (OSA) and Chronic periodontitis (CP). A case and control study that comprised a total 129 subjects from Bogotá, Colombia was conducted. The cases group was subdivided into a group with only CP, only with OSA, and presenting CP and OSA in concomitance. For genotyping, DNA extraction and PCR amplification were performed to carry out Sanger sequencing. Descriptive and inferential statistic was performed using R v3.6.2. The alleles *IL-1 β* c.-511T (OR 2.83 CI: 1.57-5.10), *IL-1 β* c.-31C (OR 2.81 CI: 1.51-5.20) and its homozygous states *IL-1 β* c.-511 TT (OR 7.92 CI: 2.09-29.8), *IL-1 β* c.-31CC (OR 7.2 CI: 1.8-27.9) had significant association with a risk effect. This effect was obtained when comparing individuals with OSA vs Controls and subjects with CP and OSA vs Controls, suggesting that individuals with the mentioned SNVs have two times more risk to develop these inflammatory phenotypes and the risk is even seven times more when having two copies of the allele. In both allelic and genotypes analyzes the risk effect of the SNVs was maintained in patients diagnosed with both diseases. In addition, this genotypic effect could be correlated to the protein level, homozygous individuals *IL-1 β* c.-511TT diagnosed simultaneously with OSA and CP had more IL-1 β protein level in saliva than controls *IL-1 β* c.-511CC (p-value 0.011), as well as when comparing controls *IL-1 β* c.-31TT with OSA and CP *IL-1 β* c.-31CT (p-value 0.001). In conclusion, the alleles *IL-1 β* c.-511T and *IL-1 β* c.-31C increase the risk of develop OSA and/or OSA with CP concomitantly, even more in a homozygous state.

Complex Traits Posters - Wednesday

PB1645. Single-Cell RNA-Seq Reveals the connections of amyloid-beta and ferroptosis tendency

Authors:

Y. Jin; Purdue Univ., West Lafayette, IN

Abstract Body:

Extracellular amyloid-beta plaques and intracellular neurofibrillary tangles have been regarded as the two primary pathological hallmarks of Alzheimer's disease (AD). The mechanism of how amyloid-beta plaques and intracellular neurofibrillary tangles trigger neuron death is still not fully understood. Evidence suggested that ferroptosis may be involved in neuron death in AD. We applied single-cell RNA sequencing method to investigate the relationship between amyloid-beta plaques, and ferroptosis tendency in AD. We used 48 individuals (24 cases and 24 controls) post-mortem brain tissue single cell data from the ROSMAP dataset. We found a positive correlation between the trends of amyloid-beta and ferroptosis. Then single-cell regulatory networks were built via SCENIC based on differentially activated transcription factors. Our findings showed there is a strong correlation between amyloid-beta and ferroptosis tendency.

Complex Traits Posters - Thursday

PB1646. SnRNA-seq probing of the differential vulnerability of motor neurons in ALS

Authors:

P. Alipour; McGill Univ., Montreal, QC, Canada

Abstract Body:

Background: selective vulnerability of some neuronal subpopulations is a common feature of neurodegenerative disorders. While upper and lower MNs degenerate in Amyotrophic Lateral sclerosis (ALS) ocular motor neurons including oculomotor nucleus (CNIII) seem to be largely spared. Diverse CNS cell types may contribute differently to neurodegeneration and are differentially vulnerable. Utilizing a single-nucleus RNA sequencing (snRNA-seq) method we aim to compare transcriptomic profile of differentially vulnerable regions to identify intrinsic properties of oculomotor nucleus that would be absent in medulla in ALS. **Methods:** Post-mortem CNS tissues from ALS cases and normal controls were obtained from the Douglas-Bell Canada Brain Bank, McGill university. Nuclei isolation was performed according to the Nagy et al. Following nuclei isolation, library preparations, sequencing, and Cellranger analyses were performed as per established protocol by 10X Genomics. Following the reception of the expression matrix, nuclei were analyzed in the single-cell analysis R package, Seurat. After quality control and clustering, the differentially gene expression analysis was performed to compare oculomotor nucleus vs medulla in ALS patients. **Results:** clustering of 92K nuclei revealed 23 cell types. Endothelial cell and astrocytes are the only major cell types under-represented in the ALS samples. The majority of DEGs in oculomotor nucleus attribute to astrocytes and oligodendrocytes precursor cells (OPCs), while in the medulla the majority of DEGs attribute to neurons, astrocytes and OPCs. Glial cells show divergent signature in medulla vs oculomotor; while in oculomotor OPCs are involved in pathway indicating activation of the proteasome and phagosome system in response to proteinopathy in medulla OPCs are mostly enriched in antigen processing and presentation including major histocompatibility complex class I (MHC-I); microglia subpopulation signature in medulla represents Disease Associated Microglia (DAM) which are associated with reactive microglia. **Conclusion:** Based on the observation we made thus far; it appears that glial cells are active in the two ALS regions examined here but top DEGs identified in oculomotor do not reveal neurotoxic pathways but are rather associated with the maintenance of cell homeostasis. Given the neuronal dysregulation observed in oculomotor nucleus from ALS cases is minimum, by comparison to what is seen in medulla region, it is presumed that glial cells might be more supportive in this region and better deal with cellular stress of the disease.

Complex Traits Posters - Wednesday

PB1647. SNX8 as a novel predisposing factor by an integrative study for the risk of childhood atopic dermatitis in COCOA

Authors:

E-A. Choi¹, S. Hong¹, S. Hong², S. Lee³, Y-Y. Kim¹, D. Yoon⁴, H-J. Lee⁵; ¹Korea NIH, Cheongju, Korea, Republic of, ²Korea NIH, Seoul, Korea, Republic of, ³Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of, ⁴Korea NIH, Cheongju-si, Korea, Republic of, ⁵NIH Korea, Cheongju, Korea, Republic of

Abstract Body:

To discover the genetic determinants for underlying unclear mechanism of atopic dermatitis, we conducted genome-wide association study using Korean chip in Cohort for Childhood Origins of Asthma and Allergic Diseases (COCO A). A novel variant SNX8 rs6974490 showed the association with atopic dermatitis of 1- year children (n=1,236). Children having TT genotypes had a higher risk of atopic dermatitis than those having C allele. Also, to identify epigenetic biomarker, we performed in a cord blood-based DNA methylation analysis using Infinium HumanMethylation850 BeadChip (n=142). CC genotype carriers of SNX8 rs6974490 showed decreased CpG signal in cg09164228 in SNX8 gene when compared to CT or TT carriers. Furthermore, the interaction between childhood SNX8 genotype and their mother's specific IgE to Dermatophagoides farina during pregnancy influenced the risk of AD and the effect of eosinophil levels on SNX8 polymorphism in children. A SNX8 variant was significantly associated with childhood atopic dermatitis, blood eosinophil, and maternal IgE level following house dust mice exposure during pregnancy. An integrative multi-target analysis might reveal new functional implications related to epigenetic control according to genotype in atopic dermatitis.

Complex Traits Posters - Thursday

PB1648. Socioeconomic Status and Risk of Stroke: A Mendelian Randomization Study.

Authors:

E. Myserlis¹, M. K. Georgakis^{2,3,4,5,6}, E. Mayerhofer^{2,3,4,5}, L. Parodi^{2,3,4,5}, J. Rosand^{2,3,4,5}, C. D. Anderson^{2,3,4,7}; ¹Dept. of Neurology, Med. Univ. of South Carolina, Charleston, SC, ²Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA, ³Program in Med. and Population Genetics, Broad Inst. of MIT and Harvard, Cambridge, MA, ⁴Henry and Allison McCance Ctr. for Brain Hlth., Massachusetts Gen. Hosp., Boston, MA, ⁵Dept. of Neurology, Massachusetts Gen. Hosp., Boston, MA, ⁶Inst. for Stroke and Dementia Res. (ISD), Univ. Hosp., Ludwig-Maximilians-Univ. (LMU), Munich, Germany, ⁷Dept. of Neurology, Brigham and Women's Hosp., Boston, MA

Abstract Body:

Introduction: Low socioeconomic status (SES) has been associated with increased stroke risk in epidemiologic studies. The extent to which this association is explained by uncontrolled modifiable stroke risk factors or whether SES reflects an independent unaddressed burden on this patient population is unclear. We sought to disentangle the association between SES and stroke risk through mendelian randomization (MR) analysis.

Methods: We utilized summary statistics of a multi-trait genome-wide association study of household income (N=505,541) informed by its correlated trait, education attainment ($r_g=0.77$), to select 123 genome-wide, independent ($r^2<0.001$) SNPs to proxy SES. We performed univariable MR evaluating the effect of lower SES on stroke and subtypes (all stroke (N=40,585), ischemic stroke (N=34,217), large artery stroke - LAS (N=4,373), cardioembolic stroke - CES (N=7,193), small vessel stroke - SVS (N=5,386)) in MEGASTROKE (N controls = 406,111). We performed multivariable MR to control for known cardiometabolic risk factors (systolic blood pressure (SBP), type 2 diabetes mellitus (T2DM), low-density lipoprotein (LDL)). Lastly, we assessed to what extent the association between low SES and stroke risk is mediated by modifiable lifestyle risk factors (smoking, alcohol, waist-hip ratio). False discovery rate (FDR) was used to control for multiple hypothesis testing. Association estimates are expressed as OR per unit decrease in the logOR of genetically predicted income category.

Results: Lower socioeconomic status was associated with increased risk of all stroke and ischemic stroke subtypes, according to the univariate IVW analysis (all stroke: OR=1.47, 95% CI: 1.30-1.66, p-FDR=2.73x10⁻⁸; ischemic stroke: OR=1.46, 95% CI: 1.27-1.67, p-FDR=5.70x10⁻⁷; LAS: OR=1.63, 95% CI: 1.10-2.43, p-FDR=0.02; CES: OR=1.35, 95% CI: 1.04-1.73, p-FDR=0.022; SVS: OR=1.75, 95% CI: 1.28-2.38, p-FDR=0.00103). Effect estimates were largely directionally consistent across univariate MR methods. After controlling for SBP, T2DM, or LDL, the association between low SES and all stroke and ischemic stroke remained significant. While 33% (95% CI: 10-36%) of the association between SES and cardioembolic stroke risk was mediated by alcohol consumption, no other lifestyle risk factors were found to mediate associations between low SES and stroke or its subtypes.

Conclusion: We found that low SES is causally associated with increased stroke risk, independent of known cardiometabolic risk factors. Further studies are needed to address social and other determinants of health as an important way of decreasing stroke burden across populations.

Complex Traits Posters - Wednesday

PB1649*. Somatic mutations in chronic lung disease are associated with reduced lung function

Authors:

J. Yun¹, W. Khan², B. Hobbs³, P. Castaldi³, C. Hersh¹, P. Miller⁴, F. Sciruba¹, L. Barwick⁵, A. Limper⁶, K. Flaherty⁷, G. Criner⁸, K. K. Brown⁹, R. Wise¹⁰, F. Martinez¹¹, E. K. Silverman¹², M. H. Cho³, A. Bick¹³; ¹Brigham and Women's Hosp., Boston, MA, ²Vanderbilt Univ., Nashville, TN, ³Brigham and Women's Hosp., Boston, MA, ⁴Massachusetts Gen. Hosp., Boston, MA, ⁵The Emmes Company, Rockville, MD, ⁶Mayo Clinic, Rochester, MN, ⁷Univ. of Michigan, Ann Arbor, MI, ⁸Temple Univ., Philadelphia, PA, ⁹Natl. Jewish Hlth., Denver, CO, ¹⁰Johns Hopkins Univ., Baltimore, MD, ¹¹Weill Cornell Med., New York, NY, ¹²Brigham & Women's Hosp, Boston, MA, ¹³Vanderbilt, Nashville, TN

Abstract Body:

The lung carries one of the highest somatic mutational loads among tissues in healthy individuals, however whether somatic mutations in the lung are enriched among patients with chronic lung diseases is unknown. We hypothesized that somatic mutations would be increased in smoking-related chronic lung diseases. To identify somatic mutations, we identified somatic single nucleotide variants (SNV) in lung tissue from RNA sequencing paired with blood-derived whole genomes from the Lung Tissue Research Consortium (n=1,364). SNVs were called with GATK MuTect and filtered to a set of 285,000 high confidence mutations. To test for associations with phenotypes, we selected subjects with confirmed histopathology, smoking history, and lung function data which included 29 normal (based on histology and lung function), 352 with chronic obstructive pulmonary disease (COPD), 164 with idiopathic pulmonary fibrosis (IPF). Surprisingly, mutational burden (the number of SNVs) was not associated with age or smoking history, overall or within subgroups ($P > 0.2$). In addition, we did not find significant enrichment for somatic mutations in known lung cancer driver genes. However, we did find mutation burden significantly associated with reduced lung function (forced expiratory volume in 1 second (FEV1) % predicted) in COPD ($R = -0.16$, $p < 0.01$) and IPF ($R = -0.29$, $p < 0.001$), but not in controls ($R = -0.069$, $p = 0.7$). In addition, mutation burden was associated with an increased proportion of airway versus alveolar epithelial cells ($p < 0.001$ across all groups). There was no association of mutational burden with immune cell or stromal cell abundance. In multivariable regression analysis adjusted for age, sex, race and smoking history, both airway/alveolar epithelial ratio and lung function (FEV1% predicted) remained statistically significantly associated with mutational burden (Beta 16.7 and -7.27 respectively, $p < 10^{-4}$). Our study suggests that somatic mutations are associated with reduced lung function and specific cell types in chronic lung disease.

Complex Traits Posters - Thursday

PB1650. Spectrum of causal genetic variants in inherited cardiomyopathies and arrhythmias in a primarily French-Canadian Population: A 14-year retrospective study from a specialized Cardiovascular Genetic Center.

Authors:

S. Grondin^{1,2}, I. Soltani^{1,2}, A. Alaoui^{1,2}, A. Messina^{1,2}, L. Gaumont^{1,2}, A. Jeuken^{1,2}, C. Barahona-Dussault¹, G. Sylvain-Drolet¹, B. Neveu¹, L. Robb¹, J. Gagnon¹, V-A. Amyot^{1,2}, R. Tadros^{1,2}; ¹Montreal Heart Inst., Montreal, QC, Canada, ²Université de Montréal, Montreal, QC, Canada

Abstract Body:

Background: The genetic spectrum of inherited cardiomyopathies and arrhythmias in the French-Canadian population is unknown. Interpretation of genetic variants can be challenging in understudied populations where founder effects are common. **Objective:** To describe the genetic pool in probands with inherited cardiovascular disorders, where the majority are of French-Canadian ancestry. **Methods:** We included probands with suspected inherited cardiomyopathies and arrhythmias seen between 2006 and 2020 at the Montreal Heart Institute Cardiovascular Genetic Center, with clinical information and genetic results available. Medical charts and genetic results were retrospectively reviewed. Diagnoses and strengths of diagnoses (definite, probable, possible) were systematically adjudicated using predefined criteria. **Results:** A total of 1605 probands (mean age 48 ± 17 years) were included. The majority were males (64%) with at least one parent of French-Canadian ancestry (72%). Genetic testing was performed using diagnosis-specific gene panels (median 17 genes, range [1-133 genes]). A total of 609 distinct variants were identified, of which 213 (35%) were classified as likely pathogenic or pathogenic (LP/P). Overall, 369/1335 (28%) of probands with definite clinical diagnoses carried a LP/P variant, as opposed to 50/270 (19%) for those with non-definite diagnoses ($P=0.002$). The rate of LP/P variants varied across diseases: 32% for hypertrophic cardiomyopathy (HCM) and dilated cardiomyopathy (DCM), 48% for arrhythmogenic cardiomyopathy and 12% for Brugada syndrome. In DCM, the proportion of probands with LP/P variants was higher for those with a positive familial history (49/102; 48%) compared to sporadic cases (41/178; 23%; $P=3 \times 10^{-5}$). Reflecting the founder effect in the French-Canadian population, 57 unique LP/P variants were identified in at least 3 unrelated probands. In HCM, 3 recurrent LP/P variants together account for 16% of French-Canadian HCM probands overall, and 35% of gene-positive HCM. These 3 variants are: *TNNT2* (NM_001001432):p.Trp287*, *MYBPC3* (NM_000256):c.551dup and *MYH7* (NM_000257):p.Arg204Leu seen in 39, 23, and 10 apparently unrelated HCM probands, respectively. **Conclusion:** Genetic testing identified a disease-causing variant in 26% of probands with a definite diagnosis in a clinical context, highlighting the high yield of rare variant genetic testing in complex conditions. Rare disease-causing variants are found in multiple unrelated probands reflecting founder effects in the French Canadian population. In HCM, 3 variants account for a large portion of all gene-positive cases.

Complex Traits Posters - Wednesday

PB1651. Stratification of a PMS population based on their response to Human Growth Hormone and Insulin-like Growth Factor 1

Authors:

B. Moffitt¹, S. Sarasua¹, D. Ivankovic², L. Ward¹, K. Valentine¹, W. Bennett³, R. Rogers⁴, K. Phelan⁵, L. Boccuto¹; ¹Clemson Univ., Clemson, SC, ²Anderson Univ., CLEMSON, SC, ³Indiana Univ., Indianapolis, IN, ⁴Greenwood Gen Ctr, Greenville, SC, ⁵Florida Cancer Specialists, Fort Myers, FL

Abstract Body:

Background: Phelan-McDermid syndrome (PMS) is caused by pathogenic variants in the *SHANK3* gene or deletions of the distal region of chromosome 22. PMS is characterized by intellectual disability, autistic features, developmental delays, and neonatal hypotonia. Previous studies have found that insulin-like growth factor 1 (IGF-1) and human growth hormone (hGH) can reverse a range of deficits in PMS. This study aims to characterize the metabolic profile of a PMS cohort, outline potential biomarkers associated with abnormal responses to IGF-1 and/or hGH, and identify individuals with PMS who would benefit from IGF-1 or hGH treatments or who would be at higher risk for reduced or adverse responses to these compounds. Methods: Metabolic profiling of lymphoblastoid cell lines from 48 individuals with PMS and 50 controls was performed using Biolog Phenotype Mammalian Microarray plates (PM-Ms) encompassing 776 metabolites. Subpopulations were determined by taking the top and bottom 25% of responders to hGH and IGF-1. Correlation of the metabolic data versus the baseline glucose metabolic activity was conducted to determine population subgroups based on only the effect of the hormones on the metabolism of glucose. Results: A distinct metabolic profile for individuals with PMS showed a reduced ability to metabolize major energy sources and a higher metabolism of alternative energy sources. This is thought to be a compensatory mechanism. The analysis of the metabolic response to hGH or IGF-1 highlighted a major overlap between both high and low responders, validating the model and suggesting that the two growth factors share a large number of target pathways. The data allowed for stratification of the PMS population with remarkable differences between the high- and low-responder profiles. When we investigated the effect of hGH and IGF- on the metabolism of glucose, the correlation between the high responder subgroups showed less similarity, whereas the low responders were still relatively similar. Conclusions: The classification of individuals with PMS into subgroups based upon response to a hormone can be used to investigate different pathogenic mechanisms, identify molecular biomarkers, explore the response to candidate drugs in an in vitro model, and eventually select better candidates for clinical trials to optimize the response to treatment and minimize the side effects.

Complex Traits Posters - Thursday

PB1652. Stratified LD score regression with 3D genomic features in metabolically relevant cell types implicates a role for pancreatic alpha cells in the pathogenesis of childhood obesity.

Authors:

K. Trang¹, M. C. Pahl¹, J. A. Pippin¹, P. Seale², P. M. Titchenell², W. Yang³, K. Kaestner², A. D. Wells¹, S. F. A. Grant¹; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Inst. for Diabetes, Obesity and Metabolism, Univ. of Pennsylvania, Philadelphia, PA, ³Inst. for Translational Med. and Therapeutics (ITMAT), Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Obesity confers a considerable burden on society and quality of life. Of note, the prevalence of it in childhood is increasing worldwide, along with comorbidities that include type 2 diabetes and cardiovascular disease in later life. We previously led the GWAS efforts for childhood obesity on behalf of the Early Growth Genetics (EGG) Consortium, revealing loci associated with the trait. However, it is unclear in which cellular context these loci confer their effects; furthermore, it is clear that additional efforts are required to characterize the causal variant(s) and corresponding effector genes at these loci. Leveraging our high-resolution Hi-C, ATAC-seq and RNA-seq datasets derived from sorted human pancreatic beta, alpha, acinar cells, skeletal muscle myotubes differentiated from primary myoblasts, adipocytes differentiated in vitro from primary preadipocytes (pre- and post-differentiation) and primary hepatocyte cells, we carried out stratified LD regression score in metabolically relevant cell types in order to further our understanding of disease etiology. This approach calculates the proportion of genome-wide SNP heritability attributable to our derived cell type-specific features in order to estimate each cell-type polygenic contributions to the disease heritability. Interestingly, we observed a significant 8.9-fold enrichment in pancreatic alpha cells ($P=0.027$), along with trends in additional key cell types. Given this observation of significant enrichment of childhood obesity loci in the specific setting of pancreatic alpha cells with our genomic features of interest, we are now motivated to carry out a variant to gene mapping strategy in this cellular setting going forward.

Complex Traits Posters - Wednesday

PB1653. Study of gene-environment interactions suggests a personalised medicine approach for ALS

Authors:

J. Cooper-Knock¹, C. Harvey¹, S. Zhang², K. Kenna³, T. Julian⁴, S. Boddy¹, M. Islam¹, C. McDermott¹; ¹Univ. of Sheffield, Sheffield, United Kingdom, ²Stanford Univ., Palo Alto, CA, ³UMC Utrecht, Utrecht, Netherlands, ⁴Univ. of Manchester, Manchester, United Kingdom

Abstract Body:

Amyotrophic lateral sclerosis (ALS) is a common and incurable neurodegenerative disease. Although 10% of ALS is monogenic, the majority of disease is caused by a complex interaction of genetic and environmental risk factors. We have previously used Mendelian randomization (MR) to show that serum isoleucine is positively linked to risk of ALS and that this effect is mediated via depletion of vitamin B12 (Boddy et al., 2022). The principle of MR is that environmental exposures can be measured by genetic predisposition. We have taken advantage of this fact to perform a data-driven gene-environment screen. Serum isoleucine was quantified as a discrete continuous variable based on the number of isoleucine-associated alleles per individual. We then applied a version of rare variant burden testing (Lin et al., 2016) to test for a significant interaction between serum isoleucine and missense genetic variants genome-wide using whole genome sequencing data from 3,727 ALS patients and 1,687 controls (number of variants = 31). There was no evidence of statistical inflation ($\lambda=1.005$) and one gene was significant after Bonferroni multiple testing: PDIA3 (iSKAT, $p=9.01E-6$). My analysis suggests that missense mutations within PDIA3 protect against isoleucine-induced ALS. Elevated levels of PDIA3 have been found in spinal cord tissue from ALS patients and recently it has been shown that PDIA3 is involved in the triggering of apoptosis in response to misfolded proteins suggesting that PDIA3 function may exacerbate neurotoxicity. Depletion of vitamin B12 induces ER stress that would in-turn be expected to increase PDIA3 expression. We propose that missense mutations within PDIA3 avert isoleucine-induced neurotoxicity resulting from this pathway. The success of this method is the platform for a larger systematic study of gene-environment interactions using the total set of ALS-associated genetic and environmental risk factors.

Complex Traits Posters - Wednesday

PB1655. Telomere length associated rare variant candidate gene study in idiopathic pulmonary fibrosis

Authors:

J. Radder, J. F. McDyer, J. K. Alder, A. Morris; Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract Body:

BACKGROUND: Idiopathic pulmonary fibrosis (IPF) is a chronic fibrosing lung disease with significant morbidity and mortality. Telomere length is increasingly recognized as a significant mediator of IPF pathogenesis. At least one third of individuals with familial IPF have telomere-related mutations and individuals with short telomeres even in the absence of known mutations have been demonstrated to have shorter lung transplant-free survival and more rapidly progressing disease. We sought to test for association between rare variants in genes previously reported to be associated with telomere length and IPF using a case-control approach.

METHODS: Whole genome sequencing was performed on 316 individuals with IPF (cases) and 429 individuals with no evidence of IPF (controls) using Illumina technology. Alignment to GrCh38 and variant calling was performed using a standard BWA/GATK4 pathway. Telomere length was calculated using TelSeq. Genes previously identified as significantly associated with telomere length were chosen as candidate genes and single nucleotide variants that were rare in a European reference population from gnomAD (MAF < 0.05). Association testing using a case-control approach was performed for gene-based tests using SKAT-O and single variant tests using the logistic score test with age, sex, and top eigenvectors from population stratification as covariates.

RESULTS: There was a significant difference in telomere length between cases and controls (cases 4.1, controls 4.5, $P=3.25 \times 10^{-10}$). Using a groupwise test across candidate genes we identified three significantly associated genes including *ABCB9* ($P=4.68 \times 10^{-6}$), *OGFOD2* (8.68×10^{-6}), and *SH2B3* (1.58×10^{-5}). We also tested for association between individual rare single nucleotide variants and the trait with top associations in the genes *ZMYM4*, *VIPR2*, *SH2B3*, and *ABCB9*.

CONCLUSIONS: Using gene-based and single rare variant-based association tests, we identified several candidate genes or rare variants in candidate genes that were associated with IPF. We chose to perform this analysis using all rare variants rather than filtering only for functional variants. Interestingly, while well-known telomere-associated genes like *TERT* reached suggestive study-wide significance using this approach, those reaching study-wide significance were less commonly recognized genes suggesting a need for further investigation of whether these genes play a non-causative but mediating role in the development of IPF.

Complex Traits Posters - Thursday

PB1656. Telomere length, and Parkinson's disease risk, age at onset, and presentation: Mendelian randomization analyses suggest no causal relationships

Authors:

A. Iyengar¹, E. Misicka¹, F. B. S. Briggs^{1,2}; ¹Case Western Reserve Univ., Cleveland, OH, ²Cleveland Inst. for Computational Biology, Cleveland, OH

Abstract Body:

Background: Parkinson's disease (PD) is the second-most common neurodegenerative disorder, affecting approximately 1 million Americans. PD is typically characterized by motor issues such as tremors and gait difficulty. Because PD is most prevalent in aging populations, shortened telomeres may be an underlying risk factor for development. This study explores a potential causal relationship between genetically-driven telomere length (TL) and various aspects of PD to determine whether TL affects PD risk, onset, and/or presentation.

Objective: To investigate the effects of TL on multiple PD phenotypes using Mendelian randomization (MR), a robust tool for causal analysis.

Methods: MR is a form of instrumental variable analysis utilizing genome-wide association (GWA) summary statistics to infer causality between phenotypes. Individual variants associated with an exposure or phenotype of interest are identified in both exposure and outcome GWA datasets, and the effect estimates for each are combined into a ratio that can then be meta-analyzed using inverse variance-weighted (IVW) meta-analysis to investigate the overall effect of the exposure on the outcome. IVW and other two-sample (2S) MR approaches were performed to investigate the potential causal effects of TL on PD risk, age at onset (AAO), tremor-dominant (TD) or postural instability/gait difficulty (PIGD) motor phenotype (MP), and a TD-PIGD score ratio (MPR). A genetic instrument for TL was created from 197 genetic variants associated with TL at genome-wide significance in a sample of 472,174 individuals from the UK Biobank. Summary statistics for PD phenotypes were extracted from the IPDGC data portal, with sample sizes of 3,212 for MP and MPR, 28,568 individuals for PD AAO, and 37,688 PD cases and 1.4 million controls for PD risk. Genetic variants in the TL instrument were clumped at an LD threshold of $r^2 < 0.05$ using the 1000 Genomes EUR Reference Panel.

Results: Using a 2SMR IVW approach, TL was not found to be associated with PD risk ($\beta_{IVW}=0.15$, $p=0.09$), AAO ($\beta_{IVW}=0.75$, $p=0.16$), MP ($\beta_{IVW}=0.36$, $p=0.17$), or MPR ($\beta_{IVW}=-0.11$, $p=0.26$). Null associations were also observed for other 2SMR approaches (i.e., MR-Egger, MR-PRESSO).

Conclusions: There is no evidence that genetically-driven TL causally influences risk, age at onset, or disease subtype of PD.

Complex Traits Posters - Wednesday

PB1657. THE ASSOCIATION OF *FSHR* POLYMORPHISMS WITH PCOS IN PUNJABI POPULATION

Authors:

A. Kaur; Guru Nanak Dev Univ., AMRITSAR, India

Abstract Body:

Background: Polycystic ovary syndrome (PCOS) is one of the most common endocrine-metabolic disorders affecting a significant number of women at their child bearing age around the world and characterized by hyperandrogenism, menstrual irregularities and polycystic ovarian morphology. Recent Genome-wide association studies (GWAS) have identified the 11 susceptibility loci for PCOS including *THADA*, *LHCGR*, *FSHR* etc. There is scarcity of data of North Indian population that signifies the underlying genetic mechanisms which lead to development of PCOS. In present study we investigated the association of *FSHR* genetic variants with PCOS in Punjabi population. **Methodology:** A case-control study, involving 200 women with PCOS and 200 age-matched healthy controls, was conducted. Relevant data of the participants was collected after taking informed consent. *FSHR* polymorphisms (rs6166, rs6165 and rs1394205) were genotyped using polymerase chain reaction-restriction fragment length polymorphism. Biochemical analysis was done in PCOS cases and controls. Statistical analysis was performed using SPSS (version21, IBM SPSS, NY, USA). **Results:** Anthropometric measurements like BMI and WHR revealed a significant difference between PCOS cases and controls ($p < 0.000$ and $p = 0.0001$, respectively). Levels of cholesterol and triglycerides were found to be significantly higher and levels of HDL was lower in PCOS women than controls. In rs6166 polymorphism, it was observed that heterozygote genotypic frequency is more than both homozygote wild and mutant genotypic frequencies (Cases: AG-49%, AA-32% and GG-19%; Controls: AG-53%, AA-28.5% and GG-18.5%, respectively). Genotypic and allelic frequency is not significantly different with $p = 0.69$ and $p = 0.66$, respectively. Significant difference between genotypes of cases and controls was found for rs6165 polymorphism with $p = 0.03$. Heterozygote genotype (AG) of rs6165 was found to conferred 1.8 times risk of PCOS with $p = 0.01$. Dominant and co-dominant model of rs6165 was also revealed that both models provide significant risk towards the progression of PCOS (1.5 and 1.7 folds, respectively). Genetic distribution of rs1394205 did not show any significant difference for genotypic and allelic frequencies. **Conclusion:** Our study reveals the significant association of *FSHR* rs6165 polymorphism with PCOS in dominant and co-dominant model whereas no association was found for other two rs6166 and rs1394205 polymorphisms. It was concluded that polymorphism rs6165 could contribute to the impaired folliculogenesis in PCOS.

Complex Traits Posters - Thursday

PB1658. The bidirectional causal effects of brain morphology across the life course and risk of Alzheimer's disease: A cross-cohort comparison and Mendelian randomization meta-analysis.

Authors:

R. Korologou-Linden¹, B. Xu², E. Coulthard¹, E. Walton³, A. Wearn¹, G. Hemani⁴, T. White¹, C. Cecil⁵, T. Sharp¹, H. Tiemeier⁶, The IMAGEN consortium, L. Howe⁴, Y. Ben-Shlomo¹, N. Davies⁴, E. L. Anderson¹; ¹Univ. of Bristol, Bristol, United Kingdom, ²Erasmus MC Univ. Med. Ctr., Dept. of Child and Adolescent Psychiatry and Psychology Rotterdam, UK, Rotterdam, Netherlands, ³Univ. of Bath, Bath, United Kingdom, ⁴Univ. of Bristol, Bristol, United Kingdom, ⁵Erasmus MC Univ. Med. center, Rotterdam, Netherlands, ⁶Harvard Univ., Boston, MA

Abstract Body:

Neuropathological changes due to Alzheimer's disease (AD) can occur decades before clinical symptoms. We used bidirectional two-sample Mendelian randomization to estimate the effects of genetic liability to AD on global and regional cortical thickness, total intracranial volume, volume of subcortical structures and total white matter in 37,680 participants aged eight to 81 years. We also examined the effects of global and regional cortical thickness and subcortical volumes on AD risk in up to 37,741 participants. AD risk alleles have an age-dependent effect on a range of cortical and subcortical brain structures. Some of the identified structures are not typically implicated in AD, such as those in the striatum such as the thalamus, with consistent effects from childhood to late adulthood. We found little evidence to suggest brain morphology alters AD risk. Genetic liability to AD is likely to affect AD risk primarily through mechanisms affecting indicators of brain morphology in later life (e.g. potential neurodegeneration), rather than structural brain reserve.

Complex Traits Posters - Wednesday

PB1659. The causal effect of blood lipid metabolism related traits with depression phenotypes: the evidence from mendelian randomization study

Authors:

S. Tao¹, X. Ye², P. Huang², W. Duan³, S. Yang¹; ¹Dept. of Biostatistics, Ctr. for Global Hlth., Sch. of Publ. Hlth., Nanjing Med. Univ., Nanjing, China, Nanjing, China, ²Dept. of Epidemiology, Ctr. for Global Hlth., Sch. of Publ. Hlth., Nanjing Med. Univ., Nanjing, China, Nanjing, China, ³Dept. of Bioinformatics, Sch. of BioMed. Engineering and Informatics, Nanjing Med. Univ., Nanjing, China, Nanjing, China

Abstract Body:

Depression is one of the most universal psychiatric disorders with severe symptoms, such as loss of interest or pleasure, recurrent thoughts of death, suicide. Emerging genome wide association studies (GWAS) have identified significant loci of depression, but its etiology and mechanism are still unknown. Previous cohort studies and cross-sectional studies have demonstrated a positive association between blood lipid metabolism related traits, including triglyceride (TG), non-alcoholic fatty liver disease (NAFLD), and alanine transaminase (ALT) and depression phenotypes, including depressive symptom (DS) and major depressive disorder (MDD), but the pathogenesis of the association has not been elucidated. Here, we used two-sample mendelian randomization (MR) strategy to identify the potential causal effect of blood lipid metabolism related traits, including blood lipids, NAFLD, and transaminase on depression phenotypes in European population. Therefore, we collected four kinds of summary statistics: (i) depressive symptom (DS) and major depressive disorder (MDD); (ii) four of blood lipid, including total cholesterol (TC), TG, low-density lipoprotein cholesterol (LDL), and high-density lipoprotein cholesterol (HDL); (iii) NAFLD activity score; (iv) ALT and aspartate transaminase (AST); First, using the same clumping criteria ($P < 5E-8$ and $r^2 > 0.001$ within 10 Mb), we identified, on average, 30 (ranging from 11 to 54) instrumental variables (IVs) for the seven traits. Then, we estimated the association of non-alcoholic fatty liver, alanine transaminase, and blood lipids with DS or MDD using the inverse-variance-weighted (IVW) method. Furthermore, to validate the reliability and robustness of results from MR analyses, we performed three types of sensitivity analyses including heterogeneity test, pleiotropic test, and leave-one-out (LOO) test. We performed IVW with multiplicative random effects when instrument SNPs showed heterogeneity ($P < 0.05$). From the results of MR analysis supported by MR-IVW, TC, NAFLD activity score, and ALT were causally associated with DS, with beta of 0.0067 (95% CI: 0.0007-0.0126, $P = 0.028$), 0.0014 (95% CI: 0.0002-0.0027, $P = 0.026$), and 0.0601 (95% CI: 0.0018-0.1184, $P = 0.043$), respectively. TG was causally associated with MDD (OR = 1.111, 95% CI: 1.033-1.188, $P = 7.8E-3$). Our research provided new evidence to support the causal effect of blood lipid metabolism related traits on depression phenotypes, which indicates screening populations with abnormal indicators related to blood lipid metabolism would be a feasible strategy to detect depression and then reduce the psychiatric disorder burden.

Complex Traits Posters - Thursday

PB1660. The effect of population structure and ancestry-related assortative mating on the genetic architecture of autism spectrum disorder.

Authors:

J. Zhang¹, J. D. Weissenkampen¹, R. L. Kember¹, E. S. Brodtkin¹, L. Almasy², M. Bucan¹, R. Sebro³; ¹Univ. of Pennsylvania, Philadelphia, PA, ²Children's Hosp. of Philadelphia, Philadelphia, PA, ³Mayo Clinic Florida, Jacksonville Beach, FL

Abstract Body:

Assortative mating in several neuropsychiatric disorders, including autism spectrum disorder (ASD) has been noted. It is unknown whether the phenotypic similarity between parents of children with ASD could be because spouse choice was based on phenotypes influenced by different ASD-related genes leading to correlations between parents ASD polygenic scores (PGS), or if spouse choice was based on ancestry and that there are ASD-related genes associated with underlying ancestry. To address these questions, we analyzed two family-based ASD collections: the Simons Foundation Powering Autism Research for Knowledge (SPARK) (1,505 families) and the Simons Simplex Collection (SSC) (2,285 families). We found phenotypic assortative mating for age ($r_{\text{SPARK}}=0.72$, $P<0.001$; $r_{\text{SSC}}=0.73$, $P<0.001$), education level ($r_{\text{SPARK}}=0.45$, $P<0.001$; $r_{\text{SSC}}=0.48$, $P<0.001$), and for quantitative autistic traits (in SSC) assessed by Social Responsiveness Scale (SRS) ($r_{\text{SSC_SRS_total}}=0.34$, $P<0.001$) and the Broad Autism Phenotype Questionnaire (BAPQ) ($r_{\text{SSC_BAPQ_total}}=0.13$, $P<0.001$) in families of European ancestry. We found ancestry-related assortative mating between spouses of European ancestry (measured by the spousal correlations of principal components (PC) from the principal component analysis with 1000 Genomes participants of European ancestry) in SPARK ($r_{\text{PC1}}=0.38$, $P<0.001$; $r_{\text{PC2}}=0.46$, $P<0.001$; $r_{\text{PC3}}=0.38$, $P<0.001$) and SSC ($r_{\text{PC1}}=0.45$, $P<0.001$; $r_{\text{PC2}}=0.54$, $P<0.001$; $r_{\text{PC3}}=0.38$, $P<0.001$). This ancestry-related assortative mating led to greater induced linkage disequilibrium (LD) measured by r^2 between highly ancestry-informative single nucleotide polymorphisms (SNPs) on different chromosomes compared to the LD between less ancestry-informative SNPs on different chromosomes (SPARK: $P_{\text{fathers}}=0.008$, $P_{\text{mother}}=0.008$, $P_{\text{unaffected_siblings}}=0.021$; SSC: $P_{\text{fathers}}=0.027$, $P_{\text{mother}}=0.055$, $P_{\text{unaffected_siblings}}=0.097$). There was no spousal correlation of ASD PGS after controlling for population substructure in SPARK ($r=0.04$, $P=0.139$). The presence of phenotypic assortative mating did not lead to a correlation between spouses' ASD PGS. This study shows that the phenotypic assortative mating for autistic traits is likely due to ancestry-based assortative mating in SPARK and SSC. The maximum induced LD between highly ancestry-informative SNPs on different chromosomes can be greater than 0.1 (measured by r^2), and although values of this magnitude were rare, is a phenomenon that is worth noting.

Complex Traits Posters - Wednesday

PB1661*. The first GWAS on intrahepatic cholestasis of pregnancy unveils novel bile acid metabolism related associations.

Authors:

Finland (FIMM), Helsinki, Finland, ¹⁷Aalborg Univ., Dept. of Hlth. Sci. and Technology, Aarhus, Denmark, ¹⁸Big Data Inst., Oxford Univ., Oxford, Oxfordshire, United Kingdom, ¹⁹Tampere Univ. Hosp. and Tampere Univ., Tampere, Finland, ²⁰Helsinki Univ. Hosp. and Univ. of Helsinki, Helsinki, Finland

Abstract Body:

Background: Intrahepatic cholestasis of pregnancy (ICP) is a common, complex disorder, usually diagnosed in the second half of pregnancy. It is characterized by pruritus and elevated serum bile acids. The incidence of ICP varies with geographic location and ancestry (between 0.2% and 2%). It is linked to increased risk of fetal complications including preterm labor, fetal asphyxia, meconium-stained amniotic fluid, stillbirth, and is associated with high maternal rates of gestational diabetes and preeclampsia. Genes coding for bile acid transporters have been implicated in ICP, but no genome-wide association study (GWAS) has been published so far. **Methods:** We performed multi-study ICP GWAS meta-analysis in >2,132 participants having a history of ICP and 415,682 female controls from the FinnGen, DeCODE, Danish blood donor study (DBDS) and Estonian genome center of the University of Tartu (EGCUT) studies. We identified putative candidate genes and assessed their potential causality within each associated locus by examining each variants eQTL, sQTL and pQTL effect in various databases. We also examined the relationship of ICP and other disorders via PheWAS, genetic correlation and comorbidity analysis. **Results:** GWAS identified twenty associated loci ($p < 5 \times 10^{-8}$). Many of the identified genes are expressed particularly in the liver and are known to be involved in bile acid synthesis (e.g. *CYP7A1*), transportation (several ABC protein coding genes), and related processing of bile acids. 14/20 loci were associated ($P < 1 \times 10^{-6}$) with liver or cardiovascular biomarkers, including albumin, LDL, cholesterol, and gamma glutamyltransferase. Comorbidity analysis suggest association with various pregnancy complications and autoimmune diseases. PheWAS for lead variants show ICP-specific findings, associations with use of statin medication, type 2 diabetes, and cholelithiasis. The latter association was further supported by genetic correlation analysis. **Discussion:** Detailed understanding of the genetic predisposition to ICP has remained elusive, but in this first ICP GWAS we discover 20 associated loci, and outline the genetic architecture predisposing individuals to ICP. We also provide more detailed support for previous findings of impaired bile secretion in ICP.

Complex Traits Posters - Thursday

PB1662. The genetic architecture of the corpus callosum and its subregions

Authors:

M. Campbell; Univ. of Cape Town, Cape Town, South Africa

Abstract Body:

Background: Regional surface area and thickness of the cerebral cortex and volume of subcortical structures are highly heritable brain morphological features with complex, polygenic genetic architectures. However, the genetic architecture of the corpus callosum (CC) and its subregions remains largely unclear. We aim to determine the heritability and investigate the genetic architecture of CC volume and each subregion and the extent to which this overlaps with that of psychiatric disorders.

Methods: MOSTest method was applied to genetic and T1-weighted MRI data of 40,894 individuals from the UK-biobank to conduct a multivariate GWAS aiming to boost genetic discovery and to assess the pleiotropic effects of common variants across the five subregions of the CC (posterior, mid posterior, central, mid anterior and anterior) obtained by running the automatic subcortical segmentation algorithm in FreeSurfer 5.3. MOSTest was run on each subregion, co-varying for total intracranial volume, sex, age squared, scanner and the first 20 genetic principal components. Gene-set enrichment analyses were performed using MAGMA. Linkage disequilibrium score regression (LDSC) was used to determine the SNP-based heritability of the CC and its subregions and the genetic correlation between each subregion and a variety of psychiatric disorders.

Results: Following MOSTest, 70 independent loci were identified across the 5 subregions of the CC ($p < 5 \times 10^{-8}$). Using LDSC, we found evidence to suggest that total CC volume is heritable ($h^2_{\text{SNP}} = 0.38$, $SE = 0.03$). Heritability estimates for volume of the subregions range from 0.22 ($SE = 0.02$) in the mid-posterior subregion to 0.37 ($SE = 0.03$) in the posterior subregion. Significant variants show enrichment in pathways related to regulation of the nervous system and cell development, neurogenesis, and regulation of neuron differentiation. Gene-set analysis revealed 156 significant genes ($p < 2.6 \times 10^{-6}$). Many of the significant SNPs have been previously associated with white matter hyperintensity volume as well as a range of psychiatric disorders. Bipolar disorder (BD) showed significant negative genetic correlation with volumes of the posterior subregion ($r_g = -0.11$; $p = 1.6 \times 10^{-3}$) and total CC volume ($r_g = -0.10$; $p = 4 \times 10^{-3}$).

Conclusions: We provide the first evidence to suggest that total CC volume and volumes of the CC subregions are heritable. Gene set enrichment analyses identified pathways related to neuron development and neurogenesis, suggesting that CC alteration may have an independent developmental origin. We also provide evidence for shared genetic etiology between BD risk and altered CC volumes.

Complex Traits Posters - Wednesday

PB1663. The genetic drivers of young- and early-onset Parkinson's Disease in India

Authors:

S. Andrews¹, P. L. Kukkle^{2,3}, R. Menon⁴, T. S. Geetha⁴, V. Goyal^{5,6,7}, R. M. Kandadai⁸, H. Kumar⁹, R. Borgohain⁸, A. Mukherjee¹⁰, P. M. Wadia¹¹, R. Yadav¹², S. Desai¹³, N. Kumar¹⁴, D. Fndn., Bangalore, India

Abstract Body:

Background: Recent studies have advanced our understanding of the genetic drivers of Parkinson's Disease (PD). Rare variants in more than 20 genes are generally accepted to be causal for PD, and the latest PD GWAS study identified 90 independent risk loci. However, there remains a gap in our understanding of PD genetics outside of the European populations in which the vast majority of these findings occurred. Limited, small-scale studies in East and South Asians have demonstrated that distinct risk factors may exist in these populations, emphasizing the need to characterize the genetic factors driving PD in these groups directly.

Methods: PD subjects with age of onset ≤ 50 years (encompassing juvenile, young, or early-onset PD) were recruited from 10 specialty movement disorder centers across India over a 2-year period. PD cases (N = 675) were genetically profiled via the South Asian Research Genotyping Array (SARGAM) and WES at 60x average coverage. Ancestry-matched controls (N = 1363) were derived from the reference WGS GenomeAsia 100K population, Phase 2 (GASPh2). GWAS of common variants (MAF > 1%) for PD diagnosis and symptom age of onset was performed using merged SARGAM PD case data and GASPh2 WGS control data. PD case WES data was merged with WGS control data, adjusted for platform and/or coverage differences, and used to quantify differential burden of rare (MAF < 1%) and predicted deleterious (per PolyPhen2 and CADD) variants. Finally, WES data was also used to identify PD cases harboring pathogenic/likely pathogenic variants in 21 previously identified monogenic PD genes.

Results: Common variant GWAS of PD diagnosis yielded a GW significant result (lead SNP p-value = 4.1E-11) in a region containing the canonical PD gene *SNCA*. This signal strongly colocalized (posterior probability = 0.88) with *SNCA* region signal from European PD GWAS. Numerous additional loci reached a suggestive significance (p < 1E-5) threshold for both PD diagnosis and age of onset phenotypes; GSEA of genes downstream of associated SNPs (via eQTL and chromatin interaction mapping) implicated synaptic transmission and immune cell migration-related pathways. Pathogenic variants, including homozygous *PRKN* deletions, were identified in 9.8% of PD cases. We will also report on top-ranked genes from WES-based gene burden studies of LoF and deleterious variants.

Conclusions & Future Directions: This study constitutes the largest genetic investigation of PD and first demonstration of *SNCA* association with PD in an Indian population to date. Ongoing work will expand

ASHG 2022 Annual Meeting Poster Abstracts

this cohort by an additional 1,000 PD cases, enabling improved statistical power to detect PD genes in this understudied group.

Complex Traits Posters - Thursday

PB1664. The genetic risk score affects the lifetime blood pressure and obesity modify the effect of genetic risk

Authors:

H-Y. Park¹, Y. Kim², B-J. Kim², N-K. Lim³; ¹Korea NIH, Cheongju, Korea, Republic of, ²Korea NIH, Cheongju-si, Korea, Republic of, ³Korea NIH, Osong-eup, Heungduk-gu, Cheongju, Korea, Republic of

Abstract Body:

Background: Both of obesity and adverse genetic predisposition are known to be major risk factors for hypertension. This study aimed to evaluate the effect of polygenic risk score (PRS) on life-time blood pressure (BP) and whether the genetic risk of hypertension is modified by obesity. **Methods:** Our study was based on a large, prospective, community-based cohort in Korea. Of 10,030, 7,603 participants aged from 40 to 69 at baseline were selected for this analysis. The genotype data were derived from genome-wide association study using the Korea Biobank Array (referred to as KoreanChip) comprised >833,000 markers including >247,000 rare-frequency of functional variants estimated from >2,500 sequencing data in Koreans. Two weighted polygenic risk scores (PRSs) was calculated by summing the number of risk alleles for 86 and 67 single-nucleotide polymorphisms associated with systolic and diastolic blood pressures, respectively. Participants were grouped by body mass index (BMI) as follows: normal, BMI <23; overweight, BMI 23-24.9; obesity, BMI ≥25. And we categorized PRSs into 5 groups based on percentile of PRS (<10%, 10-30%, 30-70%, 70-90%, and >90%). **Results:** Of 7,603 participants, the 4,229 incident hypertension were observed during a median follow-up time of 15.5 years. In blood pressure trajectories using a mixed model, the PRS affects the systolic BP over the life course, and obesity affect the BP in all PRS groups. The diastolic BP showed the similar pattern. Interestingly the diastolic BP was peaked in earlier age in highest PRS group. Compared with having a 20 to 80 percentile of PRS range, the individuals having the PRS in the highest 90% and the lowest 10% had about 2.7 years earlier and 2.7 years later of onset hypertension, respectively. The association between obesity and hypertension was modified by the PRS for systolic blood pressure (P for interaction=0.0053). The effect of obesity on hypertension was greater in individuals with the lowest PRS groups (HR, 1.57; 95% CI, 1.36-1.81 per category of obesity) compared those with the highest PRS group (hazard ratio, 1.38; 95% CI, 1.23-1.54). **Conclusions:** We demonstrated that genetic information can improve prediction of onset age of hypertension and lifetime BP, and the appropriate weight control can modify the onset age of hypertension.

Complex Traits Posters - Wednesday

PB1665. The heritable component of human longevity is highly polygenic and pleiotropic.

Authors:

R. Jabal-Ameli, J-R. Lin, Q. Zhang, J. Mitra, Z. Wang, N. Nguyen, M. Khusidman, G. Atzmon, S. Milman, J. Vijg, N. Barzilai, Z. Zhang; Albert Einstein Coll. of Med., New York, NY

Abstract Body:

The highly polygenic nature of human longevity renders cross-trait pleiotropy an indispensable feature of its genetic architecture. Leveraging the genetic correlation between the aging-related traits (ARTs), we sought to model the additive variance in lifespan as a function of cumulative liability from pleiotropic segregating variants. We tracked allele frequency changes as a function of viability across different age bins and prioritized 22 variants with an immediate implication on the lipid metabolism, body mass index (BMI) and cognitive performance, among other traits. Given the highly complex and non-linear interactions between the genetic determinants of longevity, we reasoned that a composite polygenic score would approximate a substantial portion of the variance in lifespan and developed the integrated longevity genetic scores (*iLGSs*) for distinguishing exceptional survival. We showed that coefficients derived from our ensemble model could potentially reveal an interesting pattern of genomic pleiotropy specific to lifespan. We assessed the predictive performance of our model for distinguishing the enrichment of exceptional longevity among long-lived individuals in two replication cohorts and showed that the median lifespan in the highest decile of our composite prognostic index is up to 4.8 years longer. Finally, using the proteomic correlates of *iLGS*, we identified protein markers associated with exceptional longevity irrespective of chronological age and prioritized drugs with repurposing potentials for gerotherapeutics. Together, our approach demonstrates a promising framework for polygenic modeling of additive liability conferred by ARTs in defining exceptional longevity and assisting the identification of individuals at higher risk of mortality for targeted lifestyle modifications earlier in life. Furthermore, proteomic correlates of *iLGS* highlighted the functional pathway upstream of the PI3K-Akt that can be effectively targeted to slow down aging and extend lifespan.

Complex Traits Posters - Thursday

PB1666. *The impact of copy number variants in the genetic testing yield of LQTS patients.*

Authors:

R. Celeggin¹, G. Meneguzzo², R. Bariani¹, A. Zorzi¹, M. Cason¹, G. Brunetti¹, M. Bueno Marinas¹, C. Basso¹, D. Corrado¹, P. Sarto², B. Bauce¹, K. Pilichou¹; ¹Dept. of Cardio-Thoraco-Vascular Sci. and Publ. Hlth., Univ. of Padua, Padua, Italy, ²Sports Med. Unit, AULSS 2, Treviso, Italy

Abstract Body:

Background. The long QT syndrome (LQTS) is an inherited cardiac disorder characterized by prolonged QT interval on the surface electrocardiogram. It affects 1:2500 individuals, causing lethal ventricular tachyarrhythmias. A causative variant is identified in up to 75% of cases and detection rate for copy number variants (CNVs) among genotype elusive patients by traditional analysis, seem to be around 2-11.5%. Methods. Our cohort of 96 consecutive LQTS index cases, underwent DNA sequencing on the MiSeq platform (Illumina) using the Trusight Cardio panel. CNVs calling was performed by using a modified version of the Exome Depth package. Putative CNVs identified by NGS were confirmed by Multiplex Ligation dependent Probe Amplification. Literature analysis followed the search keyword strings: copy number variants OR CNVs AND long QT syndrome OR LQTS. Results. In our cohort almost 40% (37/96) of LQTS patients carried a putative causative point variant in LQTS related major genes. Noteworthy, our analysis revealed that 5 out of the 59 (8.4%) genotype negative patients carried CNVs, either deletions or duplications. Specifically, we identified 2 deletion on KCNQ1, 1 deletion and 1 duplication on KCNH2 and a duplication of both KCNE1 and KCNE2. Cascade genetic screening revealed the co-segregation of these variants with the clinical phenotype. Conclusion. Genetic screening in LQTS patients should be implement by the research of structural variants such as CNVs. Their prevalence in the disease allow to increase the yield of the genetic testing of about 5%, and offer the chance to better investigate asymptomatic family members.

Complex Traits Posters - Wednesday

PB1667. The impact of exercise on gene regulation in association with complex trait genetics

Authors:

N. Vetr, N. Gay, S. Montgomery; Stanford Univ., Stanford, CA

Abstract Body:

Recurrent exercise can influence risk for a range of complex genetic diseases. However, the molecular basis of exercise's impact on gene function and subsequent disease risk across the body is largely restricted to easily biopsied tissues. Gene expression data across 15 distinct tissues collected through MoTrPAC's rat exercise training experiment provides a unique opportunity to clarify how exercise can affect tissue-specific gene expression and how these adaptations may impact complex disease genes in humans. We integrate this multi-tissue atlas of gene expression changes with gene-disease targets, genetic regulation of expression, and trait relationship data in humans. Consensus from multiple approaches prioritized specific tissues and genes where exercise impacts gene expression and can modify disease risk. Specifically, we identify a total of 5,523 trait-tissue-gene triplets affected by exercise that correspond to effects across a range of 114 cardiometabolic, immunological, endocrine, and other phenotypes.

Complex Traits Posters - Thursday

PB1668. The impact of HIV-1 Vpr on host transcription in macrophages.

Authors:

M. Virgilio, W. Disbennett, T. Chen, J. Lubow, J. D. Welch, K. L. Collins; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Vpr is a highly conserved HIV accessory protein that is necessary for optimal replication in macrophages, but its mechanism of action is poorly understood. Studies using human lymphoid tissue, which are rich in both T cells and macrophages, have found that loss of Vpr decreases virus production but only when the virus strain used is capable of efficiently infecting macrophages. These studies provide evidence that Vpr enhances infection of macrophages and increases viral burden in tissues where macrophages reside. Because Vpr is packaged into the virion and localizes to the nucleus, it may enhance early viral replication events. However, *vpr*-null virus in which Vpr protein is provided by trans-complementation in the producer cells replicates poorly compared to wild-type virus in mononuclear phagocytes. Thus, there is genetic evidence that Vpr's role in the HIV replication cycle continues into late stages. Our group has demonstrated that Vpr counteracts mannose receptor, a macrophage specific restriction factor that targets Env and Env-containing virions for lysosomal degradation. Mannose receptor protein levels are inversely proportional to the amount of viral output from macrophages, affecting spread to neighboring cells. Importantly, Vpr reduces transcription of the gene encoding mannose receptor, *MRC1*, as well as other innate immune genes through an unknown mechanism. Vpr's ability to specifically alter transcription levels of these genes led us to investigate the role of Vpr on global transcription in macrophages from three independent donors using single-cell RNA sequencing. Differential gene expression analysis between *vpr*-WT, and *vpr*-null infected cells revealed thousands of genes were downregulated in the presence of Vpr. Motif scanning of transcriptionally repressed genes revealed several transcription factors (TFs) of interest that Vpr may be targeting to reduce transcription in macrophages. Binding motifs for the master myeloid regulator, PU.1, were found in many suppressed genes, including two known HIV restriction factors - *MRC1* and *IFITM3*. Vpr but not other accessory proteins was able to reduce PU.1 levels in cells that both endogenously and exogenously express PU.1, including primary macrophages. Interestingly, Vpr-dependent degradation of PU.1 was successfully demonstrated with Vpr proteins from several HIV molecular clones as well as from evolutionarily similar Simian Immunodeficiency Virus molecular clones, suggesting degradation of PU.1 may be an evolutionarily conserved function of Vpr. Studies are ongoing to determine whether Vpr targets specific host TFs to alter pathways that influence viral infection and spread.

Complex Traits Posters - Thursday

PB1669. The interacting effects of environmental factors and polygenic risk scores on BMI: application to the multiethnic GENNID family study

Authors:

J. Wan, B. WU, L. Simon, A. Freedland, T. Norden-Krichmar, K. Edwards, American Diabetes Association GENNID Study Group; Univ. of California, Irvine, CA

Abstract Body:

Objective: Polygenic scores (PGS) leverage the effects of genome-wide variants to predict risk of chronic conditions such as obesity and type 2 diabetes (T2D). Environmental factors (EF) such as smoking, diet, physical activity level, and drinking are known risk factors. With the recent developments in PGS as a diagnostic tool, it is important to include EFs and their potential interactions with PGS to enhance the prediction of obesity. We use a multi-ethnic sample of families with T2D to: (1) evaluate the joint effects of a common-variant genetic burden PGS and EF on the body mass index (BMI); (2) to evaluate the prediction of obesity with different models involving the addition of the EFs and PGS-by-EF interaction terms.

Methods: Using 1502 subjects in 259 families from European-American (EA), Mexican-American (MA), African-American (AA), and Japanese-American (JA) families with T2D in the GENNID study, we constructed PGS with the Clumping and Thresholding (C + T) method based on a multi-ethnic GWAS meta-analysis. For each EF, we evaluated the joint effects of PGS and EF on BMI adjusting for age, sex, and self-reported diabetes status using a linear mixed effects model with random intercepts to account for within-family clustering. A pseudo- R^2 summarized the percentage of BMI variance explained by the addition of EF and PGS x EF interaction, and approximate p-values were computed based on a normal distribution. ROC curves and AUC values based on bootstrap resampling compared the ability of different models to predict obesity (BMI>30).

Results: For each ethnic group, the single environmental factor models that explained the most additional variance of BMI beyond PGS were: 2.1% (smoking now, AA), 2.6% (physical activity, EA), 2.5% (liquor drinking now, JA), and 1.4% (low fat diet, MA). The most additional variance of BMI was explained by including these interactions: 1.0% (PGS x diabetic diet, AA), 0.2% (PGS x high fiber diet, EA), 2.4% (PGS x low calorie diet, JA), and 0.5% (PGS x wine now, MA). By adding each EF to the PGS model, prediction beyond PGS improved with at most an AUC increase of the following: 1.1% (high fiber diet, AA), 0.8% (diabetic diet, EA), 2.2% (high fiber diet, JA), and 1% (low fat diet, MA). Adding these interactions to the joint PGS and EF model at most increased the AUC by: 1.4% (PGS x packs per day, AA), 0.8% (PGS x diabetic diet, EA), 1.5% (PGS x low calorie diet, JA), and 1.2% (PGS x low fat diet, MA).

Conclusions: In general, each ethnic group had a distinct environmental risk factor profile. The inclusion of particular environmental factors and their interactions with PGS moderately increased the explained proportion of BMI variance and prediction.

Complex Traits Posters - Wednesday

PB1670. The kynurenine pathway in Alzheimer's disease: A systematic review and meta-analysis.

Authors:

M. Inam, B. S. Fernandes, Z. Zhao; Univ. of Texas Hlth.Sci. Ctr. at Houston, Sch. of BioMed. Informatics, Houston, TX

Abstract Body:

IntroductionThe kynurenine pathway has been increasingly attracting attention as a relevant pathway in neurological disorders, including Alzheimer's disease (AD). Early detection of such metabolic alterations may allow for timely intervention and management, potentially decreasing treatment failure rates. Here, we conducted a systematic review and meta-analysis of the kynurenine pathway metabolites from blood samples in AD.

MethodsPubMed and EMBASE databases were searched from journal inception to April 2022 to identify peer-reviewed case-control studies that assessed kynurenine metabolites in AD compared to healthy controls (HC) in peripheral blood, namely, tryptophan (TRP), kynurenine (KYN), kynurenic acid (KA), quinolinic acid (QA), and 3-hydroxykynurenine (3-HK). The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines were followed. The random effects model parameter was selected when comparing the standardized mean differences (SMD) between groups.

ResultsData were extracted from 18 articles that met the inclusion criteria. The mean sample size for each study for individuals with AD and HC was 32 ± 25 and 37 ± 36 , and the mean age was 74.1 ± 10.5 and 72.7 ± 9.2 , respectively. TRP levels ($n=17$) were decreased in AD (SMD: -0.83, CI95% [-1.15 to -0.50], $p<0.001$). KA levels ($n=8$) were also decreased (SMD: -0.27, CI95% [-0.46 to -0.08], $p=0.005$). There were no significant differences in KYN ($n=10$), 3-HK ($n=7$), and QA ($n=5$) levels, but a significant increase in the KYN/TRP ratio ($n=7$) was observed in AD compared to HC (SMD: 0.55, CI95% [0.04 to 1.05], $p<0.030$).

ConclusionTryptophan, the precursor of the kynurenine pathway, is decreased in individuals with AD. KA, which has neuroprotective effects, is also decreased in AD. The KYN/TRP ratio is increased, suggesting a shift in tryptophan degradation toward the kynurenine pathway. Drugs that target the kynurenine pathway, particularly KA, might be useful in AD treatment. Future studies should validate and explore the utility of this peripheral biomarker as a treatment target.

Complex Traits Posters - Thursday

PB1671. The Largest Asian GWAS for Systemic Sclerosis Identified a Novel High Risk Candidate Causal SNP in the Fcγ-Receptor Gene Region.

Authors:

Y. Ishikawa¹, Systemic Sclerosis Working Group of Japan Ministry of Health, Labor and Welfare, C. TERAO^{1,2,3}; ¹Riken, Ctr. for Integrative Med. Sci., Yokohama, Japan, ²Shizuoka Gen. Hosp., Shizuoka, Japan, ³Sch. of Pharmaceutical Sci., Univ. of Shizuoka, Shizuoka, Japan

Abstract Body:

Objectives: While GWASs have clarified genetic architectures of systemic sclerosis (SSc), the Eurocentric nature of the studies have limited application of the findings to Asians. This study was conducted aiming to identify novel causal SNPs for SSc specific to Japanese as well as those shared with Europeans and to clarify mechanistic effects of the SNPs on SSc pathogenesis. **Methods:** A total of 1,499 cases and 112,609 controls were enrolled in the study leading to the ever-largest Asian GWAS for SSc. The imputation was conducted using the reference panel of the phase 3v5 1,000 genome project data combined with a high-depth WGS data of 3,256 Japanese subjects. We conducted logistic regression analyses and combined the Japanese GWAS results with those of Europeans by an inverse-variance fixed-effect model. Polygenicity and enrichment of functional annotations were evaluated by LDSC, Haploreg and IMPACT programs. We also constructed PRS to predict SSc development. **Results:** We identified three (*FCRLA-FCGR*, *TNFAIP3*, *PLD4*) and four (*EOMES*, *ESR1*, *SLC12A5*, *TPIIP2*) novel loci in the Japanese GWAS and the trans-ethnic meta-analysis, respectively. One of the Japanese novel risk SNPs, rs6697139, located within *FCGR* gene clusters had a strong effect size (OR 2.05, P=4.9×10⁻¹¹). We also found the complete LD variant, rs10917688, was positioned in cis-regulatory element and binding motif for an immunomodulatory transcription factor IRF8 in B cells, another genome-wide significant locus in our trans-ethnic meta-analysis and the previous European GWAS. Notably, the association of risk allele of rs10917688 was significant only in the presence of the risk allele of IRF8. Intriguingly, rs10917688 was annotated as one enhancer-related histone marks, H3K4me1, in B cells, implying that *FCGR* gene(s) in B cells may impact on SSc pathogenesis. Furthermore, significant heritability enrichment of active histone marks was found in B cells both in European and Japanese populations by LDSC, implying a shared disease mechanism where abnormal B-cell activation may be one of the key drivers for the disease development. Finally, PRS using effects sizes of the trans-ethnic meta-analysis moderately fit in the development of Japanese SSc (AUC 0.604) with further improvement by adding IMPACT-annotated SNPs for IRF8-binding in the B-cell line (AUC 0.610), paving a path to personalized medicine for SSc. **Conclusion:** Our study identified seven novel susceptibility loci in SSc. Downstream analyses highlighted a novel disease mechanism of SSc where an interactive role of *FCGR* gene(s) and IRF8 may accelerate the disease development and B cells may play a key role on the pathogenesis of SSc.

Complex Traits Posters - Wednesday

PB1672*. The Pan-UK Biobank project improves locus discovery, facilitates genetic architecture comparisons, and increases the resolution and generalizability across diverse populations

Authors:

M. Kanai¹, K. Karczewski¹, R. Gupta¹, K. Tsuo¹, Y. Wang¹, N. Baya¹, R. Walters¹, P. Turley¹, S. Callier², D. Palmer¹, J. Goldstein¹, G. Sarma¹, M. Solomonson¹, N. Cheng¹, W. Lu¹, S. Bryant¹, C. Churchhouse¹, C. Cusick¹, D. King¹, T. Poterba¹, J. Compitello¹, W. Zhou¹, C. Seed¹, M. Daly¹, H. Finucane¹, B. Neale¹, E. Atkinson³, A. Martin¹; ¹Broad Inst. of MIT and Harvard, Cambridge, MA, ²George Washington Univ., Washington, DC, ³Baylor Coll. of Med., Houston, TX

Abstract Body:

The UK Biobank (UKB) is a collection of a half million individuals that has enabled large-scale genome-wide association studies (GWAS) for common diseases. However, most GWAS in UKB primarily use the individuals of European ancestry. Analyzing more diverse participants improves locus discovery, fine-mapping resolution, and generalizability of polygenic prediction, and facilitates cross-ancestry comparison of genetic architectures. To this end, we initiated the Pan-UKB project, a multi-ancestry analysis of 7,228 biomarker, categorical, continuous, electronic health record, and prescription phenotypes across 441,331 individuals from 6 continental ancestry groups, providing 16,553 GWAS and ancestry-specific LD matrices freely available to the community.

Here, we will present the latest results of the Pan-UKB, including heritability-based phenotype QC, cross-ancestry meta-analysis of high-quality phenotypes, polygenic prediction and fine-mapping. First, we conducted extensive heritability analyses using S-LDSC and RHE-mc. We identified 317 traits with significant out-of-bounds RHE-mc heritabilities; these were enriched for likely confounded traits (e.g. UK geographic location, ethnic background). We incorporated this filter into a systematic QC pipeline to prioritize high-quality phenotypes and prevent noise from low heritability GWAS in downstream analyses.

Using 527 high-quality phenotypes passing QC in EUR and at least 1 non-EUR ancestry, we performed meta-analyses that only incorporated QC-passing ancestry-trait pairs to reduce noise while maintaining power. We identified 87,217 genome-wide significant associations, of which 3,840 were unique to non-EUR ancestries. We identified 39,416 and 5,909 associations that were not previously reported for the same Experimental Factor Ontology term or GWAS Catalog category respectively, highlighting the importance of diverse ancestries for novel discovery.

Finally, we will present a polygenic prediction using leave-one-ancestry-out meta-analysis to investigate how increasing diversity affects the generalizability of GWAS. We will also demonstrate fine-mapping of cross-ancestry meta-analysis to illustrate how diverse populations improve resolution without loss of calibration when samples are from the same cohort. Together, these efforts vastly extend the available resources for interpretation of disease-associated variants and highlight the importance of diversity in genetic studies. In addition, our new analytical pipelines provide the best practices for post-GWAS analyses across multiple ancestries, facilitating studies in underrepresented populations.

Complex Traits Posters - Thursday

PB1673. The *PPARG1* gene regulates the aging retina by the modulation of mitochondrial functions, autophagy and senescence in a mouse model of age-related macular degeneration

Authors:

J. Blasiak¹, M. Maria², A. Koskela², S. Felszeghy², K. Kaarniranta²; ¹Univ. of Lodz, Lodz, Poland, ²Univ. of Eastern Finland, Kuopio, Finland

Abstract Body:

Age-related macular degeneration (AMD), an eye disease is an important global issue concerning vision loss. We have created a model of AMD pathogenesis in which mitochondrial dysfunctions in the retinal pigment epithelium (RPE) cells interplay with senescence and declined autophagy caused by impaired PGC-1 α , a master regulator of mitochondrial biogenesis and an important factor in antioxidant defense, encoded by the *PPARG1* (peroxisome proliferator-activated receptor gamma coactivator 1-alpha) gene. The aim of this work was to evaluate the expression of genes involved in mitochondrial functions, autophagy and senescence in homo- and heterozygotic *PPARG1*-knockout (KO) mice as compared with control animals. We also assessed the influence of age on the effects induced by *PPARG1* knockout. The 3-months- or 1-year-old *PPARG1*-KO mice were derived from the C57BL/6J strain. The expression of the following genes: *TP53*, *HMGB1* and *CDKN2A* (senescence), *SDH*, *MT-COI* (mitochondria), *MTOR*, *ULK1*, *MAP1LC3B* (*Microtubule Associated Protein 1 Light Chain 3 Beta*), *SQSTM1* (*Sequestosome 1*) and *PRKN* (*Parkin RBR E3 Ubiquitin Protein Ligase*) (*macroautophagy and mitophagy*) in the retinal pigment epithelium (RPE) cells was evaluated by RT-PCR and immunohistochemistry. We observed an increased expression of the *MT-COI* gene in RPE cells in both homo- and heterozygous, 3-months- and 1-year-old animals as compared with corresponding controls. Also, an increased expression of the *HMGB1* gene in 1-year-old homozygous KO mice was observed. The *PPARG1* knockout in both alleles resulted in a decreased expression of the *MTOR* gene, but only in 1 year old animals. The expression of the *MAP1LC3B*, *SQSTM1* and *PRKN* in homozygotes was either at borderline significance or displayed a tendency to decrease. These effects were more pronounced in 1-year- than in 3-months-old animals. In conclusion PGC-1 α deficiency results in accelerated decline of the expression of autophagy-related genes with age and alterations in mitochondria- and senescence-related genes in RPE cells. The mice with knockout in the *PPARG1* gene can be useful as a model to investigate the role of impaired mitochondrial and autophagic functions associated with cellular senescence in AMD pathogenesis. This work was supported by National Science Centre, Poland grant number 2017/27/B/NZ3/00872.

Complex Traits Posters - Wednesday

PB1674. The prevalence, penetrance, and expressivity of mitochondrial disorders in a population-based cohort.

Authors:

T. Hall¹, S. Cannon¹, K. Colclough², M. Weedon¹, K. Patel¹; ¹Univ. of Exeter, Exeter, United Kingdom, ²Royal Devon and Exeter NHS Fndn. Trust, Exeter, United Kingdom

Abstract Body:

The prevalence and penetrance of heteroplasmic pathogenic mitochondrial variants that cause a range of severe multisystem diseases, including diabetes, is unknown in the population. Here, we used 118,365 whole genome sequenced individuals of unrelated European ancestry from UK Biobank to assess the prevalence, penetrance and expressivity of known pathogenic mitochondrial variants in the population. We used Mutect2 to call 95 previously reported pathogenic mitochondrial variants from whole genome sequenced individuals from UK Biobank. Individuals with heteroplasmy $\geq 2\%$ were considered carriers for that variant in line with the clinical diagnostic reporting. We performed association analysis with 30 biomarkers and 7 phenotypes commonly associated with mitochondrial disorders including deafness and diabetes, adjusting for age, sex and principal components. We used $p < 1.42 \times 10^{-5}$ as a significance threshold to correct for multiple testing.

Sixty-eight of 95 variants were seen in at least one individual with $> 2\%$ heteroplasmy in the UKbiobank. The prevalence of pathogenic variants ranged from 1 in 118,346 to 1 in 330. None of the pathogenic variants were associated with mitochondrial related phenotype and 30 blood biomarkers with $p < 1.42 \times 10^{-5}$ except *m.3243A>G*. The well-known *m.3243A>G* variant was present in 0.068% (81/118,346) individuals and was associated with diabetes (OR=3.01, 95%CI:1.79-5.05, $P < 4 \times 10^{-5}$). This association with diabetes increased with higher heteroplasmy $\geq 10\%$ (OR=10.41, 95%CI:3.99-27.21, $P < 2 \times 10^{-6}$; OR=3.38, 95%CI:1.12-9.22, $P = 0.017$ respectively).

Mitochondrial mutations are common in the population and have greatly reduced penetrance with low health-related burden. The variant *m.3243A>G* is associated with diabetes and its penetrance is dependent on heteroplasmy levels.

Hussman Inst. for Human Genomics, Univ. of Miami Miller Sch. of Med., Miami, FL, ²Maya Angelou Ctr. for Hlth.Equity, Wake Forest Sch. of Med., Winston-Salem, NC, ³Dept. of Population and Quantitative Hlth.Sci., Case Western Reserve Univ. Sch. of Med., Cleveland, OH, ⁴Dr. John T Macdonald Fndn. Dept. of Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL, ⁵Dept. of Neurology, Univ. of Miami Miller Sch. of Med., Miami, FL, ⁶Dept. of Psychiatry and Behavioral Sci., Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract Body:

Background: Alzheimer Disease (AD) is the most common cause of dementia in the elderly with a significant genetic risk. However, recent evidence highlight a more complex etiology, one that includes genetic, psychosocial, environmental, and behavioral risk factors. With the growing prevalence of AD globally, especially among racial ethnic groups, there is dire need to identify factors that reduce risk. Higher levels of educational attainment associate with a lower risk for AD, possibly due to increased cognitive reserve. It is unclear whether protective factors like education modifies AD genetic risk. Polygenic risk scores (PRS) provide a potential method to identify individuals with low and high genetic risk of developing AD. In this study, we assessed the relationship between educational attainment and the risk of developing AD in African Ancestry (AA) individuals with low and high AD PRS risk.

Methods: We analyzed 537 AA individuals (AD=156, cognitively unimpaired (CU)=381). First, we classified individuals into two educational categories: individuals with a “high school” education and individuals without a “high school” education. Second, we calculated PRS using summary statistics from the AA genome-wide association study (Kunkle et al. 2021). Based on the PRS scores, we created two groups: individuals with low genetic risk of AD (lower quartile, N=138) and individuals with high genetic risk of AD (upper quartile N=128). Within these two groups, we assessed the relationship between education and AD using the Chi-Square test (once for the low risk group and once for high).

Results: We found a significant association between higher educational attainment and reduced risk of AD in individuals with low genetic risk (OR=0.16, p-value=0.005). However, higher educational attainment was not significantly associated with decreasing risk of AD in the sub-group of individuals with high genetic AD risk (OR=0.75, p-value=0.63).

Conclusions: Our results showed that high educational attainment in AA individuals with low genetic risk reduced AD risk more than in those with a high genetic risk, thereby diminishing education’s protective effect. AD is a heterogeneous disease in which genetic, environmental and lifestyle factors contribute to risk. Thus, understanding not only the individual contribution of these factors to risk but also the impact of their coexistence can lead to more accurate risk identification and intervention strategies for AD.

PB1676. The role of host genetics on weight gain following ART initiation in people living with HIV

Authors:

T. Jia¹, K. M. Jordahl¹, S. A. Ruderman¹, R. M. Nance¹, C. B. Haas¹, A. L. Willig², A. R. Webel¹, B. M. Whitney¹, J. A. Delaney³, H. M. Crane¹, I. Peter⁴, S. Lindstrom¹; ¹Univ. of Washington, Seattle, WA, ²Univ. of Alabama at Birmingham, Birmingham, AL, ³Univ. of Manitoba, Winnipeg, MB, Canada, ⁴Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Studies suggest that certain classifications of antiretroviral therapy (ART) contribute to weight gain in people with HIV (PWH). The underlying mechanism by which ART interacts with host genetics to affect weight change is unclear. Using data from the multi-ancestry CFAR Network of Integrated Clinical Systems (CNICS) cohort, we assessed the role of host genetic factors in ART-related weight gain among PWH. We assessed weight change in 836 ART-naïve PWH initiating common ART regimens (non-nucleoside reverse transcriptase inhibitors [NNRTIs], N=256, reference; protease inhibitors [PIs], N=108; first-generation integrase inhibitors [II1], N=295; second-generation integrase inhibitors [II2], N=177) between 2012 and 2020. We examined weight change in the immediate period (first 6 months) after ART initiation. We obtained an average of 3.27 weight measurements per PWH for a total of 2,731 observations available for analysis. We generated genome-wide genotype data using the MEGA array. We assessed if ART-related weight gain differed by (i) *CYP2B6* or *UGT1A1* metabolizer genotypes or by (ii) a polygenic risk score (PRS) for body mass index (BMI). We used linear mixed models with exchangeable correlation matrices and robust standard errors to account for within-subject correlations, random intercepts, and random slopes for time on ART. All models were adjusted for nadir CD4 count (cells/mm³), CNICS site, time on ART, and the interaction of time on ART and regimen. Differences in weight gain by host genetics were assessed by including interaction terms. Compared to individuals on NNRTI, individuals who were on a PI regimen had the largest weight gain of 4.82 kg/6 months (95% CI: 2.22-7.42, $p < 0.001$) followed by II2: 2.73 kg/6 months (95% CI: 0.89-4.57, $p = 0.004$). There was no significant interaction with either *CYP2B6* or *UGT1A1* metabolizer genotypes with ART regimens (all $p > 0.05$). For individuals on a PI regimen, we observed the largest weight gain among those in the lowest BMI PRS tertile (8.41kg, 95% CI: 4.81-11.99) compared to those in the highest tertile (3.65kg, 95% CI: -0.54-7.85), although this difference was not significant ($p = 0.12$). Similarly, for individuals on II2 regimen, those in the lowest BMI PRS tertile gained the most weight (4.75kg, 95% CI: 0.52-8.98) compared to those in the highest tertile (1.15kg, 95% CI: -1.32-3.62), but this difference was not significant ($p = 0.21$). Overall, we found limited evidence that host genetic variation involved in drug metabolism and adiposity play a major role in ART-related weight gain.

Complex Traits Posters - Thursday

PB1677. The role of *POLG* in the genetic etiology of Amyotrophic Lateral Sclerosis

Authors:

N. Russell, K. Russell, L. Jorde; Univ. of Utah, Salt Lake City, UT

Abstract Body:

Amyotrophic lateral sclerosis (ALS) is a debilitating and fatal neurodegenerative disease that results in the death of motor neurons of the brain and spinal cord. Approximately 5,000 people in the U.S. are diagnosed with ALS each year, and no effective treatments exist. Previous studies have estimated the heritability of ALS to be approximately 60%. However, only 17% of ALS cases can be attributed to known ALS-causing genes. This leads to a large potential to uncover novel genes that contribute to ALS. Using two publicly available ALS cohorts and ALS patients from our University of Utah cohort, we used VAAST and Phevor to identify genes burdened with rare deleterious variants in ALS patients compared to a control cohort. Among the three cohorts, we analyzed 943 whole-genome sequences and 140 whole-exome sequences. Our highest ranked gene for both public ALS cohorts and the third highest rank gene in the Utah cohort was DNA Polymerase Gamma (*POLG*). Within *POLG*, there were 28 rare (MAF < 0.001) nonsynonymous single nucleotide variants (SNVs) found across the three cohorts. *POLG* encodes the catalytic subunit of the mitochondrial DNA polymerase. *POLG* has been implicated in numerous mitochondrial DNA syndromes and neurological diseases, but never before in ALS. However, studies from our lab have implicated mitochondrial function in ALS etiology, and *POLG*'s function in mitochondria DNA replication provides support for its role in ALS. We also acquired RNA-sequencing data from one of the public ALS cohorts and evaluated the expression of mitochondrial expressed genes. We found that ALS patients with a *POLG* mutation had, on average, higher expression for every mitochondrial expressed gene. This is significant because of the role of *POLG* in mitochondrial DNA maintenance. Additionally, we examine the read depth of mitochondrial DNA in the ALS patients to determine if there is a difference in these cases compared to a control cohort. *POLG* represents a promising candidate in the genetic etiology of ALS and warrants future functional studies to support the role of *POLG* in disease cause and progression.

Complex Traits Posters - Wednesday

PB1678. The variant in *FLNA* identified in a patient with progressive supranuclear palsy

Authors:

K. Kume¹, I. Yuishin², M. Oda³, K. Komatsu⁴, M. Takahashi⁵, Y. Tada¹, M. Kamada⁶, H. Kawakami¹; ¹Res. Inst. for Radiation Biology and Med., Hiroshima Univ., Hiroshima, Japan, ²Tokushima University, Tokushima, Japan, ³Vihara Hananosato Hosp., Mihara, Japan, ⁴Kitano Hosp., Osaka, Japan, ⁵Kitano Hosp., Osaka, Japan, ⁶Kagawa Univ., Kita-gun, Japan

Abstract Body:

Background: Progressive supranuclear palsy (PSP) is a neurodegenerative disorder characterized by tufted astrocyte and accumulation of 4-repeat tau. Because the clinical symptoms are broad, it is difficult to differentiate PSP from other tauopathies including corticobasal degeneration and Alzheimer's disease. In addition, the pathophysiology of PSP remains unknown. Recently, it has been reported that the variants in *FLNA*, encoding filamin-A, are associated with PSP. **Purpose:** The aim of this study is to confirm the significance of the variants of *FLNA* in PSP. **Methods:** Exome sequencing was performed for nine patients with PSP and five patients with corticobasal syndrome (CBS). The data analysis was performed according to the GATK best practices. The identified variant was validated by Sanger sequencing. **Results:** One patient with PSP had a variant (NM_001110556:c.7055C>T,p.S2352F). The variant is reported as a rare variant in the gnomAD (allele frequency: 0.000011) and predicted as pathogenic by several tools (CADD score: 25, PolyPhen-2: possibly damaging, MutationTaster: disease causing). In our variant database, a patient with spinocerebellar ataxia had the same variant. No variants in *FLNA* were identified in patients with CBS. **Discussion:** Our findings showed that the variant in *FLNA* may contribute to the development of PSP.

Complex Traits Posters - Thursday

PB1679. The whole blood transcriptional regulation landscape in 465 COVID-19 infected samples from Japan COVID-19 Task Force

Authors:

Q. Wang¹, R. Eda¹, H. Namkoong², T. Hasegawa³, M. Ishii², R. Koike³, A. Kimura³, S. Imoto⁴, S. Miyano³, S. Ogawa^{5,6}, T. Kanai^{2,7}, K. Fukunaga², Y. Okada^{1,8,4}, the Japan COVID-19 Task Force; ¹Osaka Univ., Osaka, Japan, ²Keio Univ., Tokyo, Japan, ³Tokyo Med. and Dental Univ., Tokyo, Japan, ⁴the Univ. of Tokyo, Tokyo, Japan, ⁵Kyoto Univ., Kyoto, Japan, ⁶Karolinska Inst., Stockholm, Sweden, ⁷Japan Agency for Med. Res. and Dev., Tokyo, Japan, ⁸RIKEN, Yokohama, Japan

Abstract Body:

Studies of gene expression dynamics and regulation landscape in Coronavirus disease 2019 (COVID-19) infected individuals are limited. Here, we report on a thorough analysis of whole blood RNA-seq data from 465 genotyped samples from the Japan COVID-19 Task Force, including 359 severe and 106 non-severe COVID-19 cases.

We discovered 1,169 putative causal ($0.9 < \text{posterior inclusion probability} = \text{PIP}$) expression quantitative trait loci (p-causal eQTLs) including 34 possible colocalizations with biobank fine-mapping results of hematopoietic traits in a Japanese population, 1,549 p-causal splice QTLs (sQTLs; e.g. two independent sQTLs at *TOR1AIP1*), as well as biologically interpretable trans-eQTL examples (e.g., *REST* and *STING1*).

We validated our cis-eQTL fine-mapping result by comparing it with that of another cohort (GTEx) and observing near half (46%) replication rate of p-causal eQTLs, as well as 100% concordance in the effect size direction when replicated. In addition, we show that integrating fine-mapping results from two cohorts improves the power (396 p-causal eQTLs are missing in GTEx and are as functionally enriched as the ones existing) and accuracy (eQTLs with inconsistent PIP between two cohorts are functionally depleted).

We performed differential gene expression analysis to elucidate 198 genes with increased expression in severe COVID-19 cases, enriched for innate immune-related functions (adjusted $p < 10^{-10}$ for the term "Immune System"). We also evaluated the non-zero but limited effect of COVID-19 on eQTL discovery, where only six out of >100K variant-genes tested were off by more than 2 in $-\log_{10}(p)$ scale when including COVID-19 severity as a covariate in the eQTL call.

13 genes, including the ones with known relevance to viral infection (e.g. *CLEC4C*), showed eQTL effects of different magnitudes for different disease severity ($\text{FDR} < 0.05$). We characterized such COVID-19 severity interaction-eQTLs (ieQTLs) in the context of cell type specificity by performing cell type decomposition and testing ieQTL effects for each of the inferred cell type composition. This suggested dynamics of cell type composition such as an increase in neutrophils along with the COVID-19 severity as a major mechanism (eQTL effects in 10/13 genes interacted with inferred neutrophil counts; Bonferroni $p < 0.05$).

Altogether, our study provides a comprehensive catalog of whole blood regulatory variants in Japanese together with a reference for transcriptional landscapes in response to COVID-19 infection, highlights the presence of ieQTLs, and serves as a showcase of improving eQTL fine-mapping performance by including diverse populations.

Complex Traits Posters - Wednesday

PB1680. Tissue-associated examination of risk factors uncovers genetic risk profiles that vary across patients of inflammatory bowel disease.

Authors:

A. Gaité¹, U. Marigorta^{1,2}, M. Sanchez-Mayor¹, Z. Mars¹, L. Bujanda^{3,4}; ¹Integrative Genomics Lab, Ctr. for Cooperative Res. in BioSci.s (CIC bioGUNE), Basque Res. and Technology Alliance (BRTA), Bizkaia Technology Park, Derio, Spain, ²IKERBASQUE, Bilbao, Spain, ³Biodonostia, San Sebastian, Spain, ⁴Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas CIBERehd, Barcelona, Spain

Abstract Body:

Polygenic risk scores (PRSs) are emerging as a tool of choice to summarize the risk of disease in each individual. The calculation of PRSs is based on genetic variants and effect sizes obtained from large studies using many different cohorts of patients. In inflammatory bowel disease (IBD), meta-analysis based on over 75.000 IBD patients from different multi-ethnic cohorts has discovered around 300 independent associated variants. This information can be used to estimate genetic risk and detect individuals with several higher probability of developing the disease during their lifetime. However, PRSs usually do not incorporate functional information about causal variants, and the potential for heterogeneity in effect sizes among subgroups of individuals is disregarded entirely. Hence, PRSs might be ill-suited to capture subcomponents of genetic risk that may account for key differences among specific profiles of patients. We use a pipeline of methodologies based on functional genomics to characterize the regulatory implications of genetic signals associated with IBD by Genome-Wide Association Studies. Using genetically-determined levels of gene expression as proxy of risk, we explore the different patterns of association of causal genes across tissues that participate in IBD etiology. We recapitulate sharing of regulatory signals across tissues for the genes involved in IBD susceptibility. Of note, a fraction of modules of co-expressed genes is enriched for disease heritability, although this correlates with the number of genes in each module, which goes in accordance with the known polygenicity of IBD risk. Besides providing novel mechanistic understanding of IBD risk, we use this information to carry out individualized multi-tissue evaluation of the presence of risk factors in each patient. This analysis serves to check the proposition that a fraction of IBD patients is characterized by enrichments for particular components of genetic risk.

Complex Traits Posters - Thursday

PB1681. To annotate the neuroprotective role of Camel α Lactalbumin and Oleic acid (CLOA) complex against Parkinson's induced model.

Authors:

S. Ubaid¹, S. Pandey¹, M. Akhtar²; ¹King George's Med. Univ., Lucknow, India, ²Central Drug Res. Inst., Lucknow, India

Abstract Body:

Parkinson's disease is a neurodegenerative disorder that affects 2-3% of the population ≥ 65 years of age. Currently, the therapeutic interventions that are available for PD have several adverse effects. Therefore, the development of novel therapies for PD based on biosimilar compounds is urgently needed. Camel α -lactalbumin is known to act as a potential therapeutic candidate for brain disorders via regulation of inflammatory and apoptotic pathways, while oleic acid is a monounsaturated fatty acid and is involved in the synthesis of myelin phospholipids as well as triggering the synthesis of dopamine. This study aims to formulate the camel α -lactalbumin and oleic acid complex and evaluate the underlying neuroprotective efficacy of the CLOA complex in MPTP-induced in vitro and in vivo models. Our result demonstrates that EDTA removes Ca^{++} from camel α -LA, which was confirmed by ICP-MS, and the arsenazo III complex was further validated by TEM, which confirms that it attains the nanostructure. The results also revealed that the viability of the SH-SY5Y cell line and the locomotor activity of the rat model were increased. Furthermore, the CLOA complex alleviated oxidative stress, and inflammation increased the level of dopamine and decreased metabolites in the MPTP-induced model. The results were further validated at the proteomic and genomic levels, where the expression of SIRT1 and FOXO3a was upregulated. Taken together, the CLOA complex shows a neuroprotective effect in MPTP-injured rat and SH-SY5Y cells via activation of the SIRT1 signaling pathway, while the neuroprotective efficacy of individual camel α -lactalbumin and oleic acid is less than that of the CLOA complex.

Complex Traits Posters - Wednesday

PB1682. Trans-ancestry genome-wide analysis of kidney disease in individuals with type 2 diabetes.

Authors:

E. Richard, S. Cao, W. Gu, A. Shadyab, R. Salem; Univ. of California San Diego, La Jolla, CA

Abstract Body:

Background: Diabetic kidney disease (DKD) is a common microvascular complication of type 2 diabetes mellitus (T2D) and is the most frequent cause of end-stage kidney disease (ESKD). However, the genetic basis of kidney disease in those with T2D remains largely unknown. **Methods:** Using data from 15 studies from dbGaP and the UK Biobank, we conducted genome-wide association studies (GWAS) for a comprehensive set of 12 dichotomous kidney disease phenotypes based on albuminuria and estimated glomerular filtration rate (eGFR) in up to 58,228 individuals with T2D. GWAS results were combined via ancestry-specific (42,140 European, 8,834 African, 4,346 Hispanic, 2,562 South Asian, and 346 East Asian- ancestry) and trans-ancestry meta-analysis with fixed-effects. MR-MEGA was also used for trans-ancestry analysis to account for heterogeneity in allelic effects between ancestries. Gene prioritization and gene-set enrichment analyses were performed using DEPICT. **Results:** We identified previously reported associations for *PDILT* and *NR1P1* with chronic kidney disease (CKD; eGFR<60ml/min vs eGFR>=60ml/min), and *CUBN*, *GCKR* and *FOXD2* with albuminuria and DKD (albuminuria and ESKD). A novel genome wide significant (GWS, $p<5\times 10^{-8}$) signal for a late DKD phenotype (severe albuminuria or ESKD) was found in the 8p23.1 region (rsID-effect allele: rs28549051-T, OR=0.54) near a β -defensin gene cluster. Analysis using MR-MEGA identified novel GWS associations between an intronic variant (rs76989357) in *CNTN4* and a CKD-DKD phenotype (DKD and eGFR<45ml/min) and between an intergenic variant (rs10238973) closest to *CDC14C* and severe albuminuria. In ancestry-specific analyses, we detected two novel GWS variants, rs7007458-A (OR=0.70) in the intergenic region between the *ZMAT4* and *SFRP1* genes for CKD-DKD in those of European ancestry and rs62364704-C (OR=0.40) in an intronic region of *MCTP1* for severe albuminuria in African ancestry individuals. Among European ancestry participants, gene-set analysis of ESKD (vs no ESKD) identified an enrichment for phospholipase A2 activity (GO:0004623, $p<0.01$), and gene-based tests identified suggestive associations (FDR <0.20) for *GJB5*, *GJB4*, *HAPLN1* and *OSMR* loci with CKD, and for *UACA*, *DPYSL5*, *TRIM54*, *EPB41L5* with DKD. **Conclusion:** Large-scale GWAS analyses coupled with comprehensive kidney disease definitions in subjects with T2D replicated previously reported loci and identified several novel loci that warrant further investigation.

Complex Traits Posters - Thursday

PB1683. Trans-ancestry PRSs of lipid traits: characterization and evaluation of clinical utility in the diverse PAGE study

Authors:

Z. Wang¹, Y. Cai², M. Kim², R. Smit¹, S. Graham³, Y. Hu⁴, S-A. Love⁵, J. Judin⁶, S. Buyske⁷, K. Young⁸, C. Willer⁹, K. North⁸, C. Kooperberg⁴, R. Loos¹⁰, U. Peters¹¹, M. Graff⁸, The Global Lipids Genetics Consortium, the PAGE Study (ZW and YC contribute equally to this work); ¹Icahn Sch. of Med. at Mount Sinai, New York, NY, ²Fred Hutch Cancer Res. Ctr., Seattle, WA, ³Univ MICHIGAN, Ann Arbor, MI, ⁴Fred Hutchinson Cancer Res. Ctr., Seattle, WA, ⁵The Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ⁶Fred Hutchinson Cancer Ctr., Seattle, WA, ⁷Rutgers Univ., Piscataway, NJ, ⁸Univ North Carolina, Chapel Hill, NC, ⁹Univ. of Michigan, Ann Arbor, MI, ¹⁰Univ. of Copenhagen, Copenhagen, Denmark, ¹¹Fred Hutchinson CA Res Ctr, Seattle, WA

Abstract Body:

Lipid profiles are heritable risk factors of cardiovascular disease (CVD), a leading cause of mortality worldwide. Accordingly, lipid polygenic risk scores (PRSs) have the potential to predict future risk of CVD. However, PRSs derived from mostly European ancestry individuals often have poor trans-ancestry portability. Systematic assessment of lipid PRSs in diverse populations is critical for a more accurate and equitable application of PRSs to clinical practice. Here, we leverage multi-ancestry PRSs for lipid traits (derived from a population of which is of 78% European - EUR, 15% of South and East Asian, 5% of African - AA, and 1% of Hispanic - HA background) constructed by the Global Lipids Genetics Consortium (GLGC) using a clumping and thresholding method and apply the PRSs to the Population Architecture through Genomics and Environment (PAGE) study, which was excluded from GLGC. The PAGE study includes 71K diverse participants with 33% HA, 32% EUR, 25% AA, 4% Asian, 3% Native Hawaiian - HI, and 1% Native American - NA. We evaluated PRSs for lipids levels (HDL, LDL, TC and TG) using incremental R² after accounting for age, sex, first 10 PCs and self-reported race and ethnicity. The GLGC multi-ancestry PRSs included 10-12K genetic variants, depending on the lipid traits, with 2-3K rare variants (MAF <1% in GLGC multi-ancestry samples). Overall, the PRSs' explained variance (R²) decreased with increasing genetic divergence from populations included in the original GWAS. For LDL, HDL and TC, the PRS performance was best in EUR, followed by HA and AA, with much lower R² in Asian and HI participants (e.g., LDL R²: 16%, 13%, 10%, 7%, 5% in EUR, AA, HA, Asian, and HI). For TG, the highest R² was still in EUR (10%), followed by Asian, HI, and HA (7%, 6%, 5%), and lowest in AA participants (2%). Results were imprecise in NA because of small sample sizes. Stratified analyses showed slightly higher R² for LDL and TC in women (women vs men: 11% vs 8% for LDL and 12% vs 9% for TC), and no difference by age strata (range 17-50, 50-60, 60-70, and 70-80 years). Although the LDL-PRS was significantly associated with incident CVD risk (HR = 1.07, P = 2.2E-6), after adjusting for traditional risk factors, summarized by the Pooled Cohort Equation, we did not observe significant improvement in prediction of 10-year risk of CVD (AUC 0.71 with or without LDL-PRS). Overall, this study highlights the challenges of implementing multi-ancestry PRS in diverse populations. We are expanding this effort by collaborating with additional biobanks to increase sample size in currently underrepresented populations.

Complex Traits Posters - Wednesday

PB1684*. Transcriptome analysis of familial dysautonomia reveals tissue-specific gene expression disruption in the peripheral nervous system

Authors:

R. Harripaul¹, E. Morini¹, E. Logan¹, E. Kirchner¹, J. Bolduc¹, A. Chekuri¹, M. Salani¹, B. Currall¹, R. Yadav², S. Erdin¹, M. Talkowski¹, D. Gao¹, S. Slauchaupt¹; ¹Massachusetts Gen. Hosp., Boston, MA, ²MGH/Harvard Med. Sch., Cambridge, MA

Abstract Body:

Familial Dysautonomia (FD) is a rare, recessive neurodegenerative disease caused by a splicing mutation in intron 20 of the Elongator complex protein 1 (*ELP1*, alias *IKBKAP*). This mutation leads to tissue-specific skipping of exon 20 and reduction of ELP1 protein, mainly in the central and peripheral nervous systems (CNS and PNS respectively). FD is a complex disorder affecting the development and survival of sensory and autonomic neurons. Little is known about why some neuronal tissues are more susceptible to ELP1 loss. We developed a phenotypic FD mouse model that recapitulates the tissue-specific *ELP1* splicing defect and the disease manifestations in patients including impaired proprioception and nociception. This model was generated by introducing the human *ELP1* gene with the FD mutation into a hypomorphic mouse expressing low amounts of endogenous *Elp1*. We performed transcriptomic profiling in dorsal root ganglion (DRG), trigeminal ganglion (TG), cortex, spinal cord, and medulla collected from the FD phenotypic mouse. We found that overall changes of gene expression were most prominent in medulla and lowest in the spinal cord. We discovered much greater sharing of differentially expressed genes (DEGs) across the TG and DRG tissues than expected by chance (191; $p = 1.6e-111$, hypergeometric test), and these genes are involved in pathways important for the regulation of synaptic signaling and transmission ($FDR < 0.1$). Such convergent transcriptomic dysfunction in the PNS was supported by gene co-expression analysis. We found that co-expressed genes strongly correlated with *ELP1* expression and were highly preserved in PNS tissues. We hypothesized unique cell types shared by PNS tissues might be the main contributor to the convergent PNS dysregulation in FD etiology. By comparing these DEGs in PNS to publicly available single-cell transcriptomic data from human and mouse DRG and TG, we found that the dysregulated PNS genes were significantly enriched for proprioceptor ($p=1e-3$), and nociceptor ($p=3.4e-3$) markers. For the first time, our data reveals the cell-type specific signatures underlying the loss of proprioceptors and nociceptors characteristic of FD. This study is the first to 1) identify tissue-specific DEGs whose expression correlates with ELP1 2) demonstrate a convergent gene dysregulation in FD mouse PNS tissues and 3) explore the cell-specific molecular pathways underlying FD neuronal degeneration. The identification of neuronal-specific gene networks underlying neuronal loss in FD provides a better understanding of disease etiology and identifies potential biomarkers for future clinical studies and new targetable pathways for therapy.

Complex Traits Posters - Thursday

PB1685. Transcriptome-wide analysis in Cameron County Hispanic Cohort (CCHC) provides novel insights into gene expression signatures of blood pressure

Authors:

X. Zhang¹, M. Graff¹, M. Yaser¹, J. Seo¹, S. Okello¹, H-H. Chen², W. Zhu², M. Lee³, J. B. McCormick³, S. P. Fisher-Hoch³, A. D. Gutierrez⁴, J. E. Below², K. E. North¹; ¹Dept. of Epidemiology, Gillings Sch. of Global Publ. Hlth., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ²Vanderbilt Univ. Med. Ctr., Nashville, TN, ³The Univ. of Texas Hlth.Sci. Ctr. at Houston, Sch. of Publ. Hlth., Brownsville, TX, ⁴Div. of Endocrinology, Diabetes and Metabolism, The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX

Abstract Body:

Background: Globally, the cardiovascular burden of hypertension is large - with ~1.4 billion adults with hypertension reported in 2010 and 8.5 million premature deaths in 2015. In particular, Hispanic/Latino Americans are disproportionately affected, with high prevalence but low rates of awareness, treatment, and control. While genome-wide association studies (GWAS) have identified > 1,400 loci associated with hypertension, functions underlying most of these loci remain unknown. To further realize the potential of GWAS, gene expression, which lies in between genetic variation and disease, can highlight pathways for targeted therapeutic intervention. However, to date, limited studies have sought molecular signatures of hypertension through gene expression, particularly in ancestrally diverse participants.

Methods: We leveraged whole blood RNA sequencing data in 806 Mexican Americans (age 51.9 ± 15.9 , 34.7% men) from the Cameron County Hispanic Cohort (CCHC) to identify differentially expressed genes. We used established protocols and alignment, yielding 15,694 protein coding genes after quality control. We adopted a two-step linear regression model to assess differentially expressed genes associated with systolic and diastolic blood pressure (S/DBP). In the first step, each outcome was adjusted for age and sex; the resulting residuals were rank normalized and then regressed on gene expression and 10 probabilistic estimation of expression residuals (PEER) factors.

Results: We identified 122 and 88 genes whose expression was significantly associated with SBP and DBP (FDR $p < 0.05$). Among our statistically significant results, we (1) replicated previous associations between gene expression and BP, including *CRIP1*, *MYADM*, *TIPARP*, *TSC22D3*, *LMNA*, *TPPP3*, *FOS*, and *TAGAP*, (2) identified possible causal genes underlying mapped BP GWAS, including *ATP2B1* and *GOSR2*, and (3) identified novel genes such as *KCNQ1* which has been shown to be associated with glomerular filtration rate and other cardiometabolic measures.

Conclusions: Our results demonstrated not only how transcriptome-wide analysis can bridge GWAS signals and hypertension, but also the importance of ancestrally diverse populations in the replication of previously published findings and in the identification of novel genes. Collectively, our findings fill the gaps in the genetics of hypertension and offer a more comprehensive picture of pathway-level alternations which ultimately could lead to actionable therapeutic targets with biological relevance.

Complex Traits Posters - Wednesday

PB1686*. Transcriptome-wide and Proteome-wide association study of Tourette's Syndrome

Authors:

S. Shekhar¹, P. JAIN², P. Paschou¹; ¹Purdue Univ., West Lafayette, IN, ²Purdue Univ., WEST LAFAYETTE, IN

Abstract Body:

Tourette's Syndrome (TS) is a neurodevelopmental disorder that is characterized by motor and phonic tics. A recent genome-wide association study (GWAS) identified *FLT3* gene as a genome-wide locus significantly linked to TS. However, determining the biological mechanism and pathways of GWAS signals remains difficult, limiting the understanding of TS. Importantly, the current iteration of GWAS does not identify *FLT3* as a significant locus and thus has an ambiguity regarding the role of *FLT3* in TS. To characterize the effect of genetic variation mediated gene expression in TS and to understand the biological underpinnings of the disease, we perform a global and unbiased transcriptome-wide and proteome-wide association study (TWAS and PWAS respectively) in the largest cohort of TS patient samples of general European ancestry consisting of 6133 TS cases and 13565 healthy controls using FUSION tool. Our TWAS analysis using an individual tissue-based prediction matrix of gene expression validates that the increased expression of *FLT3* in the dorsolateral prefrontal cortex (DLPFC) is associated with TS, as reported in a recent publication. Additionally, the analysis identifies eleven novel genes whose transcript expression is significantly associated with TS. Next, we performed TWAS analysis using a cross-tissue-based prediction matrix of gene expression and identified *FLT3* and *EP300* to be significantly associated with TS. As transcriptome expression sparingly correlates with proteome expression, we performed PWAS to complement TWAS analysis. Our PWAS analysis, based on protein expression from DLPFC tissue, identified three novel genes. For these genes, genetic variant-mediated change in protein expression is significantly associated with TS. In conclusion, results from our TWAS and PWAS analysis allow us to identify novel genes associated with TS and identify biological pathways that can be validated via biological experimentation to strengthen our analysis.

Complex Traits Posters - Thursday

PB1687. Transcriptome-wide association analyses in CD4 T-cells identify genes dysregulated in frequent cocaine users and associated with HIV latent reservoir.

Authors:

B. Quach¹, C. Willis¹, D. Hancock¹, D. Konkle-Parker², H. Bolivar³, C. Lahiri⁴, E. Topper⁵, M. Cohen⁶, S. Kassaye⁷, J. DeHovitz⁸, M. Kuniholm⁹, N. Archin¹⁰, P. Tien¹¹, K. Xu¹², B. Aouizerat¹³, E. Johnson¹; ¹RTI Intl., Research Triangle Park, NC, ²Univ. of Mississippi Med. Ctr., Jackson, MS, ³Univ. of Miami-ACRU, Miami, FL, ⁴Emory Univ., Atlanta, GA, ⁵Johns Hopkins Univ., Baltimore, MD, ⁶Cook County Hlth.System, Chicago, IL, ⁷Georgetown Univ., Washington, DC, ⁸Downstate Hlth.Sci. Univ., Brooklyn, NY, ⁹Univ. at Albany, Rensselaer, NY, ¹⁰Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ¹¹Univ. of California San Francisco, San Francisco, CA, ¹²Yale Univ., New Haven, CT, ¹³New York Univ., New York, NY

Abstract Body:

Background: Cocaine use is known to impact HIV treatment and progression and is common among people with HIV. Understanding and eliminating the HIV latent reservoir (HLR), the replication competent but repressed HIV provirus integrated into host cells' DNA, is key to an HIV cure. CD4 T-cells harbor the largest known HLR of human cell types. We examined the association of gene expression with cocaine use and HLR in CD4 T-cells and tested genes as mediators between the two.

Methods: To identify genes associated with cocaine use and HLR, we generated RNA-seq data and quantified HLR size using the intact proviral DNA assay from CD4 T-cells isolated from blood samples. Samples were contributed by HIV-infected, combination anti-retroviral therapy (cART) adherent women enrolled in the Women's Interagency HIV Study (WIHS) between 1993 and 2017 with self-reported cocaine use or no cocaine use in the 6 months prior to blood draw. We performed transcriptome-wide association studies (TWAS) of HLR (N=246) and cocaine use status (N=259) using negative binomial regression. Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) biological pathway terms were tested for enrichment of HLR- or cocaine use-associated genes. Genes associated with both phenotypes were further evaluated as potential mediators of the effect of cocaine use on HLR size using causal mediation analysis.

Results and discussion: We discovered 101 and 1,608 genes associated with HLR and cocaine use (false discovery rate [FDR] <0.1), respectively, with 47 significant for both. HLR-associated genes were enriched in 10 GO terms (FDR <0.1) related to cell division, protein-DNA complex formation, and chromatin organization. Cocaine use-associated genes were enriched in 652 GO terms and 4 KEGG pathways (FDR <0.1) largely related to immune system processes (immune cell homeostasis, cytokine signaling, inflammatory response, immune cell activation and proliferation), inter- and intra-cell transport, chromatin modification, and nucleotide and amino acid metabolism. Of the 47 significant genes from both TWAS, 31 showed nominal evidence of being mediators between cocaine use and HLR ($p < 0.05$) with *EPSTII* mediation being statistically significant (Bonferroni $p < 0.05$). *EPSTII* is known to be activated by HIV-1 Tat protein in CD4 T-cells and plays a role in the translocation of NF- κ B to the nucleus. Our results provide evidence of widespread dysregulation of gene expression in CD4 T-cells from cocaine users and a link between some of these genes to HLR. Women are underrepresented in studies of HLR, and these findings contribute to better understanding HLR and cocaine use effects among women.

Complex Traits Posters - Wednesday

PB1688. Transcriptome-wide association study identifies novel candidate susceptibility genes for migraine.

Authors:

T. Meyers¹, J. Yin¹, A. Avins¹, T. Hoffmann², C. Schaefer¹, A. Pressman³, H. Choquet¹; ¹Kaiser Permanente Northern California Div. of Res., Oakland, CA, ²UCSF, San Francisco, CA, ³PRECISIONheor, Bethesda, MD

Abstract Body:

Purpose: Genome-wide association studies (GWAS) have identified 123 genetic susceptibility loci for migraine, however, how the majority of these loci impact migraine etiology is unknown. To identify novel genes associated with migraine and interpret the transcriptional effect of those genes, we conducted a transcriptome-wide association study (TWAS). **Methods:** We performed tissue-specific and multi-tissue TWAS analyses to assess associations between imputed gene expression from 53 tissues with migraine susceptibility using FUSION software. Meta-analyzed GWAS summary statistics from 26,052 migraine cases and 487,214 controls, all of European ancestry and from two cohorts (the Kaiser Permanente Genetic Epidemiology Research on Adult Health and Aging (GERA) and the UK Biobank) were used. We evaluated associations for genes after conditioning on variant-level effects from GWAS, and we tested for colocalization of GWAS migraine-associated loci and expression quantitative trait loci (eQTLs). **Results:** In tissue-specific analyses, 47 genes were associated with migraine after correcting for multiple testing and three of these genes (KTN1-AS1, VAT1, and PNKP) did not overlap any previously identified migraine-associated loci. Of these three genes, KTN1-AS1 and VAT1 were nominally associated with migraine ($P < 0.05$) after conditioning on the lead GWAS variant in the region. Moreover, cardiovascular tissues represented the highest proportion of the 47 Bonferroni-significant gene-tissue pairs (22 genes; 47%), followed by brain tissues (8 genes; 17%), and gastrointestinal tissues (4 genes; 9%). Furthermore, the posterior probability for colocalization was high (>0.9) in 20 of the 47 genes. Finally, our multi-tissue analyses identified 1,555 migraine-associated genes outside of known loci, including 37, 124, and 41 genes for the subsets of cardiovascular, brain, and gastrointestinal tissues, respectively. **Conclusions:** Our TWAS suggests novel genes for migraine and highlights the important contribution of brain, cardiovascular, and gastrointestinal tissues in migraine susceptibility etiology.

Complex Traits Posters - Thursday

PB1689. Transcriptomic analysis of severe obesity identifies novel genes in Hispanic/Latino populations with a high burden of disease.

Authors:

P. Sharma¹, H-H. Chen², W. Zhu³, H. Polikowsky³, P. McCormick⁴, K. Karastergiou⁵, S. Fried⁵, A. Justice⁶, M. Lee⁷, S. Puppala⁸, M. Graff⁹, Y. Mohammad¹⁰, J. McCormick⁷, S. Fisher-Hoch⁷, K. North⁹, J. Below¹¹; ¹Univ. of North Carolina, Chapel Hill, NC, ²Vanderbilt Univ. Med. Ctr., Nashville, TN, ³Vanderbilt Univ., Nashville, TN, ⁴Queen Mary Univ. of London, London, United Kingdom, ⁵Mount Sinai Med. Ctr., New York, NY, ⁶Geisinger, Danville, PA, ⁷The Univ. of Texas Hlth.Sci. Ctr., Houston, TX, ⁸Wake Forest Sch. of Med., Winston Salem, NC, ⁹Univ North Carolina, Chapel Hill, NC, ¹⁰Uni. of North Carolina, Chapel Hill, NC, ¹¹Vanderbilt Univ Med Ctr., Nashville, TN

Abstract Body:

The US prevalence of severe obesity (SevO, body mass index [BMI] ≥ 40 kg/m²) is increasing at an alarming rate, with highest prevalence among adult men (6.9%) and women (11.5%), and highest increase in Mexican-American men. While genome-wide association studies (GWAS) have identified >1000 loci associated with body mass index, the function of much of this variation is unknown. Gene expression measures can illuminate the link between genetic variation and disease highlighting pathways for targeted therapeutic intervention, but to-date, only a handful of studies has examined the role of gene expression to identify molecular signatures associated with SevO. To this end, we leveraged extant whole blood (WB) RNA sequencing (RNAseq) data in 75 SevO cases and 116 controls (with BMI = 18-25) collected from randomly selected Mexican Americans in the Cameron County Hispanic Cohort (CCHC) to identify patterns associated with SevO. We used established protocols and alignment, yielding 18,565 genes after quality control. We applied DESeq2 to assess DE associated with SevO, using a negative binomial regression model with a gene-specific dispersion parameter, adjusted for sex, age, T2D, hypertension, hypercholesterolemia, and 10 probabilistic estimation of expression residual (PEER) factors. After FDR correction, 124 genes were significantly DE, including top genes *C1RL*, *IL4R*, and *RGS16*. We identified several replications of the 124 genes in our ongoing GWAS of SevO (vs normal weight controls) in a large meta-analysis of 50,000 HL participants, including the CCHC. We additionally identified several replications of the 124 genes in subcutaneous adipose tissue (SAT) from 19 community volunteers, including for *RGS16*, *C1RL*, and *IL4R*. Collectively, these data demonstrate how transcriptomic studies may elevate understanding of SevO and inform efforts to reduce health disparities associated with SevO in HL populations.

Griswold^{1,5}; ¹John P. Hussman Inst. for Human Genomics, Univ. of Miami, Miami, FL, ²Maya Angelou Ctr. for Hlth.Equity, Wake Forest Univ., Winston-Salem, NC, ³Dept. of Internal Med., Univ. Central Del Caribe, Bayamón, PR, ⁴Neurogenetics Res. Ctr., Inst. Natl. de Ciencias Neurológicas, Lima, Peru, ⁵Dr. John T Macdonald Fndn. Dept. of Human Genetics, Univ. of Miami, Miami, FL, ⁶Dept. of Population & Quantitative Hlth.Sci., Case Western Reserve Univ., Cleveland, OH, ⁷Cleveland Inst. for Computational Biology, Cleveland, OH

Abstract Body:

Background: Significant work has identified genetic variants conferring risk and protection for Alzheimer disease (AD), but study of downstream functional effects including modulation of gene regulation is lacking, particularly in individuals of diverse ancestries. To explore transcriptional changes between clinically diagnosed AD and cognitively intact age-matched controls, we analyzed RNA sequencing data from peripheral blood collected from Hispanic individuals of admixed genetic backgrounds and identified molecular pathways altered in these cohorts compared to existing data for European and African Americans. **Methods:** Total RNA was extracted from peripheral whole blood stored in PAXGene tubes from 47 Cubans (22 AD and 25 controls), 85 Peruvians (41 AD and 44 controls), and 168 Puerto Ricans (88 AD and 80 controls). PolyA mRNA was sequenced to 40 million paired end read per sample on the Illumina NovaSeq 6000. The bioinformatic pipeline included mapping to the human reference genome (GRCh38), gene quantifications against the GENCODE v35 annotation set, and differential expression calculated using DESeq2 with sex, age at blood draw, and count of *APOEε4* alleles as covariates. These data were then combined with data we previously generated from European (121 AD and 119 controls) and African American (115 AD and 119 controls) individuals (Griswold et al, 2018, PMID: 32597797) for functional categorization performed by gene set enrichment of gene ontology and KEGG pathways. **Results:** Across the new Hispanic cohorts, a total of 358 protein-coding genes ($FDR \leq 0.05$, Fold change ≥ 1.25) were differentially expressed with 238 down-regulated and 120 up-regulated in AD relative to controls. Few genes overlapped between the cohorts and across the European and African American data. However, pathway analysis revealed common pathways including up-regulation of genes involved in inflammation and RNA processing and down-regulation of genes involved in cellular detoxification and lipid transport, among others. These pathways converged with the existing European and African American data pathways as well. **Conclusion:** Identifying the genes and biological pathways involved in AD is critical in the effort to develop effective therapies. Our analysis reveals a signature of gene expression that implicates increased inflammation and decreased cellular detoxification based on gene expression analysis in genetically admixed individuals. Convergence of pathways across these and African American and European cohorts supports the idea of distinct genes but similar underlying pathological processes contributing to AD across individuals of diverse ancestries.

Complex Traits Posters - Thursday

PB1691. Transcriptomic and Epigenomic Consequences of Heterozygous Loss-of-function Mutations in *AKAP11*, a Bipolar Disorder Risk Gene, and their Effects on Responsiveness to Lithium

Authors:

N. Farhangdoost¹, A. Khayachi¹, Q. He², C. Jiao², V. Vuokila¹, B. Chaumette², P. Dion¹, G. Rouleau³; ¹McGill Univ., Montreal, QC, Canada, ²INSERM, Paris, France, ³Montreal Neurological Inst.-Hosp., Montreal, QC, Canada

Abstract Body:

Bipolar disorder (BD) is a polygenic psychiatric disorder that is characterized by recurrent episodes of mania and depression. Although BD has been shown to be a highly heritable disorder, a significant amount of the genetic risk is not yet detected. Bipolar Exome (BipEx) sequencing studies of 13,933 BD cases and 14,422 controls showed that the strongest case-control enrichment of rare protein-truncating variants is in the gene *AKAP11*. *AKAP11* is now considered a rare-variant large-effect risk gene in both BD and Schizophrenia (Palmer, D.S et al., 2022). This gene encodes A-Kinase Anchoring Protein 11 which acts as a scaffold protein to phosphorylate Glycogen Synthase Kinase 3 β (GSK3 β), the hypothesized target of lithium (Li) mainly prescribed to BD patients, through PKA. This complex has been shown to inhibit GSK3 β 's activity and affect its regulation by increasing its serine 9 phosphorylation levels. Therefore, the primary hypothesis of my study is that when *AKAP11*-Knockout (*AKAP11*-KO) induced pluripotent stem cell (iPSC)-derived neurons are treated with Li, Li would compensate for this deficit and could rescue some of the consequences of *AKAP11*'s loss of function by inhibiting GSK3B. Furthermore, since *AKAP11* has been shown to have direct protein-protein interactions with a histone lysine methyltransferase, SMYD2 (SET and MYND domain-containing protein 2), it is also my goal to investigate the chromatin dysregulation, more specifically DNA methylation and histone modifications, associated with loss of *AKAP11* in iPSC-derived neurons. To achieve these goals, I utilized a control induced pluripotent stem cell (iPSC) to knock out *AKAP11* using the RNP-CRISPR Cas9 genome editing technique. Three independent clones, each with a frameshift mutation in *AKAP11*, were obtained. Once differentiated to neurons, I performed RT-qPCR, RNA-seq, and Li treatment on the isogenic *AKAP11*-KOs. The differentially expressed genes in Li+ vs. Li- KOs, Li+ KOs vs. Li+ parental, and the Li- KOs vs. Li- parental line are currently being analyzed. Subsequently, chromatin immunoprecipitation sequencing of SMYD2-deposited histone marks, H3K36me2 and H3K4me3, and whole-genome bisulfite sequencing have are being performed on these isogenic clones and their parental, both before and after Li treatment, to determine genome-wide modifications of these histone marks along with DNA methylation level changes. This study will lead to gaining biologically meaningful information, useful for better understanding, diagnosis, and treatment of complex psychiatric disorders, such as BD and Schizophrenia, in which *AKAP11* has been shown to be a risk gene.

Complex Traits Posters - Wednesday

PB1692*. Trans-ethnic meta-analysis in a multi-ethnic population refines multiple sclerosis susceptibility loci and identifies novel locus

Authors:

A. Beecham¹, L. Gomez¹, S. Caillier², C. Manrique¹, P. Calabresi³, K. Fitzgerald³, N. Patsopoulos⁴, D. Woo⁵, S. Delgado¹, A. China⁶, L. Amezcua⁷, J. Oksenberg², J. McCauley¹; ¹Univ. of Miami, Miami, FL, ²Univ. of California San Francisco, San Francisco, CA, ³Johns Hopkins Univ., Baltimore, MD, ⁴Brigham & Women's Hosp., Harvard Med. Sch., Boston, MA, ⁵Univ. of Cincinnati, Cincinnati, OH, ⁶San Juan MS Ctr., Guaynabo, PR, ⁷Univ. of Southern California, Los Angeles, CA

Abstract Body:

In Northern European populations, 232 autosomal genetic variants have been identified for association with multiple sclerosis (MS) and explain 39% of the genetic component of MS. Despite the rising incidence of MS in African Americans and Hispanics, individuals from these communities remain underrepresented in genetic research. The genetic admixture and unique linkage disequilibrium structure inherent to these populations affords the opportunity to identify novel loci and increase power for fine-mapping. Our goal was to identify novel loci and fine-map previously identified susceptibility loci in African Americans (1625 MS cases, 1506 controls) and Hispanics (2046 MS cases, 2114 controls) ascertained from more than 10 sites across the United States. Samples were genotyped on a customized Illumina genome-wide array with targeted fine-mapping content and subsequently imputed with TopMed. MR-Mega was used for trans-ethnic meta-analysis after controlling for population substructure. We identified four loci outside of the Major Histocompatibility Complex with genome-wide significance in our combined sample of 7291 individuals; including three within 500KB of a previously identified susceptibility variant (*LCK* in 1p35.2, *CD58* in 1p13.1, and *CD86* in 3q13.33) and one which has not previously been reported (*TAF5* in 22q13.32). The most strongly associated variant (OR = 1.63, $p = 3.14 \times 10^{-8}$ and posterior probability of causality = 0.95) in *TAF5* was intronic rs17176694; having the highest allele frequency in Europeans (MAF = 0.13 gnomAD) and Native Americans (MAF = 0.08 PAGE consortium) but rare in Africans (MAF = 0.02 gnomAD). Further investigation is ongoing to determine whether ancestral origin of allele plays a role. *TAF5* is an important biological candidate for MS given that *TAF* proteins are predominantly expressed in the brain and act as regulators of immune and nervous cells. An ancestral specific effect may indicate a role for *TAF5* in the diverse manifestation of MS across populations. The *LCK* signal was fine-mapped to 5 variants in the 99% credible set, spanning 126,194 BP. The most strongly associated variant (OR = 1.85, $p = 1.76 \times 10^{-13}$ and posterior probability of causality = 0.61) is missense mutation rs145088108 which is not present in Europeans (MAF = 0 gnomAD), rare in Africans (MAF = 0.01 gnomAD), and common in Americans (MAF = 0.1 gnomAD). This indicates that novel population-specific risk alleles are yet to be identified even within known susceptibility loci. These findings highlight the utility of a trans-ethnic approach to variant discovery and fine-mapping in a way that will ultimately facilitate treatment and prevention in diverse populations.

Complex Traits Posters - Thursday

PB1693. *TTN* truncating variants in cardiac-expressed exons show high penetrance for cardiomyopathy in carriers with atrial fibrillation

Authors:

K. Barrett¹, E. Cirulli¹, A. Bolze¹, C. Rowan², G. Elhanan³, J. Grzymalski³, W. Lee¹, N. Washington¹; ¹Helix, San Mateo, CA, ²Renown Inst. for Hlth.Innovation, Reno, NV, ³Ctr. for Genomic Med., Desert Res. Inst., Reno, NV

Abstract Body:

Background: Truncating variants in *TTN* (*TTN*tv) represent the largest known genetic cause of dilated cardiomyopathies (DCM). At the population level, even when limited to *TTN*tv in cardiac-specific exons (hiPSI *TTN*tv), penetrance estimates for DCM are low. Recent work shows that individuals harboring *TTN*tv have a high prevalence of other cardiac conditions aside from heart failure, in particular, atrial fibrillation (Afib).

Objectives: (i) Identify exons in *TTN* that are statistically associated with cardiac conditions in the overall population. (ii) Assess whether using additional significantly-associated phenotypes better stratifies cardiomyopathy (CM) risk across *TTN* carriers.

Methods: We leverage longitudinal EHR and exome sequencing data from two cohorts, the UK Biobank and the Healthy Nevada Project, to determine the extent of association between different sets of *TTN*tv and a spectrum of previously implicated cardiac diagnoses using a statistical power-based sliding window analysis technique (“Power Window”). We then assess the penetrance of these variants for CM in the context of the other statistically-confirmed cardio diagnoses.

Results: Controlling for CM and Afib, additional related cardio phenotypes retain only nominal association with *TTN*tv. An unbiased sliding window analysis of *TTN*tv across the locus confirms the association is specific to hiPSI exons for both CM and Afib, with no meaningful associations in lowPSI exons nor improvements from LOFTEE designations. We find 34% of hiPSI *TTN*tv carriers with early Afib have a CM diagnosis - a 5-fold increase in risk over non-carriers with early Afib and 47-fold increase over population controls.

Conclusion: CM and Afib are often coincident in hiPSI *TTN*tv carriers, which represent varying and progressive manifestations of structurally-based heart failure. We provide statistical support for a hiPSI variant interpretation model for *TTN*tv and evidence for the first population-level screening method with clinical utility for cardiomyopathies, especially in relation to an Afib finding.

Complex Traits Posters - Wednesday

PB1694. Understanding the effect of non-coding de novo mutations within craniofacial enhancers in trios with orofacial clefts

Authors:

S. Curtis¹, K. Paraiso², P. Kumari³, S. Chung¹, M. Bishop¹, K. Diaz Perez¹, H. Brand⁴, J. Murray⁵, E. Feingold⁶, T. Beaty⁷, S. Weinberg⁶, M. Marazita⁸, M. Epstein¹, D. Cutler¹, R. Cornell³, J. Cotney⁹, A. Visel², E. Leslie¹; ¹Emory Univ., Atlanta, GA, ²Lawrence Berkeley Natl Lab., Berkeley, CA, ³Univ of Washington, Seattle, WA, ⁴MGH, Wilmington, MA, ⁵U of Iowa, Iowa City, IA, ⁶Univ of Pittsburgh, Pittsburgh, PA, ⁷Johns Hopkins Univ, Sch PubHlth, Cockeyville, MD, ⁸Univ Pittsburgh, Ctr. for Craniofacial and Dental Genetics, Pittsburgh, PA, ⁹UConn Hlth., Farmington, CT

Abstract Body:

Orofacial clefts (OFCs) are a common birth defect, affecting 1 in 700 births, with a strong genetic basis and a high recurrence risk within families. Previous studies have associated many common variants with OFCs, primarily in non-coding elements, but the contribution of de novo mutations (DNMs) in these non-coding elements is not well understood. Therefore, we analyzed two datasets of 2,168 trios with OFCs and hypothesized that non-coding DNMs in craniofacial enhancers are associated with OFC risk. The first dataset included 66 DNMs in 1,409 trios with targeted sequencing of 13 known OFC-associated loci. We annotated variants to predicted craniofacial enhancers based on epigenetic marks in human embryos during craniofacial development. 17 DNMs (24.2%) were in a predicted enhancer region, and 2 DNMs were in the same enhancer (hs1617), which is more than expected by chance ($p = 0.0038$). These DNMs are predicted to lead to binding sites for PAX6 and ZBTB7A transcription factors (TFs) and to disrupt binding sites for STAT1 and STAT3. The enhancer is in a large topologically-associated domain containing HHAT, SERTAD4, and IRF6, all of which are involved in craniofacial development, suggesting a potential mechanism where mutations in an enhancer could disrupt expression of craniofacial genes. We next looked genome-wide at 49,620 DNMs called in a cohort of 759 trios with whole-genome sequencing data from the Gabriella Miller Kids First Research Program. Compared to DNMs called in the 1000 Genome Project, trios with an OFC had a higher frequency of DNMs in enhancer regions, with 234 DNMs being in strong craniofacial enhancers, which was more than expected by chance ($p < 2e-16$). Looking at individual craniofacial enhancers, we found 2 enhancers in OFC trios with an excess burden of DNMs: one upstream of SPIN1 ($p = 3.7e-6$), a chromatin reader that regulates the Wnt signaling pathway; and one within MPPED2 and downstream of ARL14EP ($p = 5.9e-5$), which is transcribed during facial development. When testing for enrichment of TF binding sites near DNMs genome-wide, binding sites for 295 TFs were enriched in trios with OFCs (after Bonferroni correction, $p < 6.8e-5$), and were more likely to be involved with embryo development ($p = 2.8e-3$) and regionalization ($p = 1.9e-2$). By contrast, the 106 TFs enriched in 1000G trios were more likely to be involved in hemostasis ($p = 1.3e-4$) and coagulation ($p = 7.4e-4$). Taken together, this suggests that non-coding DNMs could potentially affect developmental pathways leading to OFCs, and that investigating non-coding DNMs, both near known OFC-associated loci and genome-wide, adds to our understanding of the genetic mechanisms of OFC formation.

Complex Traits Posters - Thursday

PB1695. Understanding the etiology of Alzheimer's disease using genetically predicted gene expression and brain feature models

Authors:

E. Wu, Y. Liang, F. Nyasimi, H. Im; Univ. of Chicago, Chicago, IL

Abstract Body:

Treatment of Alzheimer's disease (AD) is one of the foremost public health concerns in the modern era. The genetic component of AD remains under-explained and is a promising direction of inquiry to further understand the complex mechanisms underlying the disease and develop effective treatment methods. In light of this, we applied cutting edge genetic association techniques, S-PrediXcan and S-BrainXcan, which leverage large-scale omics data to enhance the detection of AD-associated genes and brain features. S-PrediXcan is a transcriptome-wide association study method that uses publicly available GWAS summary statistics and imputes the unobserved transcriptome to associate with a trait of interest using 49 tissue-specific reference prediction models built from GTEx (v8) eQTL data. This analysis allows us to identify significant genes that are predicted to be differentially regulated under normal and AD conditions. We performed S-PrediXcan and subsequently S-MultiXcan - an aggregation method that meta-analyzes S-PrediXcan results across different tissues - on the most recent published AD GWAS and detected 166 genes associated with AD, with 7 genes not found in a previous GWAS or TWAS locus: *RP11-138I18.2*, *AC012370.3*, *SIGLEC11*, *LRP4*, *ZNF652*, *SUSD3*, and *PITPNA*. Additionally, we performed S-BrainXcan of AD, which is a similar method to S-PrediXcan that uses GWAS summary statistics and reference MRI imaging data from the UK Biobank to predict and identify significant brain features associated with disease in the form of image-derived phenotypes (IDPs). We identified changes in 25 T1 and diffusion MRI IDPs that were significantly associated with AD, which overall suggested that structural white matter, but not grey matter atrophy predisposes disease development. While these are exciting steps towards elucidating the causes of Alzheimer's disease, additional mechanistic studies will be needed to fully understand the biological signals captured by these results.

Complex Traits Posters - Wednesday

PB1696. Understanding the molecular basis of SARS-CoV-2 pathogenesis at a gene expression level using Applied Biosystems™ TaqMan™ Flexible Array Panels

Authors:

A. Gupta¹, R. Yang¹, K. Li¹, A. Chen², P. Kilgas³, K. Kirchmeier³; ¹Thermo Fisher Scientific, south san francisco, CA, ²Thermo Fisher, Carlsbad, CA, ³Thermo Fisher Scientific, Carlsbad, CA

Abstract Body:

The broad spectrum of clinical manifestations from SARS-COV-2 infection and observed risk factors for severe disease highlight the importance of understanding molecular mechanisms underlying SARS-CoV-2 associated disease pathogenesis. Research studies have identified a large number of host proteins that play roles in viral entry, innate immune response, or immune signalling during infection. The ability to interrogate subsets of these genes simultaneously within SARS-COV-2 infected samples is critical to understanding how their expression contribute to phenotypic variability of the disease caused by the pathogen. To bridge this gap, we obtained nasopharyngeal swabs from 30 SARS-CoV-2 infected individuals with asymptomatic or symptomatic disease, and 30 healthy controls and used flexible TaqMan array panels designed to interrogate SARS-CoV-2 associated genes for virus entry, cellular restriction factors as well as cytokines, chemokines, and growth factors shown to be dysregulated in SARS-CoV-2 infection. We observed that several genes were differentially modulated between asymptomatic and symptomatic SARS-CoV-2 infected samples, as well as between infected and healthy controls, shedding light on how host-pathogen interactions influence disease development. For instance, the gene expression of ACE2 was found to be significantly downregulated in symptomatic samples compared to asymptomatic samples from infected subjects, a finding supported by other studies and shown to be associated with increased inflammation. Furthermore, we observed sex-related differences in the expression levels of specific entry receptors and inflammatory mediators, which provides insights on the relationship between sex-bias and SARS-CoV-2 associated disease severity. Ultimately, investigation of such virus and host-associated factors in various cell and sample types can greatly increase our understanding of disease pathogenesis which may help in the development of novel therapeutics against the virus and the disease caused by it.

Abstract Body:

Major advances in sequencing technologies have greatly increased diagnostic rate of neurodevelopmental disorders (NDDs). Still, a molecular diagnosis is reached in only 30%. Epigenetic marks as X-chromosome inactivation (XCI), and recently defined “episignatures” can both guide clinical re-evaluation, and further genetic analysis in unsolved NDD cases. We explored skewed XCI, episignature profiles (EpiSign™ classifier), whole genome sequencing (WGS) and integrated a-CGH/exome sequencing (ES) data in a deeply phenotyped cohort of unsolved NDD cases, negative at FRAXA, array-CGH and trio-ES [pathogenic(P)/likely pathogenic (LP) variants: 29% (173/589 cases); variant of uncertain significance (VoUS) :13% (78/589); novel genes:7% (39/589); unsolved:51% (299/589)]. We found a skewed XCI in 14/201 (7%) of mothers of undiagnosed males, and 12/98 (12%) female patients. We possibly solved 8/26 (31%) whose causative gene was previously missed. Four occurred in genes encoding chromatin remodeling proteins; in *KDM5C* and *BRWD3*, we confirmed the corresponding episignature [(i) *KDM5C*:D402N LP variant (female; 90:10 XCI); (ii) *BRWD3* c.1233-7_1233-3del LP (male; mother 90:0 XCI); (iii) *OTUD5*:P509L LP in recently described gene (two brothers, mother 100:0 XCI); (iv) *ZMYM3*: R441Q, a strong novel gene candidate (male; mother 100:0 XCI)]. We exploited episignatures to further interpret VoUS in chromatin remodeling genes (17/78; 22%). Twelve did not show a methylation profile compatible with the mutant gene, suggesting that variant was benign. Interestingly, a case with *ARID1B*:D1074N classified as VoUS, was not confirmed as Coffin-Siris syndrome 1 by EpiSign™ classifier, but confidently positive for Cornelia de Lange Syndrome (CdLS). So far, exome data did not reveal causative variant in CdLS genes. Deep phenotyping was especially useful in a boy with *ATRX*-like phenotype where subsequently was found an *ATRX* deletion of exons 3-4 (confirmed with episignature and mother 100:0 XCI), family with two different *de novo* variants in two similarly affected brothers (*TRIP12*:L1044Ffs*3, *FBN1*:A1728V), and case of Apert syndrome, negative to *FGFR2* point mutations, where was found an *Alu* insertion in intron 7 of the gene, using WGS. Combining array-CGH and ES, we solved a female case with an autosomal recessive intellectual disability associated with *HNMT*; the disease was due to a paternal missense p.Y147H and a 760kb

ASHG 2022 Annual Meeting Poster Abstracts

maternal deletion. Our work suggests that trio-ES analyses is greatly improved by deep phenotyping, XCI analysis to pinpoint X-linked genes, functional tests to verify VoUS in genes associated with epesignatures, as well as combining array-CGH and ES data.

Hosp., Glasgow, United Kingdom, ⁵Regeneron Genetics Ctr., Tarrytown, NY, ⁶Cardiff Univ., Cardiff, United Kingdom

Abstract Body:

There is large variation in the clinical presentations and progression between Parkinson's disease patients. The generation of deeply and longitudinally phenotyped patient cohorts has enormous potential to identify disease subtypes for prognosis and therapeutic targeting. Replicating across three large cohorts of Parkinson's disease patients with extensive clinical observational data repeatedly collected over many years, we developed a Bayesian multiple phenotypes mixed model incorporating the genetic relationships between individuals which was able to reduce a large number of diverse clinical measurements into a smaller number of continuous underlying factors ("phenotypic axes"). The most influential of three principal axes of Parkinson's disease patient phenotypic variation identified was specifically associated with the genetic risk of Alzheimer's disease and CSF A β 1-42 level. As observed previously for Alzheimer's disease genetic risk and in contrast to Parkinson's disease genetic risk, the loci influencing this primary axis were associated with microglia-expressed genes. These results suggest that neuroinflammation influences the development of more aggressive forms of Parkinson's disease. Finally, by integrating the individual Alzheimer's disease genetic risk into our model, we could significantly more accurately predict patient clinical progression as compared to using the full genotype. Our results propose that Parkinson's disease patients with a higher genetic risk for Alzheimer's disease are more likely to develop a more severe and rapidly progressing form of Parkinson's disease including, but not limited to, dementia.

Abstract Body:

Despite its high prevalence and high heritability, very little is known about the genetic basis of autoimmune hypothyroidism¹. For this reason, we have performed the largest GWAS meta-analysis of autoimmune hypothyroidism to date to gain more insight into the genetic basis of this disease. We obtained GWAS summary statistics from nine cohorts, including 48,149 cases and 863,954 controls. Cases were defined as individuals with an ICD9/10 code for autoimmune thyroiditis and unspecified hypothyroidism. Individuals without any thyroid disease were used as controls. Reference genomes were used to impute missing genotype data^{2,3}. Covariates adjusted for in our analysis include age, sex, population structure, and related individuals³. Using METAL, we performed the largest GWAS meta-analysis to date on hypothyroidism⁴. We identified 75 independent SNPs passing the GWAS significance threshold ($p=5 \times 10^{-8}$) after Bonferroni test correction to be associated with autoimmune hypothyroidism. Preliminary pathway analyses suggest involvement of known immune pathways as well as enrichment of associations in chromatin structure regulation. Identification of novel genetic determinants is a key step in advancing the understanding of this common disease. This knowledge could be applied to help predicting disease onset, personalized management, and treatment of autoimmune hypothyroidism.

Complex Traits Posters - Wednesday

PB1700*. Unsupervised learning revealed metabolic syndrome sub-groups with differing phenotypic and genotypic traits

Authors:

A. Lim^{1,2,3}, E. U. Lim¹, P-L. Chen^{4,5}, C. S. J. Fann^{1,2}; ¹Inst. of BioMed. Sci., Academia Sinica, Taipei, Taiwan, ²Taiwan Intl. Graduate Program in Molecular Med., Natl. Yang Ming Chiao Tung Univ. and Academia Sinica, Taipei, Taiwan, ³ASUS Intelligent Cloud Services (AICS), Taipei, Taiwan, ⁴Natl. Taiwan Univ. Hosp., Taipei, Taiwan, ⁵Natl. Taiwan Univ., Taipei, Taiwan

Abstract Body:

Metabolic syndrome (MetS) is a collection of cardiovascular risk factors of hypertension, hyperglycaemia, obesity and dyslipidaemia that overlap and highly heterogenous. Through unsupervised learning, five MetS subgroups were identified in UK Biobank which were C1: non-descriptive (n=33,707), C2: hypertensive (n=23,215), C3: obesity (n=30,089), C4: lipodystrophy (n=13,116) and C5: hyperglycaemia (n=3,869). Association of 21 clinical outcomes were compared through multivariate logistic regression. Overall combined CVD outcomes odds ratio of MetS was 5.517 (CI=5.207, 5.847). Some MetS clusters had higher CVD risks such as C1 (OR=6.765, CI=6.360, 7.192) and C5 (OR=9.486, CI=8.680, 10.360). Despite being undescriptive across all traits, C1 had higher risks for most clinical outcomes and highest CVD risk after adjustment for T2D. Intriguingly, the C2 overall had lower disease risk (combined CVD OR=3.783, CI=3.540, 4.043). GWAS of each MetS clusters with healthy control revealed different genetic variants, genes and biological pathways. *LPCAT2* was associated with all clusters and expression is specific to innate immune cells, implying an important underlying shared pathophysiology of chronic inflammation. BMI-associated genes *NUDT21* & *OGFOD1* were also associated with all clusters. C1 GWAS revealed novel findings such as *TRIM63* (rs35738294), *MYBPC3* (rs11039155, rs77509279), *MYLPP* (rs8054556) and *RAPSN* (rs77509279, rs4603265). *TRIM63* & *MYBPC3* are specifically upregulated in cardiac tissues while *MYLPP* & *RAPSN* in skeletal muscles. *MYLPP* was unique to only C1. C1, C3 & C4 were associated with genes highly expressed in brain tissues such as *CNIH2*, *TMEM151A*, *MT3* & *CIQTNF4*, highlighting the involvement of hypothalamus & pituitary in these clusters. C5 GWAS identified a novel regulatory SNP (rs142827301) which interacts with *ZPHHC6*, *SMC3*, *SHOC2*, *TCF7C2*, *VTI1A* and *BBIP1*; most are not known cardiometabolic genes. Other genes identified by C5 GWAS were known T2D genes such as *TCF7L2*, *IRS1*, *BBIP1* & *GIN1*. GWAS C2 revealed novel genetic variants in known cardiometabolic genes such as rs1260326 (*GCKR*), & rs633185 (*ARHGAP42*). When analysing the cluster-specific genes, C1 had 156 distinct genes while C2 had 18, C3 had 93, C4 had 123 and C5 had 16. C5 gene-set analysis was associated with pancreas while other clusters were associated with mostly lipoprotein and lipid homeostasis. MetS subgroups are semi-distinctively different in terms of phenotypic and genotypic traits, representing a key step towards precision medicine. GWAS of clinically relevant subgroups can reveal novel cardiometabolic genotypes which might be masked by heterogeneity of MetS.

Complex Traits Posters - Thursday

PB1701. Untargeted metabolomics on nutrient density and their genomic interaction among Mexican Americans

Authors:

S. Chung¹, C. Evans², C. F. Burant², D. Aguilar^{1,3}, E. L. Brown¹, C. L. Hanis¹, G. Jun¹; ¹Dept. of Epidemiology, Human Genetics & Environmental Sci. (EHGES), Sch. of Publ. Hlth., Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, ²Michigan Regional Comprehensive Metabolomics Resource Core, Univ. of Michigan, Ann Arbor, MI, ³Div. of Cardiovascular Med., Univ. of Kentucky, Lexington, KY

Abstract Body:

About one-third of U.S. adults suffer from prediabetes and diabetes mellitus. Since diabetes can cause damage to multiple organs resulting in diverse complications, understanding how this condition develops in its early stages is essential for efficient preventive intervention. Although evidence suggests that interactions between genetics and diet contribute to worsening glycemia little is known about gene-diet interactions due to the sheer number of possible hypotheses, limited power, and absence of appropriate data. This study aims to identify genetic variants interacting with diet by utilizing untargeted metabolomics data coupled with genome-level genotyping and extensive phenotyping. The metabolomic data are much more *proximal* to both genes and the diet than typical endophenotypes. Among 616 participants in Starr County, Texas, an initial set of 486 were available with requisite data for preliminary analyses. Genetic variants were obtained from previously imputed GWAS data. Nutrient intake was assessed by food frequency questionnaires and transformed to nutrient densities based on standardized recipes and the amount of energy intake. Metabolomic data were standardized and log-transformed. 325 identified plasma metabolites were evaluated for associations with genetic variation, glycemic traits, and nutrient intake. Age, gender, and BMI were adjusted in all analyses. Eighty metabolites were significantly associated with genetic variants via Generalized linear Mixed Model Association Tests (GMMAT) (p-value < 5E-08). Twenty metabolites showed statistically significant associations with derived nutrient intake variables by linear regression models (p-value < 1.5E-04). These included 3-hydroxybutyric acid associated with protein intake, fasting plasma glucose, 2-hour plasma glucose, HbA1c, and glucose intolerance status. To investigate gene-nutrient density interactions, Mixed-model Association tests for Gene-Environment interactions (MAGEE) are used. We analyze interactions between genetic variations and major nutrient intake, and preliminary analyses identified several significant interactions with protein and carbohydrate intake. For example, more than ten significant genetic variants were associated with 3-hydroxybutyric acid in the gene-protein and gene-carbohydrate interaction analyses, and these were not founded on the GMMAT. Our preliminary results inform which metabolites are affected both by gene and specific nutrient intakes, suggesting that more personalized approaches could be developed for preventive interventions for prediabetes and diabetes in Mexican Americans.

Complex Traits Posters - Wednesday

PB1702*. Using genetics to uncouple highly correlated metabolic phenotypes and test their separate role in disease.

Hosp., Edinburgh, United Kingdom, ¹⁵Univ. of Washington, Seattle, WA, ¹⁶Fred Hutchinson Cancer Res. Ctr., Seattle, WA, ¹⁷Brunel Univ. London, London, United Kingdom

Abstract Body:

Genetic variants are usually associated with traits that mirror observational associations - for example, alleles associated with higher LDL-Cholesterol are also associated with higher cardiovascular disease risk. However, some variants do not follow expected patterns and can be useful to understand the separate roles of different risk factors in disease that would be difficult to test with other study designs. We used genetics to uncover whether the aspect of higher adiposity causing several obesity-driven diseases is the accompanying adverse metabolic profile or a secondary (e.g. mechanical) effect.

We selected two clusters of variants - a set that follow expected patterns (alleles associated with higher adiposity and an adverse metabolic profile - metabolically unfavourable adiposity (UFA)), and a set that follow unexpected patterns (alleles associated with higher adiposity and a favourable metabolic profile - favourable adiposity (FA)). We performed two-sample Mendelian randomisation (MR) with these variants and 37 obesity-associated diseases using genome-wide association study (GWAS) summary statistics from the largest available published GWAS meta-analyses and the latest release of FinnGen consisting of 309,154 individuals, allowing real-time updates with FinnGen releases.

Our MR analysis identified two groups of diseases. First, 8 conditions where the FA effect was protective of disease but the UFA effect was a risk factor, and so the metabolic component is the likely cause, including type 2 diabetes (FA: 0.12 OR [95% CI: 0.09, 0.17], P = 3E-34; UFA: 5.14 OR [4.08, 6.48], P = 1E-43), polycystic ovary syndrome (FA: 0.46 OR [0.21, 0.99], P = 0.046; UFA: 5.72 [3.16, 10.34], P = 8E-9) and colorectal cancer (FA: 0.67 OR [0.53, 0.84], P = 6E-4); UFA: 1.23 OR [1.02, 1.49], P = 0.034). Second, 10 diseases where both FA and UFA effects were risk factors for disease and so some non-metabolic (e.g. mechanical) aspect is likely causal, including venous thromboembolism (FA: 2.50 OR [1.89, 3.31], P = 2E-10; UFA: 1.55 OR [1.23, 1.96], P = 2E-4), deep vein thrombosis (FA: 2.83 OR [1.67, 4.80], P = 1E-4; UFA: 2.04 OR [1.26, 3.32], P = 0.004) and osteoarthritis (FA: 1.43 OR [1.04, 1.96], P = 0.027; UFA: 1.85 OR [1.41, 2.44], P = 1E-5).

We found evidence for similar contributions of metabolic and non-metabolic components for heart failure (FA: 0.95 OR [0.74, 1.22], P = 0.695; UFA: 2.22 OR [1.82, 2.72], P = 9E-15) and atrial fibrillation (FA: 0.91 OR [0.61, 1.37], P = 0.656; UFA: 1.89 OR [1.46, 2.43], P = 1E-6).

Our results represent clear examples of how using genetic variants with unexpected effects on related phenotypes can be used to understand the role of different risk factors in disease.

Complex Traits Posters - Thursday

PB1703. Using Independent Component Analysis to disentangle obesity heterogeneity discovers genetic drivers of clinical disease signatures and their variation with BMI status.

Authors:

M. Shuey¹, E. Farber-Eger², T. Lasko¹, Q. Wells³; ¹Vanderbilt Univ. Med. Ctr., Murfreesboro, TN, ²Vanderbilt Univ, Nashville, TN, ³Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract Body:

Attempting to understand the heterogeneity of a condition such as obesity by assigning each patient to exactly one subgroup, depending on their pattern of clinical variables, neglects the fact that patients usually express the clinical signatures of multiple conditions simultaneously. Instead of this *hard clustering* approach, a *soft clustering* approach that disentangles multiple clinical signatures appearing in a population by allowing each patient to express any number of those signatures can more effectively identify disease variants, and potentially enabling the discovery of precise disease sources, prognoses, and optimal treatments.

We used Independent Component Analysis (ICA), a soft clustering approach that relies on the probabilistic independence of unrelated disease sources, to disentangle the clinical heterogeneity of obesity from data in electronic health records (EHRs). A set of 46 obesity-relevant clinical variables derived from demographics, laboratory measures, medications, and disease phenotype codes (Phecodes) was extracted, which we divided into those with high body mass index (BMI ≥ 30 kg/m², 16,030 patients), and low BMI (27,551 patients). Mutually independent clinical signatures were disentangled by applying ICA to the high BMI subgroup, and the records of the low BMI subgroup were projected into this space. We used the expression of each patient for each clinical signature as a phenotype for GWAS and performed gene-set and genetic correlation analyses to evaluate their genetic architecture conditioned on BMI state (high vs. low vs. unconditioned).

The analysis identified 46 clinical signatures across the spectrum of all disease, most of which were clinically recognizable, and eight (17%) of which included BMI as an important variable. Most signatures had expected genetic associations, but 11 (23.9%) signatures had associations that varied dramatically with BMI conditioning, suggesting that some genetic variants have different clinical effects on obese vs. non-obese individuals. For example, the results for an elevated liver enzyme signature demonstrated significant gene-set associations for *PNPLA3* ($p=4.1E-14$) and *SAMM50* ($p=5.0E-10$) genes in the high-BMI, but in the low-BMI cohort the most significant association was with *SLC39A12* ($p=0.8E-10$).

Our results support this data-driven approach to disentangle simultaneously-expressed clinical signatures of heterogenous disease. Some of the identified signatures demonstrate variable associations based on clinical state (e.g. BMI > 30 kg/m²) which may suggest the need for novel strategies for clinical care and intervention for these signatures based on weight.

Complex Traits Posters - Wednesday

PB1704*. Using Stimulation of B cells to uncover novel disease-associated QTLs

Authors:

D. Murphy, Y. Fu, J. Kelly, R. Pelikan, G. Wiley, J. Lynn, P. Gaffney; Oklahoma Med. Res. Fndn., Oklahoma City, OK

Abstract Body:

Although millions of disease-associated variants have been discovered using GWAS, the bulk of these occur in non-coding regions and their mechanistic link to disease is unclear. Further, separating causal from neutral variants within clusters of genetically linked loci remains challenging. To date, analyses of expression quantitative trait loci (eQTLs) in healthy tissues only account for a subset of GWAS hits, as there is limited overlap between the mechanisms driving variant discovery in the two approaches. Epigenome-based QTL phenotypes, such as chromatin accessibility (caQTL) or histone modification (hQTL), may capture distinct regulatory mechanisms that are not detected using eQTL analysis. Moreover, latent QTLs that more accurately regulate disease-specific mechanisms may be revealed by the comparison of healthy “resting” to stimulated tissue within the same set of samples. To this end, we performed ATAC-seq on resting and stimulated B cells purified from 81 genotyped healthy individuals of European ancestry using a general immune response “danger” stimulus consisting of BCR crosslinking, CD40 co-stimulation, and TLR7. We identified 42,746 differentially accessible (DA) chromatin regions when comparing pairs of resting and stimulated samples using DESeq2. We then used RASQUAL with normalized ATAC-seq read counts to identify 67,165 chromatin accessibility QTLs (caQTLs) either within the DA regions or 1kb upstream or downstream of these regions. Thousands of the discovered QTLs are stimulus-dependent (stQTLs), i.e., their effects are only revealed in the stimulated state. Relative to the total set of QTLs, stQTLs are enriched in enhancer-like sequences, transcription factor binding domains, autoimmune risk variants, and are distributed further from transcription start sites. Our approach also reveals different types of stQTLs, including variants with dominant and recessive effects, and stQTLs whose effects are lost under stimulation. Collectively, these results show the promise of stimulation for discovery of novel, conditionally regulated mechanisms associated with disease using a multi-omics approach beyond expression data alone. Incorporation of stimulus-response study designs into future QTL discovery efforts could identify QTLs that better explain risk for complex genetic diseases.

Complex Traits Posters - Thursday

PB1705. Using whole genome sequencing to understand the genetic architecture of cerebral palsy in a Canadian cohort.

Authors:

Abstract Body:

Cerebral palsy (CP) is a permanent, non-progressive brain injury leading to movement and posture disorders. It can involve comorbidities, including other neurodevelopmental disorders (NDD). Genomic changes have increasingly been found to play a role in etiology of CP. We applied Whole Genome Sequencing (WGS) to uncover a more complete landscape of genetic variation in both nuclear and mitochondrial DNA (CNVs, structural variations, SNVs, indels, tandem repeat (TR) variations, and mitochondrial DNA (mtDNA) variations) on a representative sample of 327 individuals with CP recruited from CP-NET (Ontario) and the Canadian CP Registry. The cohort included 308 complete trio and four quartet families. We also analyzed genomes from two paediatric control cohorts (100 quartets, 203 trios). These latter data were used for comparison of *de novo* rates, and for statistical analyses.

We found clinically relevant alterations (CNVs, SNVs, indels, SVs, and mtDNA variants) in 30% of cases. Roughly one-third of these (12% of the total) were classified as pathogenic/likely pathogenic. This includes pathogenic mtDNA variants in 1.5% of cases, 1q21.1 distal duplication, deletions of 17p12 and 2q13, and single-gene deletions of *NRXN1*, *ARID2*, and *DLG2*. *De novo* or rare-inherited protein truncating variants (PTVs) were found in *SPAST*, *TRIP12*, *ERLIN2*, and *MEF2C*, and *de novo* or rare-inherited missense variants in *COL4A1*, *PIK3R2*, *TUBA1A* and *GNAO1*. Two aneuploidies were detected (trisomy 21 and 47,XXX). The *de novo* rate for CNVs and PTVs was higher in CP as compared with controls (CNVs: 5.8% vs 2.7%, PTVs: 14.7% vs 11.2%). While the *de novo* variants identified in the CP cohort accounted for a portion of clinically relevant variants, all *de novo* variants in paediatric controls were assessed as not clinically relevant to CP or NDD.

We performed pathway analysis of over-transmission of large TRs from parent to child, and burden of *de novo* SNVs in both CP cases and paediatric controls. Other classes of variants were not similarly analyzed due to a lack of power. We did not find enrichment of SNVs or over-transmission of large TRs in the paediatric controls. However, in the CP cohort, we observed an enrichment of *de novo* PTVs and missense variants in neurological pathways associated with nervous system development and function. Missense variants were also enriched in genes with high expression in the brain. We also found an over-transmission of large TRs in genes related to brain function in individuals with CP. Our analysis of WGS in CP highlights the importance of searching for clinically relevant variants in all classes of genomic aberrations in this complex neuromotor condition.

PB1706. USP53 variant associated with psychosis in a consanguineous pedigree.

Authors:

J. V Pardo¹, A. Kanwal², S. Sheikh³, A. Iftikhar², F. Aslam⁴, S. Yasin², S. Naz²; ¹Univ. of Minnesota & MVAHCS, Minneapolis, MN, ²Univ. of the Punjab, Lahore, Pakistan, ³Hawkes Bay Hosp., Hastings, New Zealand, ⁴Univ. of the Punjab, Lahore. Pakistan, Lahore, Pakistan

Abstract Body:

Mendelian variants for common psychiatric disorders such as schizophrenia are rarely sought. Yet, such variants are the most direct link between disease and its pathophysiology are as well foundational to many medical fields. The paucity of understanding the underlying biology impedes translational progress. To find such rare variants where they are most likely to be identified, we recruited multiplex consanguineous families with apparent Mendelian recessive segregation and an extreme phenotype: early onset, severe, treatment-resistant psychosis without comorbidity. A Pakistani family involving first cousin parents had six children. All were healthy except for two sisters with the extreme psychosis phenotype. No intellectual disability or substance abuse was present. Whole-exome sequencing was used to determine the cause of the disorder by evaluating the DNA of the affected sisters and one parent. All rare homozygous variants (allele frequency < 0.01) absent as homozygous in normative databases were considered. The allele frequency was $(10)^{-5}$ in south Asians. Candidate variants were analyzed by computational tools and Sanger sequencing of DNA from all participants. A ubiquitin specific protease USP53 variant, p.(Cys228Arg), predicted in silico as damaging segregated with psychosis. The variant was not a polymorphism (absent in 400 ethnically-matched, indigenous controls). The affected amino acid was absolutely conserved among vertebrates. The functions of USP53 remain unclear, but it has been associated with cholestasis, hearing loss, cancer, neural tissue, and bone development. USP53 lacks deubiquitinase catalytic activity; its function must rely on protein-protein interactions. Symptoms of reported human USP53 variants center on cholestasis with or without hearing loss—both absent in the affected participants. Murine USP53 Cys228 when mutated to serine causes hearing loss—highlighting its significance in neural processing. USP53 is implicated in several pathways relevant to schizophrenia such as ubiquitin processing, folate metabolism, neurotransmission, and tight junction physiology. The variant is unlikely to be incidental or false positive: several studies using the same approaches and parameters have produced either none or single novel variants of interest per family for a variety of different disorders including patients with the psychosis phenotype. This work suggests this USP53 variant may be a potential cause of psychosis and motivates functional studies to define its pathogenicity.

Complex Traits Posters - Thursday

PB1707. Validation of a rapid TTR genotyping assay as a point-of-care tool for cardiac amyloidosis diagnosis in low-income settings

Authors:

C. Anyika¹, N. Gandotra², C. Scharfe², E. Miller², M. Murray², T. 54gene¹, D. Attiogbe Attipoe¹, A. Ene-Obong¹, C. O'Dushlaine¹, O. Popoola¹; ¹54gene, Lagos, Nigeria, ²Yale Univ., New Haven, CT

Abstract Body:

Transthyretin cardiac amyloidosis (ATTR-CA) is a form of heart failure, characterized by progressive accumulation of misfolded transthyretin (TTR) protein in tissues, predominantly the nerves and heart. The *TTR* gene variant *c.424G>A, p.V142I* (a.k.a. *V122I*) is hereditary, pathogenic, and predominant in patients of West-African origin. However, ATTR-CA is typically unrecognized in this population due to the limited information on the clinical relevance of the variant, as well as expensive diagnosis. In response to this unmet need, a low-cost PCR-based TTR assay was developed by the Scharfe Lab at Yale (<https://medicine.yale.edu/lab/scharfe/research/rapidgenotyping/>) to enable rapid genetic diagnosis of the *TTR* variant in at-risk patients.

Using this assay, we evaluated the expression of *TTR V142I* in 100 whole blood samples from the 54gene Biobank Lagos Nigeria. These samples were recruited from participants with clinically-defined cardiovascular disease, as part of an ongoing 54gene research recruitment. We identified the *TTR* wild-type successfully in all samples tested. Additionally, we identified the *TTR V142I* variant in 2 of the 100 samples tested. These findings were corroborated by whole-genome sequencing performed in-house, confirming that this rapid TTR assay is capable of successfully identifying both WT and variant *TTR* in the African population tested.

We also assessed a larger database of ~16,000 individuals with *V142I TTR* genotypes available from our in-house custom GENIISYS microarray. The average minor allele frequency in this set was 0.0196, consistent with earlier reports. These individuals spanned >200 unique self-reported ethnolinguistic groups, 42 of which were represented by at least 20 individuals. We identified significant variation in minor allele frequency of the *TTR* variant in this set, ranging from a maximum of 0.044 to a minimum of 0. For a subset of about half the individuals that had a cardiovascular disease diagnosis, we see some modest enrichment of the *TTR* minor allele frequency in a number of populations. Our resulting data set validates the use of this assay as an affordable point-of-care test for LMIC hospitals and laboratories in West Africa, to better diagnose ATTR-CA.

Complex Traits Posters - Wednesday

PB1708. Variant analysis of disease causing genes and risk factor genes in patients with Parkinson's Disease.

Authors:

L. Andriamboavonjy¹, C. Michaud², M. Labrecque¹, M. Panisset¹, S. Audet¹, M. Tétreault¹; ¹CRCHUM, Montréal, QC, Canada, ²IRCM, Montréal, QC, Canada

Abstract Body:

Parkinson's disease is a complex disorder in which environmental variables and genetic predisposition can lead to disease apparition and progression. To date, 14 highly penetrant disease-causing genes and more than a hundred risk factor genes have been described. The disease-causing genes only explain 30% of familial and 3 to 5 % of sporadic PD. On the other hand, genetic risk factors explain a larger proportion of patients, but cannot predict its apparition since other variables are required. Since most PD patients are without familial history of the disease, clinical genetic testing is not frequently performed. This lack of knowledge of the genetic pathogenicity of PD complicates its positive diagnosis as well as the distinction of atypical PD. Hence, studying the interaction of PD gene polymorphisms could help better understand the molecular pathways involved in the progression of the pathology.

For this study, 13 parkinsonian patients, who did not have access to genetic screening prior to their recruitment had their blood sampled. We conducted a whole-exome sequencing (WES) on the DNA extracted from peripheral blood mononuclear cells and extracted all the high-confidence single nucleotide variants (SNV) of PD-related genes following variant calling. Our approach led to the detection of six SNVs in disease-causing genes, four of which were in the coding region of *PINK1*, *DNAJC6* or *GBA*, and mostly of uncertain significance (VUS). All 13 patients possessed at least one of 54 SNVs identified in risk factor loci, 37 of which were coding variants causing non-synonymous changes, and eight were either a frameshift indel or a splicing site variant. In several cases, patients were carrying the exact same variant, which was the case of two *MAPT* variants. A gene clustering analysis identified an enrichment of mutations linked to pathways such as transcription regulation and maintenance of gastrointestinal epithelium which is particularly interesting due to the gut-brain axis theory of PD.

We were also able to identify 18 homozygous variants unknown to be PD-related in our population, which have an allele frequency inferior to 5% and a CADD score over 20, with all of them of uncertain significance. Those variants can potentially be PD-related and need further experiments for validation. While results are still preliminary, it will be interesting to perform a biological validation of the VUS or increase our cohort size to assess their implication in PD. Another main takeaway from our findings is the apparent clustering of variants that may affect transcription regulation; hence a transcriptomic analysis will be necessary to further our research in the genetic understanding of PD.

Complex Traits Posters - Thursday

PB1709. Variants in *GBA* and *MAPT* influence parkinson disease risk and age at onset in a colombian patient

Authors:

J. Satizabal Soto, D. Arturo-Terranova, L. Moreno Giraldo; Univ. del Valle, Cali, Colombia

Abstract Body:

Mutations in *GBA*, the gene encoding the lysosomal enzyme glucocerebrosidase, are among the most known genetic risk factors for the development of Parkinson disease and related synucleinopathies. Parkinson disease (PD) is a neurodegenerative disorder defined by the presence of motor symptoms and signs. A great deal is known about *GBA1* are causal for the rare autosomal storage disorder Gaucher disease. Over the past decades, significant progress has been made in understanding the genetics and cell biology of glucocerebrosidase. Both patients with Gaucher disease (GD) and heterozygous carriers are at increased risk of developing Parkinson disease, Age at Onset (AAO) and Dementia with Lewy Bodies, although our understanding of the mechanism for this association remains incomplete. The case of a 50 year old female patient with a clinical of generalized tremors in the extremities, with 1 year of evolution with rapid progression; imaging studies that show non-specific involuntional changes, was presented. It was decided to take the molecular study through whole exome sequencing, obtaining a heterozygous variant in the *GBA* gene (c.1448T>C p.L483P exon 10) with pathogenic clinical significance and a heterozygous variant in the *MAPT* gene (c.1270G>A p.A424T exon 5). The interaction network between both genes carried out in the GeneMania program showed a close relationship in molecular functions such as positive regulation of proteolysis, microtubule polymerization or depolymerization, regulation of cell growth, neuron projection extension and regulation of microtubule cytoskeleton organization. The L483P mutation is usually associated with GD type 2 or 3, even when presenting in a compound heterozygous state. it seems that severe *GBA* mutations, such as L483P, are associated with a higher risk of causing PD compared to milder mutations, such as the N370S. Previous studies in multiple genetically diverse cohorts of PD patients have found associations between AAO of PD and variants in multiple genes including *GBA* and *MAPT*. A recent study using polygenic score for PD risk found that individuals with earlier onset also have higher polygenic risk, indicating that some of the genetic variants associated with PD risk also affect AAO. Several groups have previously reported association between variants at the *MAPT* locus and AAO. To our knowledge, our study is the first to report an association between AAO and variants in *GBA* and *MAPT* in a Colombian Patient. Our data confirm the strong effect of *GBA* and *MAPT* on PD risk, more frequent cognitive impairment, and more rapid progression.

Complex Traits Posters - Wednesday

PB1710. Variant-to-gene mapping in human microglial cell models with clonal CRISPR validation implicates *RTFDC1* and *CASS4* at the Alzheimer's disease 'CASS4' locus.

Authors:

E. Burton¹, M. Argenziano², K. Cook³, S. Lu³, C. Su³, E. Manduchi¹, M. Leonard³, K. Hodge³, L-S. Wang¹, G. Schellenberg¹, M. Johnson³, J. Pippin³, A. Wells³, S. Anderson¹, C. Brown¹, S. Grant³, A. Chesi¹; ¹The Univ. of Pennsylvania, Philadelphia, PA, ²Univ. of South Florida, Tampa, FL, ³The Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

Late-onset Alzheimer's disease (LOAD) is the most common neurodegenerative disease among the elderly population, affecting nearly 6 million Americans over the age of 65. Despite being the 6th leading cause of death in the US, there are still no effective therapies that can slow or halt disease progression. LOAD research has principally focused on characterizing neurons as the primary causal cell type due to their production of aggregating amyloid beta ($A\beta_{1-42}$), which is thought to contribute to neurodegeneration. In contrast, recent studies suggest that genetic mechanisms drive microglia, the resident macrophages of the central nervous system, to prolonged inflammation in LOAD brains in the presence of $A\beta_{1-42}$, exacerbating neurodegeneration. Indeed, recent GWAS of LOAD have identified multiple loci near genes related to microglial function, such as *TREM2* and *CRI*. However, GWAS does not have the sensitivity to identify causal variants or effector genes. In order to map interactions between GWAS-implicated variants and their putative effector genes in LOAD, we used a combination of ATAC-seq and high-resolution promoter-focused Capture-C in two human microglial cell models (both the immortalized HMC3 microglia-like cell line and iPSC-derived iMicroglia) to map interactions between GWAS-implicated variants and their putative effector genes. Our promoter-focused Capture-C method improves upon the relatively low resolution of available Hi-C data by utilizing a 4-cutter enzyme (DpnII) instead of the traditionally used 6-cutter (HindIII). This variant-to-gene mapping in both microglial cell models identified 67 putative effector genes (51 coding) across both cell types, with 14 observed in both models. We identified a novel proxy SNP, rs6024870 ($r^2 = 0.93$ to sentinel SNP rs6014724), at the 'CASS4' locus, which coincided with open chromatin and directly contacted the promoter of *RTFDC1*, a gene not previously implicated in LOAD. Deletion of the putative enhancer region harboring rs6024870 by lentiviral CRISPR-Cas9 in HMC3 reduced the expression of *RTFDC1* at both the mRNA and protein level ($p < 0.01$ and $p < 0.05$ for mRNA and protein, respectively). It was also noted that *CASS4* levels were modestly influenced by this CRISPR-mediated perturbation. Our results implicate *RTFDC1* as a novel effector gene at the LOAD 'CASS4' GWAS locus. Further efforts will characterize the phenotypic effect of this variant in microglial cell models, including on inflammation and phagocytic activity.

Complex Traits Posters - Thursday

PB1711. Variation and impact of polygenic hematological traits in monogenic sickle cell disease

Authors:

G. Lettre^{1,2}, T. Pincez¹, K. Lo², A-L. Pham Hung d'Alexandry d'Orengiani³, M. Garrett⁴, C. Brugnara⁵, A. Ashley-Koch⁴, M. Telen⁴, F. Galactéros³, P. Joly⁶, P. Bartolucci³; ¹Université de Montréal, Montréal, QC, Canada, ²Montreal Heart Inst., Montréal, QC, Canada, ³Hôpital Henri-Mondor, Paris, France, ⁴Duke Univ., Durham, NC, ⁵Children's Hosp. Boston, Boston, MA, ⁶CHU-Lyon, Lyon, France

Abstract Body:

Several complications observed in sickle cell disease (SCD) are influenced by variation in hematological traits (HT), such as fetal hemoglobin (HbF) level and neutrophil count. Previous large-scale genome-wide association studies carried out in largely healthy individuals have identified 1000s of variants associated with HT, which have then been used to develop multi-ancestry polygenic trait scores (PTS). Here, we tested if these PTS associate with HT in SCD patients and can improve statistical models associated with SCD-related complications. In 2056 SCD patients, we found that the PTS predicted less HT variance than in non-SCD African-ancestry individuals. This was particularly striking at the Duffy/*DARC* locus, where we observed an epistatic interaction between the SCD genotype and the Duffy null variant (rs2814778) that led to a two-fold weaker effect on neutrophil count. PTS for these routinely measured HT were not associated with complications in SCD. In contrast, we found that a simple PTS for HbF that includes only six variants explained a large fraction of the phenotypic variation (17.1-26.4%), associated with acute chest syndrome and stroke risk, and improved the predictive model for vaso-occlusive crises. Using Mendelian randomization, we found that increasing HbF by 4.8% reduces stroke risk by 36% ($P = 0.0008$). Taken together, our results highlight the importance of validating PTS in large diseased populations before proposing their implementation in the context of precision medicine initiatives.

Complex Traits Posters - Wednesday

PB1712. Whole exome sequencing identifies two heterozygous novel variants in CCL21 and ITGA2 as a cause of Hypertrophic cardiomyopathy

Authors:

F. Carlus¹, L. B.Sujatha¹, A. Ganesh Kumar², V. George³, S. Justin Carlus⁴; ¹Dept. of Zoology, Pachaiyappa's Coll., Chennai, India, ²Ctr. for Res. & Dev., Dept. of Microbiol., Hindustan Coll. of Arts and Sci., Chennai, India, ³Consultant Cardiologist, Gen. Hosp.,, Ernakulam, Kerala, India, ⁴Micro Hlth.Lab., Calicut, India

Abstract Body:

Familial hypertrophic cardiomyopathy (HCM) is the most common genetic cardiac disease. While sarcomeric gene mutations explain many HCM cases, the genetic basis of about half of HCM cases remains elusive. Here we aimed to identify the gene causing HCM in a non-consanguineous Indian family with affected family members. Proband's mother and his elder sister expired due to CAD/stroke. Methods: HCM Proband and his 4 siblings screened by the whole exome sequencing. Conservative analysis, protein structural and functional prediction were performed on the identified pathogenic variants. Results: After a careful analysis, two heterozygous variants were detected in the CCL21 and ITGA2 genes in 3 siblings and not detected in 1 case. Both the variants have not been reported in the 1000 genomes and in our internal databases and have a minor allele frequency of 0.002% in the gnomAD database. The in silico predictions of the variant are probably damaging by PolyPhen-2 (HumDiv) and damaging by SIFT, LRT and MutationTaster2. The reference codon is conserved across mammals. Both the variants are a common cause of coronary artery disease. To date, CCL21 and ITGA2 have not previously been associated with HCM; to the best of our knowledge, this is the first report of heterozygous CCL21 and ITGA2 mutations associated with HCM. This study gives a broader spectrum of mutations linked to HCM and an additional scientific basis for diagnosis.

Complex Traits Posters - Thursday

PB1713. Whole Exome Sequencing revealed spectrum of mutations associated with different myopathy in clinically suspected DMD patients of Bangladesh

Shere Bangla Nagar, Dhaka, Bangladesh, ¹²Mohammed Bin Rashid Univ. of Med. and Hlth.Sci., Dubai, United Arab Emirates

Abstract Body:

BackgroundDuchenne muscular dystrophy (DMD) is an inherited genetic disorder resulting progressive skeletal, respiratory and cardiac muscle weakness. DMD is caused by point mutations along with deletions and duplications in DMD gene located on the X chromosome. Clinical phenotypes of DMD often overlaps with other kind of muscle disorders. In this study, we aimed to identify several types of mutations associated with different myopathy in clinically DMD suspected patients of Bangladesh.

MethodWe have conducted multiplex PCR test for the deletion analysis of 30 DMD suspected patients. Out of 30, Whole Exome Sequencing (WES) was done for 8 negative patients to identify single nucleotide variants (SNVs), small insertion and deletion. We have used human genome build GRCH38/UCSC hg38 as reference. Variant classification analysis was conducted based on the American College of Medical Genetics (ACMG) guidelines.

ResultsThe cohort comprises 30 male patients. From multiplex PCR analysis, we have found pathogenic deletion in 56.6% (17) patients. And no clinically relevant variants were found in 43.3% (13) patients. The diagnostic yield for this test is 56.6%. Out of 13 negative cases, WES was performed for 8 patients. Out of 8, we have found 6 pathogenic variants in a range of 4 disease-associated genes such as *DMD* associated Duchenne muscular dystrophy, *COL6A3* associated Bethlem myopathy, *LAMA2* associated Muscular dystrophy and *DOK7* associated Myasthenic syndrome. Our analysis pipeline detected a pathogenic frameshift deletion c.2604delA (p.Val869Serfs*) and a stopgain mutation c.967C>T (p.Arg323Ter) in *DMD*; a frameshift insertion c.2137_2138insGTGT (p.Ser713Cysfs*) and a splice site mutation c.4389+1G>A in *COL6A3*, a stopgain mutation c.5476C>T (p.Arg1826Ter) in *LAMA2* and a frameshift deletion c.204delG (p.Ala70Profs*) in *DOK7*. We have also found a variant of uncertain significance (VOUS) c.3220C>G (p.Gln1074Glu) in *MYH7* gene associated with Laing distal myopathy. No clinically relevant variants were found in one patient. So, the diagnostic yield of WES from PCR negative patients is 75% (6/8).

ConclusionsDMD symptoms may create confusion when overlapped with other muscle related disorders and creates trouble in future management. Our results show the utility of using both multiplex PCR test and WES for precise genetic diagnosis and its integration into the diagnosis therapeutics and management of DMD suspected cases.

Key WordsWhole Exome Sequencing (WES); Duchenne muscular dystrophy (DMD); single nucleotide variants (SNVs); American College of Medical Genetics (ACMG)

PB1714. Whole exome sequencing suggests a role for rare genetic variation in the *NLRX1* gene in HIV disease progression in pediatric African populations of Botswana and Uganda.

Authors:

M. Amujal¹, J. Mukisa², T. Diphoko³, G. Sebetso³, S. Mwesigwa⁴, G. Mboowa¹, S. Kyobe¹, E. Katagirya⁵, M. Joloba⁶, D. Kateete⁶, M. Matshaba⁶, G. Mardon⁷, N. Hanchard⁸; ¹Makerere Univ., Kampala, Uganda, ²Makerere Univ. Coll. of Hlth.Sci., Kampala, Uganda, ³Baylor Coll. of Med., Houston, TX, ⁴MAKERERE Univ., Kampala, Uganda, ⁵Coll. of Hlth.Sci., Makerere Univ., Kampala, Uganda, ⁶MAKERERE Univ., KAMPALA, Uganda, ⁷Baylor Col Med, Houston, TX, ⁸NIH, Bethesda, MD

Abstract Body:

HIV-1 remains a significant public health concern in Africa, with an estimated 26 million people living with HIV-1 in the region (UNAIDS, 2019). Children perinatally infected with HIV exhibit extremes in their temporal progression to AIDS. Rapid Progressors (RPs) have at least one documented CD4+ T-cell decline (<15%) and/or AIDS-defining illness within 3 years of HIV infection. In contrast, Long-Term Non-Progressors (LTNPs) show no signs of AIDS ≥10 years after infection, even without therapy. Common genetic variation in HLA alleles; HLA-B*5701, HLA-B27 and the *CCR5-δ32* deletion only explain a minority of the LTNP phenotype. In this study, we determine the role of rare genetic variation in HIV disease progression in African pediatric populations of Uganda and Botswana.

Approximately, 1,000 participants were recruited in HIV care centres in Uganda and Botswana; accordingly, these participants were stratified into RPs and LTNPs. To identify rare missense/nonsense variants with MAF ≤1% contributing to the LTNP phenotype, we performed WES on 388 LTNPs and 419 RPs and findings from this analysis were further validated in 400 WGS from Uganda and Botswana. Single variant enrichment analysis revealed a role for a rare missense variant (rs145985036) in the NOD-like receptor X1 (*NLRX1*) gene. The variant was reported to be either deleterious/damaging by 11 out of 14 different insilico prediction tools including SIFT, Polyphen2, LRT, MutationTaster, and MutationAssessor. Additionally, the variant site was highly conserved across different insilico conservation tools including GERP++, SiPhy, phastCons and phyloP. Genotype-Tissue Expression (GTEx) analysis showed significant expression of the *NLRX1* gene in the oesophagus-mucosa, minor salivary glands and vagina. Furthermore, analysis of the molecular structure of the *NLRX1* gene revealed the variant allele to occur at the central nucleotide-binding domain termed (NOD domain) responsible for the activation of the receptor for an immune response. Additionally, the *NLRX1* gene has been reported to facilitate HIV-1 replication by 1) sequestering STING thereby negatively regulating the interferon response and 2) enhancing oxidative phosphorylation and glycolysis during HIV -1 Infection of CD4 T cells to promote viral replication.

Findings from this study reveal the first novel/non-HLA gene directly implicated in Pediatric HIV disease progression unique to the African population. We, therefore, recommend studies to understand the functional mechanisms of this gene that would provide potential targets for HIV immunotherapeutics and vaccines.

Complex Traits Posters - Thursday

PB1715. Whole genome sequence analysis of long non-coding RNAs for plasma lipid traits

Authors:

Y. Wang¹, M. Selvaraj^{2,3,4}, P. Natarajan^{2,3,4}, G. Peloso¹, TOPMed Lipids Working Group; ¹Dept. of Biostatistics, Boston Univ. Sch. of Publ. Hlth., Boston, MA, ²Cardiovascular Res. Ctr., Massachusetts Gen. Hosp., Boston, MA, ³Program in Med. and Population Genetics, Broad Inst. of Harvard and MIT, Cambridge, MA, ⁴Dept. of Med., Harvard Med. Sch., Boston, MA

Abstract Body:

Background Elevated blood lipids are heritable risk factors and major modifiable cause of cardiovascular disease. While long non-coding RNAs (lncRNAs) have important regulatory functions for lipid metabolism in model systems, the relationship between genetic variation in lncRNAs and blood lipid levels in humans is not well understood. We now utilize large-scale whole genome sequencing (WGS) studies and new statistical methods for variant set tests to assess the association between lncRNAs across the genome and plasma lipid traits. **Methods** We analyzed 66,329 individuals with TOPMed freeze8 WGS data and lipid levels (LDL-C, HDL-C, TC and TG). We defined lncRNA testing units by integrating annotations from four different genome annotation projects: GENCODE (v38), FANTOM CAT(robust), NONCODE (v6), and lncRNAKB (v7). We aggregated rare (MAF < 1%) variants for each lncRNA based on the lncRNA genomic locations and conducted the rare variants aggregate test using the STAAR framework incorporating multiple functional annotations. We further performed conditional analyses adjusting for previously reported common variants that associated with lipids. Since there are overlapping regions between the lncRNAs, we estimated the effective number of aggregate-based tests (M_{eff}) for multiple testing correction. **Results** In total, we conducted RV aggregate tests in 166k lncRNA regions with 113,587 effective number of aggregate-based tests. We identified 40, 31, 30, and 30 genome-wide significant ($p < 0.05/113587 = 4.4e-07$) lncRNAs with LDL, TC, HDL, and TG, respectively, in 11 loci. After conditioning on known lipid-associated variants, 21, 16, 15, and 13 associations remained significant. Of the significant lncRNAs in the conditional analysis, 19, 15, 13, and 12 associations were near at least a known lipid mendelian gene, including ENSG00000233271.1 near *PCSK9* associated with LDL-C, NONHSAG026009.2 near *APOE* associated with TC, NONHSAG108446.1 near *CETP* associated with HDL-C, and NONHSAG009700.3 near *APOA5* associated with TG. The remaining associations were all in lipid GWAS regions, except ENSG00000260441.5, which is an antisense to *PLA2G15* that is associated with HDL-C. **Conclusions** We discovered several associations between lncRNAs and plasma lipid traits, which provide insights into potential lipid regulatory mechanisms of GWAS loci. We will further seek replications in UK Biobank WGS and investigate the effects of lncRNAs on gene expression.

Complex Traits Posters - Wednesday

PB1716. Whole Genome Sequencing Analyses of 87,652 Individuals Reveal Rare Variants in Promoter of *HMGAI* Associated with Height

Authors:

SPH, Boston, MA

Abstract Body:

Introduction

Height is heritable and provides insights into the genetic architecture of human traits. Thousands of common and low-frequency variants have been identified with height using GWAS. However, these common variants only explain a limited fraction of heritability. A recent study shows that rare variants (RVs) are a major source of the missing heritability of height. Large-scale whole-genome sequencing (WGS) studies, such as the multi-ethnic NHLBI Trans-Omics Precision Medicine (TOPMed) Program, enable the assessment of associations between height and rare variants across the genome, especially for the noncoding genome.

Hypothesis

Rare variant aggregations are associated with height.

Methods

We applied our newly developed STAARpipeline workflow to rare variant (MAF < 0.01) association analyses using 87,652 individuals from TOPMed Freeze 8 WGS data, including gene-centric analysis and non-gene-centric analysis using a variety of coding and noncoding masks. The gene-centric analysis provides five coding and eight noncoding functional categories. The non-gene-centric analysis includes sliding window analysis with fixed sizes and dynamic window analysis with data-adaptive sizes.

Results

In the gene-centric analysis of coding RVs, we identified 7 genome-wide significant associations at the Bonferroni-corrected level $5.00E-07$ ($=0.05/20,000/5$). After conditioning on known height-associated variants, the association between missense RVs in *ACAN* remained significant at the same level $5.00E-07$. In the gene-centric analysis of noncoding RVs, we identified 8 genome-wide significant associations at the Bonferroni-corrected level $3.12E-07$ ($=0.05/20,000/8$). The association of RVs in the promoter of *HMGAI* remained significant at the same level $3.12E-07$ in conditional analysis by adjusting for known height-associated variants. In 2-kb sliding window analysis, we identified 25 genome-wide significant associations at the Bonferroni-corrected level $1.88E-08$ ($=0.05/2.66E06$). After conditioning on known height-associated variants, the strengths of all associations reduced and 4 of these associations remained significant at level $1.00E-05$. Two of them are in the coding region of *ACAN*, and the other two are in the upstream region of *HMGAI*. The results of dynamic window analysis are similar to sliding window analysis. We identified 11 genome-wide significant associations, and 4 of these associations remained significant at level $1.00E-05$ in conditional analysis.

Summary

Two new RV associations, missense RVs in *ACAN* and RVs in the promoter of *HMGAI* with height, were identified using the TOPMed WGS Freeze 8 data through STAARpipeline.

Complex Traits Posters - Thursday

PB1717. Whole genome sequencing enables identification of a genetic susceptibility locus for idiopathic pulmonary fibrosis in the 16p subtelomere.

Authors:

L. Donoghue¹, A. Stockwell¹, M. Neighbors¹, R. Sheng¹, P. Wolters², L. Lancaster³, J. Kropski³, T. Blackwell³, B. Yaspan¹, M. McCarthy¹; ¹Genentech, South San Francisco, CA, ²Univ. of California San Francisco, San Francisco, CA, ³Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract Body:

Idiopathic pulmonary fibrosis (IPF) is a severe lung disease characterized by progressive interstitial fibrosis and inflammation. Even with available treatments, the average survival following diagnosis is ~3-5 years, highlighting the significant need for greater understanding of disease etiology and pathogenesis. Genome-wide association studies (GWAS) from large, increasingly ancestrally-diverse cohorts have identified >20 common variants associated with IPF, including a *MUC5B* promoter variant with large effect, and rare variant analyses have implicated genes involved in telomere integrity. Here, we report the first genome-wide search for common and rare IPF risk variants fully based on whole genome sequencing (WGS). We replicated 13 previously-identified common variant signals plus rare variant burden associations in *TERT* and *RTEL1* with 1,638 clinically-defined IPF cases and 7,947 controls. Access to WGS data enabled us to detect a new common variant association in the chromosome 16 subtelomere (16p13.3, rs367849850: $P=2.7 \times 10^{-20}$, OR=2.1), a region poorly and inconsistently covered by previous array-based discovery. This association replicated in an independent GWAS from the Global Biobank Meta-analysis Initiative with biobank-defined IPF cases ($P=1.1 \times 10^{-3}$, OR 1.3). Through conditional analysis with these 16p.13.3 subtelomeric variants and a recently-reported association 70kb away near *NPRL3*, we found rs367849850 (an 18-base pair indel in pseudogene *IL9RP3*) accounted for both the subtelomeric and *NPRL3* associations. Furthermore, these subtelomeric IPF-risk alleles were associated with shorter leukocyte telomeres in UK Biobank participants ($P=4.4 \times 10^{-4}$, OR=1.02). Collectively our findings highlight the advantages of using WGS data and clinically-defined IPF cases to more comprehensively evaluate genetic variation in historically ambiguous regions such as the subtelomere and identify this large-effect association missed by previous, larger GWAS. Further investigation into these risk variants may implicate a new pathogenic mechanism for IPF involving subtelomeric sequence variation.

Complex Traits Posters - Wednesday

PB1718. Whole genome sequencing of a diverse Hispanic IBD population in the United States reveals differences in previously identified risk alleles.

Authors:

T. Haritunians¹, J. L. McCauley², E. Torres³, L. Gomez², D. Li¹, M. Daly^{4,5,6}, C. Stevens⁵, J. Leavitt⁷, O. M. Damas², M. A. Quintero², M. T. Abreu², D. P. B. McGovern¹, A. H. Beecham²; ¹Cedars-Sinai Med. Ctr., Los Angeles, CA, ²Univ. of Miami, Miami, FL, ³Univ. of Puerto Rico, San Juan, Puerto Rico, ⁴Massachusetts Gen. Hosp., Boston, MA, ⁵The Broad Inst., Cambridge, MA, ⁶Inst. of Molecular Med. Finland, Univ. of Helsinki, Helsinki, Finland, ⁷GastroHlth., Miami, FL

Abstract Body:

Background: Inflammatory bowel disease (IBD), Crohn's disease (CD) and ulcerative colitis (UC) are immune-mediated diseases causing chronic inflammation of the digestive tract, with increasing incidence in the Hispanic population. Nearly all ~240 IBD risk loci were identified through studies of Northern European ancestry populations. The genetic admixture of Hispanics provides a unique opportunity to examine the ancestral origins of risk and may further elucidate underlying IBD pathophysiology. We sought to test the relevance of common European IBD variants within our diverse Hispanic cohort. **Methods:** 2415 self-identified Hispanics (854 CD; 634 UC; 44 undetermined IBD; 883 controls) and 248 previously identified susceptibility variants passed stringent quality control of whole genome sequence data. Global ancestry was calculated (Admixture) and logistic mixed model association was performed (Regenie) after controlling for population substructure. **Results:** Geographical differences in ancestry were observed across recruitment sites, with Hispanics on the west coast demonstrating higher levels of Native American (NAM) ancestry than those on the east coast. We observed one-sided replication ($p < 0.05$) of 36 of 96 CD risk variants (37.5%; expected 95% CI: 40-47%), 18 of 58 UC risk variants (31%; expected 95% CI: 31-50%), and 22 of 94 general IBD risk variants (23%; expected 95% CI: 34-41%). We found less replication than statistical power suggested for CD and IBD, indicating potential locus heterogeneity or differing linkage disequilibrium patterns between populations. We observed the strongest association ($p < 5 \times 10^{-4}$) for well-established loci including *NOD2* and *IL23R* for CD, as well as *MST1* and *EPHB4* for UC. We identified several susceptibility variants which conferred risk in Europeans but demonstrated protection in Hispanics, including *LRRK2* for susceptibility to CD. Further analysis revealed an interaction with NAM ancestry, where the *LRRK2* susceptibility variant conferred risk of CD in Hispanics with a low proportion of NAM ancestry but protection in Hispanics with a high proportion of NAM ancestry. **Conclusions:** Hispanics represent a genetically heterogeneous group often overlooked in IBD studies. We replicated association in our Hispanic population of key IBD loci originally identified in predominantly European cohorts and identified evidence for global ancestry risk modification at select loci. Work is ongoing to further assess local ancestry risk modification. Identifying differences in genetic effects between populations is crucial to facilitate individualized treatment and prevention across diverse patient populations.

Complex Traits Posters - Thursday

PB1719. Whole genome sequencing study in multiple sclerosis identifies novel CTBP2 association with change in brain lesion burden

Bronson²; ¹Genentech, South San Francisco, CA, ²Biogen, Cambridge, MA, ³Dept.s of Neurology and Epidemiology, Johns Hopkins Univ., Baltimore, MD, ⁴Case Western Reserve Univ. Sch. of Med., Cleveland, OH, ⁵Mellen Ctr. for Multiple Sclerosis, Cleveland Clinic, Cleveland, OH, ⁶Dept. of Neurology and Neuroimmunology, MS Ctr. of Catalonia, Vall d'Hebron Univ. Hosp., Barcelona, Spain, ⁷Dept. of Neurology, Univ. of Münster, Münster, Germany, ⁸Genentech, San Francisco, CA

Abstract Body:

Introduction: Over 200 GWAS loci are associated with Multiple Sclerosis (MS) risk. These loci are largely immunological, corroborating the success of immunomodulatory therapies. Here, we performed whole-genome sequencing (WGS) in MS to interrogate mechanisms driving MS age-at-onset (AAO) and rate of change in total T2-weighted hyperintense lesion volume (T2LV), an MRI measure of brain lesion burden.

Methods: MS PATHS (Partners Advancing Technology and Health Solutions) is a longitudinal study collecting clinical and MRI data and biospecimens in >20,000 persons with MS (pwMS). We performed WGS at 30X in MS PATHS subjects with genetic consent (N=7,938), followed by QC and joint genotyping (BWA-GATK). First, we performed a GWAS for AAO in 6,210 pwMS of European ancestry. We then performed a GWAS for T2LV change (T2LVC) in 2,657 pwMS with 1+ year of MRI. T2LVC was computed as annualized percent change in T2LV from first to last brain MRI (median 2.6 years between MRIs). Both continuous outcomes were rank-based inverse-normal transformed. Covariates were sex, genetic ancestry, and for T2LVC, age. We tested significant loci for shared causal variants (colocalization) with complex traits and UK Biobank phenotypes.

Results: We called >114.5 million variants across 7,938 subjects. We did not detect genome-wide test inflation ($\lambda < 1.02$). Our AAO GWAS replicated a known association with *HLA-DRB1*15:01* ($\beta = -0.10$, $P = 3 \times 10^{-6}$), and identified two novel associations: an intronic variant at *HLA-DRA* (rs3129882*A, $\beta = 0.11$, s.e. = 0.02, $P = 2.6 \times 10^{-10}$), and an intronic variant at *EYA2* (rs3091826*G, $\beta = -0.28$, s.e. = 0.05, $P = 2.7 \times 10^{-8}$). The T2LVC GWAS identified a novel association in a *CTBP2* intron (rs4962725*C, $\beta = 0.16$, s.e. = 0.03, $P = 7.8 \times 10^{-9}$), which interacts with a *CTBP2* promoter. This locus shared a causal variant with a body mass index (BMI) locus (PP4 = 0.98).

Discussion: This is the largest WGS-based GWAS of AAO and T2LVC in MS. We replicated the known association between younger AAO and *HLA-DRB1*15:01*. We identified novel AAO loci at *HLA-DRA*, the sole alpha chain for *HLA-DRB1* (together HLA-DRA and HLA-DRB1 form a heterodimer); and at *EYA2* (a transcriptional coactivator and phosphatase). We also identified a novel locus for T2LVC at the corepressor *CTBP2*. Interestingly, this association signal colocalized with BMI and *CTBP2* plays a role in adipocyte differentiation. BMI is a known risk factor for MS, and for accelerated atrophy in MS. *CTBP2* also harbors known associations with brain cortical thickness and surface area. Future directions include replicating our novel loci, and expanding our GWAS to test longitudinal brain atrophy and clinical disability progression traits.

Complex Traits Posters - Wednesday

PB1720. Whole-exome sequencing in five families with specific language impairment (SLI) suggests novel SLI genes and confirms previous findings.

Authors:

M. Raza, E. Andres, K. Earnest, C. Zhong, M. Rice; The Univ. of Kansas, Lawrence, KS

Abstract Body:

While most children acquire language with no formal instruction, about 7% of the population have specific language impairment (SLI), causing them to struggle with the language despite average or above average nonverbal intelligence (NV-IQ) and no other behavioral diagnoses or hearing loss. Twins studies provided high heritability estimates, and family studies suggest SLI is inherited in families. Genetic studies have begun to identify gene loci through next-generation sequencing, but the genetic basis of SLI remains unknown. In the current study, an age-appropriate standardized omnibus language measure was used to categorically define the SLI phenotype. We performed whole-exome sequencing (WES) in 23 individuals from five families (total $N = 48$) and prioritized 96 rare exonic variants. Co-segregation analysis revealed 31 variants of further interest. Upon Sanger sequencing of these 31 variants in additional unrelated probands with SLI ($N = 160$), seven probands carried seven unique nonsynonymous variants. Two of these variants were present in the previously suggested genes (*UBE4B* and *ATP2C2*). *UBE4B* is located within the chromosome 1p36 region previously linked to reading disorder and SLI, and we previously reported a suggestive linkage to SLI in two of the five families included in this report. In an unrelated SLI proband, we identified a homozygous variant on *ATP2C2* (rs78887288, MAF = 0.09). This variant was previously reported as a heterozygous variant in another family utilized in the current study. The remaining five variants were identified in novel genes: *YLPM1*, *PCBP4* (observed in three probands), with three of these variants identified in one proband: *PRDX5*, *AKAP9*, and *TRIM28*. These results support the utility of family-based investigation of SLI, confirming previous findings and suggesting novel genes. Further study of these proposed genes is needed to understand their role in language acquisition.

Complex Traits Posters - Thursday

PB1721. Whole-genome sequencing analysis of fructosamine and glycated albumin in Black and White participants in the Atherosclerosis Risk in Communities (ARIC) Study.

Authors:

S. Venkataraghavan¹, D. Ray^{1,2}, E. Selvin^{1,3}, J. Coresh^{1,3}, A. Kottgen^{1,4}, J. S. Pankow⁵, E. Boerwinkle⁶, B. Yu⁷; ¹Dept. of Epidemiology, Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, ²Dept. of Biostatistics, Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, ³Welch Ctr. for Prevention, Epidemiology, & Clinical Res., Johns Hopkins Univ., Baltimore, MD, ⁴Inst. of Genetic Epidemiology, Faculty of Med. and Med. Ctr., Univ. of Freiburg, Freiburg, Germany, ⁵Div. of Epidemiology and Community Hlth., Sch. of Publ. Hlth., Univ. of Minnesota, Minneapolis, MN, ⁶The UTHlth.Sch. of Publ. Hlth., Houston, TX, ⁷Dept. of Epidemiology, Human Genetics and Environmental Sci., UTHlth.Sch. of Publ. Hlth., Houston, TX

Abstract Body:

Genetic studies of serum glyceamic biomarkers, fructosamine and glycated albumin, can improve our understanding of the genetic architecture of type 2 diabetes and its complications. GWAS on both traits conducted till date have examined associations of common variants with MAF>5%. We sought to explore the associations of variants (SNVs and indels) across the entire MAF spectrum with fructosamine and glycated albumin using whole genome sequencing data on 1456 Black and 5429 White middle-aged participants (mean age 57) without diabetes from Jackson, MS; Forsyth County, NC; Minneapolis, MN and Washington County, MD in the population-based ARIC cohort. We performed single-variant analyses of log transformed glyceamic biomarkers- fructosamine and glycated albumin- for variants with MAF>1%. At a whole-genome significance threshold of 10^{-8} , we detected locus chr19q13.33 near *RCN3*, where the lead variant effect allele T was associated with a 1% decrease in fructosamine levels (rs10419198 [T/C], $p = 2.7 \times 10^{-9}$) replicating previous findings from array-based GWAS. We also identified variants found exclusively in Blacks at a low-frequency (MAF 1-5%) associated with one or both traits at chr7p14.1 (rs151030849 [C/T], fructosamine $p = 7.2 \times 10^{-16}$, glycated albumin $p = 10^{-10}$) and chr17p11.2 (rs566083925 [C/CG], glycated albumin $p = 6.4 \times 10^{-9}$ each leading to 13-15% increase in associated biomarker levels. For rare variants (MAF<1%), we performed gene-centric tests of the log-transformed biomarkers using SMMAT-E, grouping putatively deleterious variants determined using WGSa annotater from coding and regulatory segments. At a Bonferroni-corrected significance threshold of 2.7×10^{-6} , we implicated 23 genes including a novel glyceamic gene, *HIST1H2AA*, which was associated with fructosamine ($p = 5.7 \times 10^{-9}$) and glycated albumin ($p = 1.9 \times 10^{-10}$) in Blacks and showed suggestive evidence of association with fructosamine ($p = 2.6 \times 10^{-5}$) in Whites. We found associations of fructosamine with genes enriched in fatty acid metabolism pathway, *ACOT2* ($p = 1.8 \times 10^{-6}$) and *UGDH* ($p = 1.3 \times 10^{-7}$), driven by frameshift mutations and associations of glycated albumin with *SLIT2* ($p = 9.1 \times 10^{-7}$) and *ROBO3* ($p = 2.0 \times 10^{-7}$) by missense variants increasing glycated albumin levels by 32-37%. *SLIT2* and *ROBO3* were enriched in axon-guidance pathway linked to diabetic neuropathy. Our study identified similarities and differences in genetics of biomarker levels across ancestries, novel susceptibility regions for glyceamia including genes in a well-established type 2 diabetes pathway and a potential genetic basis for increased glycated albumin levels among patients with diabetic neuropathy.

Complex Traits Posters - Wednesday

PB1722. X Chromosome Wide Association Study on Latin American cohort reveals new potential loci associated with Parkinson's Disease

Natl. de Colombia, Bogotá, Colombia, ¹⁸Univ. Natl. de Colombia, Bogota, Colombia, ¹⁹VA Puget Sound Hlth Care Sys, Seattle, WA

Abstract Body:

Genome-wide association studies of autosomes have identified over 90 independent risk signals for Parkinson's disease (PD), but little is known about the impact of X chromosome (chrX) variants on PD susceptibility. Only one previous study (LeGuen et al., 2021) has investigated the X chromosome in PD, and this was done in a cohort of European ancestry. In this study we performed the first X chromosome-wide association study (XWAS) of PD in an admixed Latino cohort. We used genome-wide data from the Latin American Research consortium on the GENetics of PD (LARGE-PD) (1,294,079 variants, N=1,498), including individuals from Brazil, Chile, Colombia, Peru, and Uruguay. We used the TOPMed as a reference to impute our data. Since the chrX e has different recombination dynamics and is more impacted by evolutionary forces, we adapted and followed LeGuen et al. chrX-specific pipeline to make it viable for admixed populations. We performed association analysis (sex-stratified and not) in two different ways: (i) all samples and (ii) by country, followed by meta-analysis. For all association tests, the models were adjusted for the first 10 chrX PCs + Age. We used chrX PC due to the low correlation between autosomal and chrX PCs observed in our data. We calculated the significance threshold using the number of effective tests based on the pair-wise correlation among SNPs. We obtained 81 statistically significant variants across five loci. To replicate our findings, we used data from Latinos in the International Parkinson Disease Genomics Consortium integrated with the Brazilian Bambuí Cohort Study of Aging. We replicated the association for rs393033 in females (discovery OR = 2.012, 95% CI = 1.387 to 2.292, p= 0.000231 and validation OR = 1.911, 95% CI = 1.051 to 3.475, p = 0.033785). Also, 12 variants identified during the discovery analysis were significantly associated but in a sex-stratified analysis other than from the discovery test. In conclusion, we performed the first XWAS for PD in admixed populations. We also provided a chrX-specific pipeline to facilitate ChrX association analysis using admixed populations. Using LARGE-PD data we nominated a novel intergenic variant, rs393033, located 1.2 Mb from FMR1 gene, which needs further studies.

Mendelian Phenotypes Posters - Wednesday

PB1723. 4-years of Face2Gene in a General Genetics Clinic: Insights from Retrospective Analysis of Diagnosed Cases

Authors:

M. Muriello, N. Xiong, D. Basel; Med. Coll. of Wisconsin, Milwaukee, WI

Abstract Body:

Diagnosing patients with non-specific dysmorphic features is a challenge faced by medical geneticists. Machine learning (“artificial intelligence”) technologies in medicine have the potential to improve the diagnostic yield and shorten the diagnostic odyssey. Face2Gene (F2G) is a facial image analysis software developed using deep-learning algorithms to detect features from thousands of patient images¹. Face2Gene was used as a clinical tool for a subset of undiagnosed cases, being seen in the pediatric genetics clinic at the Medical College of Wisconsin between 2017 and 2021. Among 1747 unique F2G cases created in that timeframe, 113 had a final diagnosis added in F2G; 101 of which were molecularly confirmed and 12 were clinically diagnosed. Data was collected from the electronic medical record including demographics, final diagnosis, primary clinical features, diagnostic test that diagnosed the patient’s molecular diagnosis, other genetic testing, Face2Gene top-10 accuracy, gestalt score, and a subjective assessment of picture quality. The final diagnosis was present in the top-10 syndromes by gestalt score in 68%. Amongst those diagnosed where the diagnosis was not in the top 10, none had higher than a low gestalt score. Amongst those diagnosed where the diagnosis was in the top 10, 46% had a medium or higher gestalt score. Neither age, sex nor ethnicity had a significant impact on top-10 accuracy. Subjective assessment of picture quality rated 55% as high-quality, 40% as medium-quality, and 5% as low-quality. There was no difference in top-10 accuracy based on picture quality. Several diagnoses for which there were non-specific clinical features were made by targeted testing prompted by a medium or high gestalt score. Estimates of the utility F2G have been variable, with top-10 sensitivity of Gestalt analysis ranging from 48-91%¹⁻⁵. We found 68% top-10 accuracy which may reflect the real-world applicability of Face2Gene in a general pediatric genetics clinic. A medium or higher gestalt-score in almost all diagnosed cases suggests this cutoff may be useful. The accuracy was not significantly impacted by age, sex, ethnicity, or picture quality, suggesting Face2Gene may be useful for most patients. This study had several limitations. Not all cases had features entered, so the impact of the feature score could not be analyzed. The sample may be biased by lack of standardized process for updating F2G cases with a final diagnosis.

Mendelian Phenotypes Posters - Thursday

PB1724. A A recurrent de novo mutation in *ZMYND11*

Authors:

T. Carrion, Alba Muñoz Santa María Antonieta Ballesteros Vizoso Laura Torres Juan Alexander Damián Heine Suñe; Hosp. universitario son espases, PALMA DE MALLORCA, Spain

Abstract Body:

Background/Objectives:

A 7-year-old patient initially diagnosed as Silver-Russel syndrome due to mosaicism of chromosome 7 returns to our genetic consultation for diagnostic re-evaluation. Characteristics symptoms are global developmental delay (84%), hypotonia, feeding difficulties, short stature and several facial dysmorphisms (microcephaly, depressed nasal bridge and microretrognathia).

Methods:

Karyotype and CGH array were performed. MLPA assay (MS-MLPA Probemix ME032 DUP7-DUP14) was also done to test if there was maternal uniparental disomy of chromosome 7 (DUP7). Clinical exome was sequenced by Human Whole-Genome Sequencing with the Nextera™-DNA-Flex-Library Preparation Kit (Illumina).

Results:

Karyotype and CGH array were normal. MLPA assay revealed absence of DUP7. The analysis of the clinical exome showed a heterozygous autosomal dominant missense variant: c.1798C>T p.(Arg600Trp) in *ZMYND11* (NM_006624.5), classified according the ACMG guidelines as pathogenic. Genetic testing of both parents showed it was arisen de novo.

Conclusion:

Zinc finger MYND-type, expressed in many human tissues, acts as a transcriptional repressor, playing an inhibitory role in the muscle and neuronal differentiation steps. Specifically, the mutated position in this case Arg600 is very conserved and essential for its binding to ligands (Kateb et al.,2013). *ZMYND11* has also been proposed as a candidate gene for 10p15.3 microdeletion syndrome, which shares common clinical features with our patient (DeScipio et al., 2021). Moreover, other authors have described the same mutation (Cobben et al., 2014), so that it can be considered as definitely pathogenic. Finally, the same SNP has been reported 4 times in Decipher and 8 times in ClinVar thus the variant here reported could be a hotspot mutation.

Mendelian Phenotypes Posters - Wednesday

PB1725. A case of atypical inheritance in late-onset Pompe disease

Authors:

M. Mroczek¹, J. Meienberg¹, P. Rejmer², C. Henggeler¹, M. R. Baumgartner³, G. Matyas¹; ¹Ctr. for Cardiovascular Genetics and Gene Diagnostics, Swiss Fndn. for People with Rare Diseases, Schlieren-Zurich, Switzerland, ²Seegarten Klinik AG, Klichberg, Switzerland, ³Div. of Metabolism and Children's Res. Ctr., Univ. Children's Hosp. Zurich, Univ. of Zurich, Zurich, Switzerland

Abstract Body:

Background and Aims: Pompe disease is a rare autosomal-recessive disorder caused by acid α -glucosidase (GAA) deficiency and characterized by proximal progressive muscular weakness and/or respiratory insufficiency. Carriers of one *GAA* pathogenic variant are usually considered to be asymptomatic, although they can have reduced enzyme activity. Here, we present a case heterozygous for the *GAA* c.-32-13T>G mutation and having a GAA level and clinical symptoms comparable with late-onset Pompe disease (LOPD). **Materials and Methods:** For genetic testing, whole-genome sequencing (60x, PCR-free, PE150) has been applied. The GAA enzyme activity has been measured in leucocytes and cultured fibroblasts. RNA-Seq has been performed from the patient's fibroblasts. **Results:** A 28-year-old patient presented with an adolescent onset, proximal, lower limb weakness and lower leg atrophy. He suffers from severe myalgia and is able to walk only a few steps. Functional lung tests showed mild restriction. In fibroblasts, the activity of GAA was 0.83 (reference 6.04-17.06 nmol/min/mg prot.; 5-13%N). In leucocytes, the activity of GAA was normal, however, quotient +/- acarbose was reduced (0.24, reference 0.45-0.63). The patient inherited the following variants that we considered as possibly significant: from the mother *GAA* c.-32-13T>G (pathogenic); from the father *GAA* c.852G>A p.(=) (benign), *PHKB* c.445C>T p.(Leu149Phe) (VUS), and *AMPDI* c.133C>T p.(Gln45Ter) (VUS). No other variant with suspected significance in the *GAA* gene has been identified. RNA-Seq confirmed abnormal transcripts due to c.-32-13T>G but no other splicing defects in *GAA*. As *GAA* and *PHKB* gene products are parts of the same metabolic pathway, we hypothesize that a digenic inheritance with synergistic heterozygosity could occur. **Discussion:** In LOPD the levels of GAA enzyme activity and the severity of the clinical pictures may be highly variable among individuals. Most of the LOPD patients carry biallelic mutations in the coding region of *GAA*. However, a small number of individuals have (deep) non-coding *GAA* variants or a mosaicism. There are also several cases where only one pathogenic *GAA* variant has been identified, alone or together with other heterozygous pathogenic variants related to neuromuscular diseases, so that digenic/oligogenic inheritance has been suggested. The treatment with enzyme replacement therapy led to a clinical improvement in a few heterozygous LOPD cases. **Conclusion:** There may be a small cohort of LOPD patients where a symptomatic heterozygosity or digenic/oligogenic inheritance can be considered. Reporting further cases could confirm or contradict this hypothesis.

Mendelian Phenotypes Posters - Thursday

PB1726. A case of Fanconi anemia diagnosed due to *BRCA2* gene mutation triggered by cancer genome profiling test.

Authors:

K. Fukuda¹, S. Masuda¹, M. Matsui¹, S. Ito¹, M. Kuroda¹, H. Yamanaka¹, H. Futagawa¹, H. Muramatsu², M. Wakamatsu², H. Yoshihashi¹; ¹Tokyo Metropolitan Children's Med. Ctr., Fuchu-shi, Japan, ²Nagoya Univ. Hosp., Nagoya-shi, Japan

Abstract Body:

Fanconi anemia (FA) is a hematologic disorder characterized by progressive pancytopenia, transition to MDS and AML, abnormal body morphology, and solid tumors against a background of chromosomal instability based on DNA repair defects. There are currently 22 subgroups of FA, and the corresponding causative genes have been identified for each. Among them, FA caused by mutations in the *BRCA2* (*FANCD1*) gene (FA-D1) has a high risk of carcinogenesis and an extremely poor prognosis, and is inherited in an autosomal recessive form. We report a male infant with Glioblastoma who was diagnosed with FA-D1 and required genetic counseling for the parents, including diagnosis of carriers. A 20-month-old boy was brought in by ambulance for a cluster of seizures. He was transferred to our hospital for close examination and treatment because a CT scan of the head showed a left frontal lobe mass. He had no perinatal or medical history other than developmental delay in infancy, short stature, microcephaly, and auricular deformity. Various imaging tests were performed, including right renal hypoplasia seen on abdominal CT and a 6-7 cm intraparenchymal tumor in the left frontal lobe revealed on Head-MRI. Therefore, chemotherapy was started after partial resection. A cancer genome profile test performed to find molecularly targeted drugs detected a nonsense variant of the single-allelic *BRCA2* gene in the tumor cells. He was highly suggestive of FA in combination with multiple dysmorphic features. Chromosome fragility tests showed numerous chromosomal breaks, and whole exome analysis using the peripheral lymphocytes identified variants of the *BRCA2* gene (c.A7969T, p.K2657Ter and c.C7847T, p.S2616F) in a compound heterozygous manner. The uniallelic variant of the *BRCA2* gene was found in each of the parents. It was necessary to comprehensively examine the clinical course and physical characteristics of the affected children, as well as the consistency of the cancer genome profile test results. The results of the whole exome analysis revealed an accurate picture of the genetic background within the family. The pathological variants obtained from tumor cells provided evidence for the diagnosis of an affected child, treatment decisions, and prognosis of life expectancy, as well as for preventive cancer surveillance of hereditary breast and ovarian cancer in the parents. In addition, it was useful for estimating recurrence rates with respect to FA-D1 in the next pregnancy. Genomic practice collaboration among multiple departments was useful, leading to genetic counseling across pediatric rare diseases, hereditary tumors, and prenatal diagnosis.

PB1727. A case of fatal cardiac arrest in a neonate diagnosed with VLCADD postmortem

Authors:

P. Singh¹, D. Amaro², O. Obi², F. Kiran², E. Hediger¹, T. L. Toler¹, P. Dickson¹, D. Grange¹; ¹Washington Univ. Sch. of Med. in St. Louis, Saint Louis, MO, ²Univ. of Missouri Sch. of Med. in Columbia, Columbia, MO

Abstract Body:

Abstract: Newborn screening has become advantageous in providing nutritional intervention and medication treatment to alter long term outcomes for patients. Yet, the interventions can be limited in cases of a more severe presentation. We report on a case of Very Long-Chain Acyl-Coenzyme A Dehydrogenase (VLCAD) Deficiency diagnosed post-mortem. Our patient was born to a 26-year-old G1P0 by uncomplicated vaginal delivery after presenting in labor. Antenatally, the pregnancy was uncomplicated, and mother reports only taking prenatal vitamins. APGARS were 9 and 9 at one and five minutes, respectively, and she was transitioned for routine care neonatally. There was concern for grunting episodes on DOL1 and breath holding yet this resolved spontaneously. On the evening of DOL1 (30 hours of age), she became unresponsive resulting in resuscitation efforts by the neonatal intensive care unit and pediatric cardiology. An echocardiogram showed no abnormalities, and continuous cardiac monitoring showed a pattern of wide QRS complexes with peaked T waves refractory to intervention. Initial venous blood obtained 1 hour into resuscitation showed a pH 7.002 and a base deficit of 10. Initial K was >10 mmol/L. It was after over 2 hours of resuscitation that efforts were halted. Newborn screening results received after death indicated a positive screen for VLCAD Deficiency with a C14:1 level of 3.20 µmol/L (normal <0.60 µmol/L). Post-mortem examination was performed, and family was consented for genetic testing. Examination of the placenta was notable for rare pigmented macrophages concerning for meconium aspiration. Autopsy findings included a structurally normal heart without hypertrophy, lungs with some evidence of meconium aspiration, stomach with early ischemic changes, kidney with tubular vacuolization, and liver with microsteatosis. Genetic testing included a normal chromosomal microarray, and whole exome sequencing revealed biallelic variants in *ACADVL* (maternal c.1375dup, p.(R459Pfs*4) pathogenic variant and a paternal c.1678+3_1678+6del? likely pathogenic variant). The maternal variant is predicted to result in nonsense mediated decay, and the paternal variant supports a deleterious effect on splicing; these are consistent with the loss of function mechanism of disease of VLCAD Deficiency. Our patient suffered from cardiac arrest leading to demise, yet increased awareness of this more severe presentation could alter prognosis. We present a case with both postmortem confirmatory genetic testing and consistent postmortem findings of hepatic steatosis of an acute form of VLCAD deficiency resulting in neonatal demise.

Mendelian Phenotypes Posters - Thursday

PB1728. A case report of an Egyptian patient with a severe neurodevelopmental disorder and a novel biallelic loss-of-function variant in *GOLGA2*.

Authors:

R. Khang¹, A. Kenawy², R. N. El Kharadly², G. Seo¹, H. Lee¹; ¹3billion, Seoul, Korea, Republic of, ²Med. Res. Inst., Alexandria, Egypt

Abstract Body:

GOLGA2 gene encodes GM130 protein that constitutes Golgi apparatus (GA) which plays a critical role in protein secretion and sorting. The symptoms of various Mendelian disorders associated with GA component proteins are heterogeneous, but neurodevelopmental phenotype is one of the common phenotypes in relatively severe disorders. *GOLGA2* gene is not yet associated with a human disorder with only a couple of patients reported with homozygous loss-of-function (LoF) variants. *Golga2* knockout (KO) mice present with autophagy and fibrosis in lung and liver, and *golga2* knocked down zebrafish show severe skeletal muscle disorganization and microcephaly.

Here, we report a patient with a novel homozygous variant in *GOLGA2*. The patient was a 2-year-old female born after a full term uneventful pregnancy. Her birthweight was 2250 grams. On clinical examination, she had growth retardation, global developmental delay, hypotonia and dysmorphic features including microcephaly, deep-set eyes, upturned nasal tip, long philtrum, thin upper lip, and pointed chin. She also had bridged simian creases, hypoplastic nails and overlapping toes. Brain MRI showed hypoplastic corpus callosum and delayed myelination for age. EEG showed generalized epileptiform activity. The ophthalmological fundus examination and hearing assessment were normal. Family history was significant with 3 deceased siblings presenting with similar symptoms. Exome sequencing was performed on the patient using xGen Exome Research Panel v2 (Integrated DNA Technologies) and Illumina NovaSeq 6000. A mean coverage of 231X was achieved and the patient had regions of homozygosity across ~1.4% of the genome, suggesting the parents are distantly related. There were no clinically significant variants that could explain the patient's phenotype. However, there was a homozygous 4-base deletion variant that is predicted to result in LoF (NM_001366244.1:c.2018_2021del; p.Lys673ArgfsTer31), truncating the last 345 amino acids of the protein.

The two previously reported patients with variants in *GOLGA2* were a 10.5-months old female and a female who started showing symptoms at 6 months of age. They had homozygous LoF variants c.1311_1314delAGAG (p.Glu423ArgfsTer6) and c.2296C>T (p.Gln766Ter), predicted to result in similar consequences as the variant found in our patient. All of our patient's symptoms were reported in these two patients with a similar age-of-onset. Although finding additional cases with similar symptoms and variants, and performing functional studies are warranted, our patient augments the possibility of biallelic LoF variants in *GOLGA2* leading to a severe neurodevelopmental disorder.

Mendelian Phenotypes Posters - Wednesday

PB1729. A case with mosaicism pigmentary and Prader-Willi Syndrome: importance of molecular diagnosis in cases of mosaicism

Authors:

Y. Gasparini, E. Moura, M. Montenegro, V. Almeida, B. Wolff, G. Carvalho, A. Mendes, L. Vieira, L. Kulikowski; Univ.e de Sao Paulo, Sao Paulo, Brazil

Abstract Body:

Mosaicism is a usual event in the world population, defined by the presence of two or more genetically different cell lines in the same individual, arising from the same zygote. However, the characterization of mosaicism still poses a great challenge for laboratorial medicine, since variants may not be present in all tissues. This is associated with mosaicism confined to tissue or pigmentary mosaicism, which constitutes a heterogeneous group of skin pigmentation alterations associated with multisystem involvement. We present a case of a three year-old male infant, born from a non-consanguineous healthy couple. The patient displayed hypotonia, sinophre, long eye-lashes, ptosis, simplified helix ear, retrognathia, high palate, congenital heart disease, spots in Blaschko lines and bilateral cryptorchidism. We have collected samples from peripheral blood, saliva and skin fibroblasts. Results from cytogenetic analysis (GTG Band) performed in peripheral blood were normal (46,XY). Unexpected results from skin fibroblasts and saliva using genomic array (cytoSNP850k-Illumina) revealed a trisomy of chromosome 15 in mosaic. Additionally, a methylation test was performed for the *SNURPN* gen, which showed an exclusively maternal methylation pattern, with no evidence of the paternal allele. The most commonly accepted mechanism behind cases of UPD for different chromosomes reported in literature is trisomy rescue. This mechanism may cause different outcomes in somatic cells mitosis: hetero-UPD (rescue), a normal cell (rescue) or trisomy (no or incomplete rescue). Incomplete rescue of trisomy 15 may lead to the development of mosaic mutations and chromosome rearrangements, which are associated with cases of PWS with maternal UPD.

Mendelian Phenotypes Posters - Thursday

PB1730. A Difficult Dual Diagnosis: Dilemmas in the Era of Next Generation Sequencing

Authors:

A. Rekab, K. Anyane-Yeboah; Div. of Clinical Genetics, Dept. of Pediatrics, Columbia Univ. Med. Ctr., New York, NY

Abstract Body:

The advent of next generation sequencing (NGS) in the clinical setting has increased the frequency of identification of dual diagnoses, which can present challenges for clinicians. Here we describe a case involving a dual diagnosis of two rare neurological conditions with overlapping phenotypes.

Our patient is a 2-month-old female with seizures at 6 weeks old. Brain MRI was unremarkable, and EEG demonstrated focal seizures. On physical exam she was hypotonic with asymmetric facies, plagiocephaly and torticollis. SNP microarray was negative, but an epilepsy panel revealed a likely pathogenic variant in *CDKL5* (c.826-1G>A, splice acceptor) and a pathogenic variant in *KIF1A* (c.2362G>T, p.E788*). Both variants are expected to cause loss of function and were de novo.

CDKL5 deficiency disorder (CDD) is an X-linked developmental epileptic encephalopathy caused by pathogenic variants in the *CDKL5* gene and is characterized by epilepsy with onset by three months of life, global developmental delays, intellectual disability, hypotonia and cortical visual impairment. CDKL5 plays a role in brain development and function. KIF1A-associated neurological disorder (KAND) is a neurodegenerative condition characterized by spastic paraplegia, peripheral neuropathy, developmental delays, seizures and optic nerve atrophy. KAND is caused by mono- or bi-allelic pathogenic variants in *KIF1A* which encodes a component of intracellular transport in axonal microtubules, essential for neuronal survival.

The overlapping phenotypes of these two conditions bring to light several management and counseling dilemmas for clinicians. In cases such as ours, a dual diagnosis complicates the ability of clinicians to clearly delineate symptoms, anticipate the possible evolution of phenotype, and has the potential to be a source of confusion and anxiety for families. This patient's clinical picture is well explained by the *CDKL5* variant, yet the possibility of future *KIF1A* contribution to her phenotype cannot be overlooked. A dual diagnosis can also complicate eligibility criteria for some clinical research studies. With KAND treatments on the horizon, our patient's eligibility may be challenged due to her *CDKL5* variant. Thus, raising the question of how clinicians can equitably care for patients with dual diagnoses.

A dual diagnosis can present challenges for clinicians and families alike. Greater structure in clinical management recommendations could alleviate the uncertainty in these cases. Further research on patients with dual diagnoses is paramount to better equip clinicians' management and counseling, as NGS increases the recognition of multiple genetic diagnoses.

PB1731*. A dysmorphology physical examination entry system facilitates structured genetic phenotype capture and natural language processing

Authors:

I. Campbell^{1,2}, A. Magge³, J. C. Priestley¹, K. M. Szigety¹, S. F. Schmidt¹, M. L. McManus¹, S. E. Sheppard⁴, E. M. Lourie^{1,2}, N. Muthu^{1,2}, H. Hakonarson^{1,2}, G. Gonzalez-Hernandez³; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Univ. of Pennsylvania, Philadelphia, PA, ³Cedar Sinai Hosp., Los Angeles, CA, ⁴Eunice Kennedy Shriver Natl. Inst. of Child Hlth.and Human Dev., Rockville, MD

Abstract Body:

The dysmorphology physical examination is a critical component of diagnostic evaluation in clinical genetics, as it directly influences the selection and interpretation of genetic testing. Such information is also extremely useful to researchers attempting to delineate undescribed genetic conditions. However, this key information is nearly always captured within the electronic health record (EHR) as unstructured free text, making it unavailable for downstream computational analysis. To address this issue, we implemented a specialized dysmorphology exam system in our EHR that speeds the clinical workflow while also capturing common examination findings discretely through button clicks and continuous anthropometric measurements through numeric fields. Other findings are documented in free text fields. To extract additional structured phenotypic findings from the free text, we implemented a novel recurrent neural network classifier to predict human phenotype ontology (HPO) terms. We trained the classifier using the synonyms present in the HPO and UMLS Metathesaurus. We generated additional training data by manually annotating 2,013 physical exam text strings describing pediatric patients. Review of inter-annotator agreement among our 4 annotators found 76% complete concordance for the 890 text strings annotated at least twice. We found the classifier had 83% accuracy on the validation data, which was a substantial improvement upon a previously published HPO classifier, PhenoTagger (68% accuracy). Using this system, we captured a median of 1 abnormal HPO phenotype per participant from discrete data and a median of 3 abnormal phenotypes from free text. Finally, we analyzed the most frequently documented findings in free text and used this information to improve options for discrete capture. In conclusion, the development of specialized physical exam systems has the potential to both speed clinical documentation and facilitate capture of discrete human phenotypes. Moreover, natural language processing is a promising approach for secondary EHR data reuse in genetics. We have partnered with the EHR vendor to bring this functionality to other customers.

PB1732. A Highly Polymorphic VNTR in the *DRD4-DEAF1* Intergenic Region

Authors:

D. Vandenbergh, C. A. Brogan, A. T. Apsley, A. J. Burich; Penn State Univ, University Park, PA

Abstract Body:

Adolescent Idiopathic Scoliosis (AIS) impacts 4 out of every 100 adolescents (Konieczny et al., 2013), but its etiology is not well understood. In a Genome-Wide Association Study, an association was found with SNP rs11604855 (Liu et al., 2017), which is in the intergenic region between *DRD4* and *DEAF1*. Whether it plays a causative role in AIS, or is linked to a second causative site is unknown. We identified a novel Variable Number of Tandem Repeats (VNTR) locus less than 2 kb from the SNP that is a 28-nucleotide repeat present as 4.9- and 75-copy variants in the reference and alternate genomes. Analysis of 64 long-read sequences revealed 34 variants ranging from 3 to 156 copies of the repeat. Alleles at this VNTR are in linkage disequilibrium with rs11604855 raising the possibility that the association of the SNP and AIS might be due to functional effects of this highly variable tandem repeat.

Mendelian Phenotypes Posters - Wednesday

PB1733. A homozygous variant in a novel gene "*AP2A2*" causes an early-onset hereditary spastic paraplegia in a Malian family.

Grunseich¹; ¹Neurogenetics Branch, NINDS, NIH, Bethesda, MD, ²Université des Sci., Techniques et Technologies de Bamako (USTTB), Bamako, Mali, ³Pediatric Genomics Discovery Program (PGDP), Yale school of Med., New Haven, CT, ⁴NeuroSci.s and Cellular and Structural Biology Div., NICHD, NIH, Bethesda, MD, ⁵Service de Neurologie, CHU du Point "G", Bamako, Mali, ⁶Service de Neurologie, CHU du Gabriel Touré, Bamako, Mali, ⁷Service de Chirurgie pédiatrique, CHU of Gabriel Touré, Bamako, Mali, ⁸Cytogenetic Dept., Univ. of Cape Town, Cape Town, South Africa, ⁹Service de Cytogénétique et la Réproductive Biologique, INRSP, Bamako, Mali, ¹⁰Neuroimmunology Div., NINDS, NIH, Bethesda, MD, ¹¹Massachusetts Gen. Hosp., Charlestown, MA

Abstract Body:

Background: Hereditary spastic paraplegias (HSPs) are a heterogeneous group of neurodegenerative disorders characterized by lower-extremity spasticity with "pure" and "complicated" forms. Several genes and loci have been associated HSPs, but many other clinically entities remain with no molecular diagnosis. **Objectives:** Characterize patients with HSPs and identify the underlying genetic defect. **Methods:** After consent, patients went through a thorough clinical examination. Blood chemistries, brain and spinal imaging were done to exclude common causes. DNA was extracted for WES. Variants were checked in public and local SNP databases, and classified according to (ACMG). Functional studies were performed using iPSC cells differentiated into iPSCs like neurons (iNeur) obtained from patients and relatives' fibroblasts (fib). SgRNA were made for CRISPR/cas9 knockout of the target gene in frog embryos to further confirm variant pathogenicity. **Results:** We identified a consanguineous Malian family with three siblings presenting symptoms consistent with complicated HSP. The age of onset was ~8months-old. Neurological examination found lower limb weakness, equine feet, spastic gait, and cognitive decline. Brain imaging showed thin corpus callosum with cortical and cerebellar atrophy and EEG was abnormal. HSP candidate gene and targeted panel gene were negative. However, WES identified a homozygous missense variant in *AP2A2* gene. The variant segregated with the disease phenotype in the family and not present in SNP databases. *AP2A2* has not been previously associated with any disease, but it is a member of a complex associated with other HSPs. *AP2A2* protein is known to be highly expressed in the spinal cord and fetal brain and has role in endocytosis function. It is also conserved through diverse species and located in appendage C-terminal domain, a platform of protein-protein interactions domain. Functional studies showed no difference in protein and mRNA levels in fibroblasts, however reduction in protein levels was observed in neuronal cells. Immuno-precipitation of mutant AP2-appendage alpha-C construct shows a defect of binding to accessory proteins. Endocytosis function was tested through transferrin receptor (TfR) uptake in fib and iNeur, and showed decreased uptake of iron uptake in patients neuronal cell. In additional, we observed neurite swelling in 11-day-old patient neuronal cultures. **Conclusion:** Our findings suggest a novel candidate gene causing HSP. Further studies are underway to evaluate the functional implication of this variant in *X. tropicalis* model. **Keyword:**HSPs, exome sequencing, *AP2A2*, clathrin-mediated endocytosis, Mali

PB1734. A multi-branch family with mutation in *SLC26A4* gene from a village in the southeastern region of Iran.

Authors:

M. Mohseni¹, S. Dorgaleleh², M. Beheshtian¹, F. Keshavarzi¹, F. Ghodratpour¹, F. Zare Ashraf¹, K. Jalalvand¹, S. Arzhangi¹, N. Nikzat¹, K. Kahrizi¹, H. Najmabadi¹; ¹Genetics Res. Ctr., Univ. of Social Welfare and Rehabilitation Sci., Tehran, Iran, Islamic Republic of, ²Student Res. Committee, Golestan Univ. of Med. Sci., Gorgan, Iran, Islamic Republic of

Abstract Body:

In order to reduce the burden of hereditary hearing loss (HHL), the most frequent sensorineural disorder influencing 1 in 500 newborns around the globe, molecular diagnosis is crucial; particularly in countries with higher rates of consanguineous marriages such as Iran. Recently, we identified a village located at the southeastern part of Iran with many people suffering from HHL and decided to determine the causative gene. In present study, investigation of molecular cause of autosomal recessive hearing loss (ARHL) in a multi-branch family originating from a village in southeastern Iran with 31 affected members manifesting moderate to severe HL. After a comprehensive clinical examination on affected individuals with the history of GJB2-negative HL, we subjected an affected individual to whole exome sequencing (WES). Analysis of WES data was mainly performed by filtering out variants with minor allele frequency >0.05, particularly reported in Iranian populations using the Iranome database. Applying Sanger sequencing, we confirmed candidate variants. We detected the known missense mutation, c.716T>A (p.V239D), in the sixth exon of the *SLC26A4* gene, which had been firstly reported in Iran in Kurdish families. Our Sanger sequencing data confirmed the presence of this pathogenic variant in the rest of 30 affected members in this family. Previously, the p.V239D mutation was reported from Pakistan, in the southeast of Iran, causing ARHL. Given that the *SLC26A4* gene as the most common gene after *GJB2* in Iran, causing ARHL, Finding this mutation in a village next to the border of Pakistan might reflect the magnification of a founder effect, and contribute to the final genetic make-up of this region's population.

Mendelian Phenotypes Posters - Wednesday

PB1735. A new case of YARS1 associated multisystemic disorder with compound heterozygous in a patient with Klinefelter syndrome.

Authors:

J. Kuan, A. B. Hansen, H. Wang; Loma Linda Univ. Sch. of Med., Loma Linda, CA

Abstract Body:

Introduction: Aminoacyl-tRNA synthetases are a group of enzymes that catalyze the coupling of amino acids to their respective tRNAs. Tyrosyl tRNA synthetase, encoded by the gene YARS1, is responsible for the aminoacylation of tyrosine to its tRNA. Heterozygous variants in YARS1 are associated with autosomal dominant Charcot-Marie-Tooth type C. Recently, cases of biallelic variants in YARS1 have been reported to result in an autosomal recessive multisystemic disease. Here we report a new case with compound heterozygous variants in YARS1 in a patient with Klinefelter syndrome. **Case presentation:** A 12-week-old Hispanic male born at 37 weeks was admitted for 6 weeks of emesis and 2 weeks of intermittent seizure-like activity. Abdominal ultrasound was suggestive of possible hepatocellular dysfunction. EEG showed focal sites of hyperexcitability. Brain MRI was unremarkable. He failed initial and subsequent hearing screenings in the left ear. The hospitalization was complicated by intermittent hyperkalemia. Microarray revealed Klinefelter syndrome. At 14 months old he presented to genetics with microcephaly, hypotonia and significant delay in milestones. A PEG tube was placed for failure to thrive. Family history revealed that his father has adult-onset hearing loss, wears hearing aids, and has pain and weakness in his feet. Consanguinity was denied. Considering that Klinefelter cannot explain the patient's clinical phenotypes, whole exome sequencing was performed, which revealed one likely pathogenic variant (c.1099C>T, p.R367W, paternally inherited, reported before) and one variant of uncertain significance (c.782T>G, p.L261R, maternally inherited, never been reported) in the YARS1 gene. Based on the clinical phenotypes, the diagnosis of YARS1 related multisystemic disorder was established. **Discussion/Conclusion:** This disorder was recently updated by OMIM #619418 and named as infantile-onset multisystem neurologic, endocrine, and pancreatic disease type 2 (IMNEPD2). It is characterized by global developmental delay, microcephaly, FTT, sensorineural deafness, retinal abnormalities with visual defects, hypotonia, hepatomegaly, endocrine abnormalities, and brain findings of dysmyelination, thin corpus callosum, cerebral atrophy and white matter abnormalities. Unique for this case is that the father likely has Charcot-Marie-Tooth disease, indicating that both dominant and recessive disorders are present in the same family, and that this is the first report of this disorder in a patient complicated with Klinefelter syndrome, demonstrating that comprehensive genetic testing is important for patients with complicated phenotypes.

Mendelian Phenotypes Posters - Thursday

PB1736. A novel de novo nonsense variant in *TBX2* cause osteochondrodysplasia

Authors:

M. Umair, M. Alfadhel; Med. Genomics Res. Dept., King Abdullah Intl. Med. Res. Ctr. (KAIMRC), King Saud Bin Abdulaziz Univ. for Hlth.Sci. (KSAU-HS), Ministry of Natl. Guard Hlth.Affairs (MNG-HA), Riyadh, Saudi Arabia., Riyadh, Saudi Arabia

Abstract Body:

Background: Genetic skeletal disorders are a diverse heterogeneous group of developmental disorders of the skeletal system and cartilaginous tissues. According to the nosology classification, many types have been classified according to molecular analysis and clinical presentation. **Methods:** Using molecular and clinical methods we characterized a proband having features of osteochondrodysplasia. The affected individual's age was 5 years at the time of study and who passed away at 6.5 years exhibited features such as chondrodysplasia phenotypes, short stature, and global developmental delay. Additional clinical investigation revealed platybasia at the skull base delayed myelination, chest showing bilateral subsegmental atelectasis/consolidation in the lower lobes, bilateral hip dislocation, and diffuse central vertebral endplate depression. Molecular diagnosis was performed using Trio-Whole-exome sequencing using standard methods. **Results:** WES identified a novel heterozygous nonsense mutation p.Lys177Ter in exon 2 of the *TBX2* gene, confirmed by Sanger sequencing. The amino acid Lys177 is conserved across different species. **Conclusion:** *TBX2* is important for the development of the skeleton and the brain and four prior reports described *TBX2* association with craniofacial dysmorphism, complex vertebral anomalies, and endocrine dysfunctions. Our findings expand the current spectrum of *TBX2* associated genetic skeletal disorder and support the evidence that disease causing variants in *TBX2* have heterogeneous clinical presentations associated with osteochondrodysplasia.

Mendelian Phenotypes Posters - Wednesday

PB1737. A novel homozygous missense mutation in *ARSK* causes a new subtype of MPS.

Authors:

M. Sun¹, L. Randolph²; ¹Children's Hosp. Los Angeles/Keck Sch. of Med. of USC, Los Angeles, CA, ²Children's Hosp. Los Angeles, Los Angeles, CA

Abstract Body:

Mucopolysaccharidoses (MPS) are a group of rare inborn errors of metabolism caused by defective lysosomal enzymes which prevent cells from recycling certain carbohydrates and fats, causing storage of glycosaminoglycans in cells throughout the body. This leads to multisystem abnormalities including connective tissues, brain, blood, spinal cord and other tissues. A recent study suggested defects in *ARSK* may lead to a new subtype of MPS, MPS X.

Our patient is a 13-year-old cognitively intact boy of Syrian ancestry with Perthes disease and pectus carinatum referred for possible skeletal dysplasia. He was born to nonconsanguineous parents. His height is at the 18th percentile, relatively short for his mean parental height. His skeletal survey showed partially collapsed concave bilateral femoral capital epiphyses, striated trabecular appearance of the ends of the long bones, platyspondyly with anterior beaking, and exaggerated thoracic kyphosis, consistent with skeletal dysplasia, “likely spondyloepiphyseal dysplasia”. At that time he had normal levels of glycosaminoglycans in his urine.

Trio exome sequencing revealed a novel homozygous missense germline variant, c.1067C>A (p.S356Y), in *ARSK* (reference sequence: NM_198150.3). Both parents were confirmed as heterozygous carriers. This variant occurs at a highly conserved amino acid position within conserved sulfatase domain. *In-silico* predictions suggest a deleterious effect of this change. This variant has not been reported either as a benign or disease-causing variant in human. It has not been observed in the gnomAD database (<https://gnomad.broadinstitute.org/>).

To date, only two variants (p.R84C and p.L184X) associated with *ARSK*-related conditions have been reported in the literature. Both showed childhood onset with relatively mild MPS features, such as a mild elevation of dermatan sulfate detected by the more sensitive method of LC-MS/MS. Additional cardiac and ophthalmological abnormalities were noticed on follow-up examination. Our exome findings of the homozygous *ARSK* variant (p.S356Y) combined with the constellation of clinical presentation suggest that our patient likely has the newly defined MPS type X condition. The effect of *ARSK* deficiency due to the p.S356Y variation in *ARSK* are under investigation with functional studies and repeat urine MPS testing at an alternative laboratory, which may help us better understand its pathogenic roles on GAG storage in humans.

Mendelian Phenotypes Posters - Thursday

PB1738. A novel homozygous variant in *HECW2* gene is associated with intellectual disability and epilepsy in a Malian family.

Hosp.ier Univ.ire du Point G, Bamako, Mali, Bamako, Mali, ³Pediatric Genomics Discovery Program, Yale Univ. Sch. of Med., New Haven, CT, New Haven, CT, ⁴Service de Neurologie, Ctr. Hosp.ier Univ.ire de Gabriel Touré, Bamako, Mali, Bamako, Mali

Abstract Body:

Background: Epilepsy is a chronic neurological condition particularly common in patients with intellectual and developmental disabilities (IDD). To date, several genes are reported to be associated with IDD. Variants in the *HECW2* gene were shown to cause this phenotype in European and North African patients. However, no case was reported in sub-Saharan African population. We report here the first *HECW2* variant associated with epilepsy and intellectual disability in a Malian family. **Objective:** To clinically characterize patients with IDD and identify the underlying genetic defects. **Materials and Methods:** Institutional ethical approval was obtained from the Faculty of Medicine and Dentistry, Bamako, Mali. Patients and available family members were enrolled after given a written consent. They were also carefully examined by a multidisciplinary team including neurologist, neurogeneticist. Blood chemistries including blood glucose, cell counts and ions; and EEG were performed in some patients. DNA was extracted from peripheral blood for whole exome sequencing. Putative variants were checked in all individuals for segregation analysis. We used several *in silico* prediction tools to detect deleteriousness including CADD. **Results:** Three siblings (two males and one female) from a non-consanguineous family were referred to our clinic for familial epilepsy. The age at diagnosis was 8,4 years and 16 months respectively. All patients had a focal tonic seizure with a psychomotor delay (neck tone, seat, crawl, gait) and absent speech. They received antiepileptic drugs which reduced the severity of the seizures. WES identified a homozygous missense variant **c.1856C>G; p. Pro619Arg** in *HECW2* gene in two affected individuals whereas parents were heterozygous for the variant. This variant was absent in various SNP databases including gnomAD and is predicted to be damaging by several tools (CADD = 23, Fathmm = 0.98; Consequence score = 6). Further investigations including functional analysis are ongoing. **Conclusion:** We report here the first case of IDD with epilepsy caused by mutation in the *HECW2* gene in a Malian family, expanding its genetic epidemiology. A large cohort study may help identify several other genetic variants for a better understanding of the pathophysiology of IDD.

Mendelian Phenotypes Posters - Wednesday

PB1739. A Novel Homozygous Variant in Homologous Recombination Repair Gene *ZSWIM7* Causes Azoospermia in Males and Primary Ovarian Insufficiency in Females

Authors:

S. Nawaz, Shah Hussain, Ihsan Khan , Nida Khan, Shabir Hussain, Imran Ullah, Khalid A. Fakhro, Wasim Ahmad; Sidra Med., Doha, Qatar

Abstract Body:

A Novel Homozygous Variant in Homologous Recombination Repair Gene *ZSWIM7* Causes Azoospermia in Males and Primary Ovarian Insufficiency in Females Infertility is a common, clinically heterogeneous reproductive disorder worldwide with a prevalence of about 15%. To date about 80 genes have been discovered to cause non-syndromic infertility, affecting males and females equally, though traditionally the genetic analysis of each group has been conducted separately. Here, we report the clinical and genetic characterization of a consanguineous family of Pakistani origin with multiple individuals, including male and female, affected with infertility. Males exhibited azoospermia whereas females had primary ovarian insufficiency. Whole exome sequencing revealed a missense variant (c.176C>T, p.(Ser59Leu)) in the *ZSWIM7* gene which functions in homologous recombination repair. The variant was found in a homozygous form in all affected males and females. To our knowledge, this is the first mutation in *ZSWIM7* to be shown to cause infertility in both sexes, pointing at the utility of large consanguineous families with multiple affected siblings to reveal joint mechanisms affecting human reproduction. **Keywords** Infertility, azoospermia, primary ovarian insufficiency, *ZSWIM7*

Mendelian Phenotypes Posters - Thursday

PB1740. A novel homozygous variant in *IBA57* causing multiple mitochondrial dysfunction syndrome type 3

Authors:

S. Lang, E. de Joya, P. Borjas-Mendoza; Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract Body:

The multiple mitochondrial dysfunction syndromes (MMDS) are a rare cause of autosomal recessive leukodystrophy. Their molecular basis is rooted in impaired maturation of the cubane [4Fe-4S]-cluster containing proteins including complexes I-III of the respiratory chain and lipoic acid synthase, essential for critical modifications of several mitochondrial enzymes. Biallelic pathogenic variants in *IBA57* have been implicated in MMDS type 3, a phenotypically heterogeneous entity with presentations ranging from neonatal demise to benign neuropathy with survival into the sixth decade. In this report, we describe a novel homozygous variant in *IBA57* (NM_001010867.3): c.310G>T (p.Gly104Cys) causing MMDS type 3 in an infant.

A two-month-old female presented with one month history of progressive hypotonia, weakness, and upward gaze deviation. The patient was born full term from a consanguineous 27-year-old G1P0 mother and a 50-year-old father of Cuban origin. Prenatal history and perinatal period were unremarkable. Prior to the onset of symptoms, the patient achieved milestones appropriate for a one month old. Initial exam revealed significant head lag and upgaze deviation. Labs were notable for a lactic acidosis. MRI revealed widespread signal abnormalities involving subcortical and deep white matter tracts, optic nerves, as well as cystic signal abnormality within the medulla. Brain MR spectroscopy revealed a significant lactate peak. Multigene sequencing revealed a homozygous variant in *IBA57*, confirmed in trans on trio exome analysis. The infant showed worsening hypotonia and impending respiratory failure requiring intubation and ventilatory support by 3-month-old, ultimately expired.

This patient's findings of cystic leukodystrophy, lactate peak on MRS, progressive hypotonia, and developmental regression taken together with her homozygous missense variants in *IBA57* were strongly suggestive of MMDS 3. The variant, located within exon 1 of *IBA57*, is flanked by three pathogenic variants previously reported in MMDS 3 (OMIM ID: 615316.0007, 615316.0008, 615316.0010). In silico analysis supported a deleterious effect. Interestingly, the phenotypic outcomes of patients with any one of these four variants are highly variable, complicating the establishment of a clear genotype-phenotype correlation.

The MMDS present as a severe or fatal early onset encephalopathy. Clinical suspicion correlating with brain imaging and biochemical findings should prompt rapid confirmation through molecular analysis. This report describes novel homozygous variants in *IBA57* and expands the genotypic and phenotypic spectrum of MMDS 3.

PB1741. A novel *LZTR1* variant in a Brazilian familial case with Noonan syndrome: comparative modeling and structural analysis

Authors:

N. Chaves Rabelo¹, D. Antunes², M. Gomes¹, I. de Oliveira Moraes¹, E. Caffarena³, J. Llerena⁴, S. Gonzalez¹; ¹Genomic Med. Lab./Reference Ctr. of Rare Diseases/Fernandes Figueira Inst./Fiocruz, Rio de Janeiro, Brazil, ²Functional Genomics and Bioinformatics/Oswaldo Cruz Inst./Fiocruz, Rio de Janeiro, Brazil, ³Computational Biophysics and Molecular Modeling Group, Scientific Computing Program/Fiocruz, Rio de Janeiro, Brazil, ⁴Med. genetics Dept./Reference Ctr. of Rare diseases/Fernandes Figueira Inst./Fiocruz, Rio de Janeiro, Brazil

Abstract Body:

Noonan syndrome (NS) is the most common genetic disorder in RASopathy group, that is characterized by short stature, congenital heart defects and facial features. Many genes involved in RAS/MAPK pathway activation have already been associated with NS, and the most frequently are: *PTPN11* (50%), *SOS1* (10-13%) and *LZTR1* (8%), among others. Pathogenic heterozygous and homozygous variants in the *LZTR1* gene have been associated with NS. The LZTR1 protein is composed by the Kelch and BTB domains that mediates protein-protein interactions with RAS family (HRAS, NRAS, and KRAS), acting as a negative regulator of the RAS-MAPK signaling pathway. A familial case of a father and daughter with suggestive features of RASopathy was investigated in a Reference Center of Rare Diseases in Brazil (RCRD/IFF/Fiocruz). Genomic DNA was obtained from the proband and her parents. The library construction was performed for the proband focused on 6,700 genes disease-associated (clinical exome sequencing), and the sequencing was performed in paired-end mode in the NextSeq 500 Platform. Data analysis was performed using a pipeline based on GATK Best Practices. Were considered variants in RASopathy-associated genes; non-synonymous or frameshift or in splicing sites; and, low-frequency variants (<0.1%). A missense not previously reported variant p.Pro225Leu in the *LZTR1* gene was found in heterozygosis, that has not yet been described in the population databases. Sanger sequencing revealed the same variant in her mildly affected father. This is a nonsynonymous substitution in a highly conserved region located in the Kelch domain of the LZTR1 protein and *in silico* predictors classified it as probably damaging. A symmetric structure of six blades characterizes this domain, and each of them is composed of four antiparallel β -strands, as previously described. Mutant and wild-type LZTR1 structural model comparison through Swiss-Model server showed differences in the loop that connects strand D (blade III) with strand A (blade IV), in addition to changes in blade III in the local secondary structure of the Kelch domain. Global changes are also observed, showing a decrease of approximately 1% in the β -sheet content (34.04% wild-type versus 32.97% mutant). These results reinforce the probable pathogenicity of the p.Pro225Leu variant, indicating the need for functional studies to assess its impact on RAS/MAPK pathway hyperactivation. Furthermore, the incorporation of NGS combined with computational analysis in the RCRD/IFF/Fiocruz have been contributing significantly to the clinical practice and the prognosis prediction of Rasopathy diseases.

Mendelian Phenotypes Posters - Thursday

PB1742. A novel *PUM1* heterozygous missense variant causing severe developmental delay and epilepsy from infancy with dysmorphic features.

Authors:

E. Sato¹, M. Fujimoto¹, T. Iwaki¹, Y. Nakamura¹, D. Ieda¹, A. Hattori^{1,2}, K. Kato^{1,3}, K. Narita⁴, H. Muramatsu⁴, Y. Okuno⁵, Y. Takahashi⁴, J. Natsume^{4,6}, S. Saitoh¹; ¹Dept. of Pediatrics and Neonatology, Nagoya City Univ. Graduate Sch. of Med. Sci., Nagoya, Japan, ²Dept. of Pediatrics, Nagoya City Univ. East Med. Ctr., Nagoya, Japan, ³Sch. of Biochemistry, Faculty of Life Sci., BioMed. Sci. Building, Univ. of Bristol, Bristol, United Kingdom, ⁴Dept. of Pediatrics, Nagoya Univ. Graduate Sch. of Med., Nagoya, Japan, ⁵Dept. of Virology, Nagoya City Univ. Graduate Sch. of Med. Sci., Nagoya, Japan, ⁶Dept. of Dev.al Disability Med., Nagoya Univ. Graduate Sch. of Med., Nagoya, Japan

Abstract Body:

[Background]PUM1 is an RNA-binding protein that acts as a transcriptional repressor of Ataxin1. Although specific missense variants in *PUM1* were known to cause adult-onset ataxia, recently it has been shown that complete loss of function in one *PUM1* allele causes severe early onset developmental delay, epilepsy and ataxia. However, there have been few reports of infantile onset *PUM1*-associated diseases, and the clinical features are yet to be elucidated. We herein describe an additional patient with a de novo heterozygous missense variant in *PUM1*. [Case report]The patient is a 27-year-old female born with a weight of 3230g at 39 weeks of an uneventful pregnancy. She could hold her neck at 5 months and sit at 9 months of age. She was diagnosed with West syndrome at 10 months of age. After that, she showed spasms, tonic seizures, myoclonic seizures, and other seizures despite multiple antiepileptic medications. Gradually she has shown severe developmental delay and does not speak any meaningful words. She shows some dysmorphic features, with hypertelorism, almond-shaped eyes, epicanthus, broad-nasal bridge, low-set ears, oligodontia with widely spaced teeth. Her head MRI at 17 years showed slight ventricular enlargement. We performed trio-based whole exome sequencing analysis and identified a de novo heterozygous variant in *PUM1* gene, NM_001020658: c.1760T>C, p.(V587A). This was a rare variant and was not registered in databases including gnomAD. CADD score was 30. Furthermore, her dysmorphic features were very similar to those in other reports. We considered that this newly identified variant caused severe developmental delay and epilepsy from infancy with dysmorphic features. [Conclusion]We identified a novel *PUM1* pathogenic variant in a patient with severe early onset developmental delay, and intractable epilepsy. Thus far only a recurrent variant of c.3439C>T (p.R1147W) has been reported to be associated with severe developmental delay and epilepsy. This case suggests that p. V587A, which is located outside RNA-binding Pumilio homology domain, has as much deleterious consequence as p.R1147W in PUM1 function.

Mendelian Phenotypes Posters - Wednesday

PB1743. A novel splice-site variant causes *MYH2*-associated myopathy in a large family.

Authors:

T. Cassini¹, M. Malicdan², E. Macnamara¹, T. Lehky¹, I. Horkayne-Szalaky³, Undiagnosed Diseases Network, Y. Huang¹, R. Jones³, R. godfrey⁴, L. Wolfe⁴, W. Gahl⁵, C. Toro²; ¹NIH, Bethesda, MD, ²NIH, Bethesda, MD, ³Defense Hlth.Agency, Silver Spring, MD, ⁴NIH - NHGRI, Bethesda, MD, ⁵NHGRI (NIH), Bethesda, MD

Abstract Body:

MYH2 encodes MyHCIIa, a myosin heavy chain found in fast type 2A fibers. Pathogenic variants in this gene have previously been implicated in dominant and recessive forms of myopathy typically manifesting as predominantly proximal muscle weakness and atrophy with external ophthalmoplegia. Onset is typically in adolescence or early adulthood and the course may be either slowly progressive or non-progressive. Additional features include facial weakness, tremors, and joint contractures at birth that sometimes resolve over time.

Three individuals evaluated by the Undiagnosed Diseases Program are part of a family in which four generations are affected by a slowly progressive, predominantly proximal myopathy in an autosomal dominant inheritance pattern. Affected individuals in this family lacked certain classic features of an *MYH2*-associated myopathy such as congenital contractures and ophthalmoplegia. Additional clinical evaluations included MRIs on all three individuals with muscle atrophy and fatty infiltration. A muscle biopsy was also performed on the proband and showed small type 2 myofibers involving some of the fascicles, and very tiny and markedly lost type 2 fibers in the adjacent fascicles accompanied by denervation atrophy and mild myopathic changes.

A novel variant, *MYH2* c.5673+1G>C, was detected in the proband. This variant was found to segregate with disease in five additional affected family members and was absent from population databases. Further studies confirmed that this variant affects splicing, resulting in novel transcripts. Reverse transcriptase PCR revealed the expected 402 base pair band and two additional bands in the proband and an affected relative as compared to an unaffected individual. Sanger sequencing of clones revealed the normal and three novel isoforms: an isoform with skipping of exon 39; an isoform with intronic retention of 83 nucleotides; and an isoform with partial deletion of exon 37 and 38. These data indicate that this family's *MYH2* variant is causative of their myopathy, adding to our understanding of the clinical and molecular characteristics of the disease.

Mendelian Phenotypes Posters - Thursday

PB1744. A novel XL gene for autism with psychiatric illness in adults

Authors:

H. Alakeel, W. Eyaid, A. AlZaben; Natl. Guard For Hlth.Affairs, Riyadh, Saudi Arabia

Abstract Body:

Mohammad; 7 years old male , known to have developmental delay, autism and ADHD. His WGS showed research finding, structural variant analysis demonestrated a hemizygous duplication (chrX:118541361-118569156 28kb) within SLC25A43, that is expected to affect the protien function. This variant was classified as 2P (likely affecting protein function).To date no OMIM phenotype has been associated to the pathogenic variants in the SLC25A43 gene. Quantative real time -PCR detected variable expression of SLC25A43 in almost all rat tissues examined. Expression was highest in brain coronal sections containing olfactory bulb and cerebral cortex, followed by adrenal gland and skeletal muscles. The segregation analysis showed that it is maternally inherited, the grandmother is not a carrier, but the grandfather is, and for that reason all his daughters are carriers. The grandfather and his elder brothers are reported to suffer from psychosis, maternal family history is as well significant for diverse mental manifestation (psychosis, ? Autism, and developmental delays). We aim to furtherly study this gene function and it's pathogenicity to help this family. The young couple of Mohammad decided to stop reproducing till a definite diagnosis with prevention is made. He is there only child.

Mendelian Phenotypes Posters - Wednesday

PB1745*. A *Plod2* mutant mouse model of Bruck syndrome

Authors:

A. Kot¹, I. Duran², J. H. Martin¹, D. Wachtell¹, C. Chun¹, D. M. Hudson³, M. Weis³, D. R. Eyre³, J. Zieba¹, D. Krakow¹; ¹UCLA, Los Angeles, CA, ²Univ. of Malaga, Malaga, Spain, ³Univ. of Washington, Seattle, WA

Abstract Body:

Bruck syndrome is an autosomal recessive form of osteogenesis imperfecta (OI) caused by biallelic mutations in *PLOD2* or *FKBP10* and is characterized by joint contractures, bone fragility, short stature, and kyphoscoliosis. *PLOD2* encodes LH2, which hydroxylates type 1 collagen telopeptide lysines, an important step in proper collagen crosslink formation. *PLOD2* is alternatively spliced into short (LH2a) and long (LH2b) isoforms - LH2a is the dominant form early in development until LH2b predominates later. The role of *PLOD2* mutations in the pathogenesis of Bruck syndrome is not well understood and the global *Plod2* knockout mouse model is limited by early embryonic lethality. Therefore, we generated a novel *Plod2* mouse line to model a human mutation identified in two unrelated Bruck syndrome cases: *PLOD2* c.1559dupC, predicting a frameshift and loss of LH2b through nonsense mediated decay. We observed mice homozygous for the mutation in non-Mendelian ratios at E13.5 and E18.5 indicating variable, but early lethality. Homozygous mice were present at P0 but died immediately after birth. At E18.5, heterozygous mice were indistinguishable from WT. Homozygous mice displayed bilateral forelimb and hindlimb contractures, smaller body weights and crown-to-rump lengths, normal skeletal patterning but poorly mineralized calvaria, and loss of cervical spine curvature. Compared to WT, calvaria derived LH2b mRNA and protein were decreased in both heterozygous and homozygous mice. Type 1 collagen telopeptide lysine hydroxylation was reduced in homozygous but not in heterozygous bone. Von Kossa stained distal femurs showed homozygous mice had fewer and thinner trabeculae as well as smaller calcospherites. Femoral growth plate analysis revealed heterozygous and homozygous mice had decreased proliferative zone lengths indicating alterations in chondrocyte differentiation. Our model of *PLOD2* c.1559dupC survives longer than the existing global *Plod2* knockout model and demonstrates that loss of LH2b recapitulates important features of the Bruck syndrome phenotype including congenital contractures. The growth plate phenotype suggests *Plod2* plays a heretofore unknown role in chondrocyte development. This new model can be used to explore the role of LH2b in the developing skeleton and aid in understanding the molecular mechanisms underlying Bruck syndrome.

Mendelian Phenotypes Posters - Thursday

PB1746. A prospective, longitudinal observational natural history study of patients with NGLY1 Deficiency.

Authors:

S. Tong¹, P. Ventola^{2,3}, S. S. Dwight¹, W. F. Mueller¹, C. R. Stanclift¹, B. J. Beahm¹, M. Wilsey¹, K. J. Lee¹; ¹Grace Sci. Fndn., Menlo Park, CA, ²Yale Child Study Ctr., New Haven, CT, ³Cogstate, New Haven, CT

Abstract Body:

NGLY1 Deficiency is a debilitating, rare, autosomal recessive neurodevelopmental disorder with shortened life span and unmet need. It is caused by loss of *N*-glycanase 1 (NGLY1), a cytosolic enzyme that deglycosylates glycoproteins, and is characterized by global developmental delay, intellectual disability, hyperkinetic movement, elevated transaminases, (hypo)alacrima, and chronic polyneuropathy. A substrate biomarker, aspartylglucosamine (GNA), directly reflects loss of NGLY1 function. A prospective, longitudinal observational study was conducted to define NGLY1 Deficiency natural history. Participants (pts) (n=29; 15 on-site, 14 remote) with confirmed diagnosis of NGLY1 Deficiency were identified through the Grace Science Foundation and enrolled. The following were assessed: developmental status using validated, age-appropriate instruments; movement disorder; quality of life (QL); liver function tests; plasma GNA levels. On-site pt data are presented here; remote pt and additional longitudinal data will be presented. 15 on-site pts (11 unrelated, 2 sibling pairs; 7 girls, 8 boys), were followed for up to 3 yr (years). Mean age [range] was 12 [2.8-22] yr at entry and 6 [prenatal-14] yr at diagnosis. At baseline, caregivers were interviewed using the Vineland-3 (n= 14); adaptive skills were varied but generally low (ABC Standard Score mean 49 [23 - 88]). Age equivalents were globally delayed with mean [standard deviation (SD)]: Expressive 31months (m) [66m] or Receptive 38m [69m] Communication; Personal Care 22m [26m]; Fine 11m [7m] or Gross 9m [5m] Motor. On-site pts who completed the Mullen Scales of Early Learning (n=10) presented with marked developmental delay, mean DQ 11, range 1.4-18.8, with impairment across all domains. The age equivalent means [range] were: Visual Reception 16m, [1-27m]; Fine 11m [1-18m] or Gross 8m [1-16m] Motor; Receptive 12m [1-27m] or Expressive 7m [2-21m] Language. Caregivers for both onsite and remote pts reported poor QL: PedsQL (Total Score Mean [range] 50.48 [33.7-95.7]). Liver transaminase baseline mean values were elevated and improved slightly. Mean [SD] GNA was 115 ng/mL [28.4], range 57.8 - 189.0, which was 4.3-fold over related and 8.5-fold over unrelated unaffected controls. There was no significant correlation between GNA levels and age. Longitudinal GNA samples (n=10) showed ≤ 37 ng/mL change over 2-3 years (max - min concentration; mean change 23.0 ng/mL +/- 10.8ng/mL). In sum, pts with NGLY1 Deficiency have developmental delay, movement disorders, and inability for self-care. GNA biomarker levels are universally elevated and provide a potential tool for advancing a therapeutic intervention.

Mendelian Phenotypes Posters - Wednesday

PB1747. A recessive variant in *TFAM* causes mtDNA depletion associated with primary ovarian insufficiency, seizures, intellectual disability and hearing loss

Authors:

F. Ullah¹, W. Rauf², K. Khan³, S. Khan⁴, K. Bell⁵, V. Oliveira⁶, M. Tariq², S. Bakhshalizadeh⁵, P. Touraine⁷, A. Sinclair⁸, S. He⁹, E. Tucker¹⁰, S. Baig¹¹, E. Inst., Melbourne, Australia, ⁹BGI-Shenzhen, Shenzhen, China, ¹⁰Murdoch Children's Res. Inst., Royal Children's Hosp., Melbourne, Australia, ¹¹Pakistan Sci. Fdn., Islamabad, Pakistan, ¹²Lurie Children's Hosp. of Chicago, Chicago, IL

Abstract Body:

Mitochondrial disorders are individually rare but collectively common conditions that impact both pediatric and adult populations. A majority are caused by molecular defects in oxidative phosphorylation, failure of essential bioenergetic supply to mitochondria, and apoptosis, and therefore, it is not surprising that they are underscored by extensive genetic heterogeneity. Here, we present the genetic and functional analysis of four affected individuals from two independently analyzed consanguineous families of Pakistani origin with reproductive deficits accompanied by variable neurodevelopmental phenotypes and hearing loss. The females display primary ovarian insufficiency and incompletely penetrant seizures and hearing loss, while the male shows intellectual disability and abnormal sex hormone levels. We performed whole exome sequencing and homozygosity mapping and identified a recurrent recessive missense variant c.694C>T, p.Arg232Cys in *TFAM* that segregates with disease. TFAM (mitochondrial transcription factor A) is a component of the mitochondrial replisome machinery is involved in regulation of mitochondrial genome integrity and replication. There is a paucity of previously reported *in vivo* TFAM ablation data; *Tfam* knockout mice are lethal prior to weaning and one pathogenic p.Pro178Leu change has been shown to cause lethality during infancy in humans due to liver failure and intrauterine growth restriction. In patient derived fibroblasts from a p.Arg232Cys bearing case, we show significant depletion of mtDNA and significantly altered mitochondrial function and morphology. Moreover, we observed reduced nucleoid numbers with significant changes in nucleoid size or shape in fibroblasts from an affected individual compared to controls. Furthermore, we investigated the effect of *tfam* loss in zebrafish; homozygous knockout mutants recapitulate the mtDNA depletion and ovarian dysgenesis phenotypes observed in affected humans. Together, our genetic and functional data confirm that TFAM plays a pivotal role in gonad development, expands the repertoire of mitochondrial disease phenotypes, and exemplifies the increasingly prevalent phenomenon of variable phenotype penetrance and expressivity in Mendelian disorders.

Mendelian Phenotypes Posters - Thursday

PB1748*. A recurrent missense variant in *ITPR3* causes demyelinating Charcot-Marie-Tooth neuropathy.

Authors:

D. Beijer¹, M. F. Dohrn¹, A. Rebelo¹, C. Record², S. Feely³, M. Saporta¹, M. Reilly², S. Scherer⁴, Y-C. Lee⁵, M. Shy³, S. Zuchner¹; ¹Univ. of Miami, Miami, FL, ²UCL Queen Square Inst. of Neurology, London, United Kingdom, ³Univ. of Iowa, Iowa City, IA, ⁴Univ. of Pennsylvania, Philadelphia, PA, ⁵Taipei Veterans Gen. Hosp., Taipei, Taiwan

Abstract Body:

Charcot-Marie-Tooth disease is a rare neuromuscular disorder affecting the peripheral nervous system. The diagnostic yield in demyelinating CMT (CMT1) is typically ~80-95%, of which at least 60% is due to the *PMP22* gene duplication. The remainder of CMT1 is more genetically heterogeneous. We used whole exome sequencing (WES) and whole genome sequencing (WGS) data to investigate novel causal genes and mutations in a cohort of ~2,000 individuals with CMT disease submitted to the Genesis project. We identified a recurrent missense variant in *ITPR3*, a recently described CMT gene, in more than 16 individuals from seven different families. All families presented with slow nerve conduction velocities and an autosomal dominant or *de novo* inheritance, matching the diagnostic category of CMT1. Sanger sequencing confirmed the co-segregation of the CMT phenotype with the presence of the variant, including a four-generation family with multiple affected second-degree cousins, and a *de novo* inheritance in an isolated patient. *ITPR3* encodes IP₃R3 (inositol 1,4,5-trisphosphate receptor 3), which, like its paralogs *ITPR1* and *ITPR2*, is highly expressed in the nervous system. Based on protein modelling, this residue is located in the dimerization interface and could interfere with the dimerization process. We are currently testing this hypothesis using *in vitro* modelling. Here we show that a recurrent *ITPR3* missense mutation specifically causes a demyelinating Charcot-Marie-Tooth phenotype and could account for a relatively large proportion of unsolved CMT1 patients.

Mendelian Phenotypes Posters - Wednesday

PB1749. A single-center genetic analysis of oculopharyngeal myopathy

Authors:

T. Shimizu¹, H. Ishiura², M. Hara¹, S. Shibata³, A. Unuma^{1,4}, A. Kubota¹, K. Sakuishi^{5,6}, K. Inoue⁷, J. Goto^{8,6}, Y. Takahashi^{4,6}, J. Shimizu^{9,6}, S. Tsuji^{2,10}, T. Toda²; ¹The Univ. of Tokyo Hosp., Bunkyo-ku, Japan, ²The Univ. of Tokyo, Tokyo, Japan, ³Saitama Med. Ctr., Jichi Med. Univ., Tokyo, Japan, ⁴Natl. Ctr. of Neurology and Psychiatry, Kodaira, Tokyo, Japan, ⁵Teikyo Univ. Chiba Med. Ctr., Chiba, Japan, ⁶The Univ. of Tokyo Hosp., Bunkyo-ku, Tokyo, Japan, ⁷Fujieda Heise Mem. Hosp., Sizuoka, Japan, ⁸Intl. Univ. of Hlth.and Welfare Ichikawa Hosp., Ichikawa, Chiba, Japan, ⁹Tokyo Univ. of Technology, Tokyo, Japan, ¹⁰Inst. of Med. Genomics, Intl. Univ. of Hlth.and Welfare, Chiba, Japan

Abstract Body:

Background: Oculopharyngodistal myopathy (OPDM) is a distal myopathy characterized by ocular, pharyngeal, and facial muscle weakness with an autosomal dominant mode of inheritance. Recently, we have identified heterozygous CGG repeat expansions in *low-density lipoprotein receptor related protein 12 (LRP12)* that cause OPDM, and the disease was designated as OPDM type 1 (OPDM1). Thereafter, CGG repeat expansions in *NOTCH2NLC*, *GIPC1*, and *RILPL1* have been identified as causes of other types of OPDM. To further delineate molecular epidemiology, we performed genetic analysis of patients with OPDM. **Methods:** This study is a single-center case series of OPDM including ten patients from seven families. Every family had been shown to have rimmed vacuoles in the muscle biopsy and excluded to have GCN repeat expansions in *PABPN1*. Repeat-primed polymerase chain reaction and Southern blot analyses were performed to confirm the CGG repeat expansions in *LRP12*, *GIPC1*, and *NOTCH2NLC*. Whole genome sequencing (WGS) was performed in one patient. **Results:** Seven patients from five families and two patients from one family were identified as having CGG repeat expansions in *LRP12* (OPDM1) and *GIPC1* (OPDM2), respectively. In the remaining one patient, CGG repeat expansion was not found in these genes. In three OPDM1 patients, multiple expanded alleles, probably reflecting somatic instability, were found. In one patient without CGG repeat expansions in these genes, WGS failed to identify expanded CGG repeats. **Discussion:** In this single-center study of OPDM, OPDM1 is most common in Japan. In one patient, WGS did not reveal expanded CGG repeats, further suggesting pathomechanistic heterogeneity.

Mendelian Phenotypes Posters - Thursday

PB1750. A substantial proportion of high myopia is caused by mutations in *CACNA1F* (XL CSNB)

Abstract Body:

CACNA1F is involved in the neurotransmission between the rod photoreceptors and the bipolar cells in the retina, and has been mostly associated with (in)complete congenital stationary night blindness (CSNB) (CSNB2A, OMIM 300071), but also with X-Linked (XL) Åland eye disease (OMIM 300600) and XL cone-rod dystrophy (CRD) (CORDX3, OMIM 300476). During the last six years, we have diagnostically screened >750 patients with various eye disorders (mainly inherited retinal dystrophy, age related macular degeneration, opticopathy, high myopia) using Whole Exome Sequencing with filtering for a panel of ~500 genes associated with vision disorders. In this cohort, 220 patients with high myopia were included in which we identified 11 males with mutations in *CACNA1F* (5%). Mean age of these patients was 19.7 years (SD 23.5). Early onset high myopia was the first symptom. At time of first investigation, the mean refractive error was -12.1 diopters (SD 3.36; range -6 to -24). Other reported symptoms at time of first investigation were night blindness (n=4) and decreased best corrected visual acuity (n=11), with a mean of 0.45 (SD 0.11). In young children, these symptoms can be difficult to notice. Eventually an electroretinogram (ERG) was conducted in 6 patients. This led to the diagnosis of CSNB (n=4) and CRD (n=1). At young age an ERG cannot always be made for practical reasons. Our data suggest that in young males with early onset high myopia *CACNA1F* should be investigated, and this should be part of the screening strategy.

PB1751. A Zebrafish Model of Congenital Muscular Dystrophy Caused by POMT1 Loss of Function

Authors:

M. Manzini, B. F. Karas, K. R. Terez, B. M. Gural, N. Battula, K. Flannery; Rutgers Robert Wood Johnson Med. Sch., New Brunswick, NJ

Abstract Body:

Dystroglycanopathies are a group of rare autosomal recessive congenital muscular dystrophies (CMDs) that present at birth and severely affect the brain, eyes, and muscles. While these disorders are highly genetically and clinically heterogeneous, the function of most known dystroglycanopathy genes converges on defects of glycosylation of the transmembrane glycoprotein alpha-dystroglycan (alpha-DG). Without proper alpha-DG glycosylation, transmembrane communication between the cell and extracellular matrix (ECM) is compromised in multiple tissues. In fact, most dystroglycanopathy genes are glycosyltransferases participating in the assembly of a specific glycan chain on alpha-DG involved in binding ECM components. The initial step in glycosylation is the addition of an O-linked mannose via Protein O-Mannosyltransferase 1 (POMT1) to alpha-DG and *POMT1* mutations in patients frequently manifest as the most severe form of CMD with early lethality, Walker-Warburg Syndrome (WWS). In mice, only conditional *Pomt1* knockouts (KOs) could be generated, since *Pomt1* loss of function leads to early embryonic lethality. In this study, we characterized a *pomt1*-deficient zebrafish model that could provide new insight into the mechanisms of disease and treatment interventions. The zebrafish strain carries a premature stop codon leading to complete loss of POMT1 and loss of alpha-DG glycosylation. Our data show that loss of *pomt1* leads to early lethality starting at 30 days post fertilization (dpf), small size, impaired mobility, muscle disease, and retinal defects. However, these phenotypes are delayed compared to dystroglycan (*dag1*) KO in fish. Since *pomt1* is critical for early embryonic development and mRNA is provided by the mother in the embryo's yolk, we asked whether KO embryos and larvae obtained from *pomt1* KO mothers would present more severe phenotypes. We found that zebrafish larvae from KO X heterozygote crosses begin to die at 10 dpf similar to *dag1* KO zebrafish and show severe mobility impairment starting at 5 dpf. Collectively, these data suggest the *pomt1* mutations in the zebrafish lead to disease phenotypes consistent with the human presentation and could be used to test novel therapeutic approaches.

PB1752. Allele-specific inactivation of epidermolysis bullosa simplex mutations using CRISPR-Cas9 and spraying of the corrected cell suspension onto the wounds

Authors:

M. Bchetnia¹, J. Powell², C. Morin³, C. McCuaig², A. Dupérée³, L. Germain⁴, J-P. Tremblay⁵, C. Laprise¹; ¹Université du Québec à Chicoutimi (UQAC), Département des Sci.s fondamentales, Saguenay, QC, Canada, Chicoutimi, QC, Canada, ²Hôpital Ste-Justine, Montréal, QC, Canada, Montreal, QC, Canada, ³Ctr. intégré universitaire de santé et des services sociaux du Saguenay–Lac-St-Jean, Saguenay, QC, Canada, Chicoutimi, QC, Canada, ⁴Ctr. de recherche en organogénèse expérimentale de l'Université Laval/LOEX, Québec, QC, Canada;, Québec, QC, Canada, ⁵Ctr. de recherche du Ctr. Hosp.ier universitaire (CHU) de Québec, Université Laval, QC, Canada;, Québec, QC, Canada

Abstract Body:

Background: Epidermolysis bullosa simplex (EBS) is a rare mechanobullous disease caused by dominant-negative mutations in either keratin 5 (*KRT5*) or keratin 14 (*KRT14*) genes responsible for skin integrity via the building the keratin filament network in the epidermis. Until now, there is no cure for EBS and the care is primarily palliative. The discovery of the clustered regularly interspaced short palindromic repeat (CRISPR-Cas9) system, raised hope for the treatment of EBS and many other autosomal dominant diseases by specific disruption of the mutant allele. Moreover, the recent, clinically used, ReCell Spray-On Skin device seems to be a rapid autologous cell processing and delivery system where the corrected cell suspension could be sprayed onto the lesions in a non-invasive way. The regenerative nature of these skin cells is intended to promote rapid wound healing and the growth of healthy skin. **Objectives:** We aim to disrupt the mutant allele for the heterozygous EBS pathogenic variation c.449T>C (p.Leu150Pro) within *KRT5*. This mutation generates, naturally, a novel protospacer-adjacent motif (PAM) for the endonuclease *Streptococcus pyogenes Cas9* (*SpCas9*). The corrected cells will be delivered on the patient wounds by using the ReCell Spray-On Skin device. **Methods:** We designed a single guide RNA (sgRNA) that guides the Cas9 to introduce a DNA cleavage of the mutant allele in patient's keratinocytes. Transfected cells were subsequently single-cell cloned and analysed by deep sequencing at the DNA and RNA level. *KRT5* and *KRT14* expression were quantified in edited and non-edited cells and keratin intermediate filaments stability was assessed. **Results:** Single cell cloning showed stringent mutant allele specific knockout in some clones. An absence of synthesis of mutant transcript was further confirmed indicating permanent mutant allele-specific inactivation. Edited EBS patient keratinocytes have a lower amount of K5 and K14 compared to non-edited EBS cells but the protein product of the unaffected wild type allele should be sufficient for normal cellular function. No disturbance of cellular properties was observed. The cell suspension delivery protocol optimisation is in progress. **Conclusion:** This study is the first description of allele specific CRISPR-Cas9 gene inactivation at a novel PAM created by one EBS causing heterozygous pathogenic variation. The next step will be to use the ReCell Spray-On Skin device to deliver the corrected cells in the EBS lesions by a rapid and non-invasive method.

Mendelian Phenotypes Posters - Wednesday

PB1753. Alteration of mitochondrial proteostasis in Costello syndrome

Authors:

D. Lacombe^{1,2,3}, L. Dard^{4,3}, C. Hubert^{4,3}, N. Amoedo^{4,3}, R. Rossignol^{4,3}; ¹CHU BORDEAUX, BORDEAUX, France, ²BORDEAUX Univ., Bordeaux, France, ³INSERM U1211, Bordeaux, France, ⁴BORDEAUX Univ., BORDEAUX, France

Abstract Body:

Normal 0 21 false false false FR JA X-NONE /* Style Definitions */ table.MsoNormalTable {mso-style-name:"Tableau Normal"; mso-tstyle-rowband-size:0; mso-tstyle-colband-size:0; mso-style-noshow:yes; mso-style-priority:99; mso-style-parent:""; mso-padding-alt:0cm 5.4pt 0cm 5.4pt; mso-para-margin:0cm; mso-para-margin-bottom:.0001pt; mso-pagination:widow-orphan; font-size:12.0pt; font-family:"Times New Roman",serif; mso-bidi-font-family:"Times New Roman"; mso-bidi-theme-font:minor-bidi;} Germline mutations that activate genes in the canonical RAS/MAPK signaling pathway are responsible for rare human developmental disorders known as RASopathies. Here, we analyzed the molecular determinants of Costello syndrome (CS) using a mouse model expressing HRAS^{G12S}, patient skin fibroblasts, hiPSC-derived human cardiomyocytes, a HRAS^{G12V} zebrafish model and human fibroblasts expressing lentiviral constructs carrying HRAS^{G12S} or HRAS^{G12A} mutations. The findings revealed alteration of mitochondrial proteostasis and bioenergetics, and defective oxidative phosphorylation in the heart and skeletal muscle of Costello mice that were also found in the cell models of the disease. The underpinning mechanisms involved the miR-221*-dependent inhibition of AMPK α 2 expression and the concomitant alteration of LKB1 activation by mutant forms of HRAS, leading to alteration of mitochondrial turnover and bioenergetics. Pharmacological rescue of mitochondrial proteostasis restored organelle bioenergetics in HRAS^{G12A/S} cell models, reduced heart mass in CS mice and reduced the occurrence of developmental defects in the CS zebrafish model.

Mendelian Phenotypes Posters - Thursday

PB1754. An initiative for the diagnosis and study of rare and undiagnosed diseases in Mexico

Authors:

C. Gonzaga-Jauregui; Univ. Natl. Autónoma de México (UNAM), Juriquilla, Mexico

Abstract Body:

About 7000 rare diseases have been documented to date, the majority of which have a genetic cause or component and therefore can be molecularly diagnosed. The implementation of genomic sequencing of patients with suspected genetic disorders has revolutionized the investigation, diagnosis, treatment, and care of patients with rare diseases. Nevertheless, these technologies are mostly available to patients from higher income countries, exacerbating the health disparities suffered by patients living with rare and undiagnosed diseases in low- and middle-income countries where these technologies are difficult to access and too expensive.

Mexico has a population of 126 million people and it is the 17th economy in the world. However, the majority of the estimated 10 million people that live with a rare disease in the country do not have an accurate molecular diagnosis due to lack of access to genetic testing methods. Furthermore, an estimated 2 to 3 million of patients living with rare diseases are part of indigenous or underserved communities with poor access to healthcare services.

In 2022, we have launched a registry of patients with rare and low prevalence diseases in Mexico to obtain more accurate information on the number of patients, diseases, and disease prevalence in this population, and the challenges faced by these patients. The first analysis of the data collected from the registry reveals a great need for information and access to diagnostic options among patients and families living with rare diseases. The majority of patients registered so far are affected by neurodevelopmental or connective tissue disorders; other rare disorders have also been reported. Only 20% of registered patients have received a molecular diagnosis for their disorder. Concurrently, we have initiated a research program to investigate the molecular causes of diseases of rare and undiagnosed diseases in Mexico. We are performing genomic sequencing and analyses to identify the causes of rare and undiagnosed genetic disorders in this genomically underrepresented population. We present some initial findings from these efforts, including a novel candidate disease gene identified through the study of Mexican patients. We expect that these efforts will reveal novel disease associated variation present in Mexican genomes not previously reported in genomic databases, identify new candidate disease genes, and provide insights on medically relevant variation in the Mexican population that may serve for population screening and implementation of precision medicine in a middle-income country setting.

Mendelian Phenotypes Posters - Wednesday

PB1755. Angelman syndrome with mosaic paternal uniparental disomy caused by mitotic nondisjunction.

Authors:

M. Fujimoto¹, Y. Nakamura¹, T. Iwaki¹, E. Sato¹, D. Ieda¹, A. Hattori¹, A. Shiraki^{2,3}, S. Mizuno⁴, S. Saitoh¹; ¹Dept. of Pediatrics and Neonatology, Nagoya City Univ. Graduate Sch. of Med. Sci., Nagoya, Japan, ²Dept. of Child Neurology, Toyota Municipal Child Dev. Ctr. Nozomi Clinic, Toyota, Japan, ³Dept. of Pediatrics, Nagoya Univ. Graduate Sch. of Med., Nagoya, Japan, Nagoya, Japan, ⁴Dept. of Pediatrics, Central Hosp., Aichi Human Service Ctr., Kasugai, Aichi, Japan

Abstract Body:

Angelman syndrome (AS) is a severe neurodevelopmental disorder and caused by the functional absence of the maternal copy of the *ubiquitin-protein ligase E3A (UBE3A)* gene. Paternal uniparental disomy of chromosome 15 (UPD(15)pat) leads to absence of maternal *UBE3A* expression and is known as one of the molecular pathomechanisms of AS. Approximately 5% of AS is caused by UPD(15)pat, most of which are thought to be caused by monosomy rescue. However, few attention has been focused on how the UPD(15)pat would occur in each patient. Here, we demonstrated the mitotic nondisjunction mechanism that caused UPD(15)pat in a patient with AS. A 6-year-old boy presented neurodevelopmental disorder and distinctive physical findings that were in line with AS features. DNA methylation screening of 15q11-q13 showed a paternal band and a faint maternal band, suggestive of mosaic status. By trio-based microsatellite analysis using their blood, we confirmed the mosaic status, including a large proportion of UPD(15)pat cells and a small proportion of biparental-origin cells. Single nucleotide polymorphism (SNP) microarray revealed that the isodisomic region spanned the entire length of chromosome 15. Overall, these results suggest that the UPD(15)pat in the current patient did not occur by a pre-zygotic monosomy rescue mechanism but by post-zygotic mitotic nondisjunction mechanism. This report suggests that some AS patients with UPD(15)pat of entire isodisomy that thought to be caused by monosomy rescue may be caused by mitotic nondisjunction.

Mendelian Phenotypes Posters - Thursday

PB1756. *ARG1* variants in Arginase 1 Deficiency: genetic characterization of participants in the pegzilarginase clinical trials.

Authors:

M. McNutt¹, G. Bubb², L. Neuman², R. Zori³; ¹UT Southwestern Med. Ctr., Dallas, TX, ²Aeglea BioTherapeutics, Inc., Austin, TX, ³Univ. of Florida, Gainesville, FL

Abstract Body:

Arginase 1 Deficiency (ARG1-D; OMIM 207800) is a rare autosomal recessive metabolic disorder caused by homozygous or compound heterozygous mutations in *ARG1* (60813; chromosome 6q23) resulting in loss of arginase 1 activity and pathologic accumulation of arginine. ARG1-D is characterized by the hallmark of hyperargininemia and manifestations including developmental delay, intellectual disability, and prominent, progressive lower-limb spasticity. ARG1-D is distinct from other urea cycle disorders as symptomatic hyperammonemia is not uniformly present and not thought to be a key disease driver. The typical clinical course includes unremarkable infancy followed by development of progressive neurologic manifestations that begin in early childhood; however, for reasons currently unknown, there is a significant variability in age of onset, sequence and rate of progression, and severity, even among patients with the same *ARG1* variant(s). More than 60 *ARG1* variants have been reported to date, and since recent genetic prevalence estimates are higher than originally thought, additional variants may exist. The Phase 1/2 and Phase 3 clinical trials of pegzilarginase, which demonstrated significant reduction of plasma arginine to or below the guideline-recommended level of 200 $\mu\text{mol/L}$, provided the opportunity to investigate *ARG1* variants in 2 robustly characterized cohorts of patients with ARG1-D. Disease manifestations were heterogenous in nature and degree, as is typical of ARG1-D, and all patients had characteristic elevated plasma arginine levels despite dietary protein restriction. Genotyping data were available for 47 of 48 trial participants and identified 37 unique variants (homozygous, n=37 patients; compound heterozygous, n=10 patients). The most frequent variant was C.466-1G>C, identified in 9 patients (6 homozygous), followed by C.314_345delins20 (homozygous, n=3, heterozygous, n=1), C.61C>T (homozygous, n=2; heterozygous, n=2), and C23T>A (n=3, all homozygous). A total of 18 variants (in 29 patients) have been described in the literature suggesting the pegzilarginase study patients are representative of the broader ARG1-D population. The remaining 19 variants, including C.314_345delins20, appear to be novel. Consistent with the literature, no clear genotype/phenotype association was evident in this large cohort. Future research into the impact of *ARG1* variants, both known and novel, is warranted and may increase understanding of this heterogenous and debilitating disease. Importantly, the arginine-lowering effect of pegzilarginase was consistent irrespective of patients' genetic variant(s) and clinical presentation.

Mendelian Phenotypes Posters - Wednesday

PB1757. *ARHGAP32*, encoding the Rho GTPase Activating Protein 32, is a novel candidate gene involving in autosomal dominant neurodevelopmental disorder spectrum

Authors:

Y. Cao^{1,2,3}, A. Kwan¹, Y. ZHENG¹, M. Chau^{1,3}, Z. Dong^{1,3}, S. Chong², Y. Kwok¹, P. Liu⁴, Y. Yang⁴, R. Choy^{1,3}, H. Dai⁴; ¹Dept. of Obstetrics and Gynaecology, Prince of Wales Hosp., The Chinese Univ. of Hong Kong, Hong Kong, China, ²Dept. of Paediatrics, Prince of Wales Hosp., The Chinese Univ. of Hong Kong, Hong Kong, China, ³Hong Kong Hub of Paediatric Excellence, The Chinese Univ. of Hong Kong, Hong Kong, China, ⁴Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX

Abstract Body:

Rho GTPase-activating proteins (GAPs) regulate the Rho GTPases which play essential roles in regulating neuronal morphology and function. Currently more than 70 types of Rho GTPase Activating Protein have been discovered. Recent evidence suggests that dysfunction of Rho GTPase signaling contributes substantially to the pathogenesis of neurodevelopmental and neuropsychiatric disorders. Studies in large cohorts of subjects with autistic spectrum disorders or intellectual disability have identified de novo variants in *ARHGAP32* gene, suggesting that this gene is involved in the development of such disorders. The *ARHGAP32* isoform including PX, SH3 domain deficient mice mimic autistic feature of patients while its ASD-like behavioral problems are ameliorated by enhancing inhibitory synaptic transmission with a GABAAR agonist. In this study we would further provide evidence supporting *ARHGAP32* gene-disease validity. Total 8 patients were collected in this study including four unrelated patients harboring a heterozygous de novo variant in *ARHGAP32* gene through worldwide collaboration and four previously published patients from large cohort studies. Except a prenatal case, all case showed neurodevelopmental or neuropsychiatric disorders commonly presenting autism spectrum disorders(43%), ADHD(43%), moderate intellectual disabilities(29%), brain image abnormalities(43%). One postnatal case presented macrocephaly while the prenatal case had head circumference higher than 97th percentile. Its pLi Score as 1 and LOEUF as 0.25 indicated its intolerance to the loss of function. We demonstrated that 4 de novo truncating variants in our patients are in the latter half of *ARHGAP32* Protein. However, we did not observe a clear genotype-phenotype correlation between the types and locations of these 8 variants and variability of clinical features. We suggest *ARHGAP32* gene is involved in development of the autism spectrum disorder with variable additional neurodevelopmental abnormalities.

Mendelian Phenotypes Posters - Thursday

PB1758. *ATP2C1* as a candidate for Interstitial Cystitis/Bladder Pain Syndrome

Authors:

E. Estrella¹, S. Rockowitz¹, M. Thorne², P. Smith¹, J. Petit¹, V. Zehnder¹, R. Yu¹, S. Bauer¹, C. Berde¹, P. Agrawal³, A. Beggs¹, A. Gharavi⁴, L. Kunkel¹, C. Brownstein³; ¹Boston Children's Hosp., Boston, MA, ²Biogen, Cambridge, MA, ³Boston Children's Hosp., Boston, MA, ⁴Columbia Univ, New York, NY

Abstract Body:

Interstitial Cystitis/Bladder Pain Syndrome (IC/BPS) is a chronic pain disorder causing symptoms of urinary frequency, urgency and bladder discomfort or pain. Although this condition affects a large population, little is known about its etiology. We performed genetic analyses of whole exome sequencing on a total of 109 individuals with IC/BPS. One family had a previously reported *SIX5* mutation (p.A158T), consistent with Branchiootorenal syndrome 2 (BOR2). A likely pathogenic heterozygous variant in *ATP2A2* (p.E79K) was identified in another proband, indicating possible Darier-White disease. Two private heterozygous variants were identified in *ATP2C1* (p.E786D (VUS/Likely Pathogenic) and p.T330S (Likely Pathogenic)), indicative of Hailey-Hailey Disease. Both Darier-White and Hailey-Hailey have specific therapies. SKAT analysis found a trend towards increased burden of rare *ATP2C1* variants in the IC/BPS cases vs a control cohort (p=0.03, OR=6.76), though did not survive Bonferroni correction. Our data suggest that some individuals with IC/BPS may have unrecognized Mendelian syndromes. Comprehensive phenotyping and genotyping aids in understanding the range of diagnoses in our population-based IC/BPS cohort. Conversely, *ATP2C1*, *ATP2A2*, and *SIX5* could be candidate genes for IC/BPS. Further evaluation with larger numbers is needed. Genetically screening individuals with IC/BPS may be useful in diagnosing and treating this painful disorder due to its heterogenous nature.

Mendelian Phenotypes Posters - Wednesday

PB1759. Atypical 260 kb deletion on distal 22q11.22 involving *TOP3B* shows the significance of this gene in autism spectrum disorder

Authors:

D. Evans¹, Y. Qiao², K. Calli³, S. Martel⁴, M. Hrynychak⁵, S. Lewis⁶; ¹Univ. of British Columbia, Vancouver BC, BC, Canada, ²Univ. of British Columbia, Vancouver, BC, Canada, ³Univ British Columbia, Vancouver, BC, Canada, ⁴Med. Genetics, Univ. of British Columbia, Vancouver BC, BC, Canada, ⁵Royal Columbian Hosp, New Westminster, BC, Canada, ⁶BC Children's & Women's Hlth.Ctr, The Univ. of British Columbia, Vancouver, BC, Canada

Abstract Body:

In Canada the prevalence of autism spectrum disorder (ASD) is 1 in 66 children. ASD is a heterogeneous group of neurodevelopmental disorders defined by deficits in social communication and interaction, as well as restrictive, repetitive patterns of behavior. There are more than 40 recurrent CNVs that have been implicated in ASD susceptibility. The 22q11.21 deletion syndromes result in an array of phenotypes such as velocardiofacial syndrome (OMIM 192430) and DiGeorge syndrome (OMIM 188400). Interestingly, distal deletions at the recurrent 22q11.2 locus (OMIM# 611867) comprise a distinct disorder separate from DiGeorge and velocardiofacial syndrome, which has been the topic of several candidate gene studies. Notably, *TOP3B* and *IGLV2-14* were previously described as putative candidate genes within a 22q11.22 critical interval. Here, we investigate and characterize a 13-year-old male with psychometrically confirmed ASD and other co-morbidities such as intellectual disability, ADHD, specific learning disabilities and growth delays in the absence of any craniofacial dysmorphisms. We employed whole genome sequencing of the parent-offspring trio and did not identify any candidate pathogenic variants. Our CNV analysis identified a 260Kb deletion at 22q11.2 in the proband: arr[Hg38]22q11.21-q11.22(21960001-22220000)X1. This deletion was confirmed using FISH and involves only the *TOP3B* gene. Therefore, our study narrows the critical interval to *TOP3B*, extensively characterizes the phenotype in this patient with ASD, and demonstrates *TOP3B* is a strong candidate gene for ASD.

Mendelian Phenotypes Posters - Thursday

PB1760. Atypical molecular findings in patients with capillary malformations.

Authors:

C. Montano¹, E. Wohler², S. Yeom³, B. Cohen², C. Weiss², T. Garg², A. Hammill⁴, A. Comi³, N. Sobreira²; ¹NHGRI/NIH, Bethesda, MD, ²Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ³Kennedy Krieger Res. Inst., Baltimore, MD, ⁴Cincinnati Children's, Cincinnati, OH

Abstract Body:

Capillary malformations (CMs), commonly known as port-wine stains, are partially blanchable erythematous patches. Sturge-Weber syndrome (SWS), the most well-known CM, is characterized by facial port-wine stains involving the upper quadrant of the face with ipsilateral ocular and leptomeningeal anomalies. CMs occurring as part of SWS or in isolation are sporadic events frequently associated with somatic gain-of-function variants in *GNAQ*, leading to constitutive activation of the RAS/MAPK pathway. CMs also can occur in combination with other vascular anomalies and limb overgrowth, such as in Klippel-Trenaunay syndrome (KTS) and in Parkes Weber Syndrome (associated with arteriovenous malformations and loss of function variants in *RASA1*). Hemangiomas, vascular tumors that mimic CMs, can occur in PHACES syndrome (posterior fossa or other CNS malformations, facial hemangioma, arterial anomalies, cardiac defects, eye anomalies, and sternal defects). The molecular basis for KTS and PHACES syndrome is not known. Here, we describe the phenotypic features and the germline and somatic exome sequencing findings of four patients with CMs: two with clinical diagnosis of SWS, one with a clinical diagnosis of KTS and one with a clinical diagnosis of PWS. Of the two patients with clinical diagnosis of SWS, one had a 580kb germline deletion on chromosome 2 that included *COL3A1*, *COL5A2* and *SLC40A1*; the other had a paternally inherited pathogenic variant in *KIT*. The patient with a clinical diagnosis of KTS had a somatic pathogenic variant in *PIK3CA* and was diagnosed with megalencephaly-capillary malformation (MCAP). The patient with a clinical diagnosis of PWS had a somatic pathogenic variant in *KRAS*. Understanding the genetic drivers of vascular anomalies is critical for classification, management, and the development of targeted therapeutics. Our molecular findings have implications for prognosis, drug trial eligibility, and clinical care. Based on our experience, germline exome sequencing, followed by somatic exome sequencing if germline testing is negative, is indicated for molecular evaluation of these patients to ensure the identification of germline and somatic single nucleotide variants, indels and copy number variations.

Mendelian Phenotypes Posters - Thursday

PB1761. Bi-allelic ACBD6 variants lead to a neurodevelopmental syndrome with progressive complex movement disorders

Authors:

R. Maroofian; The UCL Queen Square Inst. of Neurology, london, United Kingdom

Abstract Body:

The acyl-CoA-binding domain-containing protein 6 (ACBD6) is ubiquitously expressed, plays a role in the acylation of lipids and proteins, and regulates the N-myristoylation of proteins via N-myristoyltransferase enzymes (NMTs). However, its precise function in cells is still unclear, as is the consequence of ACBD6 defects on human pathophysiology. Utilizing exome sequencing and extensive international data sharing efforts, we describe 35 affected individuals from 22 unrelated families with bi-allelic pathogenic variants in ACBD6. The affected individuals, with ages ranging from 1 to 50 years old, present with moderate-to-severe global developmental delay/intellectual disability combined with complex and progressive movement disorders (mainly dystonia phenotype), epilepsy, behavioral abnormalities, facial dysmorphism, and midline brain malformations. Unlike ACBD5, ACBD6 did not show a peroxisomal localisation and ACBD6-deficiency was not associated with altered peroxisomal parameters in patient fibroblasts. No significant difference in N-myristoylation of the 57 detected co-translationally N-myristoylated proteins between healthy and patient-derived fibroblasts was observed. Functional studies in a zebrafish knockout generated by CRISPR/Cas9 recapitulated many clinical phenotypes reported in affected individuals. The present study provides evidence that defective ACBD6 causes a distinct neurodevelopmental syndrome accompanied by complex and progressive cognitive and movement disorders.

Mendelian Phenotypes Posters - Wednesday

PB1762*. Biallelic *DMD* variants in a mildly-affected female without a Duchenne or Becker phenotype

Authors:

X-R. Yang¹, C. Hahn², R. Lamont¹, S. Ashtiani¹, M. Innes¹; ¹Dept. of Med. Genetics, Univ. of Calgary, Calgary, AB, Canada, ²Dept. of Clinical NeuroSci.s, Univ. of Calgary, Calgary, AB, Canada

Abstract Body:

Very few females with biallelic *DMD* variants have been reported in the literature to date. While hemizygous males tend to manifest with Duchenne or Becker muscular dystrophy (DMD or BMD), female carriers are most often asymptomatic, or exhibit mild symptoms secondary to skewed X-inactivation. Of the few reported cases of biallelic females, their clinical presentations seem consistent with those seen in males with DMD or BMD (Quan et al. 1997, Fujii et al. 2009, Soltanzadeh et al. 2010, Takeshita et al. 2017). However, here we report a biallelic female with unexpectedly mild, late-onset symptoms.

We report a 74 y.o. female who had two sons with a clinical diagnosis of DMD. Both passed away in their teenage years prior to the introduction of molecular testing. Once molecular testing became available in the early 2000s, our proband underwent MLPA testing for deletions and duplications in *DMD*, confirming carrier status for an in-frame duplication of exons 10-41 of the *DMD* gene as the likely explanation for her two sons with DMD. She had no clinical symptoms at this time. Her healthy daughter subsequently had carrier testing and was found not to have inherited the duplication. However, that daughter went on to have an affected son with DMD. Further testing revealed a c.5475del, p.(Glu1826Asnfs*22) pathogenic frameshift variant in *DMD* - present in the affected grandson, his mother, and our proband.

Our proband went on to develop slowly progressive proximal > distal weakness in her 60s. Her CK levels ranged from 200-1400 U/L. A muscle biopsy revealed myopathic features and loss of dystrophin staining in scattered fibers (approx. 1%). Recent updated genetic testing confirmed the presence of both *DMD* variants in our proband, with variant allele frequencies providing strong evidence for the variants being present in trans. Chromosomal microarray showed no other evidence of X chromosome copy number variants. Currently, in her mid-70s, her symptoms remain milder than would be expected for even BMD.

In this female with a pathogenic *DMD* frameshift variant in trans with a multi-exon duplication, the question remains as to why she did not manifest symptoms until her early 60s, and even now why she is not more severely affected. Although her exact duplication has never been reported, multi-exon deletions and duplications are the most common mutational mechanism, and overlapping and nested duplications have been reported in affected individuals (Kesari et al. 2008). Long-read sequencing may perhaps provide insight, as it is possible her duplication may be inserted elsewhere in the genome, leaving an intact copy of *DMD*. Alternate theories to account for her mild phenotype will also be discussed.

Mendelian Phenotypes Posters - Thursday

PB1763. Biallelic founder mutation in *PDE2A* causes paroxysmal dyskinesia with Intellectual disability in Pakistani families

Authors:

A. Fatima¹, H. Yousaf², S. Baig³, I. zafar⁴, M. Toft⁵; ¹Aga Khan Univ., Karachi, Karachi, Pakistan, ²Natl. Inst. for Biotechnology and Genetic Engineering (NIBGE), Faisalabad, Pakistan, Faisalabad, Pakistan, ³Dept. of Biological and BioMed. Abstract Body:

Intellectual developmental disorder with paroxysmal dyskinesia or seizures (IDDPADS, OMIM# 619150) is an ultra-rare childhood-onset movement disorder manifesting paroxysmal dyskinesia slowly progressive global developmental delay, impaired cognitive development and seizures. We investigated three unrelated Pakistani families with six affected individuals born to cousin marriages. Belonging to diverse age groups (13 years - 60 years), patients presented with severe developmental delay, cognitive abnormalities, speech impairment and seizures with onset in early years of age. Whole exome sequencing (WES) was used to detect potentially pathogenic variants and identify shared regions of homozygosity. We identified a rare homozygous missense variant c.1490T>C (p. Phe497Ser) in Phosphodiesterase2A (*PDE2A*) gene NM_002599.5. c.1490T>C variant segregates with the phenotype in all three families. To assess the possibility of a founder mutation, we performed homozygosity mapping which revealed a shared 5.5 Mb homozygous region at Chr11: q13.4-q13.5 among all three families. *PDE2A* is involved in hydrolysis of second messengers cAMP and cGMP. It is activated by binding of cGMP to GAF-B domain of the protein. The function of *PDE2A* is very critical for temporal regulation of these second messengers consequently modulating critical cellular processes like proliferation, neuronal function, apoptosis and differentiation¹. So far, only five variants and five patients are reported with disrupted *PDE2A*¹⁻³. Our findings add important details to the clinical and genetic spectrum of *PDE2A*, and highlight c.1490T>C (p. Phe497Ser) as a founder mutation in Pakistani families.

PB1764*. Bi-allelic LETM1 variants perturb mitochondrial ion homeostasis leading to a clinical spectrum with predominant nervous system involvement

Authors:

R. Kaiyrzhanov, LETM1 study group; South Kazakhstan Med. Academy, Shymkent, Kazakhstan

Abstract Body:

Background/Objectives: The Leucine zipper-EF-hand containing transmembrane protein 1 (*LETMI*) gene encodes an inner mitochondrial membrane protein with an osmoregulatory function controlling mitochondrial volume and ion homeostasis [1]. *LETMI* is deleted in Wolf-Hirschhorn syndrome, which results from de novo monoallelic deletion of chromosome 4p16.3 [1]. Here we describe the first association of bi-allelic *LETMI* variants with human disease. Methods: Exome sequencing and international gene-matching efforts were used to identify affected families with bi-allelic pathogenic variants in *LETMI*. Biochemical and morphological studies on mitochondrial K⁺ activities, proteins, and shape in patient-derived fibroblasts, muscles, and in *S. cerevisiae* as an important model organism for mitochondrial osmotic regulation were performed. Results: Eighteen affected individuals from eleven unrelated families harboring ultra-rare bi-allelic *LETMI* variants and clinical presentations highly suggestive of mitochondrial disease were identified. These manifested as a spectrum of predominantly infantile-onset (14/18, 78%) and variably progressive neurological, metabolic, and dysmorphic symptoms, and multiple organ dysfunction associated with neurodegeneration. The common features included respiratory chain complex deficiencies (100%), global developmental delay (94%), optic atrophy (83%), sensorineural hearing loss (78%), and cerebellar ataxia (78%) followed by epilepsy (67%), spasticity (53%), and myopathy (50%). Our experiments showed defective mitochondrial K⁺ efflux, swollen mitochondrial matrix structures, and loss of important mitochondrial oxidative phosphorylation protein components. Conclusion: Our findings highlight the implication of perturbed mitochondrial osmoregulation caused by *LETMI* variants in neurological and mitochondrial pathologies.

PB1765. Biallelic Loss of Function Mutations in *PYGM* Cause Hereditary Macular Dystrophy

Authors:

R. Hussein, A. Tayyib, K. Ahmed, E. Tavares, E. Heon, A. Vincent; The Hosp. for Sick Children, Toronto, ON, Canada

Abstract Body:

BACKGROUND: Hereditary Macular Dystrophies (HMDs) are a genetically and phenotypically heterogeneous group of disorders that lead to irreversible vision loss. Biallelic mutations in the *PYGM* gene, encoding glycogen phosphorylase, cause McArdle disease, with a few cases documented to have HMD as an association. **PURPOSE** To identify the disease-causing variants in an autosomal recessive family with HMD. **METHODS:** The proband tested negative for ~280 known retinal dystrophy genes. Hence, additional family members were recruited (n = 7; two affected) to a research study. Both affected individuals underwent eye exams and paired-end genome sequencing. Candidate variants likely to cause disease were filtered based on customized pipelines. Variants were prioritized if they were shared between the affected, were rare (population frequency < 0.5%), had at least two variants per gene, and had high pathogenicity scores in two predictive algorithms. Variants of interest were segregated in all family members using Sanger sequencing. Immunohistochemistry (IHC) of human retinal sections was conducted using an anti-*PYGM* antibody. **RESULTS:** Both affected individuals showed progressive distance vision loss and patchy macular and peripheral retinal atrophy. Genome filtering revealed a known pathogenic loss of function single nucleotide variant in *PYGM* (NM_005609 c.148C>T; p.Arg50*) in a homozygous state in both individuals. Segregation analysis revealed the variant was also present in a sibling who had not undergone eye exam. Although this variant in *PYGM* is known to cause McArdle disease, the affected individuals in the study were never diagnosed with any systemic features and hence, re-phenotyping was performed. Affected individuals had symptoms and signs of McArdle disease on re-phenotyping, including early muscle pain, exercise intolerance, rhabdomyolysis, and elevated serum creatine kinase. IHC results showed *PYGM* presence in retinal nuclear layers, outer plexiform layer, ganglion cell layer, and nerve fiber layer. **CONCLUSIONS:** This study has identified the cause underlying HMD in the pedigree to be consequent upon biallelic *PYGM* variants and supports the inclusion of *PYGM* in clinical HMD panels. IHC demonstrated *PYGM* presence in the cytoplasm of multiple retinal layers. Together, these findings suggest a role for *PYGM* in retinal glucose metabolism and this mechanism should be further explored. Despite the relatively common prevalence of McArdle disease, the association of HMD is sparse. As such, evaluating McArdle patients for retinopathy may be useful to further delineate this connection.

Mendelian Phenotypes Posters - Wednesday

PB1766. Bi-allelic loss of function variant in the *NRCAM* gene is associated with hereditary polyneuropathy phenotype

Authors:

Z. Elahi^{1,2}, M. Soveyzi¹, M. Goleyjani Moghadam¹, S. Nafissi³, Y. Nilipour⁴, A. Kariminejad², H. Najmabadi^{1,2}, Z. Fattahi^{1,2}; ¹Genetics Res. Ctr., Univ. of Social Welfare and Rehabilitation Sci.s, Tehran, Iran, Islamic Republic of, ²Kariminejad-Najmabadi Pathology & Genetics Ctr., Tehran, Iran, Islamic Republic of, ³Dept. of Neurology, Iranian Ctr. of Neurological Res., Tehran Univ. of Med. Sci., Tehran, Iran, Islamic Republic of, ⁴Pediatric Pathology Res. Ctr., Res. Inst. for Children's Hlth., Mofid Children Hosp., Sch. of Med., Shahid Beheshti Univ. of Med. Sci., Tehran, Iran, Islamic Republic of

Abstract Body:

Recently, the role of Neuronal Cell Adhesion Molecule (NRCAM) in a neurodevelopmental disorder (NDD) has been defined. The phenotype is mainly recognized by varying severity of global developmental delay/intellectual disability, hypotonia, spasticity, and peripheral neuropathy. The affected individuals carry homozygous pathogenic variants located in different domains of the NRCAM protein, mainly in immunoglobulin-like (Ig-like) and fibronectin type III (FN-III) domains. The varying severity of the symptoms ranges from motor neuropathy with secondary myopathic involvement without developmental delay due to homozygous missense variant in Ig-like 1 domain into the most severe forms represented by severe global developmental delay (GDD) along with the neurological and neuromuscular features due to homozygous loss of function (LOF) variants.

Here, as the second report, we present a 19-year-old male, who manifests polyneuropathy, progressive muscle weakness in proximal limbs, and lordosis with no other NDD features. Whole-exome sequencing led to prioritizing a homozygous LOF variant defined as c.73C>T (p.Gln25X) in the *NRCAM* gene (NM_001037132.4). The variant was inherited from the consanguine parents and was located in an 8.82 Mbp ROH interval which is among the most considerable ROH intervals detected in this patient.

We expand the clinical and molecular spectrum of the *NRCAM*-related disorder as a requisite for a more accurate genotype-phenotype correlation, ultimately delineating the *NRCAM*-related conditions. Although in the first *NRCAM* study, patients with LOF variants showed more severe clinical features, the obtained clinical data, together with the molecular findings in our patient, shows that the type of the pathogenic variant in the *NRCAM* gene does not necessarily determine the severity of the phenotype. Accordingly, there could be modifier effects like other genes that compensate for the absence of NRCAM protein, leading to a single but heterogeneous neurodevelopmental disorder. However, the disorder might be categorized as different separate syndromes caused by the *NRCAM* deficiency in future, similar to the other members of the L1 subgroup of immunoglobulin (Ig)-CAMs proteins such as LICAM- and NFASC-related diseases.

Abstract Body:

Evolutionary expansion and gyrification of the cerebral cortex are both linked to an abundance of basal radial glial cells (bRGCs) because of their highly proliferative potential leading to a pronounced increase in the number of neurons. However, genes involved in bRGC development are not fully understood. We herein report two patients with severe neurodevelopmental disability exhibiting congenital microcephaly with simplified gyral pattern, who carried biallelic loss-of-function variants in *PNPLA8*. *PNPLA8*, encoding mitochondrial phospholipase, is essential for maintaining mitochondrial shape and function through tailoring mitochondrial membrane lipid metabolism and composition, without known link to developing human cortex. To gain insight into brain development of *PNPLA8*-deficient patients, we generated cerebral organoids using *PNPLA8* gene-edited human induced pluripotent stem cells (hiPSCs). The number of bRGCs and upper-layer neurons were significantly reduced in *PNPLA8* knockout (KO) cerebral organoids compared to wild type cerebral organoids. These data suggest that loss of *PNPLA8* function results in microcephaly and simplified gyrus through the reduced number of bRGCs. To further investigate how the bRGCs are reduced, we *in vitro* generated neural stem cells (NSCs) induced from *PNPLA8* gene-edited hiPSCs. Mitochondria were hyperfused and enlarged with obscure cristae shape in *PNPLA8* KO hiPSC-derived NSCs. Given many links between mitochondria and cell fate decision, loss of *PNPLA8* function could affect mitochondria in NSCs, thereby dysregulate bRGC generation. Overall, our data reframe our understanding of the pathophysiology of *PNPLA8*-related disorder, and more broadly, underscore the importance of *PNPLA8*-dependent mitochondrial quality control for NSC fate decisions in gyrencephalic species.

Abstract Body:

PPFIBP1 encodes for the liprin-β1 protein which has been shown to play a role in neuronal outgrowth and synapse formation in *Drosophila melanogaster*. By exome and genome sequencing, we detected nine ultra-rare homozygous loss-of-function variants in 16 individuals from 12 unrelated families. The individuals presented with moderate to profound developmental delay, often refractory early-onset epilepsy and progressive microcephaly. Further common clinical findings included muscular hyper- and

hypotonia, spasticity, failure to thrive and short stature, feeding difficulties, impaired vision, and congenital heart defects. Neuroimaging revealed abnormalities of brain morphology with leukoencephalopathy, ventriculomegaly, cortical abnormalities, and intracranial periventricular calcifications as major features. In a fetus with intracranial calcifications, we identified a rare homozygous missense variant that by structural analysis was predicted to disturb the topology of the SAM-domain region that is essential for protein-protein interaction. For further insight in the effects of *PPFIBP1* loss-of-function, we performed automated behavioural phenotyping of a *Caenorhabditis elegans* *PPFIBP1/hlb-1* knockout model which revealed defects in spontaneous and light-induced behaviour and confirmed resistance to the acetylcholinesterase inhibitor aldicarb suggesting a defect in the neuronal presynaptic zone. In conclusion, we establish bi-allelic loss-of-function variants in *PPFIBP1* as a cause of an autosomal recessive severe neurodevelopmental disorder with early-onset epilepsy, microcephaly and periventricular calcifications.

Mendelian Phenotypes Posters - Thursday

PB1769. Biallelic nonsynonymous variants in *LTV1* are associated with LIPHAK syndrome, a novel poikiloderma-like disorder

Authors:

NHS FT, Birmingham, United Kingdom, ¹²Coll. of Med. and Dental Sci., Univ. of Birmingham, Birmingham, United Kingdom

Abstract Body:

As part of the 100,000 Genomes Project, we investigated the genetic origin of a previously undescribed recessive dermatological condition that we named LIPHAK (*LTV1*-associated Inflammatory Poikiloderma with Hair abnormalities and Acral Keratoses) in four affected individuals from two UK families of Pakistani and Indian origins, respectively. Patients' skin conditions did not entirely fit the term 'poikiloderma', as they displayed limited telangiectasia and atrophy, as well as a pattern of discrete hyper- and hypopigmented macules. By combining *in silico* high-resolution homozygosity mapping with filtered WGS data, we identified a single variant that had characteristics compatible of those of a Mendelian mutation: the NM 032860.5:c.503A>G, p.(Asn168Ser) change in *LTV1*, a gene encoding a protein involved in the biogenesis of the 40S subunit of the ribosome. This DNA change was present homozygously in all four patients and heterozygously in their parents. Despite potentially leading to a simple missense, *in silico* analysis predicted that the c.503A>G transition might interfere with the canonical splicing pattern of *LTV1*, and in particular it could potentially create a new donor site for exon 5. We tested this hypothesis by producing a recombinant exon-intron-exon construct bearing this variant, as well as its wild-type counterpart. Following transfection of HEK293T cells, *LTV1* minigenes with the mutation indeed resulted in an aberrant and shorter transcript, carrying the deletion of 37 bp at the 3' side of exon 5, leading in turn to a frameshift and the creation of the premature termination codon. RNA analysis and immunofluorescence microscopy of a patient's skin biopsy showed the same splicing pattern, which resulted in an overall reduced expression of *LTV1* protein. Although the precise role of *LTV1* mutations in LIPHAK is still unknown, our data suggest that this novel dermatological condition could be classified as a ribosomopathy.

Mendelian Phenotypes Posters - Wednesday

PB1770. Biallelic pathogenic variants in the endosomal transport regulator *SNAPIN* cause a rare prenatal neuroanatomical syndrome

Abstract Body:

Fetal brain anomalies cast a considerable healthcare burden with ~1/1,000 affected newborns every year in the US. To identify underlying etiology, prenatal ultrasound and/or magnetic resonance imaging combined with trio whole exome sequencing (WES) has emerged as a comprehensive diagnostic paradigm with a reported diagnostic rate up to ~35%. As part of an ongoing fetus-parent trio WES research study, we identified a fetus presenting with brain anomalies that harbors biallelic nonsense variants in *SNAPIN*, encoding SNARE-associated protein. *SNAPIN* is a ubiquitously expressed component of the autophagy-lysosomal pathway that catalyzes retrograde axonal transport, late endocytic transport, synaptic transmission, and synaptic vesicle fusion and release. Previously reported homozygous *Snapin* knockout mice are embryonic (E14.5) and perinatal lethal and show complex brain deficits. Using GeneMatcher, we identified 5 additional cases from three unrelated families with biallelic rare variants in *SNAPIN*. Prenatal imaging revealed ventriculomegaly (6/6), cerebellar hypoplasia (5/6), corpus callosum agenesis (3/6), abnormal head size (4/6), and lissencephaly (3/6). We also noticed additional anatomical features with variable incidence; talipes equinovarus (5/6) and abnormal craniofacial morphology (3/6) were the most prevalent. None of the cases survive beyond the perinatal period either due to intrauterine demise (1 case), elective termination (3 cases), or neonatal death (2 cases). To investigate further the role of *SNAPIN* in development of anterior structures, we targeted the single ortholog in zebrafish. We generated F0 mutants using CRISPR/Cas9 and performed transient knockdown using morpholinos. Both *snapin* loss-of-function models recapitulated human-relevant disease phenotypes including cerebellar hypoplasia, reduced intertectal neuron count, diminished optic tectum size, and aberrant facial patterning in comparison to wild type. Our data suggest that biallelic variants in *SNAPIN* are a likely cause of a hitherto unreported severe neuroanatomical syndrome and add to the growing list of lysosome-autophagy effectors that are critical for human brain development.

Mendelian Phenotypes Posters - Thursday

PB1771*. Biallelic *RAD51C* loss-of-function variants drive perizygotic SNV/indel hypermutator phenotype in a subject with Fanconi anemia complementation group O.

Authors:

R. Zemet Lazar¹, H. Du¹, T. Gambin², J. Lupski¹, P. Liu^{1,3}, P. Stankiewicz¹; ¹Baylor Coll. of Med., Houston, TX, ²) Inst. of Computer Sci., Warsaw Univ. of Technology, Warsaw, Poland, ³Baylor Genetics, Houston, TX

Abstract Body:

The mutation rate of single nucleotide variants (SNVs) in humans has been estimated at 1.0-1.8x10⁻⁸ variants per base per generation, giving rise to 60-70 *de novo* variants per genome, including approximately two affecting the coding sequence. Locus-specific mutation rates for CNVs are approximately 100 to 10,000 times greater, i.e., ~10⁻⁶ to 10⁻⁴ per generation, resulting in 0-1 *de novo* CNV per genome. Interestingly, a rare phenomenon of hypermutation with unusually large numbers of *de novo* mutations (DNMs) has been described for multiple *de novo* CNVs (PMID 28235197) and SNVs (PMID 35545669). We have reported a family with a prenatal diagnosis of multiple congenital anomalies in whom exome sequencing (ES) study revealed compound heterozygous *RAD51C* variants, and the fetus was diagnosed with Fanconi anemia (FA), complementation group O (FANCO). FA proteins have been classified into three groups based on their primary function in interstrand crosslinks (ICL) repair: components of the FA core complex, components of the FA ID2 complex, and the group of repair factors. Belonging to the third category, *RAD51C* is essential for homologous recombination-mediated repair of ICL and double-strand DNA breaks. Unexpectedly, in addition to *RAD51C* variants, the trio-ES analyses also detected eight apparent *de novo* mosaic variants with variant allele fraction (VAF) ranging between 13 and 35% (PMID 29278735). Subsequent trio whole-genome sequencing also revealed an unusual rise in the number of apparent *de novo* SNVs (n=467) and indels (n=34) with no evidence of an increased CNVs rate. Heterozygous variants with VAF ranging between 36% and 64% were considered nonmosaic, likely representing germline mutations (n=82). The VAFs of mosaic variants showed multinomial distribution with most of the mosaic variants' VAFs oscillating around 25%, indicating they most likely occurred during DNA replication in the zygote. Of note, the mutational pattern analyses of the mosaic variants revealed multiple known single base substitution signatures (SBS1, SBS5), including one associated with homologous recombination-based DNA damage repair error (SBS3). In conclusion, our data demonstrate that biallelic *RAD51C* variants and defects in the DNA damage repair process result in a hypermutator phenotype at least in the prenatal period, potentially with the accumulation of mutations in the post-zygotic period. This phenomenon might contribute to the hematological manifestations and the predisposition to tumors in patients with FA. We propose that other FA groups should be investigated for DNMs.

Mendelian Phenotypes Posters - Wednesday

PB1772. Biallelic variants in *CSPG4* cause a novel neurodevelopmental disorder with intellectual disability, global developmental delay, and facial anomalies.

Abstract Body:

Background: Chondroitin sulfate proteoglycan 4 (CSPG4) is an extracellular matrix (ECM) component involved in cell proliferation and differentiation, angiogenesis, and neuronal development. **Method:** Clinical and genetic data from affected individuals were collected through the recruitment of patients with neurological disorders and by analyzing rare variants of candidate genes across families from four global sites. We investigated the impact of novel *CSPG4* missense variants utilizing *in silico* tools and *in vivo* functional characterization in the zebrafish model. The impact on neurological and craniofacial development was analyzed in CRISPR/Cas9-mediated zebrafish models. **Results:** Here, we report four recessive *CSPG4* (NM_001897) missense variants [three homozygous: c.A1370G (p.Asp457Gly), c.2627G>A (p.Arg876His) and c.3247C>A (p.Gln1083Lys), and one compound heterozygote: c.A1370G and c.5156A>G (p.Asp457Gly and p.Gln1719Arg)] identified by next-generation sequencing of four unrelated families. All subjects share a novel neurodevelopmental syndrome characterized by severe intellectual disability, global developmental delay, delayed ability to walk, speech and language delay, distinctive facial features, along with varying degrees of neurological impairment, including hypotonia, cerebellar hypoplasia, and / or seizures. All *CSPG4* variants were predicted to be damaging using *in silico* tools, and three-dimensional molecular modeling suggested significant alterations in protein stability, compromising inter- and intra-molecular interactions. Functional studies in zebrafish using CRISPR gene-editing showed that *CSPG4* variants affected notochord development, motor neuron axonal growth, cerebellar structure along with disorganized head scaffold with anomalous skeletal and cartilage components. RNA sequencing of crispant and control fish revealed significant perturbation of ECM regulating pathways and genes previously described to cause mental retardation, dwarfism, and facial anomalies in humans. **Conclusions:** Our study links rare, damaging variants in the ECM gene *CSPG4* to a novel recessive Mendelian neurodevelopmental disorder in humans and supports the role of CSPG4 in early development.

Mendelian Phenotypes Posters - Thursday

PB1773. Biallelic variants in *FICD* leading to inactivation of BiP cause motor neuron disease.

Authors:

A. Rebelo¹, A. Ruiz¹, M. Dohrn¹, M. Wayand², A. Farooq¹, M. Danzi³, D. Beijer¹, B. Aaron¹, J. Vandrovцова⁴, H. Houlden⁴, L. Matalonga⁵, I. abreu¹, G. Rouleau⁶, E. Mehrdad⁷, L. Van der Vondel⁸, Z. Gan-Or⁹, J. Baetz⁸, R. Schule¹⁰, S. Zuchner¹; ¹Univ. of Miami, Miami, FL, ²Univ. of Tübingen, Tübingen, Germany, ³Univ. of Miami, Dakota Dunes, SD, ⁴UCL Queen Square Inst. of Neurology, London, United Kingdom, ⁵CNAG-CRG, Barcelona, Spain, ⁶Montreal Neurological Inst.-Hosp., Montreal, QC, Canada, ⁷McGill Univ., Montreal, QC, Canada, ⁸Univ. of Antwerp, Antwerp, Belgium, ⁹Montreal Neurological Inst., McGill Univ., Montreal, QC, Canada, ¹⁰Ctr. for Neurology and Hertie Inst. for Clinical Brain Res., Tübingen, Germany

Abstract Body:

The chaperone protein BiP, binding immunoglobulin protein, is the master regulator of the unfolded protein response in the endoplasmic reticulum. BiP activity is regulated by the post-translational modification AMPylation, exclusively provided by FICD (FIC domain protein adenylyltransferase) in humans. FICD is a bifunctional enzyme that inactivates BiP by AMPylation during low levels of unfolded proteins, while it deAMPylates BiP when the levels of unfolded proteins rise. Here we identify biallelic variants in *FICD* causing a neurodegenerative disease of upper and lower motor neurons. Affected individuals in four unrelated families harbor a recurring missense variant, Arg374His, critically positioned in the catalytic sequence motif of the enzyme and important for ATP binding. The mutated residue abolishes intramolecular interaction with the regulatory residue Glu234, which is essential to inhibit AMPylation and to promote de-AMPylation by FICD. Consequently, fibroblasts from patients with *FICD* variants have a defective deAMPylase activity, resulting in abnormally increased levels of AMPylated and thus inactivated BiP. Loss of BiP activity in patients likely results in a chronic impairment of the protein quality control system in the ER. These findings will guide the development of therapeutic strategies for motor neuron and related diseases linked to proteotoxic stress.

Mendelian Phenotypes Posters - Wednesday

PB1774. Bibliometric analysis of Alport Syndrome - the impact of next generation sequencing on diagnosis.

Authors:

E. Salia¹, C. L. Simpson¹, R. Wadie², S. Salia³; ¹Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN, ²Korle Bu Teaching Hosp., Accra, Ghana, ³Cape Coast Teaching Hosp., Cape Coast, Ghana

Abstract Body:

New Generation Sequencing (NGS) technology has revolutionized the field of genomics. Since the advent of NGS, there has been an improvement in the diagnosing of genetic conditions and the identification of novel mutations associated with some genetic conditions. Alport Syndrome is a rare, inherited disorder characterized by kidney disease, and ocular and hearing abnormalities. It has primarily been linked to mutations in genes belonging to the collagen family, notably: *COL4A3*, *COL4A4*, and *COL4A5* variants. However, some literature has also suggested that novel mutations are implicated. In this study, we analyze the global scientific research output relating to Alport Syndrome. Again, we look at the impact of NGS on the diagnosis of Alport Syndrome and the identification of novel mutations since its commencement at the start of the 21st century. We also look at the number of peer-reviewed articles on Alport Syndrome that emerged from Africa among other indices in this analysis. In addition, we will explore the number of persons diagnosed with Alport Syndrome who had overt abnormalities involving all the 3 organ systems. A standard bibliometric approach is underway. The team first defined the search criteria, keywords, and a definite time period and chose the relevant databases. Currently, the team is refining the research criteria, will export the result, and perform analysis of the results generated. Two independent reviewers are involved in the screening of selected articles based on robust inclusion and exclusion criteria, with a third reviewer acting as a tiebreaker. We will further create graphics to visualize the network of collaborators. In its conclusion, this study will provide a clearer picture of the research done in the field of Alport Syndrome, identify key contributors and collaborations, and highlight the influence of the NGS on the discovery of pathogenic variants. It will also identify gaps in the body of knowledge available and serve as a guide toward targeted future research in such rare conditions.

Mendelian Phenotypes Posters - Thursday

PB1775. Biallelic *ATOH1* Variant in Siblings With Pontocerebellar Hypoplasia, Developmental Delay, and Hearing Loss

Authors:

K. Writzl¹, T. Višnjari¹, A. Maver¹, O. Maloku², G. Bergant¹, H. Jaklič¹, D. Neubauer³, F. Fogolari², N. Pečarič Meglič⁴, B. Peterlin¹; ¹Clinical Inst. of Genomic Med. UMCL, Ljubljana, Slovenia, ²Dept. of Mathematics, Informatics and Physics, Univ. of Udine, Udine, Italy, ³Div. of Paediatrics (D.N.), Dept. of Child, Adolescent & Dev.al Neurology, Univ. Med. Ctr. Ljubljana,, Ljubljana, Slovenia, ⁴Clinical Inst. of Radiology, Univ. Med. Ctr. Ljubljana,, Ljubljana, Slovenia

Abstract Body:

Background and Objectives:To report on the novel association of biallelic variant in atonal basic helix-loop-helix transcription factor 1 (*ATOH1*) gene and pontocerebellar hypoplasia (PCH), severe global developmental delay, intellectual disability, and hearing loss in a family with 2 affected siblings.**Methods:**A detailed clinical assessment and exome sequencing of peripheral blood sample were performed. Segregation analysis with Sanger sequencing and structural modeling of the variant was performed to support the pathogenicity of the variant.**Results:** A homozygous missense variant (NM_005172.1:c.481C>G) in the *ATOH1* gene was identified in the proband and his affected sister. The segregation analysis subsequently confirmed its segregation with an apparently recessive PCH in this family. *ATOH1* encodes for the atonal basic helix-loop-helix (bHLH) transcription factor 1, a core transcription factor in the developing cerebellum, brainstem, and dorsal spinal cord, and in the ear. The identified variant results in the p.(Arg161Gly) amino acid substitution in the evolutionarily conserved DNA-binding bHLH domain of the ATOH1 protein. Biallelic missense variants in this domain were previously reported to result in disordered cerebellar development and hearing loss in animal models. In silico homology modeling revealed that p.Arg161Gly in ATOH1 protein probably disrupts a salt bridge with DNA backbone phosphate and increases the flexibility of the bHLH helix-both of which together affect the binding capability of the bHLH domain to the DNA.**Discussion:**Based on the sequencing results and evidence from structural modeling of the identified variant, as well as with previous reports of *ATOH1* gene disruption, we conclude that *ATOH1* may represent a novel candidate gene associated with the phenotype of PCH, global developmental delay, and hearing loss in humans.

Mendelian Phenotypes Posters - Wednesday

PB1776. Biotin-thiamine responsive basal ganglia disease: A retrospective review of the clinical, radiological and molecular findings of cases in Kuwait with novel variants

Authors:

M. Aburezq¹, A. Alahmad², R. Alsafi³, A. Al-Tawari⁴, D. Ramadan⁴, M. Shafik¹, O. Abdelaty⁵, N. Makhseed⁶, R. Elshafie², M. Ayed⁷, A. Hayat⁸, F. Dashti⁹, D. Marafi^{10,3}, B. Albash², L. Bastaki², H. Alsharhan^{1,10,2}; ¹Dept. of Pediatrics, Farwaniya Hosp., Ministry of Hlth., Farwaniya Governorate, Kuwait, ²Kuwait Med. Genetics Ctr., Ministry of Hlth., Sulaibikhat, Kuwait, ³Dept. of Pediatrics, Adan Hosp., Ministry of Hlth., Hadiya, Kuwait, ⁴Dept. of Pediatrics, Al-Sabah Hosp., Ministry of Hlth., Shuwaikh, Kuwait, ⁵Dept. of Tadiology, Farwaniya Hosp., Ministry of Hlth., Farwaniya Governorate, Kuwait, ⁶Dept. of Pediatrics, Jahra Hosp., Ministry of Hlth., Hadiya, Kuwait, ⁷Dept. of Neonatology, Farwaniya Hosp., Ministry of Hlth., Farwaniya Governorate, Kuwait, ⁸Dept. of Radiology, Adan Hosp., Ministry of Hlth., Hadiya, Kuwait, ⁹Dept. of Radiology, Ibn Sina Hosp., Ministry of Hlth., Shuwaikh, Kuwait, ¹⁰Dept. of Pediatrics, Hlth.Sci. Ctr., Faculty of Med., Jabriya, Kuwait

Abstract Body:

Background: Biotin-thiamine-responsive basal ganglia disease (BTRBGD) is a rare autosomal recessive neurometabolic disorder caused by biallelic pathogenic *SLC19A3* variants. It is characterized by subacute encephalopathy that is usually triggered by febrile illness and associated with confusion, convulsions, or other neurological manifestations.

Methods: A retrospective analysis conducted on the data registry in Kuwait Medical Genetics Center for all cases clinically and radiographically diagnosed with BTRBGD and genetically confirmed to have deleterious biallelic variants in *SLC19A3*.

Results: Eighteen individuals from 12 families were diagnosed with BTRBGD in Kuwait including 10 (55%) males and 8 (44%) females aged 2-36 years. All were Kuwaiti nationals except for two individuals. Average age of diagnosis ranged from 2 to 3 years with four cases having a significantly delayed diagnosis at 32, 20, 6 and 4 years of age. Most cases (89%) presented initially with dystonia, subacute encephalopathy, confusion, convulsions, dysarthria, or dysphagia that has resolved completely over 2 weeks in most cases (66%) but progressed in only few (22%) to severe cogwheel rigidity, dystonia and quadriparesis. Two individuals were diagnosed pre-symptomatically and were started on treatment. Neuroradiological findings of most cases (83%) revealed bilateral central necrosis of the head of the caudate with partial or complete involvement of the putamen. The molecular diagnosis was confirmed in all cases, which revealed a previously reported Saudi founder homozygous pathogenic *SLC19A3* variant, c.1264A>G p.(Thr422Ala) in 16 cases and two novel homozygous missense variants, c.952G>A, p.(Ala318Thr) in a Kuwaiti individual and c.175T>C, p.(Trp59Arg) in a Jordanian individual. All individuals are still alive at age 2-32 years on high doses of biotin and thiamine with no neurological sequelae, apart from the oldest four cases who have residual neurological deficits in form of persistent dystonic movements and quadriparesis.

Conclusion: We present 18 unreported individuals from Kuwait with BTRBGD and describe two novel *SLC19A3* variants, in addition to the previously reported Saudi founder variant. BTRBGD is a rare treatable condition that requires high level of suspicion to achieve early diagnosis and prompt management. Individuals presenting with unexplained encephalopathy and characteristic brain MRI findings of bilateral signal alteration of caudate nucleus and putamen should be managed immediately with a trial of high dose of biotin and thiamine supplements as disease progression and prognosis is greatly affected by the timing of treatment initiation.

Mendelian Phenotypes Posters - Thursday

PB1777. Brachyolmia with amylogenesis imperfecta: Identification of a Novel LTBP3 gene Mutation in several Druze Arab patients from the north of Israel

Authors:

Y. Hadid; The Bnai Zion Med. Ctr., Haifa, Israel

Abstract Body:

Background: Short stature is a common finding among the general population. A few cases of the combination of short stature and dental congenital anomalies have been reported. Recently, we examined several patients from related families sharing the same clinical phenotype which includes: short stature and congenital dental abnormalities. **Purpose:** We describe seven patients (5 males 2 females) 8-60 years old from four consanguineous Arab Druze related families from the north of Israel. All patients presented with: short stature, short trunk (brachyolmia), and teeth abnormalities (defect in enamel formation and mineralization, oligodontia, abnormal shape and color, retarded eruption and avulsion). **Methods:** the clinical characterization of patients: medical information retrieved from medical history interviewing patients and parents, from medical records and by patient's physical examination. In order to identify the causing gene and mutation, DNA samples were extracted from sixteen patients and healthy family members from the four families. The analysis was done by using CMA- chromosomal microarray analysis with the **Homozygosity mapping and candidate gene approach**. We used the SNP chromosomal microarrays (CMA) 750K CytoScan kit from Affymetrix. We look for the candidate genes within the homozygote mapped regions and then sequenced the selected gene by Sanger technology. **Results:** CMA analysis in 3 patients and 2 healthy members from the four families showed no CNV-copy number variations alterations. The analysis revealed only one homozygote region of 20 Mb in chromosome 11, shared between all affected patients. This region spans from 11p11.2- 11q13.3 and is shared in all affected patients. Revision of the physical map revealed a chromosomal region that contains 301 OMIM genes. This region harbors the LTBP3 gene (LATENT TRANSFORMING GROWTH FACTOR-BETA-BINDING PROTEIN-3) which is responsible for brachyolmia with amylogenesis imperfecta (OMIM 602090). Thus, it was the first candidate gene to be sequenced. We sequenced all 29 LTBP3 exons all were normal but a splice mutation, c.1346-1G>A chr11:65319629, in exon 8 was identified. All tested patients were homozygous for this alteration and as expected, the available parents were heterozygous. This is a novel mutation since it segregated very well in patients and healthy family members. **Conclusions:** Here we describe the full clinical picture of brachyolmia with amylogenesis imperfecta patients and the identification of their LTBP3 gene novel mutation.

Mendelian Phenotypes Posters - Thursday

PB1780. Characterization of associated non-classical phenotypes in patients with deletion in WAGR region identified by chromosomal microarray: new insights and literature review

Authors:

S. Oliveira, V. Souza, G. Cunha, B. Versiani, C. de Oliveira, M. da Silva Rosa, **C. Mendes-Júnior**, P. Moretti, J. Mazzeu, A. Pic-Taylor; Univ.e de Brasilia, Brasilia, Brazil

Abstract Body:

WAGR syndrome (Wilms' tumor, aniridia, genitourinary changes, and intellectual disability) is a contiguous gene deletion syndrome characterized by the joint deletion of PAX6 and WT1 genes, located in the short arm of chromosome 11. However, most deletions include other genes, leading to multiple associated phenotypes. Therefore, understanding how genes deleted together can contribute to other clinical phenotypes is still considered a challenge. In order to establish genotype-phenotype correlation in patients with interstitial deletions of the short arm of chromosome 11, we selected 17 patients with deletions identified by chromosomal microarray analysis: 4 new subjects and 13 subjects previously described in the literature with detailed clinical data. Through the analysis of deleted regions and the phenotypic changes, it was possible to suggest the contribution of specific genes to several nonclassical phenotypes, contributing to the accuracy of clinical characterization of the syndrome and emphasizing the broad phenotypic spectrum found in the patients. This study reports the first patient with a PAX6 partial deletion who does not present any eye anomaly thus opening a new set of questions about the functional activity of PAX6.

Mendelian Phenotypes Posters - Wednesday

PB1781. Characterization of *CFTR* Variants Across Ancestries

Authors:

J. Ideozu, M. Liu, B. Riley-Gillis, A. Singh, J. Waring, A. Vasanthakumar; AbbVie, North Chicago, IL

Abstract Body:

Introduction: Cystic fibrosis (CF) is an autosomal recessive disease caused by pathogenic variants in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene. Small molecule therapies targeting the basic *CFTR* defects have shown clinical benefits, but therapeutic responses are largely dependent on the patients' *CFTR* genotype. Although CF is most common among Caucasians, CF-causing variants tend to be ancestry-specific. Therefore, characterizing the broad spectrum of pathogenic and non-pathogenic *CFTR* variants across ancestries is critical for revolutionizing molecular diagnoses of CF. **Methods:** We interrogated 454,857 whole exome sequences available in UK Biobank (UKBB) to characterize the ancestral diversity of *CFTR* variants. We used the ancestry assignment performed by the pan-UKBB to investigate the distribution of *CFTR* variants in African, American, Central South Asian, East Asian, European, and Middle Eastern populations. We then performed an overlap analysis to decipher ancestry-specific *CFTR* variants. CF-causing variants were annotated using the CFTR2 database, and then their distribution across the six ancestries was recorded. **Results:** Overall, we detected more than 3000 variants in the *CFTR* gene. Many of these variants have never been reported in CF. The highest number of *CFTR* variants were detected in Europeans [n=3,192] while the American group had the least number of *CFTR* variants [n=1507]. We found several variants specific to each ancestry, with Europeans having most of the unique variants [n=2118], while the American group had the least number of unique *CFTR* variants [n=19]. F508del was the most prevalent CF-causing variant found in all ancestries, except in East Asia, where V520F was the most prevalent. **Conclusion:** Systematic characterization of *CFTR* variants across six ancestral populations in the UKBB identified several unreported *CFTR* variants, with most of the unique variants found in Europeans. The identification of several unique variants in other ancestries warrants the need for further studies to characterize their possible phenotype relevance.

Mendelian Phenotypes Posters - Thursday

PB1782. Characterization of transthyretin *TTR* missense variants for associations with hereditary transthyretin-mediated (hATTR) amyloidosis and hallmark symptoms in 470,000 UK Biobank whole exome sequences

Authors:

M. Plekan, R. Hoffing, L. Ward, A. Deaton, C. Willis, P. LoGerfo, L. Krohn, A. Holleman, P. Nioi; Alnylam Pharmaceuticals, Cambridge, MA

Abstract Body:

Over 100 distinct missense variants in the *TTR* gene are known to cause hereditary transthyretin-mediated (hATTR) amyloidosis, a progressively debilitating, life-threatening disease. We aimed to characterize missense *TTR* variants in a large cohort of 470,000 exomes and to test their association with hATTR amyloidosis and hallmark symptoms of hATTR amyloidosis. Missense variants in *TTR* were classified as pathogenic, benign, conflicting interpretation, uncertain significance, or novel based on ClinVar annotations, with “novel” indicating the variant had not been previously assessed for pathogenicity. For these variants, the prevalence of an hATTR amyloidosis diagnosis and common hATTR amyloidosis symptoms (polyneuropathy, carpal tunnel syndrome, heart failure and cardiomyopathy) were characterized. Of 84 missense *TTR* variants identified in the European ancestry population (N=363,973), carriers of eight different missense variants had a diagnosis of amyloidosis. Of these eight variants, six are rare (minor allele frequency [MAF] < 0.1%), including known pathogenic variants Glu89Lys (1/1 carriers with a diagnosis), Ser23Asn (1/1 carriers with a diagnosis), Thr60Ala (4/19 carriers with a diagnosis), and Val122Ile (9/358 carriers with a diagnosis), and two variants presenting with conflicting interpretation of pathogenicity, Arg104His (1/60 carriers with a diagnosis) and ENST00000610404.5:p.Glu119Lys (6/235 carriers with a diagnosis). Carriers of two more common (MAF > 0.1%) benign variants Gly6Ser (66/67,191 carriers with a diagnosis) and Thr119Met (1/3,207 carriers with a diagnosis) were also diagnosed with amyloidosis. However, we did not detect significant associations of these benign variants with hATTR amyloidosis or any hallmark symptoms. Despite low penetrance of an hATTR amyloidosis diagnosis among missense *TTR* variant carriers, 58/416 carriers of pathogenic *TTR* variants have been diagnosed with common symptoms of hATTR amyloidosis but no formal diagnosis of amyloidosis, suggesting an underdiagnosis of disease. There is no evidence to suggest pathogenicity in novel *TTR* variants after assessing diagnoses of these variants for hATTR amyloidosis.

Mendelian Phenotypes Posters - Wednesday

PB1783. Characterizing human disease-causing mutations: A zebrafish-based approach

Authors:

J. Burgess¹, R. Noche², X. Cui¹, R. Simonian¹, E. Pannia¹, J. Dowling¹; ¹The Hosp. for Sick Children, Toronto, ON, Canada, ²Yale Zebrafish Res. Core, Dept. of Comparative Med., Yale Sch. of Med., New Haven, CT

Abstract Body:

Next-generation sequencing has allowed for rapid advances in the identification of candidate disease-causing mutations. However, functional testing and validation of these mutations has lagged, particularly for rare mutations found only in single families or small populations. At the Hospital for Sick Children in Toronto (SickKids), we have established a Zebrafish Genetics and Disease Models Core Facility to allow for testing of candidate disease genes in zebrafish, and to facilitate precision medicine initiatives. Zebrafish have quickly emerged as a powerful model organism to validate gene function due to several key features. Zebrafish exhibit high genetic conservation, with 84% of human disease-associated genes having a clear zebrafish counterpart. As a vertebrate, zebrafish also have many organs and tissues that are similar to humans. Zebrafish offer several distinct advantages over mouse models, including large clutch sizes, ex-utero development, transparent bodies through early development which facilitates imaging, and the ability to perform large-scale drug screens in 96-well plates using zebrafish larvae. Our Zebrafish Core Facility provides services to efficiently generate mutations in zebrafish. We make use of CRISPR-Cas9 to generate small insertion/deletion mutations in a gene of interest. We can also perform targeted gene knock-ins to introduce specific mutations identified in patients. Once mutant zebrafish lines are established, we can perform phenotypic analysis to validate zebrafish disease models, and conduct drug screens to help identify novel therapeutic agents. To date, we have developed zebrafish models for a diverse set of human diseases including inflammatory bowel disease, pediatric cancer, cardiac arrhythmia, and childhood muscle disease. In addition, we can use *Tol2*-mediated transgenesis for overexpression studies. We have worked with over 20 labs and generated insertion-deletions in over 30 genes using CRISPR-Cas9, including at least 3 large deletions (several kb), as well as over 9 targeted mutation knock-ins based on candidate human disease genes. Here we present results of our high-throughput mutation generation efforts and summarize our pipeline approach.

Mendelian Phenotypes Posters - Thursday

PB1784. Chd8 mutation in mouse impacts cerebellar function across anatomical, genomic, electrophysiological and behavioral axes

Authors:

C. Canales, A. D'Ambra, S. Jung Jung, N. Seban, N. Chu, S. Lozano, K. Cichewicz, E. Smith, R. Ortiz, J. Zhu, M. Corea, D. Rahbarian, D. Fioravante, A. Nord; Univ. of California Davis, Davis, CA

Abstract Body:

The role of the cerebellum (CB) in proprioception and motor control is well-established, however recent studies implicate this structure in high order cognitive functions that are tightly related to Intellectual Disability and Autism Spectrum Disorder ASD. Nevertheless, its role of non-motor contributions such as cognitive processing and affective regulation, though often overlooked in ASD research, is becoming an intriguing focal point for CB research. De novo mutations in the chromatin-remodeling factor *CHD8* are strongly associated with ASD and more generally with neurodevelopmental disorders (NDDs). Using a germline *Chd8*^{5bp-del} haploinsufficient mouse model, we applied neuroanatomical, genomic, and electrophysiological assays to test for deficits in cerebellar development at postnatal day (PND) 12. Additionally, we evaluated putative Chd8 function in Deep Cerebellar Nuclei (DCN) signaling by assessing anxiety-like behavior, motor-coordination, associative learning and social behavior in CB-specific, viral-induced Cre mediated null *Chd8* adult mouse. We analyzed transcriptional landscape in the CB at single cell resolution at PND12 via snRNA-sequencing as well as neuroanatomical and electrophysiological properties via immunohistochemistry (IHC) and Purkinje neuron (PN) patch clamp. Ex vivo PN electrophysiology showed sexually dimorphic phenotypes indicating differences in inhibitory synaptic transmission. Adult Chd8 cre-mediated mutation resulted in aberrant sex-specific associative learning and social behavior, with no effects in anxiety-like behavior or motor coordination. Differentially expressed genes (DEGs) indicated perturbation to metabolic and synaptic pathways within specific cerebellar cell populations. Ongoing work aims to replicate findings and validate impacted cell types and functional signaling consequences of these effects. Altogether, our findings are foundation for future studies towards the ultimate goal of understanding how *Chd8* mutation impacts specific cerebellar cell-types and circuits, and how aberrant CB signaling is associated with ASD-relevant neuropathology and social and cognitive deficits.

Mendelian Phenotypes Posters - Wednesday

PB1785. *CHP2* is a genetic modifier of risk of chronic *Pseudomonas aeruginosa* airway infection in cystic fibrosis.

Authors:

K. Buckingham¹, W. Gordon¹, A. Faino², A. Stilp³, E. Blue^{4,5}, Y-H. Zhou^{6,7}, M. Rosenfeld^{8,9}, P. Qu², J. Collaco¹⁰, R. Pace¹¹, G. Cutting¹², M. Knowles¹¹, R. Gibson^{8,9}, M. Ctr., North Carolina State Univ., Raleigh, NC, ⁷Dept. of Biological Sci., North Carolina State Univ., Raleigh, NC, ⁸Ctr. for Clinical and Translational Res., Seattle Children's Res. Inst., Seattle, WA, ⁹Dept. of Pediatrics, Univ. of Washington, Seattle, WA, ¹⁰Eudowood Div. of Pediatric Respiratory Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ¹¹Marsico Lung Inst./UNC CF Res. Ctr., Sch. of Med., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ¹²McKusick-Nathans Dept. of Genetic Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ¹³Dept. of Genome Sci., Univ. of Washington, Seattle, WA

Abstract Body:

Chronic *Pseudomonas aeruginosa* (Pa) airway infection in persons with cystic fibrosis (PwCF) is common, and is associated with substantial morbidities (e.g., lung function decline) and mortality. Utilizing whole genome sequencing and phenotypic data from 2,358 participants in the Cystic Fibrosis Genome Project (CFGP) who had their first Pa culture by age 3, we conducted a time-to-event genome-wide association study (GWAS) using a definition of chronic Pa that is applicable to both annual and encounter-based Pa culture data. Specifically, we performed a survival analysis of chronic Pa with an endpoint defined as the second Pa positive year within a sliding window of three years (i.e., the "2 of 3" chronic Pa definition). A Cox regression, adjusting for study site, sex, and stratifying on birth cohort to account for treatment eras was performed. Martingale residuals from this regression were normalized and used as the GWAS outcome. Relatedness estimates and principal components (PCs) were calculated using PC-Relate and PC-AiR. A GWAS of the normalized Martingale residuals from the survival analyses was performed, adjusting for sex, study site, and PCs 1 and 2 as covariates, birth cohort as a grouping covariate, and the genetic relatedness matrix as a random effect. Additive effect score tests were conducted for high quality variants with minor allele frequency (MAF) >1% and missingness <2%. We identified a region of association on chromosome 16 containing a lead single nucleotide variant (SNV), rs194810 (MAF=0.43), that meets the threshold for genome-wide significance ($p=2.2E-8$). Genomic inflation was absent ($\lambda=1.01$). This SNV is located near *CHP2*, which encodes calcineurin like EF-hand protein 2. The protein product of *CHP2* is a calcium-binding protein that contributes to the regulation of cell pH by controlling the exchange of sodium and hydrogen ions across the plasma membrane. Another SNV nearby *CHP2*, rs194788, has been previously associated with lower lung function in PwCF and higher risk for *Mycobacterium avium* complex airway disease in persons without CF, and in our cohort, showed strong association ($p=5.5E-8$) with time to chronic Pa. Sensitivity analyses repeating the GWAS while adjusting for lung function revealed little change in the strength of association for either rs194810 ($p=8.6E-8$) or rs194788 ($p=7.4E-7$). Collectively, these results suggest that *CHP2* is a novel risk modifier of time to chronic Pa airway infection in PwCF and that it plays multiple roles in lung function and disease in persons with and without cystic fibrosis.

Mendelian Phenotypes Posters - Wednesday

PB1787. Clinical and molecular characteristics of idiopathic midaortic syndrome in pediatric patients - preliminary results.

Authors:

M. Pelc¹, E. Ciara¹, L. Obrycki¹, J. Antoniewicz¹, P. Halat-Wolska¹, D. Piekutowska-Abramczuk¹, B. Chalupczynska¹, M. Gawlik¹, D. Siestrzykowska¹, K. Chrzanowska¹, R. Ploski², M. Litwin¹; ¹The Children's Mem. Hlth.Inst., Warsaw, Poland, ²Warsaw Med. Univ., Warsaw, Poland

Abstract Body:

Introduction: Midaortic syndrome (MAS) is a rare malformation causing segmental or diffuse stenosis of the thoracic or abdominal aorta, which leads to severe, refractory hypertension. It can be associated with stenoses of other arteries, including visceral, renal, carotid and intracranial, and result in an extensive vascular disease. Congenital MAS may occur in the course of genetic syndromes such as neurofibromatosis type 1, Williams, Alagille, or in moyamoya angiopathy. However, most cases are considered idiopathic/non-syndromic (nMAS), presumably with monogenic background. The molecular basis and clinical symptoms of nMAS are not well characterized.

Methods: Whole-exome sequencing was performed in 10 unrelated Polish children diagnosed with nMAS. The primary analysis focused on over 200 genes potentially associated with the etiology of vasculopathy, including 39 candidates for MAS.

Results: Five of ten patients had isolated middle aortic stenosis (one case of atresia), while in the other five children extra-aortic locations involved renal and visceral arteries. One patient also presented with stenoses of carotid arteries and in two cases aortic aneurysm was found. In 3 of 10 patients a new single nucleotide variant of potential clinical significance was identified in a candidate gene for nMAS: *ELN* (n=2, a missense change and a frameshift/splice-site duplication) or *TBX1* (n=1, missense). Two of three patients with candidate gene defect had extra-aortic stenoses (*ELN* or *TBX1*-positive) and the third (with *ELN* missense variant) only isolated aorta narrowing. Candidate genes were proposed for clinical evaluation in another 3 probands: *ABCC6*, *ABLI*, *CNOT3*, *MYLK2*, *SKI*.

Conclusions: Idiopathic MAS is an anatomically variable vasculopathy, which may be problematic to classify as non-syndromic or diffuse/syndromic depending on the extent of multivessel involvement and associated clinical findings. It is still unclear if the location, extent and the course of vascular disease depends on the genetic background of nMAS. Our preliminary results suggest that postulated gene candidates: *ELN* and *TBX1* may be involved in the etiology of nMAS. Also, we broaden the molecular spectrum of MAS. Nevertheless, unraveling the molecular background and genotype-phenotype correlations in nMAS requires studies in larger groups of patients. It is important for genetic counseling, risk stratification and individualized therapy for each patient, as severe vascular occlusions associated with nMAS require multiple invasive interventions in all children, as well as long-term monitoring.

Grants: Supported by CMHI S162/2018, MEiN 7071/IB/SN/2020, 7088/II-KDM/SN/2020.

Hosp., Toyota, Japan, ⁷Human Genetics, Yokohama City Univ., Graduate Sch. of Med., Yokohama, Japan, ⁸Clinical Genetics Dept., Yokohama City Univ. Hosp., Yokohama, Japan, ⁹Dept. of Genetics, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract Body:

Purpose. The Retriever subunit *VPS35L* is the third responsible gene for Ritscher-Schinzel syndrome (RSS) after *WASHC5* and *CCDC22*. To date, only one pair of siblings have been reported and their condition was significantly more severe than typical RSS. This study aimed to understand the clinical spectrum and underlying molecular mechanism in *VPS35L*-associated RSS. **Methods.** We report three new patients with biallelic *VPS35L* variants. Biochemical and cellular analyses were performed to elucidate disease etiology. **Results.** In addition to typical features of RSS, we confirmed hypercholesterolemia, hypogammaglobulinemia and intestinal lymphangiectasia as novel complications of *VPS35L*-associated RSS. The latter two complications as well as proteinuria, which was observed in three of four patients with *VPS35L* variants, have not been reported in patients with *CCDC22* and *WASHC5* variants. One patient showed a severe phenotype and the other two were milder. Cells established from patients with the milder phenotypes showed relatively higher *VPS35L* protein expression compared to those from patient with more severe form. Cellular analysis found *VPS35L* ablation decreased the cell surface level of LRP1 and LDLR, resulting in reduced LDL cellular uptake. **Conclusion.** *VPS35L*-associated RSS is a distinct clinical entity with diverse phenotype and severity, with a possible molecular mechanism of hypercholesterolemia. These findings provide new insight into the essential and distinctive role of Retriever in human development.

PB1789. Clinical usefulness of a custom Next Generation Sequencing gene panel in providing molecular diagnosis to patients with a broad spectrum of Neurodevelopmental Disorders

Authors:

M. Giordano¹, C. Puricelli², D. Vurchio², S. Ronzani³, S. Favini³, A. Maruzzi², A. Spano³, F. SIRCHIA⁴, G. Mandrile⁵, A. Pelle⁶, A. Zonta⁷, I. Rabbone¹, M. Viri³, S. Genetics, Univ. of Turin, Torino, Italy, ⁶Unit of Med. Genetics, Univ. of Turin, Torino, Italy, ⁷Unit of Med. Genetics, Univ. of Turin, Novara, Italy

Abstract Body:

Neurodevelopmental disorders (NDDs) comprise a clinically and genetically heterogeneous group of conditions that affect 2-5% of children and represents a public health challenge due to complexity of the etiology. Only few patients with unexplained syndromic and nonsyndromic NDDs receive a diagnosis through first-tier genetic tests as array-CGH and the search for FMR1 CGG expansion. The aim of this study was to evaluate the clinical performance of a targeted next-generation sequencing (NGS) gene panel as a second-tier test in a group of undiagnosed patients with NDDs. A cohort of 450 individuals (268 males and 182 females) with a broad spectrum of NDDs (ID, ASD, motor and/or language disorders, and dysmorphic features potentially due to a syndromic condition) was analyzed with a NGS panel including 221 genes found to be altered in NDDs. Epilepsy and ASD, as well as other clinical features, were present both as a comorbidity in subjects with ID and as conditions in subjects with normal cognitive function. A manual prioritization procedure based on expert knowledge related to the disease phenotype and gene functions detected Pathogenic (N=84) and Likely Pathogenic variants (N=11) in 95 patients corresponding to 21% of the whole cohort. A de novo origin was present in 61 (64%) of the available trios. The diagnostic yield was significantly higher in females than in males (29.4% vs 15.3%; p=0.0019) in particular in ASD (36.8% vs 7.6%; p=0.0026) and Epilepsy (38.9% vs 14.4% p= 0.001). The most involved genes were SLC2A1, SCN1A, ANKRD11, ATP1A2, CACNA1A, FOXP1, and GNAS altered in more than two patients accounting for the 19.7% of the diagnosis. SLC2A1, causing GLUT-1 deficiency, was mutated in 5 patients with both comorbid and isolated epilepsy. Early detection of this alterations is clinically important, since subjects may benefit from ketogenic diet, which may mitigate symptoms and even prevent their progression. Our findings showed that this NGS panel represents a powerful and affordable clinical tool, significantly increasing the diagnostic yield in patients with different form of NDDs in a cost- and time-effective manner without the need of large investments in data storage and bioinformatic analysis.

Mendelian Phenotypes Posters - Wednesday

PB1790. Combined brain abnormalities in patients with beta-tubulin mutations.

Authors:

H. Bae¹, G-H. Kim², I. Choi³, H. Do⁴, S. Kim⁴, J. Kim⁴, B. Lee^{1,2}; ¹Dept. of Pediatrics, Asan Med. Ctr. Children's Hosp., Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of, ²Med. Genetics Ctr., Asan Med. Ctr., Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of, ³Dept. of Genetic Counseling, Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of, ⁴Asan Inst. for Life Sci., Asan Med. Ctr., Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of

Abstract Body:

Background/Objectives: Tubulins are the structural subunit proteins that form the microtubules. There are 7 beta-tubulin genes with products known, out of a total 26 human tubulin genes (*TUBB*, *TUBB2A*, *TUBB2B*, *TUBB3*, *TUBB4A*, *TUBB4B* and *TUBB6*). Mutations of these genes result in an extremely rare neuronal migration disorder known as tubulinopathy. **Methods:** The genetic and clinical characteristics of 10 unrelated Asian patients with causative beta-tubulin gene mutations were described. **Results:** The median age at diagnosis was 2.4 years (range, 1 month to 9 years). Delayed development was noted in all 10 patients. In addition, hypotonia, ataxia, seizure, and tremor were observed in 10, 5, 3, and 1 patients, respectively. Brain abnormalities were revealed as anomaly of corpus callosum (8pts), enlargement of ventricle (7 pts), and basal ganglia abnormalities (7 pts). In addition, there were complete corpus callosal agenesis (1 pts), thin corpus callosum (7 pts), thinning of white matter (7 pts), hypoplasia of pons (6 pts), cerebellar atrophy/hypoplasia (6 pts), periventricular abnormal intensities (3 pts), and perisylvian polymicrogyria (2 pts). Of note, combined brain abnormalities were observed; three (2 pts), and four or more abnormalities (7 pts). A total of 8 different variants were identified (two *TUBB2A*, one *TUBB2B*, three *TUBB3*, and two *TUBB4A* variants). All variants were missense variants and classified as pathogenic (4 variants) or likely-pathogenic (4 variants) according to the ACMG guidelines. One *TUBB2A* variant was previously unreported. All patients were confirmed as a de novo variant by trio Sanger sequencing. **Conclusions:** The tubulinopathy, even if it is extremely rare, should be suspected in patients with delayed development and abnormal combined brain abnormalities such thin corpus callosum, basal ganglia and ventriculomegaly.

PB1791. Comparing phenotypes across five developmental and epileptic encephalopathies (DEEs) through evaluation of 2490 patient data years.

Authors:

E. Mallory, M. Zanna, G. Beek, E. McNaughton, A. Lacoste, E. Brimble; Invitae, San Francisco, CA

Abstract Body:

Developmental and epileptic encephalopathies (DEEs) are severe early-onset epilepsy syndromes with poor prognosis. Characterizing onset and evolution of phenotypes can provide valuable insights, but remains challenging given their rarity and heterogeneity. To address this, we leverage a novel real-world data platform to evaluate relative severity and phenotypic variability in five DEEs. Invitae's Ciitizen is a patient-facing platform that transforms medical records into structured datasets that describe phenotypes and interventions. In this work, we compared diagnoses and volume of data across five DEEs. To quantify relative seizure burden, we developed a composite seizure severity score. Data were analyzed using nonparametric tests. We evaluated data from 338 individuals with DEEs caused by variants in *FOXG1* (n=85), *SCN2A* (n=46), *SCN8A* (n=72), *STXBPI* (n=70), and *SYNGAPI* (n=65). Mean age of participants was 8.5 ± 5.6 years; there were no significant differences in age or sex between DEE cohorts. Mean number of medical record pages reviewed per patient ranged from 791.9 ± 673.4 (*SYNGAPI*) to 2034.9 ± 2696.1 (*SCN8A*); individuals with an *SCN8A* variant had significantly more pages than those with variants in *FOXG1* ($P=0.0273$) and *STXBPI* ($P=0.0001$). This volume of data represents an average of 7.4 ± 5.0 years of observed data per patient, totaling 2490 years. We reviewed 9565 extracted clinical concepts to evaluate relative enrichment between cohorts in the first years of life. We observed significant enrichment for "microcephaly" and "strabismus" in *FOXG1*; "apnea" and "respiratory distress" in *SCN8A*; "infantile spasms" and "ataxia" in *STXBPI*; and "gastroesophageal reflux disease" in *SYNGAPI*. Through ages 0-4 years, the five DEEs shared 12.8% of clinical concepts, with *FOXG1* and *SCN8A* showing the highest number of unique concepts (12.0% and 12.8%, respectively). Mean lifetime seizure severity scores were lowest in *STXBPI* and highest in *SCN8A*. Scores for *SCN8A* were significantly greater than *FOXG1* ($p<0.0001$), *SCN2A* ($P=0.0167$), *STXBPI* ($p<0.0001$), and *SYNGAPI* ($p<0.001$). Seizure severity scores were also significantly different across cohorts grouped by age, primarily in years 0-12. *SCN8A* and *STXBPI* were both associated with early and severe onset, with scores at 0 years significantly greater than subsequent years. In contrast, *SYNGAPI* was associated with childhood onset, and scores in childhood were significantly greater than those in infancy. This study demonstrates the utility of real-world data in describing clinical phenotypes in rare disease populations, highlighting age-dependent phenotypic distinctions between five genetic DEEs.

Mendelian Phenotypes Posters - Wednesday

PB1792. Compound heterozygosity for variants in *DCAF1* in fraternal twins with neurodevelopmental disorder

Authors:

J. Pappas, R. Rabin; NYU Grossman Sch. of Med., New York, NY

Abstract Body:

We present fraternal twins with autism spectrum disorder (ASD), intellectual disability (ID) and compound heterozygosity for variants in the *DCAF1*. *DCAF1* codes for the CRL4 substrate receptor protein DDB1/CUL4-associated factor 1 involved in many cellular processes (Schabla NM et al, 2019). The DDB1/CUL4 E3 ubiquitin ligase complex is involved in methylation-dependent ubiquitination (Lee et al., 2012). Several variants in E3 ligase genes have been associated with neurological conditions (George AJ et al, 2018). De novo variant in *DCAF1* has been reported in possible association with ASD and ID in a case report (Clothier JL et al, 2022). Our patients are boy-girl twins born after 38-week gestation via cesarean section to 38 year old G2P1 without perinatal complications. Both children had delayed speech development and some signs of autism in their second year. Our evaluation at 6 revealed that the girl had ID functioning at 3-4 year old level. The boy was less delayed but had attention deficit and hyperactivity. Both children had frequent behavioral outbursts. Both parents had typical development. Chromosome microarray and DNA test for fragile-X were reported negative. Whole exome sequencing with samples from both parents and both twin children revealed three variants of uncertain clinical significance (VUS). Maternally inherited VUS c.680 G>C p.(R227P) was reported in *SH2B1* in both children. This variant is likely noncontributory to the developmental disorder of the twins because it is present in the unaffected mother and the twins do not present with severe early-onset obesity and insulin resistance as affected individuals with *SH2B1* related disorder (Li et al., 2016). Both twins were compound heterozygotes for VUSs in *DCAF1*. The paternally inherited variant p.(Ala270Thr) (GCA>ACA): c.808 G>A in exon 8 of the *DCAF1* (NM_014703.2) has been observed 0.0699% in the population cohort gnomAD and it is unlikely to change the protein structure/function by in silico analysis (PROVEAN). The maternally inherited variant p.(Leu209Pro) (CTG>CCG): c.626 T>C in exon 8 of the *DCAF1* (NM_014703.2) has not been observed in gnomAD and it is predicted to change the protein structure/function by in silico analysis (PROVEAN). The compound heterozygosity for *DCAF1* variants in our patients suggests possible association of *DCAF1* with neurodevelopmental disorders. Our patients share ASD, ID and frequent behavioral outbursts with the case with de novo variant in *DCAF1* (Clothier JL et al, 2022). Functional studies to establish pathogenicity of the *DCAF1* variants and additional case reports are needed to validate this possible association of *DCAF1* with neurodevelopmental disorders.

Mendelian Phenotypes Posters - Thursday

PB1793. *Compound heterozygous IFT81 variants causing brachydactyly with cone-shaped epiphyses and generalized metaphyseal dysplasia*

Authors:

E. Carter; Hosp. for Special Surgery, New York, NY

Abstract Body:

Skeletal dysplasias are a heterogeneous group of >450 disorders impacting the size and shape of the skeleton. The ciliopathies with major skeletal involvement comprise a single group within the current skeletal dysplasia nosology. IFT81 is core protein in the intraflagellar transport complex B (IFT-B), which is involved in anterograde transport in the cilium. Most patients reported with skeletal dysplasia due to recessive variants in *IFT81* have a short-rib thoracic dysplasia phenotype (OMIM 617895). We report 2 unrelated individuals with recessive *IFT81* gene variants and a milder skeletal dysplasia phenotype of brachydactyly with cone-shaped epiphyses, generalized metaphyseal dysplasia, and progressive growth delay. Patient 1 is a now 13-year-old girl with a history of progressive short stature and metaphyseal dysplasia who was referred to our service for work-up and genetic analysis when she was 6 years old. Radiographic review detected generalized metaphyseal dysplasia, and brachydactyly with cone-shaped epiphyses. Initially her height plotted at the 10th percentile, decreasing to -3 SD with time (mid-parental height 70"/177.8cm). Prior consultations had ruled out hypochondroplasia (*FGFR3* negative). Panel testing detected compound heterozygous pathogenic *IFT81* variants: p.Leu29Phe (paternally-inherited) and splice acceptor c.249-1G>A (maternally-inherited). Patient 2 is a now 27-year-old man referred at age 23 years for diagnosis by the spine surgeon treating him for symptomatic spinal stenosis. Radiographic review when he was 8 years old detected generalized metaphyseal dysplasia and brachydactyly with cone-shaped epiphyses. Early childhood height measurements plotted ~50th percentile decreasing with age. His final adult height is 4'4"/133cm (mid-parental height 5'4.5"/63.7cm). Prior consultations had ruled out cartilage hair hypoplasia (*RMRP* negative). Panel testing detected compound heterozygous pathogenic *IFT81* variants: p.Arg512* (maternally-inherited) and p.Leu29Phe. Paternal DNA was unavailable for confirmatory testing. We present clinical and X-ray characteristics of 2 patients with a milder skeletal dysplasia phenotype without polydactyly or any visceral or congenital anomalies due to recessive *IFT81* variants. Interestingly, both variants detected in patient 1 have been reported before in a child with asphyxiating thoracic dystrophy who died at 19 months of age due to progressive respiratory compromise. Functional studies of the cilia and IFT components in our patients would be useful for further characterization of the pathogenesis of their diagnosis.

Mendelian Phenotypes Posters - Wednesday

PB1794. Compound heterozygous variants in *UFMI* gene in a case of hypomyelinating leukodystrophy

Authors:

B. Kang¹, M. Wagner¹, E. Ames²; ¹Univ. of Michigan, Ann Arbor, MI, ²Univ MICHIGAN Hlth.System, Ann Arbor, MI

Abstract Body:

UFMI-related hypomyelinating leukodystrophy is a severe, early-onset, autosomal recessive neurodevelopmental disorder characterized by developmental delay, hypotonia, absent speech, and hypomyelination. Some of the patients also have additional features such as seizures, hearing loss, or blindness. To date, only 20 patients have been reported and 16 of them are of Roma descent and the other four of them are from two consanguineous Sudanese families. Here we present the case of a seven-month-old Caucasian male with a hypomyelination by MRI, developmental delay, hypotonia, delayed visual maturation, feeding difficulty, absence of speech, abnormal breathing, mild pulmonary valve stenosis, and an abnormal electroencephalogram without definitive epileptiform abnormalities. The patient's parents are healthy and denied consanguinity. There is no significant family history. A chromosomal microarray was normal and two heterozygous variants of unknown significance in the *UFMI* gene (c.215G>A (p.Gly72Glu) and c.277C>T (p.Arg93Trp), NM_001286704.1) were identified by leukoencephalopathy sequencing and deletion/duplication panel testing of 697 genes via Invitae. Subsequent parental testing confirmed these variants to be in *trans*. *UFMI* is located on chromosome 13 and encodes ubiquitin-fold modifier 1 (UFM1) protein. UFM1 protein is a ubiquitin-like protein that is conjugated to target proteins by E1-like activating enzyme UBE1DC1 encoded by the UBA5 gene and E2-like conjugating enzyme UFC1 in a manner analogous to ubiquitylation. Loss-of-function is a known disease mechanism. The paternally inherited variant (p.Gly72Glu) has not been reported in the general population (gnomAD database), in the published literature, or variant database associated with leukodystrophy (ClinVar and HGMD). The maternally inherited variant (p.Arg93Trp) has been reported in the general population (13 heterozygous alleles in the gnomAD database) and also reported in one affected individual of Roma descent with *UFMI*-related hypomyelinating leukodystrophy. Both parental variants result in alteration of highly conserved amino acids across species. *In silico* tools (SIFT, MutationTaster, PolyPhen2, MCAP, and PredictSNP2) predict a deleterious effect for both variants. To our knowledge, it is the very first *UFMI*-related hypomyelinating leukodystrophy case with compound heterozygous missense variants. Research on the molecular basis of the disease and the various signaling pathways involved will help improve the diagnosis and management of patients with hypomyelinating leukodystrophy, as well as develop more precise genetic counseling and screening tests.

Mendelian Phenotypes Posters - Thursday

PB1795. Confirmation of association of *TGFBI* p.Ser591Phe mutation with variant lattice corneal dystrophy

Authors:

D. Chung¹, C. Choo¹, K. Ledwitch², A. Kassels¹, J. Meiler², A. Aldave¹; ¹Stein Eye Inst., Univ. of California, Los Angeles, Los Angeles, CA, ²Ctr. for Structural Biology, Vanderbilt Univ., Nashville, TN

Abstract Body:

Purpose: To provide the initial confirmation of the c.1772C>T (p.Ser591Phe) mutation in the transforming growth factor-beta-induced (*TGFBI*) gene as being associated with variant lattice corneal dystrophy (LCD).

Methods: Ophthalmologic examination of the proband was performed with slit lamp biomicroscopy. Saliva was collected as a source of DNA for screening all 17 exons of *TGFBI*, after which three family members were selectively screened for identified presumed pathogenic variants. Rosetta-based structure prediction was used to calculate changes in *TGFBI* protein (TGFBIp) stability secondary to the c.1772C>T (p.Ser591Phe) missense mutation.

Results: Slit lamp examination of the 38-year-old proband revealed a clear cornea in the right eye and unilateral, discrete and branching lattice lines in the anterior and mid-stroma of the central cornea in the left eye. Screening of *TGFBI* in the proband revealed a heterozygous missense mutation in exon 13 (c.1772C>T (p.Ser591Phe)) that was also identified in her affected mother but not in her unaffected brother or maternal grandmother. Calculated energy changes in Rosetta (deltaG) for the TGFBIp variant p.Ser591Phe was 23.5, indicating a thermodynamic destabilization resulting from energetic frustration.

Conclusions: The p.Ser591Phe mutation in TGFBIp is associated with a unilateral variant of LCD. Rosetta-predicted stability changes indicate that this mutation is destabilizing, which is consistent with the observations of decreased protein stability in other LCD-associated mutations.

Mendelian Phenotypes Posters - Wednesday

PB1796. Congenital Anomalies Cluster: Linking clinicians and model system experts.

Authors:

S. Twigg¹, D. J. Henderson², S. Wells³, N. D. E. Greene⁴, P. Mill⁵, K. J. Liu⁶; ¹Oxford Univ., Oxford, United Kingdom, ²Newcastle Univ., Newcastle, United Kingdom, ³MRC Natl. Mouse Genetic Network, Mary Lyon Ctr. at MRC Harwell, Harwell, United Kingdom, ⁴Univ. Coll. London, London, United Kingdom, ⁵MRC Human Genetics Unit, The Univ. of Edinburgh, Edinburgh, United Kingdom, ⁶King's Coll. London, London, United Kingdom

Abstract Body:

As part of the new UKRI MRC National Mouse Genetics Network we have launched a research cluster, *Congenital Anomalies: patient-led functional genomics*, to accelerate basic research into the genetic causes and pathomechanisms underlying early life anomalies. Approximately 1 in 20 babies are born with severe anatomical malformations, such as cleft lip/palate, spina bifida and heart anomalies. Each year this equates to 8 million affected newborns, with lifelong impacts for patients and families. With advances in sequencing technology and the advent of large genome sequencing programmes, the identification of possible disease-causing variants in these patients is rapidly increasing. However, it remains a challenge to determine the causal variant, and to establish mechanistic links between genetic changes and anatomical anomalies. Many of the genes implicated in congenital anomalies play multiple roles in different tissues before and after birth. These genes are difficult to study in humans, even in 'disease-in-a-dish' models. Our goal is to make precisely-engineered mouse models of patient variants, which will help to replicate complex interactions disrupted during early life, across multiple organ systems with a focus on craniofacial, neural, cardiac and kidney anomalies. We also aim to improve live monitoring of that critical perinatal window in our disease models, which currently remains technically challenging thus obscuring roles for these candidates in those first few hours of life. Importantly, we will align our deep phenotyping of these mouse models with human pathology to better understand disease progression with age but also to serve as platforms for developing much needed therapeutic interventions. This is a community-led initiative looking to bring together human geneticists, rare disease specialists, pathologists and developmental biologists. Here we discuss how we will: 1) prioritise clinically relevant variants submitted to our pipeline; 2) apply deep phenotyping to investigate multi-system abnormalities; 3) analyse phenotypic pleiotropy; 4) integrate with the wider Mouse Genetic Network and other stakeholders; and 5) improve discussions on genetic cause and effect together with clinical geneticists, medical teams, patients and families. In summary, with our pipeline, we hope to provide a route for establishing and investigating pathogenicity, and for improved understanding of penetrance, phenotypic pleiotropy and environmental influence in congenital anomalies.

Mendelian Phenotypes Posters - Thursday

PB1797. Co-occurring anomalies in cases with achondroplasia

Authors:

C. Stoll; Faculté de Médecine, Strasbourg, France

Abstract Body:

Co-occurring congenital anomalies may be observed in cases with achondroplasia. The prevalence reported in the literature and the types of co-occurring congenital anomalies are variable between the reported studies. The aim of this study was to establish the prevalence and to describe the co-occurring anomalies in cases with achondroplasia. This study included 25 cases ascertained from our registry of congenital anomalies including all terminations of pregnancy, stillbirths and live births between 1979 and 2007 in 387,067 births (the prevalence of achondroplasia was 6.4 per 100,000 births), and 223 cases ascertained from the French organization, Association des Personnes de Petite Taille (APPT) built on the model of LPA (Little People of America, Inc.). Out of these 248 cases of achondroplasia 37 (14.9 %) had associated anomalies including 4 (1.6 %) cases with chromosomal abnormalities (2 trisomies 21, one 22 q11.2 deletion, and one 47, XXX), 2 (0.8%) cases with recognizable non-chromosomal conditions (one Moebius syndrome and one Pierre Robin sequence) and 31(12.5%) cases with MCA (multiple congenital anomalies). The 31 patients with MCA had 54 anomalies. Anomalies in the central nervous system (25.9%), the urogenital system (20.3%), the cardiovascular system (16.6%), the musculoskeletal system (12.8%), the eye (9.2%), and the orofacial system (7.4%) were the most common MCA. The overall prevalence of associated anomalies shows that the cases with achondroplasia need a careful screening for other congenital anomalies.

Mendelian Phenotypes Posters - Wednesday

PB1798*. C-X3-C motif chemokine receptor 1 (*CX3CR1*) gene variants associated with lesion burden in Cerebral Cavernous Malformation

Authors:

S. Weinsheimer¹, J. Nelson², B. Gongol³, M. C. Mabray⁴, J. M. Zabramski⁵, A. Akers⁶, B. L. Hart⁴, L. Morrison⁷, A. A. Abl⁸, N. U. Ko⁹, C. Tsang², C. E. McCulloch¹⁰, H. Kim¹¹, M. A. Abstract Body:

Background: Familial cerebral cavernous malformation (FCCM) is an autosomal dominant disorder caused by mutations in *KRIT1*, *CCM2* and *PDCD10* genes. Clinical heterogeneity of FCCM suggests a role for genetic modifiers of lesion burden and neuroinflammation. CCM mouse transcriptomics studies from major cell types involved in CCM disease, such as astrocytes and CCM endothelium, have identified a role for hypoxia-related genes. However, it is unknown whether these genes contribute to disease severity phenotypes, including intracranial hemorrhage (ICH), total and large lesion count in FCCM. We hypothesized that common genetic variants in hypoxia-related genes are associated with ICH and lesion burden in FCCM. **Methods:** FCCM cases (mean age 39±21y, 62% female, 93% White) enrolled in the Brain Vascular Malformation Consortium were included (n=338). Total and large lesions (≥5mm) were counted on MRI; clinical history of ICH at enrollment was assessed by medical records. Individuals were genotyped using the Affymetrix Axiom Genome-Wide LAT1 Human Array. We tested the association of 5,909 single nucleotide polymorphisms (SNPs) mapping within 5kb of 309 hypoxia-related genes identified from CCM mouse cell-type-specific transcriptomes with minor allele frequency (MAF) ≥1% using multivariable logistic regression for ICH and multivariable linear regression for log transformed total and large lesion count, adjusting for age, sex, and 3 principal components to adjust for population stratification. Significance was based on Bonferroni adjustment for multiple comparisons (P=0.05/5,909 SNPs=8.5E-06). **Results:** Two missense SNPs in *CX3CR1*, T2080M (rs3732378 G>A, MAF = 0.15) and V249I (rs3732379 C>T, MAF 0.23), were significantly associated with reduced CCM lesion count (Beta_{T2080M} = -0.5, 95% Confidence Interval = -0.71 to -0.29, P = 3.7E-06; Beta_{V249I} = -0.4, 95% Confidence Interval = -0.60 to -0.24, P = 7.0E-06). Thus, individuals with the T2080M variant have a 39% reduction in lesion count. These functional SNPs affect CX3CR1 protein activity and are associated with several neuroinflammatory disorders. No SNPs were associated with ICH or large lesion size. **Conclusions:** Two missense SNPs in the hypoxia-related *CX3CR1* gene are associated with total lesion count in FCCM. Further work is needed to confirm these findings in a replication cohort. These data in addition to functional studies in animal models support a role for *CX3CR1* inflammatory genetic modifiers in specific cell types that influence lesion burden, perhaps by altering the CX3CR1-CX3CL1 signaling, and provide an example of how genetic markers may be used for patient stratification for CCM severity.

Mendelian Phenotypes Posters - Thursday

PB1799. De novo (deep-)intronic splicing mutations in patients with neurodevelopmental disorders

Authors:

B. van der Sanden^{1,2}, G. Schobers^{1,2}, J. Corominas Galbany^{1,3}, G. Khazeeva^{1,3}, R. Derks¹, D. Koolen^{1,3}, M. Sinnema⁴, M. Nelen¹, H. Brunner^{1,2,4,5}, C. Gilissen^{1,3}, A. Hoischen^{1,3}, L. Vissers^{1,2}; ¹Dept. of Human Genetics, Radboud Univ. Med. center, Nijmegen, Netherlands, ²Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands, ³Radboud Inst. for Molecular Life Sci., Nijmegen, Netherlands, ⁴Dept. of Clinical Genetics, Maastricht Univ. Med. Ctr., Maastricht, Netherlands, ⁵GROW Sch. for Oncology and Dev.al Biology, Maastricht, Netherlands

Abstract Body:

Multiple studies have shown that de novo mutations (DNMs) are a major cause of unexplained neurodevelopmental disorders (NDD). However, these studies are often limited to coding variant interpretation. Whole genome sequencing (WGS) allows for comprehensive variant calling of all types of variation not limited to the coding sequence. Others previously showed that non-coding DNMs in conserved fetal brain-active regulatory elements may explain up to 0.15% of NDD. We hypothesized that intronic splice-altering variants could also have a pathogenic effect. In this study, we systematically assessed (deep-)intronic splice-altering DNMs and their potential pathogenic effect for NDDs. We performed WGS for a cohort of 156 exome-negative NDD patient-parent-trios. De novo single nucleotide variants (SNVs) were called using two algorithms, a standard in-house GATK-based algorithm and DeNovoCNN, a deep-learning based algorithm. DNMs called by both methods were marked as high confidence DNM and considered for this study. DNMs called by only one of the two methods were only considered when surpassing high quality thresholds. Splicing effects for all DNMs were predicted using SpliceAI, and variants with a SpliceAI delta score ≥ 0.02 were included in this study. In total, we identified 26,354 DNMs in 156 patients, resulting an average of 169 variants per patient. Of these, 12,083 were called by both algorithms and 14,271 by only one. On average, 63 DNMs affected a protein-coding gene, as defined by the start of 5'UTR, all intronic and coding sequence, up to the last base of the 3'UTR. Of these 70, only two were located in the gene's coding sequence. Filtering the variants located in a gene for predicted splice-altering effects based on SpliceAI prediction scores yielded a total of 633 DNMs (2.4%), of which 494 were located in intronic sequence, 94 in coding sequence, and the remaining 45 in either of the UTRs. In total, 68 of the intronic splice DNMs (0.26%) were located in one of 1,596 previously NDD associated genes. However, there was no enrichment of DNMs in the introns of NDD genes compared to the introns of other genes ($p = 0.326$, chi-squared test). We find that intronic splice DNMs in NDD associated genes occur at a rate of 0.44 events per genome. Using the recommended SpliceAI delta score threshold of ≥ 0.5 for pathogenicity, provides a potential diagnosis in 2/156 patients (1.3%). Pending functional confirmation of these variants in our patients, this suggests that de novo splice-altering mutations might be contributing to NDD to a larger degree than non-coding DNMs in conserved fetal brain-active regulatory elements.

PB1800. *De novo* missense variants in *RPS5* cause a newly characterized ribosomopathy.

Authors:

F. Ladha¹, M. Balasubramanian², T. Juul³, L. Hansen³, C. Fagerberg³, Q. Hao³, Undiagnosed Diseases Network, J. Rosenfeld¹, L. Burrage¹, C. Murali¹; ¹Baylor Coll. of Med., Houston, TX, ²Univ. of Sheffield, Sheffield, United Kingdom, ³Odense Univ. Hosp., Odense, Denmark

Abstract Body:

RPS5 encodes one of eighty proteins that make up the mammalian ribosome. Ribosomopathies constitute a diverse spectrum of disorders. We detail three individuals with *de novo* missense variants in *RPS5* who present with dysmorphic features, developmental delay, hypotonia, poor growth, visual and ocular anomalies, and immunodeficiency. Patient 1 is a 12-year-old female with prenatal intrauterine growth restriction (IUGR). She had mild global developmental delay with hypotonia, immunodeficiency, myopia, relative short stature, learning disability, and dysmorphic features. Her variant in *RPS5* is NM_001009.3:c.593G>A (p.Arg198His). Patient 2 is a 21-month-old male with a prenatal history of small placenta. He has global developmental delay with hypotonia, short stature, poor growth, renal hypoplasia, and ocular anomalies with dysmorphic features. His *RPS5* variant is the same as Patient 1's. Patient 3 is an 8-year-old female with a prenatal history of IUGR. She has global developmental delay with hypotonia, intellectual disability, renal anomalies, bilateral sensorineural hearing loss, dysmorphic features, and hypogammaglobulinemia. Her *RPS5* variant is NM_001009.3: c.554C>T (p.Ser185Leu). Both variants are novel and located in exon 6, the final exon of *RPS5*. Both affect residues that are highly conserved through zebrafish. The variant in Patients 1 and 2 is located in the final turn domain of the protein, and Patient 3's variant is located in the final helix domain. The predicted constraint metric for missense variants in *RPS5* shows a Z-score of 2.79, indicating high intolerance to amino acid changes. Our findings suggest that *de novo* missense variants in *RPS5* may cause a newly recognized ribosomopathy. Further studies are needed to provide insight on the functional effects of these variants and whether exon 6 is a hotspot for variation associated with this novel ribosomopathy phenotype.

Abstract Body:

Selenophosphate synthetase (SEPHS) plays an essential role in selenium metabolism. SEPHS is an ATPase that synthesizes selenophosphate from ATP and selenide. As the primary selenium donor in the selenocysteine biosynthetic pathway, SEPHS is necessary for the efficient production of selenoproteins. Two mammalian SEPHS paralogues, *SEPHS1* and *SEPHS2*, share high sequence identity and structural homology with SEPHS. These two genes have yet to be implicated in human disease. It is conceivable that variants in *SEPHS1* (MIM 600902) or *SEPHS2* (MIM 606218) may be linked to a genetic disorder. Here, we report nine individuals with heterozygous missense variants in *SEPHS1*, all residing in the C-terminal domain in or near the AIR synthase-related domain. Eight of these individuals had a recurrent variant at amino acid position 371 of SEPHS1. Eight of these variants were known to be *de novo*. This cohort demonstrated a variable neurodevelopmental disorder characterized by developmental delay, hypotonia, muscle weakness, speech delay, and growth delay. Structural modeling and biochemical assays were utilized to understand the effect of these variants on SEPHS1 protein function. We found that a variant at residue W352 results in local structural changes of the C-terminal region of SEPHS1 that decrease the overall thermal stability of the enzyme. In contrast, variants of a solvent-exposed residue R371 do not impact enzyme stability and folding but could modulate direct protein-protein interactions of SEPHS1 with cellular factors involved in promoting cell proliferation and development. Our study supports that SEPHS1 plays a critical role during human development and provides a basis for further investigation into the molecular mechanisms employed by SEPHS1. In summary, variants in *SEPHS1* are associated with a novel neurodevelopment disorder.

Mendelian Phenotypes Posters - Wednesday

PB1802. De novo non-synonymous *CTR9* variants are associated with motor delay and macrocephaly

Authors:

H. Suzuki¹, K. Aoki², K. Kurosawa³, K. Imagawa⁴, T. Ohto⁴, M. Yamada¹, T. Takenouchi¹, K. Kosaki¹, T. Ishitani²; ¹Keio Univ., Tokyo, Japan, ²Osaka Univ., Osaka, Japan, ³Kanagawa Children's Med Ctr, Yokohama, Japan, ⁴Univ. of Tsukuba, Tsukuba, Japan

Abstract Body:

[Background]*CTR9* is one of five genes that form the PAF1 complex, which binds to RNA polymerase II and plays critical roles in transcriptional elongation and transcription-coupled histone modifications including histone H3K4me3 and H3K36me3. We identified two de novo missense variants in *CTR9* gene (NM_14633.3) in two unrelated patients with macrocephaly, motor delay, and intellectual disability. To confirm the pathological significance of *CTR9*, we performed functional analysis using zebrafish.

[Patients]Patient 1 was a 4-year-old girl. At 4 years of age, her height was 107 cm (+0.7 SD), her weight was 17.0 kg (+0.1 SD), and her head circumference was 53.3 cm (+2.1 SD). She walked alone at 36 months and spoke meaningful words at 42 months. Her developmental quotient was 40 at the age of five years. An exome analysis revealed that the patient had a *de novo* heterozygous variant in the *CTR9* gene: c.74C>G, p.(Pro25Arg). Patient 2 was a 6-year-old girl. At 4 years of age, her height was 100.8 cm (-0.2 SD), her weight was 18.0 kg (+0.9 SD), and her head circumference was 54.5 cm (+3.8 SD). She walked alone at 19 months and spoke meaningful words at 18 months. An exome analysis revealed that the patient had a *de novo* heterozygous variant in the *CTR9* gene: c.45G>A, p.(Glu15Asp).

[Method]We generated a *ctr9*-knockout zebrafish using the triple-target CRISPR method. The rescue experiments were performed on *ctr9*-knockout zebrafish with human wild-type and mutant *CTR9* mRNA inserted. Overexpression studies were also performed on the wild type and each variant.

[Result]The *ctr9*-knockout zebrafish showed macrocephaly and poor movement. Those with wild-type mRNA inserted in rescue experiments returned to normal, whereas the co-injection of the two hCTR9 variants did not exhibit such rescue effects. Overexpression studies showed no phenotypic change in the wild type, but the mutant was able to reproduce macrocephaly. The results suggest that the mutants detected have a dominant-negative effect.

[Discussion]The mechanistic link between the aberrant function of *CTR9* and macrocephaly associated with intellectual disability is unknown. We speculated that a reduction in lysine-36 trimethylation of histone H3 (H3K36me3) may be responsible, since H3K36me3 levels were also downregulated in *ctr9*-KO zebrafish [Conclusion] We concluded that the two missense variants in *CTR9* (p.(Glu15Asp) and p.(Pro25Arg)) cause a new syndrome involving macrocephaly, motor delay, and intellectual disability through the loss of the normal function of *CTR9* and the inhibition of the normal intrinsic *CTR9* function of the contralateral allele.

Mendelian Phenotypes Posters - Thursday

PB1803. *De novo* truncating *ADNP* variants as a recurrent cause of neurodevelopmental disorders

Authors:

M. Gusic, S. Eck, O. Wachter, J. Philippou-Massier, K. Hörtnagel; MVZ Martinsried GmbH / Med.ver Genetics, Martinsried, Germany

Abstract Body:

Neurodevelopmental disorders (NDDs) are defined as a heterogenous group of conditions affecting the brain and resulting in impaired cognition, behaviour, language and motor function, as well as additional (non)-neurological symptoms¹. Increased implementation of large-scale sequencing methods in the last decade has revealed a significant enrichment of *de novo* variants in individuals with NDDs^{2,3}. By performing parent-offspring trio exome sequencing as a diagnostic approach in a genetic diagnostics center, we report three unrelated individuals carrying *de novo* pathogenic variants in the *ADNP* gene, encoding for a transcription factor involved in the SWI/SNF remodeling complex⁴. The reported individuals presented global developmental delay and intellectual disability (ID) in common, in addition to other various craniofacial and muscular symptoms, reflecting the typical manifestations of the *ADNP*-associated Helsmoortel-Van der Aa syndrome⁵. All three variants (the most prevalent one and two novel) were truncating, located in the fifth (the last) exon of the gene and thus predicted to escape the nonsense-mediated decay. In addition to the three case reports, we provide an overview of clinical and genetic spectrum of the *ADNP*-related disorder. By doing so, we highlight the *ADNP* gene as one of the most frequent causes of neurodevelopmental disorders as well as the clinical utility of trio sequencing for the rapid discovery of pathogenic variants.

PB1804. Deciphering a Diagnostic Odyssey of Atypical Free Sialic Acid Storage Disorder Associated with Tissue Specific Mosaic Variant in *SLC17A5*

Authors:

M. Shinawi¹, D. Wegner¹, A. Paul¹, J. Sheehan¹, S. Jaiprakash¹, S. Marco¹, J. Cooper¹, W. Buchser², S. Sukipolvi¹, K. Sisco¹, M. Schroeder³, K. Bowling¹, T. Turner⁴, R. Mitra¹, D. Grange⁴, D. Baldrige⁴, T. Wang⁵, U. Undiagnosed Diseases Network¹, J. Wambach⁶, P. Dickson¹; ¹Washington Univ. Sch. of Med., Saint Louis, MO, ²Washington Univ. Sch. of Med., St Louis, MO, ³Washington Univ. Sch. of Med., Webster Groves, MO, ⁴Washington Univ. Sch. of Med., St. Louis, MO, ⁵Washington Univ. in St. Louis, St. Louis, MO, ⁶Washington Univ, St. Louis, MO

Abstract Body:

Background: Free sialic acid storage disorder (FSASD) is a rare autosomal recessive lysosomal storage disease caused by bi-allelic pathogenic variants in *SLC17A5*, which encodes sialin. Patients with FSASD exhibit a spectrum of phenotypes and severity that correlates with their genotype and free sialic acid levels. Because of its nonspecific symptoms and lack of routine biochemical markers, FSASD has a diagnostic lag and is likely underdiagnosed. **Methods:** We performed a multidisciplinary clinical assessment of a patient with suspected lysosomal storage disease of uncharacterized molecular etiology. We conducted comprehensive molecular studies, including deep sequencing and RNASeq, biochemical analyses and in vitro functional studies. **Results:** The proband is now a 15-year-old girl with mild to moderate intellectual disability, coarse facial features, multi-valvular heart disease, thoracolumbar scoliosis post-surgical repair, abnormally shaped ribs, surgically repaired pes cavus and tendo-Achilles tightness, restricted joint movements, periarticular subcutaneous nodules, gingival hypertrophy, and faint corneal whirling. Electron micrographs showed prominent cytoplasmic vacuolation in diverse cell types in skin and muscle. Clinical exome identified a maternally-inherited frameshift variant, c.533delC;p.Thr178Asnfs*34, in *SLC17A5*. Free sialic acid levels in urine were 860-1434 (nl:123-508). These findings prompted us to search for a second pathogenic variant in *SLC17A5*. Whole genome sequencing, exome and genome data reanalysis, and targeted sequencing and dosage studies of *SLC17A5* were negative. RNASeq in fibroblasts revealed exon 3 skipping in ~50% of reads on the paternal allele, which was not detected in blood or in her parents. Western blot using protein extracted from proband's fibroblast showed 2 bands corresponding to a predominant wild type protein (47 KD) and a smaller size protein (40 KD). Targeted capture/deep sequencing of fibroblast DNA revealed a 185 bp deletion in ~15% of reads, encompassing the 3' end of exon 3, including the donor splice site. **Conclusions:** We report an unusual case of FSASD with tissue specific mosaicism for a copy number variant. Significant residual sialin function in different tissues may explain the mild elevation of sialic acid and atypical clinical course and findings. Our work illustrates the difficulty in diagnosing FSASD and highlights the need to pursue advanced molecular technologies when there is a high index of suspicion of a specific phenotype with incomplete molecular diagnosis.

Mendelian Phenotypes Posters - Thursday

PB1805. Deciphering the phenotypic variability of the most common deafness-causative *GJB2* p.V37I variant in Asia

Authors:

Y-T. Chiang¹, P-H. Lin², M-Y. Lo³, H-L. Chen², C-Y. Lee¹, C-Y. Tsai⁴, Y-H. Lin⁴, P-L. Chen⁵, J. Hsu¹, C-C. Wu⁶; ¹Natl. Taiwan Univ., Coll. of Med., Taipei City, Taiwan, ²Natl. Taiwan Univ. Hosp., Dept. of Otolaryngology, Taipei City, Taiwan, ³Natl. Taiwan Univ. Hosp., Dept. of Otolaryngology, Taipei city, Taiwan, ⁴Natl. Taiwan Univ., Coll. of Med., Taipei, Taiwan, ⁵Natl. Taiwan Univ. Hosp., Taipei, Taiwan, ⁶Natl. Taiwan Univ. Hosp., Taipei, Taiwan

Abstract Body:

The *GJB2* p.V37I (rs72474224) variant is the most prevalent genetic cause of sensorineural hearing impairment (SNHI) worldwide: approximately 500 million Asian individuals are homozygous for *GJB2* p.V37I. The phenotypes associated with p.V37I homozygosity are widely variable, with most patients presenting slight to moderate SNHI. However, severe to profound SNHI are occasionally observed in 10-20% of the patients (e.g., 10%, 57/561 in our Taiwanese cohort). To investigate the genetic factors contributing to the phenotypic variabilities, we performed targeted sequencing for *GJB2* and other deafness genes, including gap junction genes *GJB4*, *GJA1*, *GJB1*, *GJB3*, and *GJB6* in 121 p.V37I homozygotes. We identified at least one additional pathogenic variant in other deafness genes (*TBC1D24*, *COL4A3*, *SIX1*, *GRHL2*, *CDH23*, *NARS2*) in six patients who presented profound SNHI. We randomly selected p.V37I homozygotes with severe-to-profound SNHI (n=36), p.V37I homozygotes with mild-to-moderate SNHI (n=79), and subjects from the Taiwan Biobank (TWB, n=120) for case-control association analyses. We found the severe-to-profound group had a higher frequency of a *CRYL1* synonymous variant (rs14236), which is located in the upstream cis-regulatory element of *GJB2*, compared to the mild-to-moderate (p < 0.02; OR = 2.69; 95% CI, 1.06-7.23) and TWB group (p < 8.34 × 10⁻⁷; OR = 5.16; 95% CI, 2.58-10.35) respectively. Although digenic inheritance of *GJB2* and other gap junction genes had been documented previously, we did not detect any significant gap junction variants across the three groups. Our results uncover that additional pathogenic variants in other deafness genes and the *CRYL1* rs14236 variant may contribute to more severe hearing phenotypes in *GJB2* p.V37I homozygotes, underscoring the importance of the comprehensive genomic survey for these patients in clinical diagnostic practice.

Mendelian Phenotypes Posters - Thursday

PB1806. Deep resequencing of the 1q22 locus in non-lobar intracerebral hemorrhage

Authors:

L. Parodi^{1,2,3}, M. E. Comeau⁴, G. J. Falcone⁵, D. Woo⁶, J. Rosand^{1,2,3}, C. D. Langefeld⁴, C. D. Anderson^{7,1,2,3}; ¹Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA, ²McCance Ctr. for Brain Hlth., Massachusetts Gen. Hosp., Boston, MA, ³Broad Inst. of MIT and Harvard, Cambridge, MA, ⁴Dept. of Biostatistics and Data Sci., Div. of Publ. Hlth.Sci., Wake Forest Sch. of Med., Winston-Salem, NC, ⁵Div. of Neurocritical Care and Emergency Neurology, Dept. of Neurology, Yale Sch. of Med., New Haven, CT, ⁶Dept. of Neurology, Univ. of Cincinnati, Cincinnati, OH, ⁷Dept. of Neurology, Brigham and Women's Hosp., Boston, MA

Abstract Body:

Background: Genome-wide association studies have identified *Iq22* as a susceptibility locus for non-lobar intracerebral hemorrhages (ICH), arising following the rupture of small vessels in deep structures of the cerebral hemisphere, brainstem and cerebellum. We performed targeted high-depth sequencing of *Iq22* in ICH cases and controls to further characterize this locus and prioritize potential causal mechanisms.

Methods: 95,000 base pairs spanning *Iq22*, including *SEMA4A*, *SLC25A44* and *PMF1/PMF1-BGLAP* were sequenced in 1,055 ICH cases (534 lobar and 521 non-lobar) and 1,078 controls. Because *Iq22* is a susceptibility locus for non-lobar ICH alone, non-lobar ICH patients were compared with lobar ICH patients and ICH-free controls pooled together, with sensitivity analyses comparing non-lobar ICH with only ICH-free controls. Analyses included: 1) Firth regression to assess the role of common variants, 2) z-score based RIFT analysis to assess the role of rare variants, 3) chromatin interaction using ChIA-PET data from ENCODE and Hi-C data (analyzed using Juicebox), and 4) multivariable Mendelian randomization of expression data from the eQTLGen Consortium to assess whether alteration in gene-specific expression relative to regionally co-expressed genes could be causally related to non-lobar ICH risk at *Iq22*.

Results: Common and rare variant analyses both prioritized variants in *SEMA4A* 3'-UTR and *PMF1* intronic regions, overlapping with active promoter and enhancer regions based on ENCODE annotation. ChIA-PET data analysis highlighted the presence of long-range interactions between the two *SEMA4A*-promoter and *PMF1*-enhancer regions previously prioritized. Hi-C data analysis clarified that the *Iq22* locus is spatially organized in a single chromatin loop and that the harbored genes belong to the same Topologically Associating Domain (TAD), with potentially shared expression regulation. Mendelian randomization analyses revealed that only overexpression of *PMF1*, controlling for co-expression of other genes across the TAD, could be causally related to the higher risk of non-lobar ICH observed at *Iq22* ($p = 0.004$). *PMF1* codes for Polyamine Modulated Factor-1, a regulator of polyamine catabolism.

Conclusion: Single variant and gene-based analyses of targeted sequencing data combined with orthogonal methods revealed potential causal mechanisms for the established associations between variants at *Iq22* and non-lobar ICH. Based on our findings, we hypothesize the increased promoter-enhancer interactions leading to *PMF1* overexpression, potentially causing the dysregulation of polyamine catabolism, as a possible underlying causal mechanism.

Mendelian Phenotypes Posters - Wednesday

PB1807. Defining the clinical heterogeneity of *GARS1*-related Charcot-Marie-Tooth disease

Authors:

S. Marte, A. Antonellis; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Aminoacyl-tRNA synthetases (ARSs) are essential enzymes required for charging tRNA molecules to cognate amino acids in the cytoplasm and mitochondria. Although ARSs are essential and ubiquitously expressed, loss-of-function (LOF) missense and small, in-frame deletion mutations in five dimeric ARS enzymes have been associated with dominant peripheral neuropathy (also known as Charcot-Marie-Tooth disease [CMT]). CMT is a genetically and clinically heterogeneous inherited peripheral neuropathy characterized by the progressive loss of motor and sensory function. Mutations in glycyl-tRNA synthetase (*GARS1*) have been associated with distinct clinical phenotypes where individuals present with either later-onset CMT or early-onset infantile spinal muscular atrophy. While protein translation and the integrated stress response have been implicated in *GARS1*-related CMT, the mechanism by which mutations in *GARS1* lead to distinct clinical phenotypes is unclear. Since all five implicated ARSs function as dimers and since the majority of CMT-associated ARS variants cause a loss-of-function effect, we propose the possibility of a dominant-negative mechanism. To test dominant-negative effects of pathogenic glycyl-tRNA synthetase (*GARS1*) variants, we will develop a humanized yeast model and test *GARS1* mutations for the ability to repress a wild-type copy of *GARS1*. To better understand the distinct clinical phenotypes, we will assess the dominant toxicity of a series of pathogenic *GARS1* alleles to determine if toxicity in our yeast model correlates with disease severity. Finally, we will identify pathways that, when manipulated, improve *GARS1* function by performing experimental evolution and gain-of-function studies using a hypomorphic *GARS1* allele and yeast growth assays. Here, we will present our unpublished data on development of our humanized model and on initial assessments of pathways that can improve *GARS1* function. These studies will aid in defining the molecular mechanism of *GARS1*-related CMT and in identifying the genetic underpinnings responsible for the observed clinical heterogeneity.

Abstract Body:

Mitochondrial function is under bi-genomic control; pathogenic variants in the nuclear and mitochondrial genomes (mtDNA) can result in clinical mitochondrial disease. The most common cause of multi-system adult mitochondrial disease (mtDNA variant m.3243A>G; NC_012920.1) is associated with extensive unexplained clinical heterogeneity. Variant m.3243A>G allele level, age and sex explain only a small proportion of this variability (pseudo-R² range = 0.05-0.26), whereas high to moderate estimates of heritability for some m.3243A>G-related phenotypes provide evidence for the influence of unidentified nuclear factors.

Using Haseman-Elston regression-based genetic linkage analysis in a cohort of 208 individuals from 83 pedigrees, we explored the nuclear genetic architecture of eleven phenotypes related to the m.3243A>G variant. For three phenotypes (migraine, cardiovascular involvement, and gastro-intestinal disturbance), no regions of interest were identified; simulation results suggest that any nuclear genetic contribution is highly polygenic in origin.

For seven phenotypes (cerebellar ataxia, chronic progressive external ophthalmoplegia, diabetes, myopathy, psychiatric disturbance, ptosis, and stroke-like episodes), at least one region of interest (LOD > 1.8) was identified. Seven regions of interest were identified for encephalopathy, including two (LOD > 3.3) on chromosomes 7 and 11, suggesting that a small number of nuclear factors play a key role in the development of this severe neurological phenotype.

This work describes the genetic architecture of the nuclear factors that influence m.3243A>G-related disease, revealing that different phenotypes are influenced by nuclear variation in different ways. Using

ASHG 2022 Annual Meeting Poster Abstracts

the results of this work to inform future studies will enable the further elucidation of the underlying genetic architecture of this complex disease via genome-wide association studies, polygenic scores, and whole-genome sequencing. This work will build a better understanding of disease development and progression, and will have a tangible impact on patients and patient care.

Mendelian Phenotypes Posters - Wednesday

PB1809. Delayed developmental milestones in *MBD5*-associated neurodevelopmental disorder (MAND) associated with 2q23.1 deletions highlight need for early diagnosis

Authors:

L. Zhan¹, S. H. Elsea², S. V. Mullegama¹; ¹Sam Houston State Univ. Coll. of Med., Conroe, TX, ²Baylor Coll. of Med., Houston, TX

Abstract Body:

Introduction: *MBD5*-associated neurodevelopmental disorder (MAND) is a group of conditions characterized by developmental delay, speech impairment, seizures, hypotonia, sleep disturbances, intellectual disability, and abnormal behaviors. MAND can be caused by haploinsufficiency due to single-nucleotide variants, microdeletions, or microduplications in *MBD5*, a dosage-sensitive gene which encodes a protein involved in gene activity regulation. Recent studies have shown that genes involved in speech and motor development are dysregulated in individuals with *MBD5* variants. Thus, this study focuses on characterizing motor and speech phenotypes in children with 2q23.1 deletions inclusive of *MBD5*. **Methods:** A survey was administered to caregivers (n=38) of children under 18 years of age with a heterozygous *MBD5* deletion confirmed through clinical genetic testing. Questions covered demographic information, milestone achievement, therapies received, gross and fine motor movement assessment, speech assessment, and other behaviors. **Results:** The mean age of diagnosis was 3.17±2.88 years. The mean age at the time of survey was 7.03±4.20 years. The majority of the cohort did not meet major developmental milestones for gross motor skills on time, with crawling and standing not achieved by 63.6% (20/32) and walking not achieved by 55.5% (19/35). Further, 84.3% (26/31) missed the speaking milestone. Multiple therapeutic interventions were engaged by all respondents, with 84.6% (32/38) receiving at least three types. These therapies aimed to improve motor control associated with feeding, walking, running, and full limb movements. Despite multiple approaches for therapeutic intervention, a majority of the cohort still reported difficulties with coordination, fine motor movements, and speech development. **Conclusions:** The motor phenotype observed with *MBD5* haploinsufficiency includes gait abnormalities, poor coordination, difficulty with fine motor control, and difficulty swallowing. Speech is markedly impaired, with severely delayed development and inappropriate control of tempo, volume, and pitch in children that are verbal. These missed milestones were apparent by 1 year of age, but most children were still not diagnosed after 3 years of age. These data highlight the need to define the underlying cause of MAND and target critical milestones earlier in the child's life. Earlier genetic evaluation for children who miss key milestones would lead to earlier diagnosis and would offer education and specific interventions to families navigating these complex syndromes, improving outcomes in these populations.

Ctr., Washington, DC, ¹⁴NIH Office of the Clinical Director, Bethesda, MD

Abstract Body:

Introduction: Small nuclear RNAs (snRNAs) play integral roles in RNA splicing and are critical for cell function. Transcription of snRNAs is initiated by the small nuclear RNA activating protein complex (SNAPc), which binds to a promoter element upstream of snRNA genes and recruits transcriptional machinery. Impaired transcription of SNAPc subunits has been shown to reduce snRNA transcription; however, the role of SNAPc in mammalian cells remains to be elucidated. Moreover, variants in the genes encoding SNAPc have not been associated with human disease. Here, we present 6 individuals from 5 families with bi-allelic deleterious variants in *SNAPC4*, which encodes a key SNAPc subunit.

Methods: Clinical and biochemical phenotyping was performed on all probands. Exome or genome sequencing of the probands and available family members was performed to identify candidate disease-causing variants. The functional impact of *SNAPC4* variants on RNA splicing was assessed using patient-derived fibroblasts and a *SNAPC4*-deficient HeLa cell line, generated using CRISPR-Cas9 technology. **Results:** Six individuals with bi-allelic *SNAPC4* variants presented with a progressive spasticity disorder, which was characterized by normal development until one year, when developmental delays began to be evident, as well as spasticity. Affected individuals also showed cerebellar or cerebral atrophy on brain MRI, deep tendon reflex abnormalities, dysarthria, and gait alterations. Bi-allelic *SNAPC4* variants segregated with disease, most of which are likely loss-of-function. Premature stop codons were introduced by 5 variants, including 1 nonsense and 4 intronic, which were validated by cDNA sequencing of patient-derived cell lines. All 5 missense variants were predicted to be deleterious by *in silico* tools, with 3 located in the DNA-binding domain. Patient cells showed decreased SNAPC4 and snRNA expression and disruptions in global splicing patterns. *SNAPC4*-deficient HeLa cells showed similar changes, confirming those consequences were specific to *SNAPC4* deficiency. **Conclusion:** Our work supports the role of *SNAPC4* in snRNA transcription and splicing in mammalian cells through functional studies in HeLa and patient-derived cells. The common clinical phenotypes, alteration of *SNAPC4* expression, and global splicing dysregulation in patient cells support bi-allelic variants in *SNAPC4* as a compelling explanation for disease in our cohort. The etiology of neurological disease may be linked to the importance of alternative splicing in the development and function of the nervous system, but future experiments will be required to assess this hypothesis.

Mendelian Phenotypes Posters - Wednesday

PB1811. Deletions of 14q32.2 result in severe neurodevelopmental outcomes and multiple congenital anomalies: three affected males and review of the literature.

Authors:

J. Black¹, M. de Koning², R. Lebel¹, S. Smith¹, M. Byler¹, A. Van Haeringen², C. Ruivenkamp², H. Goel^{3,4}; ¹SUNY Upstate Med. Univ., Syracuse, NY, ²Leiden Univ. Med. Ctr., Leiden, Netherlands, ³HNELHD-Hunter Genetics, Newcastle, Australia, ⁴Univ. of Newcastle, Callaghan, Australia

Abstract Body:

Deletions of 14q32.2 have previously been reported, and most often involve the imprinted region of chromosome 14, giving rise to paternal or maternal UPD(14)-like phenotypes. Few individuals with deletions that spare the imprinted region have been reported. Deletion size and gene involvement have been highly variable.

We report three males with similar size deletions (2.5 to 3.9 Mb), two of which do not involve the imprinted region. These deletions overlapped for 13 different genes, three of which are associated with autosomal dominant conditions: *BCL11B*, *CCNK*, and *YY1*. All three patients present with prenatal and postnatal growth restriction, severe intellectual and developmental disability, feeding problems, cryptorchidism, hypotonia, and similar dysmorphic features (microstomia, micrognathia, wide nasal bridge, small nasal passages, and low set ears). The two with deletions sparing the imprinted region shared additional features including recurrent infections, strabismus, and kidney problems.

Other reported patients with similar 14q32.2 deletions show some clinical overlap with our patients, but none have the same combination or severity of features. Those with smaller deletions involving *BCL11B* and *CCNK* but not *YY1* had severe intellectual and developmental disability but no congenital abnormalities, while others with smaller deletions of only *YY1* had mild to moderate neurodevelopmental problems and minor dysmorphic features. We propose that deletions involving these three genes result in a discrete clinical entity entailing severe neurodevelopmental phenotype, characteristic facial features, and multiple congenital anomalies.

Mendelian Phenotypes Posters - Thursday

PB1812*. Delineation of gain-of-function MYCN-induced novel megalencephaly syndrome and possible out-of-brain complications implicated by a mouse model.

Authors:

Graduate Sch. of Med., Nagoya, Japan, ³Dept. of Genetics, Res. Inst. of Environmental Med., Nagoya, Japan, ⁴Dept. of Clinical Genetics, Tokyo Metropolitan Children's Med. Ctr., Tokyo, Japan, ⁵Dept. of Hematology and Oncology, Tokyo Metropolitan Children's Med. Ctr., Tokyo, Japan, ⁶Unité Fonctionnelle 6254 d'Innovation en Diagnostique Génomique des Maladies Rares, Pôle de Biologie, CHU Dijon Bourgogne, Dijon, France, ⁷Service de Génétique Clinique, CLAD Ouest, CHU Rennes, Hôpital Sud, Rennes, France, ⁸Dept. of Comparative and Experimental Med., Nagoya City Univ. Graduate Sch. of Med. Sci. and Med. Sch., Nagoya, Japan, ⁹Ctr. for Med. Genetics, Keio Univ. Sch. of Med., Tokyo, Japan

Abstract Body:

Background: *MYCN*, a member of the *MYC* proto-oncogene family, encodes a transcription factor that regulates genes promoting cell growth and proliferation. We previously reported two patients, a 15-year-old boy and an artificially-aborted fetus, with a novel megalencephaly syndrome with ventriculomegaly and polydactyly, who carried a gain-of-function variant in *MYCN* (p.Thr58Met and p.Pro60Leu, respectively). Although the concept of a novel megalencephaly syndrome was established through these patients, additional patients were needed to confirm it and delineate the clinical entity. Furthermore, although a mouse model exhibited a postaxial polydactyly and macrocephaly with increased number of neuronal cells, the comprehensive analysis of other organs was needed to understand possible out-of-brain complications. **Methods:** Exome sequencing was performed to identify a pathogenic variant. We also investigated the multiple organs of knock-in mice (*Mycn*^{WT/T58M}). **Results:** We identified a *de novo* *MYCN* missense variant (p.Thr58Met) in an 8-month-old boy. The patient exhibited megalencephaly, ventriculomegaly, postaxial polydactyly and dysmorphic facial gestalt, that were the very same phenotypes as those of the 1st patient. Furthermore, as with the 1st boy who was diagnosed with neuroblastoma that was successfully treated, the 3rd patient was diagnosed with neuroblastoma, that was already present at birth, when he was 3 months old. Through the analysis of a mouse model other than a macrocephaly and polydactyly, we identified the phenotypes in kidney and female reproductive systems possibly due to the over-proliferation of the tissues that forms these organs. **Conclusions:** These results delineate gain-of-function *MYCN*-induced novel megalencephaly syndrome. The out-of-brain phenotypes of the *Mycn* gain-of-function mouse model suggest the possible complications for clinicians carefully to examine.

Mendelian Phenotypes Posters - Wednesday

PB1813. Developmental Delay at the Single Cell Level in Prader-Willi Syndrome

Authors:

L. Reiter¹, D. Johnson¹, D. Garmire², C. Roco³, A. Victor¹; ¹Univ Tennessee HSC, Memphis, TN, ²Univ. of Michigan, Ann Arbor, MI, ³Parse BioSci.s, Seattle, WA

Abstract Body:

Prader-Willi Syndrome (PWS) is a neurodevelopmental disorder defined by a range of phenotypes including pronounced developmental delay, intellectual disability, sleep disorders and increased autism risk. Motor and language development is impaired in most PWS individuals and about 10-20% of PWS adults experience cycloid psychosis. The heterogeneity of the cognitive phenotypes in PWS warrant further study into the early neural development of PWS. We have established the largest collection of dental pulp stem cell (DPSC) lines from the deciduous teeth of PWS subjects. We regularly differentiate these stem cells into cortical-like neurons. Using neuronal cultures derived directly from DPSC of individuals with PWS and neurotypical controls, we performed single cell sequencing (scRNA-seq) via the SplitSeq pipeline (Parse Biosciences). Enrichment analysis on single neuron sets revealed shared pathways among the differentially expressed transcripts in PWS versus neurotypical controls, including the regulation of neurogenesis and neuronal differentiation. Expression of critical neurodevelopmental genes *NRXN1*, *NRXN2*, and *NAV2* was significantly increased in neurotypical control versus the PWS neurons. Several of these transcripts have now been validated at the protein level in independent control and PWS DPSC-derived neuronal lines. These preliminary results suggest that the PWS neurons display a delayed neurogenesis phenotype, at the single neuron level, that may explain the cognitive developmental delay in PWS and reveal potential therapeutic targets. We are currently increasing both the number of independent cell lines and the number of individual neurons being sequenced in order to further elucidate the mechanisms contributing to developmental delay in PWS.

Mendelian Phenotypes Posters - Thursday

PB1814. Diagnosis, treatment, and follow-up care for patients with Barth syndrome is presented through the results from 1:1 interviews of pediatric cardiologists.

Authors:

D. Curtis¹, M. Windrem², G. Kelly³; ¹Curtis Analytic Partners, Philadelphia, PA, ²Stealth BioTherapeutics, Needham, MA, ³Stealth BioTherapeutics, Needham, MA

Abstract Body:

Background: Barth syndrome (BTHS) is a rare genetic disease characterized by numerous impairments which are associated with substantial morbidity and mortality driven by heart disease. BTHS often manifests at an early age. To improve outcomes, additional information is needed regarding the level of knowledge pediatric cardiologists have identifying and managing patients with BTHS. After conducting a survey of 200 pediatric cardiologists to increase understanding of BTHS patient management, we conducted interviews with a small subset of those physicians who recently managed at least 1 BTHS patient.

Methods: Pediatric cardiologists were invited via email to participate in interviews, followed by a phone screening. Qualitative 1:1 interviews were conducted virtually in October 2021. Interviews were approximately 1-hour in duration and included discussion around BTHS patient engagement, management, and referrals to additional physicians.

Results: Most (n=4/6) respondents were currently involved with 1 or 2 BTHS patients, with the remaining respondents (n=2/6) having notable previous involvement. First patient interaction occurred at ages ranging from prenatal through toddler. Patient involvement typically began in the hospital setting, with the most serious phenotype initially presenting with the following symptoms: neutropenia, low muscle tone, low white blood cell count, skeletal abnormalities, renal dysfunction, arrhythmia, high potassium, failure to thrive, cardiomyopathy, and heart failure. The number of BTHS patients treated remained constant at 1-3 per year. At time of diagnosis, additional medical care team included ECHO cardiologists, neonatologists, and neurologists. Initial diagnostic tests included complete blood work, ECHO, genetic testing, and cardiopipin analysis. Various medications (i.e., ACE inhibitors, digoxin, and beta blockers) and supplements were used for medical management of BTHS. Respondents noted that after leaving the hospital, patient management was variable with most stable BTHS patients returning every 3 months for follow-up. Most respondents (n=5/6) identified the general pediatrician as the overall medical manager of patients with BTHS.

Conclusions: Pediatric cardiologists are aware of, diagnose, and treat patients with the most serious presentation of BTHS (i.e, heart disease/cardiomyopathy) and, along with pediatricians, would benefit from additional training to recognize and diagnose milder phenotypes. To increase understanding of trends in BTHS diagnosis and management, additional interviews will be conducted with a larger population of medical professionals and BTHS caregivers.

Mendelian Phenotypes Posters - Wednesday

PB1815. Diagnostic rate and clinical utility of whole genome sequencing in adults with intellectual disability

Authors:

A. Sabo, S. Pereira, S. Dugan, P. Trotter, M. Gingras, D. Murdock, B. Yuan, D. Muzny, R. Gibbs; Baylor Coll. of Med., Houston, TX

Abstract Body:

Establishing a genetic diagnosis for individuals with intellectual disability (ID) benefits patients and their families as it may inform the prognosis, lead to appropriate therapy, and facilitate access to medical and supportive services. Exome and genome sequencing are routine in a diagnostic setting for pediatric patients, but many adults with ID are lacking a comprehensive genetic evaluation. The families are not readily accessing these tests due to a lack of access to care, insurance coverage, or knowledge of new opportunities.

Our unique recruitment strategy involved partnering with service and education providers as well as three clinical sites. We utilized genome sequencing and analysis, identified SNVs, indels, and CNVs, and performed clinical variant interpretation for each recruited family. Families where genome sequencing analysis identified pathogenic or likely pathogenic variants discussed the results and any potential medical follow-up with a board-certified clinical geneticist. We formally evaluated clinical utility, including measures related to diagnosis, patient clinical management, and familial and psychosocial implications using C-GUIDE questionnaire.

We were able to establish a molecular diagnosis in 45% (13/29) of individuals. Our results include *de novo* variants in *MED13L*, *POGZ*, *BRAF*, *EHMT1*, *SATB2*, and *DNMT3A*, homozygous or compound heterozygous variants in *TUSC3* and *VRK1*, and heterozygous variants with unknown inheritance in *KANSL1*, *SATB1*, *ASH1L*, *CHD4*, and *TBL1XR1*. Clinicians completed a C-GUIDE questionnaire for five individuals. A measure of utility of the genetic testing scores ranged from 16-21; the mean score was 18.6 (SD=2.1; on a scale of -2 - 32, higher scores indicating more utility). When asked whether the genetic testing prompted better care for the patient or their family overall, clinicians reported it prompted better care in three cases and somewhat better care in one case; the clinician was unsure in the remaining case.

Our study suggests a high yield of genome sequencing as a diagnostic tool in adult patients with ID who have not undergone comprehensive sequencing based genetic testing. Currently, medical insurance providers rarely cover the expense of exome or genome sequencing testing for adults due to perceived limited clinical utility. Research studies like ours that include assessment of clinical utility will be critical in the evaluation of the usefulness of genetic testing.

Mendelian Phenotypes Posters - Thursday

PB1816. Diagnostic utility of comprehensive genomic and transcriptomic profiling of anorectal malformations.

Authors:

S. Ramadesikan¹, M. Marhabaie¹, R. Supinger¹, R. Williamson¹, E. Varga¹, P. White^{1,2}, D. C. Koboldt^{1,2}, R. Wood^{3,4}, E. Mardis^{1,2}; ¹The Steve and Cindy Rasmussen Inst. for Genomic Med., Nationwide Children's Hosp., Columbus, OH, ²Dept. of Pediatrics, The Ohio State Univ. Coll. of Med., Columbus, OH, ³Dept. of Pediatric Colorectal & Pelvic Reconstructive Surgery, Nationwide Children's Hosp., Columbus, OH, ⁴Dept. of Surgery, The Ohio State Univ. Coll. of Med., Columbus, OH

Abstract Body:

Anorectal malformations (ARM) constitute a group of congenital defects of the gastrointestinal and urogenital systems. They affect males and females, with an estimated worldwide prevalence of 1 in 3,000 live births. These malformations are clinically heterogeneous and can occur as part of syndromic conditions (rare) or as a non-syndromic entity. Despite the well-recognized heritability of non-syndromic ARM, the etiology in most patients is unknown. As an international leader in pediatric colorectal/pelvic reconstructive surgery, our institution follows around 1,500 ARM patients and adds 150-200 cases per year. We recently established a multidisciplinary, IRB-approved translational research study to interrogate the molecular landscape of ARM through comprehensive molecular profiling of patients, family members, and (when available) surgically resected tissue. To date, we have enrolled and sequenced 16 individuals from four multiplex families representing some rare, and diverse ARM types, as well as 3 surgically resected tissue specimens. In one of the families, we identified a novel paternally inherited heterozygous *CDX2* variant (c.722A>G (p.Glu241Gly)), that was present in all 3 affected siblings. *CDX2* encodes a transcription factor and is considered the master regulator of gastrointestinal development. The variant is absent from population databases and predicted to be damaging by most *in silico* pathogenicity tools. It maps to the homeobox domain of the protein, which is critical for interaction with DNA targets. So far, only 2 other reports implicate variants in *CDX2* with ARM. Remarkably, patients described in these studies exhibit similar clinical phenotypes and genetic alterations in *CDX2*. Our finding provides a potential molecular diagnosis for our family's condition and supports the role of *CDX2* in anorectal anomalies. It also highlights the clinical heterogeneity and variable penetrance of ARM predisposition variants, a well-documented phenomenon. Finally, it underscores the diagnostic utility of genomic profiling of ARM to identify the genetic etiology of these defects.

Mendelian Phenotypes Posters - Wednesday

PB1817. Dilated cardiomyopathy in a 3-month-old female: The answer in genetics.

Authors:

M. Patel, Y. Martinez-Fernandez, J. Bolivar, P. Jayakar; Nicklaus Children's Hosp., Miami, FL

Abstract Body:

Introduction:Dilated cardiomyopathy (DCM) in infancy has a broad differential diagnosis leading to challenges in work-up, treatment, and counseling. Herein described is a case of a 3-month-old female who presented with DCM due to a rare genetic variant.

Case:A 3-month-old female with no significant medical history, presented with decreased PO intake for 48hr, cough, and increased work of breathing for 5 weeks. She has history of a URI one month prior. Tachycardia and a gallop were noted on physical exam. CXR showed cardiomegaly with vascular congestion. She had abnormal troponin and BNP. TEE revealed severe MR, markedly reduced LV systolic function, and severely dilated LA and LV. She was started on a heart failure regimen with clinical improvement. CTA showed a normal origin of coronary arteries. Infectious workup (CMV, Adenovirus, Coxsackie, Enterovirus, Hepatitis, Parvovirus, Toxoplasma) was negative. Cardiomyopathy panel positive for -Variants of Uncertain Significance (VUS), HRAS- c.284A>G (p.Gln95Arg and RYR2- c.7955T>C (p.Leu2652Pro)- both inherited from an asymptomatic mother.

WGS (whole genome sequencing) TRIO- identified 2 VUS- compound heterozygous variants in the autosomal recessive RPL3L gene; maternally inherited missense variant, c.173G>A (p.Arg58Gln) and paternally inherited missense variant, c.922G>A (p.Asp308Asn). The patient continues with depressed LV function, is followed outpatient with cardiology and genetics, and is referred to the heart transplant team.

Discussion:DCM in infancy is often idiopathic. Even as more genes are identified, the yield of genetic testing remains low, especially in nonsyndromic cases. RPL3L encodes for the 60S ribosomal protein L3-like protein, which is highly expressed in striated muscles.

Ganpathy et al in 2020 reported neonatal-onset severe cardiomyopathy, with rapid progression to cardiac decompensation and death unless the patient undergoes heart transplantation. Similar to our case, Ganpathy describes a patient of 2.5 month old with emesis and tachypnea, found to have severely reduced LV function requiring a heart transplant by 5 months of age. A multidisciplinary team approach and early heart transplant referral are key. This case highlights the importance of WES/WGS in the evaluation, treatment, and counseling of infantile DCM.

Conclusion:Most cases of DCM in infancy are idiopathic, limiting disease-specific treatment, followed by inborn errors of metabolism. Early diagnosis is imperative to treatment, such as early referral for heart transplant. We therefore suggest genetic evaluation should be part of the initial evaluation of DCM with non-syndromic DCM in infancy.

Mendelian Phenotypes Posters - Thursday

PB1818. *Drosophila* model of *de novo* *MRTF-B* variants highlights the critical role of actin regulation.

Authors:

J. Andrews¹, J-W. Mok¹, O. Kanca¹, C. Tiffit², E. Macnamara³, B. Russell⁴, S. Yamamoto⁵, H. Bellen¹, S. Nelson⁶, M. Malicdan², M. Wangler⁷; ¹Baylor Coll. of Med., Houston, TX, ²NIH/NHGRI, Bethesda, MD, ³NIH, Bethesda, MD, ⁴UCLA Sch. of Med., San Luis Obispo, CA, ⁵Baylor Coll. of Med., HOUSTON, TX, ⁶UCLA Med Ctr, Los Angeles, CA, ⁷Baylor Coll. Med., Houston, TX

Abstract Body:

Myocardin-related transcription factor B (MRTFB) is a member of a family of genes which serve to potentiate serum response factor (*SRF*)-dependent transcription and is highly conserved in both vertebrate and invertebrate model organisms. MRTF-B is not currently associated with a human disease but has been shown to be highly expressed in all human tissues save the lung. Here we report a pair of probands with a *de novo* variants in the second RPEL domain of *MRTF-B* with intellectual disability, minor dysmorphic features, expressive language delay, impulse control issues, and fine motor delay. We have generated a *Drosophila* model of the variants (p.R104G and p.A91P) found in these probands using the UAS/Gal4 system to drive the expression of human cDNA within the fly. Expression of either of the putatively pathogenic variants within wing tissues via a *Nubbin-Gal4* driver was sufficient to induce significant morphological changes in the fly wing, including truncations of wing veins, expansion of intervein space, loss of crossveins, and blistering. Conversely, expression of a reference human *MRTF-B* cDNA produced only minor changes in the posterior crossvein. Expression of *Drosophila Mrtf* using the *Nubbin-Gal4* driver produced a similar change in crossvein length as was observed with the human reference. To identify if this change in wing morphology was due to a lack of RPEL domain functionality, a *UAS-MRTF-B^{ΔRP}* line was established which lacked the entire 2nd RPEL domain. Expression of this line within the flies wings resulted in damage which was indistinguishable from the changes in morphology caused by the expression of either the p.R104G or p.A91P variants. In *Drosophila*, the *SRF* ortholog, *blistered (bs)*, is known to suppress wing vein formation and promote the development of intervein cells. Exogenous co-expression of *bs* and *Mrtf* has been previously shown to significantly alter wing morphology; therefore we expressed the human reference and p.R104G variant cDNA lines concurrently with a *UAS-bs* line. We found that wing morphology was highly disrupted when *bs* and the reference human cDNA were co-expressed, while the co-expression of p.R104G variant cDNA and *bs* was lethal. As the interaction between *MRTFB* and *SRF* is dependent on actin binding within the RPEL domain, *MRTFB* variants could disturb actin binding. We identified a significant decrease in the ability of the p.R104G variant to bind to actin, suggesting that a lack of regulation may cause its effects on the fly wing. Our results show that the p.R104G *MRTFB* variant disrupts actin binding and underlies a novel disorder.

Mendelian Phenotypes Posters - Wednesday

PB1819. Effect of FOXO3 and Air Pollution on Cognitive Function: A Longitudinal Cohort Study of Older Adults in China

Authors:

J. Ji; Tsinghua Univ., Beijing, China

Abstract Body:

Forkhead Box O 3 (FOXO3) genotype is strongly associated with human longevity and may be protective against neurodegeneration. Air pollution is a risk factor for cognitive decline and dementia. We aimed to study the individual and combined effects of FOXO3 and air pollution on cognitive function in a large prospective cohort with up to 14 years of follow-up. We measured cognitive function and impairment using the Mini-Mental State Examination (MMSE). We used tagging SNPs rs2253310, rs2802292, and rs4946936 to identify the FOXO3 gene, of which roughly half of the population had the longevity-associated polymorphism. We matched annual average fine particulate matter (PM_{2.5}) concentrations within a 1 km² grid. We conducted cross-sectional and longitudinal analyses using multivariable linear and logistic regression models and generalized estimating equations. At baseline, carriers of the longevity-associated homozygous minor alleles of FOXO3 SNPs had a higher MMSE score than the carriers of homozygous major alleles. In the longitudinal follow-up, carriers of FOXO3 homozygous minor alleles had lower odds of cognitive impairment compared with noncarriers. Higher PM_{2.5} was associated with a lower MMSE score and higher odds of cognitive impairment. The positive effects of FOXO3 were the strongest in females, older people, and residents in areas with lower air pollution.

Mendelian Phenotypes Posters - Thursday

PB1820*. Effective Genetic Diagnosis for Unilateral and Asymmetric Pediatric Hearing Loss via Exome Sequencing

Authors:

S. Redfield¹, J. Perry¹, A. Oza¹, S. Rouse¹, C. Stewart¹, H. Khela¹, V. Albano¹, E. Shearer², M. Kenna¹; ¹Boston Children's Hosp., Boston, MA, ²Boston Children's Hosp., Dept. of Otolaryngology, Boston, MA

Abstract Body:

The current standard of care for the evaluation of bilateral symmetric pediatric sensorineural hearing loss (SNHL) includes genetic testing. Current clinical algorithms do not recommend genetic testing as an initial test for the etiological evaluation of asymmetric or unilateral SNHL, given previously reported low diagnostic rates for these populations. However, these studies largely did not focus on a pediatric population, include parental testing, use exome sequencing (ES), or have a large sample size. Our goal was to determine the diagnostic yield of ES for pediatric patient with asymmetric and unilateral SNHL compared to bilateral SNHL in a large cohort of pediatric patients. ES was performed from buccal-derived DNA for pediatric patients with confirmed SNHL without a known genetic or environmental etiology. Biological relatives were also tested (typically trios). ES mapping and variant calling, including copy number variants, was performed with the DRAGEN Bio-IT Platform (Illumina). Primary variant analysis focused on 366 known and candidate hearing loss genes. ES was performed for 218 probands and 333 relative (551 participants, including 130 trios). This cohort was clinically heterogenous in terms of SNHL phenotypes, including probands of varied laterality of SNHL, configuration of audiogram, age of onset of SNHL, and presence of other clinical features. A genetic cause of SNHL was identified for 31.2% of probands (n=68) with causative variants in 37 genes. The overall genetic diagnostic rate was 40.7% for bilateral, 23.1% for asymmetric, and 18.0% for unilateral, with syndromic diagnoses made in 20.8%, 33.3%, and 54.5% of cases in each group, respectively. In several cases of syndromic SNHL diagnosis, a genetic syndrome had not been suspected and no other clinical features were appreciated prior to study enrollment. We identified a genetic cause of SNHL in a significant percentage of pediatric patients with asymmetric and unilateral SNHL. Syndromic SNHL was more common in these cases compared to bilateral SNHL. Increased access to genetic testing for patients with all SNHL phenotypes will facilitate tailored intervention, early referral to appropriate specialists, and improved prognostic and recurrence information for families.

PB1821. Ellis-Van Creveld Syndrome: Clinical and Molecular Analysis of 50 Individuals

Authors:

M. Aubert-Mucca¹, C. HUBER², G. Baujat¹, C. Michot¹, M. Zarhrate³, M. Bras⁴, L. Boutaud⁵, Clinical Contributors, V. Malan⁵, T. Attie-Bitach⁵, V. Cormier-Daire^{1,2}; ¹Reference Ctr. for Constitutional Bone Diseases, Genomic Med. and Rare Disorders Dept., Necker-Enfants Malades Univ. Hosp., AP-HP, Paris, France, ²Paris Cité Univ., INSERM UMR 1163, Imagine Inst., Necker Enfants Malades Univ. Hosp., Paris, France, ³Genomics Core Facility, Imagine Inst. - Structure Fédérative de Recherche Necker, INSERM U1163 and INSERM US24/CNRS UMS3633, Paris Cite Univ., Paris, France, ⁴Bioinformatics Platform, Imagine Inst.-Structure Fédérative de Recherche Necker, Paris Cite Univ., Paris, France, ⁵Genomic Med. and Rare Disorders Dept., Necker-Enfants Malades Univ. Hosp., AP-HP, Paris, France

Abstract Body:

Background:

Ellis-Van Creveld syndrome (EVC) is one of the entities belonging to the skeletal ciliopathies short-rib-polydactyly subgroup. Major signs are ectodermal dysplasia, chondrodysplasia, polydactyly, and congenital cardiopathy, with a high degree of variability in phenotypes ranging from lethal to mild clinical presentations. The *EVC* and *EVC2* genes are the major genes causative of EVC syndrome. However, an increased number of genes involved in the ciliopathy complex have been identified in EVC syndrome, leading to a better understanding of its physiopathology, namely *WDR35*, *GLII*, *DYNC2LII*, *PRKACA*, *PRKACB*, and *SMO*. They all code for proteins located in the primary cilia, playing a key role in signal transduction of the Hedgehog pathways.

Methods: The aim of this study was the analysis of 50 clinically identified EVC cases from 45 families, to further define the phenotype and molecular bases of EVC.

Results: Our detection rate in the cohort of 45 families was of 91.11%, with variants identified in *EVC/EVC2* (77.8%), *DYNC2H1* (6.7%), *DYNC2LII* (2.2%), *SMO* (2.2%), or *PRKACB* (2.2%). No distinctive feature was remarkable of a specific genotype-phenotype correlation. Interestingly, we identified a high proportion of heterozygous deletions in *EVC/EVC2* of variable sizes (26.92%), mostly inherited from the mother, and probably resulting from recombinations involving Alu sequences.

Conclusion: We confirmed that *EVC* and *EVC2* are the major genes involved in the EVC phenotype, and highlighted the high prevalence of previously unreported CNVs.

Mendelian Phenotypes Posters - Thursday

PB1822. Enrichment of *RAI1* genetic aberrations associated with sleep disturbances in Smith-Magenis syndrome and autism spectrum disorder.

Authors:

A. Kaden, J. Brzezynski, C. Johnson, S. Smieszek, C. Polymeropoulos, G. Birznieks, M. Polymeropoulos; Vanda Pharmaceuticals Inc., Washington, DC

Abstract Body:

Autism spectrum disorder (ASD) comprises a complex of neurodevelopmental disorders primarily characterized by deficits in verbal communication, impaired social interactions, and repetitive behaviors. Previous genetic studies have pointed to hundreds of presumptive causative or susceptibility variants in ASD, making it difficult to find common underlying pathogenic mechanisms and suggesting that multiple different genetic etiologies for ASD influence a continuum of traits.

Smith-Magenis syndrome (SMS) is a rare genetic disorder that results from an interstitial deletion of 17p11.2 and, in rare cases, from a retinoic acid induced 1 (*RAI1*) gene variant. The prevalence is estimated to be 1 in 15,000-25,000 people. Haploinsufficiency of *RAI1* is the primary cause of the neurobehavioral and metabolic phenotype in SMS. Individuals with SMS present with a distinct pattern of mild to moderate intellectual disability and, almost uniformly, significant sleep disturbances.

We conducted a large-scale association analysis of The MSSNG Project whole genome sequencing data to elucidate the prevalence of *RAI1* single-nucleotide variants (SNVs) and copy number variations (CNVs) in the ASD population. We accessed the MSSNG database hosting over 6,080 probands and queried both SNVs and CNVs.

We report a single case of a classic deletion (17p11.2 critical region) and an additional three cases of microdeletions. Moreover, we report two frameshift mutations and one splicing variant. Given that the frequency of SMS is 1 in 15,000 people in the general population, we observe a 2.5x enrichment of the major deletion (1 in 6,080 samples) and a > 5x enrichment of the frameshift variants (2 in 6,080 samples). In a set of 6,080 probands, we also observe 54 unique missense variants in 84 individuals within exon 3 of the *RAI1* gene.

Both ASD and SMS patients suffer from sleep disturbances. In this population of individuals with ASD, we report an enrichment of variants known to cause SMS. We estimate the enrichment to be at least 2.5-fold and potentially higher than 10-fold, considering the types of variants observed in the population. The sleep disturbances seen in individuals with SMS may also be the underlying mechanism for sleep disturbances in at least a subset of individuals with ASD, especially in those with consequential variants in the *RAI1* gene. Further studies are needed to help delineate the role of *RAI1* variants in sleep physiology.

Mendelian Phenotypes Posters - Wednesday

PB1823. Enzymatic testing for MPSI in Kuwait: A Pilot Study toward newborn screening.

Authors:

H. Alsharhan¹, A. Alnassar², A. Alyaqoub², M. Almaie², B. Qadoura², U. M. Elkazzaz², D. G. Ramadan², M. Ayed², B. Albash², R. Alsafi², M. Haider³, G. S. Dhaunsi¹, H. Alkandari², N. Makhseed²; ¹Kuwait Univ., Kuwait, Kuwait, ²Kuwait Ministry of Hlth., Kuwait, Kuwait, ³Kuwait Univ., Faculty of Med., Safat, Kuwait

Abstract Body:

Introduction: Mucopolysaccharidosis type I (MPSI) is an autosomal recessive lysosomal storage disorder characterized by deficiency or absence of α -L-iduronidase (IDUA) enzyme due to pathogenic variants in *IDUA* gene. Early treatment with hematopoietic stem cell transplantation and/or enzyme replacement therapy is associated with improved outcomes in this progressive multisystem disease. The diagnosis is usually delayed due to late presentation and nonspecific symptoms resulting in high morbidity and mortality. The world-wide prevalence of MPSI is estimated to be 1:100,000, however, it is unknown in Kuwait. This ongoing pilot study to screen MPSI involves all Kuwaiti neonates born in Farwaniya Hospital over a period of 12-months. This study is aimed to examine the incidence of MPSI in Kuwait for inclusion in our national newborn screening program to enable early detection and adequate treatment. **Methods:** All Kuwaiti neonates born at Farwaniya Hospital, Kuwait from December 2021 to April 2022 have been screened for MPSI. The screening consisted of determining IDUA enzyme activity in dried blood spots (DBS)-derived samples by Tandem Mass Spectrometry. A follow-up genetic analysis of *IDUA* gene is planned to screen the cases with diminished IDUA enzyme activity as second-tier testing. **Results:** A total of 268 Kuwaiti newborns including 139 (52%) males and 129 (48%) females were screened. None of them had deficient or absent IDUA enzyme activity and thus, no genetic testing was conducted. However, we have diagnosed one additional female baby with MPSI, who belongs to Farwaniya Hospital, but the parents chose to deliver in a private hospital. She presented at age three months with recurrent upper airway infections, snoring and extensive Mongolian spots. The molecular study revealed previously reported pathogenic nonsense variant in *IDUA* c.1882C>T; p.(Arg628Ter), associated with severe phenotype. That being included, MPSI is estimated to be about 0.8% among tested females and 0.4% of all screened cases in Kuwait. **Conclusion:** Our study is the first to evaluate the incidence of MPSI in Kuwait. Given the small number of screened babies and the short study duration thus far, it is premature to calculate the incidence of MPSI. As the study continues and more infants are screened, we will be able to estimate the incidence of the disease in our population correctly. Our data support including MPSI in national newborn screening program to allow early initiation of treatment and thus improve the outcome of the disease.

Mendelian Phenotypes Posters - Thursday

PB1824. ERF-Related craniosynostosis: further delineation of the new craniosynostosis syndrome

Authors:

R. Santillán Martínez, M. Abreu-González, L. Hernández-Ancheyta, S. Martínez-Gutiérrez, E. Rojas-Toledo, C. O. Azotla-Vilchis; Laboratorio de Biología Molecular y Secuenciación Masiva. Genos Médica, Centro Especializado en Genética, Mexico City, Mexico

Abstract Body:

ERF-Related craniosynostosis-4 (CRS4) is a multisutural synostosis predominant characterized by pansynostosis or sagittal/bilamboid with the Crouzonoid triad (ocular hypertelorism, exorbitism and malar hypoplasia). It may also present with Chiari Type 1 malformation, speech delay, learning problems, motor control deficiency, hyperactivity and poor concentration.

CRS4 has been recently recognized to be caused by pathogenic variants in *ERF* (MIM: *611888), coding for ETS2 repressor factor. ETS2 is a transcription factor and protooncogene involved in development, apoptosis, and regulation of telomerase. The protein encoded by *ERF* gene binds to the ETS2 promoter and is a strong repressor of ETS2 transcription.

In this study we present a 5-years-old Mexican female patient referred to genetic evaluation for facial dysmorphism. She has mild plagiocephaly, facial asymmetry, mild frontal bossing, hypertelorism, epicanthic folds, a broad nasal bridge, anteverted nares, malar hypoplasia, arched palate, low-set ears and a normal neurodevelopment. No other anomalies were detected. The family history was relevant, because the mother have the same phenotype.

Due to the clinical suspicion of an autosomal dominant entity, complete exome sequencing was performed (Twist Comprehensive Exome Panel). The bioinformatics pipeline analysis of 1,040 genes associated with facial dysmorphism and bone dysplasia identified the NM_006494.4:c.566_567delGT (p.Cys189*) pathogenic variant in *ERF*. This indel is present in ClinVar database (rs1555750816) and is predicted to result in a loss of the last 360 amino acids of the protein.

The overall prevalence of *ERF* mutations in patients with syndromic craniosynostosis is approximately 2%, and 0.7% in clinically no syndromic craniosynostosis [Glass et al 2019]. These frequencies support CRS4, as a new syndrome, is mostly under diagnosed. This case exemplifies that isolated craniosynostosis and mild crouzonoid phenotypes should be sequenced with a panel that includes *ERF*.

Mendelian Phenotypes Posters - Thursday

PB1826. Exome Sequencing in Understanding the Etiologies of Ataxia in Children

Authors:

S. Phadke, A. Shambhavi, H. Sait, S. Srivastava, A. Moirangthem; Sanjay Gandhi Postgraduate Inst. of Med. Sci., Lucknow, India

Abstract Body:

Background/ Objectives: Childhood ataxia can be due to acquired abnormalities or genetic causes. Ataxia can present in its pure form or in association with other neurological features such as spasticity, brainstem signs, or even a more complex phenotype with additional systemic and neurological features. Triplet-primed PCR (TP-PCR) is a method to detect triplet-repeat expansions which is seen in many genetic ataxias. Here, this study aims to provide information about the utility of exome sequencing in identifying single nucleotide variants in cases with ataxia and expand the genotypic spectrum in children presenting with ataxia in Indian population. **Methods:** Children presenting either with ataxia telangiectasia or complex rare ataxias with unknown etiology based on preliminary evaluation were enrolled. Detailed clinical evaluation and pedigree data was collected. Exome sequencing was done followed by genotype-phenotype correlation. Friedreich ataxia and other triplet repeat disorders confirmed by molecular testing were excluded. **Results:** Fifteen cases with childhood-onset ataxia were recruited with average age at clinical evaluation of 11 years. Consanguinity was present in 1 case. In 4 cases, a provisional diagnosis of ataxia telangiectasia was made, while others had no diagnosis based on clinical evaluation. Exome sequencing was performed where causative variant(s) were identified in 12 cases of which 5 cases had biallelic variants (2 homozygous and 3 compound heterozygous variants) in ATM gene. Out of these 8 variants in ATM gene, 3 were novel (c.5957delT, c.3576+2T>G, c.1236G>A). In 2 cases, variants in ERCC6 gene associated with Cockayne syndrome B were identified. In addition, causative variants (3 pathogenic/likely pathogenic and 2 VUS) were identified in 5 more cases. These included 4 genes for autosomal recessive disorders (C19orf12, PLA2G6, MTHFR, SNX14) and one X Linked gene (ATP2B3). SNX14 causes a rare form of spinocerebellar ataxia (SCA 20) was identified in a child with facial dysmorphism, intellectual disability and ataxic gait. The novel splice variant was identified in SNX14 gene which was functionally validated (PMID: 35195341). Out of 11 cases with autosomal recessive disorders, 7 from non-consanguineous families were homozygous. **Conclusion:** In this cohort of 15 childhood-onset ataxia we have identified variants in 12 cases. Six of the 14 variants identified were novel. Homozygosity is commonly seen in many nonconsanguineous families due to inbreeding. Additionally, our study expands the genotypic and phenotypic spectrum of the rare monogenic forms of ataxia. **Grant:** DBT (BT/PR26428/MED/12/783/2017)

Mendelian Phenotypes Posters - Wednesday

PB1827. Exome sequencing leads to the identification of a rare case of an autosomal dominant non-syndromic hearing disorder in a German family

Authors:

R. Birkenhager, S. Hollander, S. Weis, S. Arndt, A. Aschendorff, A. Knopf; Univ Freiburg, Freiburg, Germany

Abstract Body:

Hearing impairment is the most common sensorineural disorder in humans. Approximately 1 - 3 out of thousand newborns suffer from severe hearing loss or deafness at birth or in the first few years of life. Based on the form of the physiological defect, hearing disorders are classified into conductive hearing loss, sensorineural hearing loss, or a combination of both. Hearing disorders can be caused by environmental factors or viral infections, strong sources of noise, ototoxic substances and genetic causes. About ~ 60% of all prelingual hearing disorders are genetic. Inherited hearing disorders are divided into syndromal (SHL) or non-syndromal (NSHL). Almost 70% of cases of inherited hearing disorders are non-syndromic and mainly due to sensorineural causes. About 80% of the cases follow an autosomal recessive (DFNB) and 18% an autosomal dominant (DFNA) inheritance, about 2% are x-chromosomal (DFNX) or mitochondrial (MT) linked. A total of 187 gene locations have been described to date, for which 143 genes have so far been identified, 44 genes at least still unknown. Autosomal non-syndromic hearing loss (ANSHL) is a genetically heterogeneous sensorineural disorder, with prelingual hearing loss and absence of other clinical manifestations. Based on the clinical diagnosis it is not possible to recognize in which genes mutations are present. The aim of this study is to identify the pathogenic gene in a non-consanguineous German family over three generations, with seven affected members. Hearing testing BERA/Electrocochleography and radiological a high-resolution CT scan was made. Mutational analysis of two affected family members was performed using direct sequencing of the coding exon and intron transitions of the genes *GJB2* and *GJB6*, including deletion analysis. For investigation of autosomal nonsyndromic hearing loss genes, whole exome sequencing was performed, with the "INVIEW HUMAN EXOME" platform; array Agilent Genomics SureSelectXT All Exon V5. No mutations could be identified in the DNFB1 gene locus, containing the genes *GJB2* and *GJB6*. A further targeted analysis of other genes was not possible; therefore complete exome sequencing took place. All known genes for hearing impairment were analyzed. A heterozygous pathogenic variation was only detected in the gene *TMCI*, c.1249G> A, Gly417Arg, confirmed by Sanger sequencing. The inheritance pattern of the mutation in the family indicates a dominant non-syndromic hearing impairment. So far, mutations have been described in the *TMCI* (MIM 606706) gene which, on the one hand, leads to recessive (DFNB7/B11; MIM 600974) or dominant (DFNA36; MIM 606705) inherited hearing impairment.

Mendelian Phenotypes Posters - Thursday

PB1828. Exome sequencing uncovers novel variants in two Malian families with Epileptic encephalopathies

Authors:

A. Maiga¹, D. Mohamed Emile¹, S. Bamba², A. Yalcouye³, S. Diarra⁴, L. CISSE⁵, A. Tamega¹, C. Guinto^{1,6}, G. Landoure^{1,6}; ¹Univ. of Sci., Techniques and Technologies of Bamako, Bamako, Mali, ²USTTB, Bamako, Mali, ³Univ. of Sci., Techniques, and Technologies of Bamako, Mali, Bamako, Mali, ⁴NIH, ROCKVILLE, MD, ⁵Regional Hosp. of Segou, Segou, Mali, ⁶Univ. Hosp. "Point G", Bamako, Mali

Abstract Body:

Introduction : The term “Epileptic encephalopathy” refers to a heterogeneous group of brain affections in which the continuous epileptic activity leads to progressive deterioration of cerebral functions. It is mainly characterized by refractory seizures, severe electroencephalographic (EEG) abnormalities and global developmental delay or decline. Most epileptic encephalopathy cases are clinically sporadic, coinciding with frequently identified de novo variants with the application of next-generation sequencing (NGS). Here we report two novel variants in 2 Malian families with epileptic encephalopathies. **Aim:** To explore the genetic defects underlying Epileptic Encephalopathy in two Malian families **Methods:** We recruited probands and their families after formal consent. Detailed history was collected from each family to construct the pedigrees. Affected individuals went through a careful clinical assessment. When possible, EEG was performed. Peripheral blood was collected for DNA extraction. Whole Exome Sequencing (WES) was done, and Sanger Sequencing protocol is underway for segregation studies. **Results:** 16 participants, including seven affected individuals from two families (F1 and F2) with epileptic syndromes, were recruited. Tonic and/or clonic seizures associated with cognitive and developmental impairments were the main clinical features in patients. EEG was not performed in any of them due to limited access. Using WES, we found two pathogenic novel variants (SYNJ1(NM_003895.3): c.1255C>T in F1; SCN7A(NM_002976.4): c.4045C>A in F2). In silico prediction tools were used to confirm the pathogenicity of these variants. Segregation studies are underway through Sanger sequencing. **Conclusion:** Epileptic encephalopathies are one of the most heterogeneous groups of conditions, both clinically and genetically. We report here two de novo genetic alterations consistent with epileptic encephalopathy, expanding the genetic epidemiology of these conditions. This also highlights the important role of NGS in the diagnosis of complex neurological disorders. Further studies are necessary to evaluate the accuracy of NGS in African cohorts, but this opens the way to potential future therapeutics. **Keywords:** Epileptic encephalopathy, Genetics, NGS, Mali, Africa

Mendelian Phenotypes Posters - Thursday

PB1829. Expanding the Phenotypic spectrum of *SMARCA5*-related neurodevelopmental disorder

Authors:

R. Zambrano¹, H. Meddaugh²; ¹LSUHSC, New Orleans, LA, ²Children's Hosp. of New Orleans, New Orleans, LA

Abstract Body:

SMARCA5-related disorder is a newly described syndrome associated with variable neurodevelopmental differences, poor growth, and distinct dysmorphic craniofacial features. At least 10 affected families have been identified in the medical literature to-date. We describe a patient with a novel, de novo, likely pathogenic variant in *SMARCA5* (c.2172+1G>A) identified through clinical whole exome sequencing. The proband displays significant phenotypic overlap with the *SMARCA5* disease spectrum as described, including global developmental delay, autism spectrum disorder, microcephaly, and failure to thrive. However, the patient also displays additional features including central precocious puberty with advanced bone age, and cardiac anomalies, including atrial septal defect and cardiomyopathy, which have not been reported in the *SMARCA5* literature to-date. We propose an expansion of the phenotypic spectrum of *SMARCA5*-related neurodevelopmental disorder.

Mendelian Phenotypes Posters - Wednesday

PB1830. Expanding the phenotypic spectrum of *TAB2* related disorders.

Authors:

P. Gupta, E. Lopez, L. King, L. Fried; St. Joseph's Children's Hosp., Paterson, NJ

Abstract Body:

Introduction: Frontometaphyseal dysplasia (FMD) is a progressive skeletal dysplasia primarily associated with joint contractures, cervical vertebral fusion, and scoliosis. X-linked FMD caused by mutations in *FLNA* are responsible for 50% of all cases of FMD and termed FMD1. Mutations in *MAP3K7* cause autosomal dominant-FMD and termed FMD2. *TAB2* is a novel gene associated with AD-FMD with a small number of individuals exhibiting a wide range of symptoms with close relation to *MAP3K7*-related FMD. A proposed FMD3 for *TAB2*-FMD has been suggested. Additionally, *TAB2* is also associated with AD polyvalvular syndrome, which is characterized by cardiac valve defects, distinct facial features, short stature, and connective tissue abnormalities. Case Presentation: The patient was born to a 39 year old mother G3P2 at 37 weeks gestation, via repeat C-section. Prenatal history was unremarkable. Birth weight was 7 lbs 5oz. Family history was significant for polydactyly in patient's father, paternal grandfather, and paternal great-grandfather. Bilateral post axial polydactyly was noted at birth which were tied by 3 weeks of age. The patient was seen by a neurologist at 2 weeks of age for hypotonia and a head ultrasound noted mild asymmetry of the ventricles. A sacral dimple was noted on physical exam and an ultrasound of the spine ruled out tethered cord. The initial genetics evaluation was done at 7 weeks of age via telehealth -physical exam noted significant head lag, hypertelorism, flat nasal bridge and micro-retrognathia. A SNP microarray analysis, and SMA deletion/duplication analysis were normal. Follow up genetic evaluation at 1 year of age noted prominent forehead with frontal bossing, bitemporal narrowing, hypertelorism, low-set ears, overfolded pinnae, depressed nasal bridge, short nose, long smooth philtrum, thin upper lip, retrognathia, short sternum, protruberant abdomen and generalized joint laxity. Height was less than the 1st percentile. A skeletal dysplasia panel was ordered and revealed a heterozygous pathogenic variant in the *TAB2* gene, resulting in premature translational stop codon associated with polyvalvular syndrome and FMD. Discussion: The diagnosis of our patient adds to the phenotypic spectrum of *TAB2*-related frontometaphyseal dysplasia (FMD3). There is much overlap in facies when comparing to previous individuals diagnosed with FMD3. Our patient is the 4th individual to have features consistent with FMD3, adding on to the phenotypic spectrum in the literature.

Mendelian Phenotypes Posters - Thursday

PB1831. Expert perspectives on sequencing newborns for treatable genetic conditions

Authors:

N. Gold¹, S. Adelson², N. Shah³, S. Williams², S. Bick⁴, J. Gold⁵, A. Strong⁵, R. Ganetzky⁵, A. Roberts⁴, M. Walker¹, A. Holtz⁴, V. Sankaran⁴, O. Delmonte⁶, W. Tan¹, I. Holm⁴, J. Thiagarajah⁴, J. Kamihara⁷, J. comander⁸, E. Place⁹, J. Wiggs⁸, R. Green²; ¹Massachusetts Gen. Hosp., Boston, MA, ²Brigham and Women's Hosp., Boston, MA, ³Dartmouth Children's Hlth.Ctr., Lebanon, NH, ⁴Boston Children's Hosp., Boston, MA, ⁵Children's Hosp. of Philadelphia, Philadelphia, PA, ⁶NIH, District of Columbia, DC, ⁷Dana Farber Cancer Inst., Boston, MA, ⁸Massachusetts Eye and Ear Inst., Boston, MA, ⁹Massachusetts Eye & Ear, Boston, MA

Abstract Body:

Newborn screening (NBS) is a public health program that has decreased morbidity and mortality among infants with rare disorders. The Recommended Universal Screening Panel for NBS state labs includes 35 core and 26 secondary conditions, but targeted treatments and management approaches for hundreds of additional genetic disorders are available. Efforts such as the NIH-funded BabySeq Project explore the implications of sequencing in healthy infants with the aim of designing strategies for implementation. We designed an online survey for rare disease experts (n = 398), investigating which additional treatable genetic conditions they recommend screening in newborns using genomic sequencing. We also assessed attitudes about the inclusion of disorders that are untreatable, lack confirmatory orthogonal tests, are of low penetrance, or are adult-onset. A total of 227 (57.0%) experts, including directors of genetics and genomics programs accredited by the Accreditation Council for Graduate Medical Education (n = 60), clinicians and academicians specializing in the care of rare disease patients (n = 158), and senior scientists within pharmaceutical companies specializing in rare disease therapeutics (n = 9) participated. We analyzed concordance among experts regarding screening specific genes in newborns, as well as assessed responses to a series of descriptive questions. We generated logistic regression models to predict which types of genes were most likely to be recommended for screening by experts, as well as identify the qualities of experts that predicted their likelihood to recommend the inclusion of additional genetic disorders. Experts agreed with $\geq 90\%$ concordance that 11 genes associated with disorders not currently included in universal NBS programs should be evaluated in presymptomatic infants (OTC, G6PC, SLC37A4, CYP11B1, F8, F9, CYP17A1, SLC2A1, ARSB, RB1, DMD). A total of 50 genes had $\geq 80\%$ concordance and 458 genes had $\geq 50\%$ concordance. Overall, 155 of 176 (88.1%) of experts agreed or somewhat agreed that genomic sequencing should be used to expand the number of conditions included in NBS. While several of these genes are associated with clinical domains that are currently included in NBS, there are multiple candidates that represent new frontiers for NBS, such as hereditary cancer predisposition syndromes. This study highlights that experts endorse the expansion of NBS programs to include additional treatable monogenic disorders, including 11 high-priority conditions which could be efficiently screened using genomic sequencing.

Abstract Body:

Context: The Ubiquitin-Proteasome System (UPS) is a major regulator of intracellular protein degradation -and subsequently proteostasis- in eukaryotic cells. A growing number of the 1200 genes constituting the UPS is associated with NeuroDevelopmental Disorders (NDDs), causing 10 to 15% of them. Our team has contributed to the identification of the first genes involved in proteasome-related NDDs: *PSMD12*, *PSMC3*, *BAP1* and *PSMC5*. Our objective is to better understand the pathophysiological mechanisms in play in patients with a UPS-related NDD (UPS-NDD), using cellular models. **Method:** In collaboration with French and international clinical and molecular geneticists, we have gathered blood samples from UPS-NDD patients, from whom we isolated and expanded T-cells. With this cell model, we have been studying the impact of UPS variants on proteostasis and inflammation, through the assessment of proteasomal function and structure, and the evaluation of type 1 interferon response. We have also been exploring the impact of our variants on the expression and regulation of partner proteins, that can be specific for each gene of interest. To further investigate the mechanisms involved, we have produced neuronal models derived from iPSCs, in order to analyze morphological development and, in parallel, gather multi-omics data to be compared to control cell lines. **Results:** To date, we have gathered in a dedicated biobank 170 samples from patients, and their unaffected relatives as controls, with variants in 30 UPS genes, encoding proteasomal subunits (*PSMA3*, *PSMA5*, *PSMB3*, *PSMB5*, *PSMB8*, *PSMB10*, *PSMC1-5*, *PSMD10-14*, *PSMD4*, *PSMD10-14*), ubiquitin-ligases (*CUL2*, *CUL3*, *CUL4B*) as well as deubiquitinases (*OTUD6B*, *USP7*, *USP8*, *USP11*, *USP14*, *BAP1*), therefore encompassing the 3 major actors of the UPS degradation pathway. Common underlying mechanisms in these UPS-NDDs are related to proteasomal enzymatic function, polyubiquitinated proteins aggregation, and abnormal type 1 interferon response. Preliminary results in Chip-Seq highlight dysregulated expression of genes already known for their role in neurodevelopmental processes and intellectual disability. **Discussion:** Current data suggest an overlap in the molecular mechanisms involved in the different UPS-NDDs explored. We wish to expand our study to all UPS-NDDs, thanks our collaborative network, in order to identify molecular keypoints involved in physiopathological processes. Identifying such markers will hopefully allow us to determine which tissues and cell types are the most relevant, to establish reliable genotype-phenotype correlations, and target specific levers for further therapeutic screening.

Mendelian Phenotypes Posters - Thursday

PB1833. Exploring cancer cachexia on the spatial plane

Authors:

Y. Park, L. Song, B. Paulhus, B. Albuquerque, Z. Wu, J. Kim-Muller, B. Zhang, E. Fauman, K. Hales; Pfizer, Cambridge, MA

Abstract Body:

Cachexia is a serious but underrecognized consequence of many chronic diseases characterized by unintentional weight loss, anorexia, muscle/fat wasting, fatigue, muscle weakness and chronic inflammation. The prevalence of cachexia ranges from 20-30% per year in chronic heart failure and chronic kidney disease to 50-80% in advanced cancers. Cachexia is associated with generally poor quality of life and poor prognosis across all affected patients. Growth differentiation factor 15 (GDF15) is a circulating protein implicated in energy homeostasis and body weight regulation. Circulating levels of GDF15 cause anorexia, emesis and weight loss in preclinical species, and correlate with cachexia and reduced survival in patients with cancer. GDF15 inhibition effectively reverses weight loss, muscle and fat loss in mouse models. Interestingly, it remains unclear whether cachexia and GDF15 inhibition have cell-specific effects and whether muscle weakness and muscle atrophy can both be reversed by GDF15 inhibition. We investigated these questions in a mouse tumor model, TOV21G, using a potent and selective monoclonal anti-GDF15 antibody (mAB2) that neutralized circulating GDF15. mAB2 globally reversed cachexia including weight loss, lean and fat mass loss as well as declined muscle function and physical performance in tumor bearing mice. Comprehensive mapping of tissue, cell and disease architecture via spatial transcriptomics (spRNAseq) offers the promise of understanding their modes of dysfunction in the context of intact tissues. We applied Visium H&E protocol to skeletal muscle from non-tumor-bearing mice and tumor-bearing mice with/without mAB2. We also developed and optimized a novel Visium quadplex IF protocol to probe MHC1, MHC2a, MHC2b and WGA. We profiled spRNAseq data deconvolved at single cell resolution using snRNAseq, validated histological fiber typing within each sample and identified rare cell types such as FAPs and tenocytes. Anatomical features such as vasculature were defined by combining communities of cell types. We investigated whether mAB2 has cell-specific effects on atrophy as measurable by fiber size and muscle weight. We identified several novel genes that are significantly associated with TOV21G-induced tumors and subsequently reversed by mAB2 treatment in a fiber- and anatomical-region-specific manner. Together, our findings suggest that spatial data can be used to identify fiber- and anatomical-region-specific effects of cachexia and mAB2 treatment with histological context. Our study demonstrates the great potential for spatial data to be used in therapeutic target validation and exploration of complex diseases.

PB1834. Exploring the distinct phenotypes of nine Romanian patients harboring a homozygous Arg355* variant in *BBS12*

Authors:

I. Focsa^{1,2}, C. Rusu^{3,4}, M. Pânzaru^{3,4}, L. Butnariu^{3,4}, M. Budisteanu^{5,6,7}, L. Bohiltea¹, A. Tutulan-Cunita², D. Stambouli², S. Khan⁸, E. Davis⁸, M. Balgradean^{1,9}; ¹Univ. of Med. Carol Davila, Bucharest, Romania, ²Cytogenomic Med. Lab., Bucharest, Romania, ³Gr T Popa Univ. of Med. and Pharmacy, Iasi, Romania, ⁴Regional Med. Genetics Ctr., “Sf. Maria” Children’s Hosp., Iasi, Romania, ⁵Psychiatry Res. Lab., “Prof. Dr. Alexandru Obregia” Clinical Hosp. of Psychiatry, Bucharest, Romania, ⁶Med. Genetic Lab., “Victor Babeş “Natl. Inst. of Pathology, Bucharest, Romania, ⁷Faculty of Med., “Titu Maiorescu” Univ., Bucharest, Romania, ⁸Stanley Manne Children’s Res. Inst., Ann & Robert H. Lurie Children’s Hosp. of Chicago, Chicago, IL, ⁹Dept. of Pediatrics and Pediatric Nephrology, Emergency Clinical Hosp. for Children “Maria Skłodowska Curie”, Bucharest, Romania

Abstract Body:

Bardet Biedl syndrome (BBS; MIM 209900) is a rare primary ciliopathy that is distinguished by significant genetic and clinical heterogeneity. The core features of the disease are rod-cone dystrophy, postaxial polydactyly, central obesity, urogenital anomalies, learning difficulties and kidney disease. In addition, the impairment of any organ or system may complicate the clinical picture. Twenty-seven genes have been associated with BBS pathogenesis, of which *BBS12* accounts for about 10% of cases of European origin. Here we report the clinical findings of nine patients harboring a homozygous p.Arg355* variant in *BBS12*. Five females and four males from eight unrelated pedigrees were recruited; their ages are between 2 months and 21 years and two individuals are siblings. Ophthalmological assessment confirmed retinal degeneration in five patients while two additional individuals displayed poor vision, however the latter two cases have not been investigated clinically. The other two patients are under the age (2 months and 1 year 7 months, respectively) of development of rod-cone dystrophy symptoms. Polydactyly was observed in all patients, affecting either all four limbs, only the feet, both feet and one hand or left limbs. Obesity was noted in all individuals, with body mass index exceeding the World Health Organization growth standards with 3.2 to 19 deviations. Learning difficulties were present in seven of seven assessed patients ranging from mild to severe. Genitourinary abnormalities were seen in eight patients while different kidney defects, either structural or functional, affect five of eight assessed individuals. Additional clinical findings including neurodevelopmental and behavioral abnormalities, liver involvement, endocrine and metabolic abnormalities, oral-dental anomalies, craniofacial dysmorphic features, or cardiovascular impairment were variably present in our cohort. Detailed clinical assessment of multiple individuals harboring the same primary causal variant confirms the heterogeneous clinical features among individuals and across families shown in previous reports on BBS.

Mendelian Phenotypes Posters - Thursday

PB1835. Family with case of HMG-CoA lyase deficiency with novel pathogenic variant in *HMGCL*

Authors:

T. Froukh; Philadelphia Univ., Amman, Jordan, Jordan

Abstract Body:

3-Hydroxy-3-methylglutaryl coenzyme A lyase deficiency is a rare autosomal recessive disorder characterized by metabolic acidosis without ketonuria, hypoglycemia, and elevated urinary organic acid metabolites including 3-hydroxy-3-methylglutaric, 3-methylglutaric, and 3-hydroxyisovaleric acids. Clinical signs include irritability, lethargy, coma, hepatomegaly and recurrent vomiting. Here, I report a consanguineous family-first cousin parents- with five children, three of them died shortly after death and before diagnoses, one child is healthy and another (born on October 18 2014) experienced similar symptoms to her three dead siblings and she is still alive. The family remained undiagnosed until the exome sequence was read to the index patient in September 2021. The following homozygous variant was identified in the gene *HMGCL* ENST00000374490:c.498-1G>A probably affecting the splicing and thus the final protein structure. The variant was confirmed by sanger sequencing and found to be heterozygous in the parents and in the healthy sibling and therefore the family is diagnosed with HMG-CoA lyase deficiency and is considered the cause of the dead sibling. However, the currently alive affected patient experienced the symptoms of the disease in the past and is currently experiencing mild symptoms. The likely explanation is a random effect of the variant on splicing which might range from very severe, observed in the passed away children, to mild as observed in the still alive patient.

Mendelian Phenotypes Posters - Wednesday

PB1836. First patient reported with a *TPP1* missense mutation pathogenic variant predicted in silico causing *CLN2*

Authors:

L. Moreno Giraldo¹, E. Austin Ward²; ¹Univ. del Valle, Univ. Santiago de Cali, Univ. Libre, Cali, Colombia, ²Hosp. Especialidades Pediátricas (HEPOTH) CSS, Panamá. Hosp. Pacífica Salud, Inst. de Investigaciones Científicas y Servicios de Alta tecnología. Panamá, Panama, Panama

Abstract Body:

Patient 6 years old female, second child born from a nonconsanguineous couple, by cesarean section because of a previous cesarean delivery. Her development was normal until 3 years when she began with tonic-clonic seizures, initially treated with Levetiracetam 4mg/kg. At this age, simple Brain MRI showed a generalized increase in the arachnoid space. An Epilepsy Panel at Invitae™ was performed at age 6. This report included one pathogenic variant and other four variants categorized initially as VUS at that moment. Both the pathogenic and three VUS were in heterozygosis. A variant in *TPP1* gene was reported in homozygosis (c.614T>C (p. Ile205Thr). The bioinformatic analysis of all the variants found, using bioinformatic software, reported a pathogenic clinical significance in the variants reported in the *ARSA*, *COL18A1* and *TPP1* genes; the variant in the *ADAR* gene had benign clinical significance, and the variant in *PCLO* was classified as Unclear Significance; In addition, all variants are currently reported. We present a non-previously reported pathogenic variant of *TPP1* in a patient, although predicted by in silico analysis. *TPP1* is the gene responsible for the enzymatic functioning of tripeptidyl peptidase 1, found in lysosomes. Tripeptidyl peptidase 1 acts as a peptidase, cleaving peptides into groups of three amino acids. This case is especially important for our Latin-American region, which is genetically sui generis and for the patient's country of origin, being the first patient with *CLN2* diagnosed to date.

Mendelian Phenotypes Posters - Thursday

PB1837. First report of severe hemolysis associated with *SCARB1*

Authors:

P. Tanpaiboon^{1,2}, M. Gotesman², E. Panosyan², X. Qing³, J. M. J. Graham², H. J. Lin²; ¹Quest Diagnostics, San Juan Capistrano, CA, ²Dept. of Pediatrics, Harbor UCLA Med. Ctr., Torrance, CA, ³Dept. of Pathology, Harbor UCLA Med. Ctr., Torrance, CA

Abstract Body:

Scavenger receptor class B member 1 is encoded by the *SCARB1* gene on chromosome 12q24.31. The receptor is essential for reverse cholesterol transport by mediating uptake of high-density lipoprotein (HDL) by the liver and free cholesterol efflux from tissues to HDL. Three variants (c.335C>T, c.523A>G, and c.889C>T) in *SCARB1* have been associated with high HDL levels and subclinical atherosclerosis in both homo and heterozygous adults. *SCARB1* variants have not been associated with any other significant phenotypes in humans. We report a neonate with severe hemolysis, elevated cholesterol and HDL levels, and biallelic *SCARB1* variants.

The male infant was born at 36 weeks' gestation. He developed severe jaundice and anemia within the first 24 hours of life. The highest total bilirubin level was 17 mg/dL, and the lowest hemoglobin was 7.4 g/dL. A peripheral blood smear showed numerous acanthocytes. Results of Coombs tests (direct and indirect), G6PD and pyruvate kinase enzyme assays, and hemoglobin electrophoresis were normal. Exome sequencing showed compound heterozygous variants of uncertain significance in *SCARB1*. One variant was a maternally inherited ~7.10 kb deletion encompassing exons 3 to 6 with breakpoints in introns 2 and 6. The second variant was a paternally inherited c.1133C>T change (p.T378M), which has been reported in the compound heterozygous state with another *SCARB1* variant in an individual with hypercholesterolemia. Lipid profiles collected after exome sequencing showed elevated total cholesterol (281 and 241 mg/dL; normal 64-237) and HDL (84 and 68 mg/dL; normal 12-71) levels at 8 and 11 months of age, respectively. The child was doing well at 2.5years, with normal blood counts, he did not receive any treatment after discharge.

The above testing excluded enzymopathies, membranopathies, and hemoglobinopathies as causes of the infant's nonimmune hemolysis and acanthocytosis. Elevated cholesterol and HDL levels were consistent with levels reported for adult patients and support the pathogenicity of these *SCARB1* variants found by exome sequencing.

To our knowledge, this is the first report of hemolytic anemia associated with *SCARB1* variants. Liao et al. (2015) found that *SCARB1* knockout induced hemolysis in hypercholesterolemic mice, hypothesizing that high plasma levels of free cholesterol caused hemolysis by disrupting erythrocyte membranes. Our findings suggest a link between *SCARB1* variants and hemolysis-related membranopathies in humans; functional studies are needed to assess whether such variants have a causative role

Mendelian Phenotypes Posters - Wednesday

PB1838. Fracture prevalence in children diagnosed with Ehlers-Danlos Syndrome and Generalized Joint Hypermobility

Authors:

F. Yeung, J. Smith, **R. Mendoza**, C. O'Connor, A. Howard, J. Sorbara, S. Schwartz; Hosp. for Sick Children, Toronto, ON, Canada

Abstract Body:

Background: Given the substantial consequences for patients and their families, physicians must consider medical conditions that may predispose to injuries seen in cases of suspected child abuse. Recently, hypermobile Ehlers-Danlos Syndrome (hEDS) and hypermobility have been raised as a possible cause for fractures in infants. However, there is no clear evidence to support this hypothesis in the limited pediatrics literature, and no fractures have been documented in infants <1 year of age with EDS. Despite this, the small sample size of this literature continues to be a limitation and hEDS and hypermobility continue to be brought up in the legal setting as a possible cause of unexplained fractures in infants. Thus, we sought to add to the existing literature by assessing fracture prevalence and fracture characteristics in a population of children diagnosed with EDS and Generalized Joint Hypermobility (GJH) by a specialized EDS clinic.

Methods: This retrospective descriptive study identified children aged 0-17 years who were assessed and diagnosed by the EDS clinic with EDS or GJH from April 1st, 2017 - December 15th, 2021. This clinic adhered to the 2017 international EDS diagnostic criteria. Cases were included if they had a history of one or more fractures. Cases were excluded if there were concurrent medical diagnoses and/or use of medications that were known to be associated with bone fragility. Data collection included the subtype of EDS, fracture location, fracture type, age of sustaining each fracture, and injury mechanism. Descriptive statistics were used to analyze the data.

Results: 30 cases of EDS and 60 cases of GJH were identified. Of the EDS patients, 6 were hypermobile type. Four patients were excluded due to underlying medical conditions. Fracture prevalence in the EDS population was 26.7% (8/30). 2 of 6 patients with hypermobile EDS had fractures. Of the fractures with a reported age at time of injury, none occurred at < 2 years of age. In the GJH group, fracture prevalence was 25% (15/60) and no fractures occurred at < 17 months of age. In both groups, all fractures occurred in the limbs, with the exception of 4 fractures which had clear accidental explanations (broken nose after punch, fall on trampoline, fall during cheerleading). There were no rib or skull fractures. Most fractures were the result of an identifiable accidental injury event.

Conclusion: This study supports that children with EDS or GJH do not have an increased prevalence of unexplained fractures in infancy. All fractures occurred in ambulatory age groups. Most fractures were in the limbs and/or were the result of a clearly identified accidental injury event.

Mendelian Phenotypes Posters - Thursday

PB1839. Fragile X Syndrome in a female patient: A case of strong family history and developmental delay.

Authors:

B. Marbaker, R. Lebel, M. Byler, N. Brescia; Upstate Med. Univ., Syracuse, NY

Abstract Body:

Introduction Fragile X Syndrome (FXS) is caused by a triplet repeat expansion in the *Fragile X Mental Retardation 1 (FMR1)* gene on the X chromosome. It manifests with intellectual and developmental disability (especially speech delays and autism spectrum behaviors), macroorchidism in adult males, and a long face with large ears and prognathism. Given its X-linked recessive inheritance pattern, FXS more commonly affects males and is one of the most common inherited causes of intellectual and developmental disability in this population. Females who inherit a full mutation can also exhibit the characteristic developmental phenotype.

Case Description A 15mo female patient with an extensive family history of FXS was referred to genetics after developmental delay and hypotonia were noted. The patient was born at 39 weeks to a 32 year old G4P3>4 mother and a 58 year old father via spontaneous vaginal delivery. Ultrasound and maternal serum screen were unremarkable prior to delivery and there were no pre- or post-natal complications. She exhibited no apparent dysmorphic features and had been growing appropriately but had mild diffuse hypotonia and was delayed in reaching speech and motor milestones. Family history is significant for *FMR1* premutation (70 repeats) in her mother and FXS in two maternal half-brothers and a maternal half-sister. Her mother's paternal half-sisters (monozygous twins) are each premutation carriers, and each has a son affected with FXS. There is no known family history of premature ovarian failure or tremor/ataxia. The patient's Fragile X repeat analysis confirmed a diagnosis of FXS with 24 CGG repeats on one X chromosome and >200 repeats on the other.

Discussion The typically milder phenotype and wide range of severity in female patients with FXS is related to the degree of X inactivation in females who inherit the full mutation. If X inactivation is skewed toward silencing the wild-type *FMR1* allele, less protein product is produced and a more severe phenotype would be expected. Although some female patients affected with FXS display the characteristic facial features, intellectual or developmental delay may be the sole sign of FXS in a female patient. Genetic testing should be considered in any such patient.

Conclusion Fragile X Syndrome is an important diagnostic consideration for any child, male or female, who presents with intellectual or developmental delay. Molecular testing and genetic counseling should be considered for patients and their families in cases of unexplained intellectual or developmental disability, or where a family history of FXS, POI, or FXTAS exists.

Mendelian Phenotypes Posters - Wednesday

PB1840. Frameshift *PPP1R12A* pathogenic variant in a mexican patient with differences of sex development (DSD), middle line defects and hemangiomas.

Authors:

S. Contreras-Capetillo¹, M. Abreu-Gonzalez², Y. Centeno-Navarrete³, S. Ferro-Muñoz⁴; ¹Univ. Autonomous of Yucatan, Merida, Mexico, ²Genos Medica, Ciudad de México, Mexico, ³Hosp. Gen. Dr. Agustín O'Horán, Merida, Mexico, ⁴Hosp. Lic. Ignacio García Téllez, Merida, Mexico

Abstract Body:

Differences of sex development (DSDs) are heterogeneous group of congenital conditions in which chromosomal, gonadal, or anatomical sex do not match. An accurate diagnosis is essential for the care and quality life of the patient, so it must be evaluated by a multidisciplinary team between genetics, endocrinology, urology and surgery. Recently, Hughes et al. reported pathogenic variants in the *PPP1R12A* gene associated with defects in the embryogenesis of the central nervous system and the urogenital system. Here we describe a female assigned patient with hypertelorism, multiple skin hemangiomas and ambiguous genitalia in whom a c.1880delC in *PPP1R12A* was detected. This report main objective is to expand the phenotype of *PPP1R12A* pathogenic variant.

Mendelian Phenotypes Posters - Thursday

PB1841. Frequency of Y chromosome microdeletion and its correlation with spermatogenesis defect in north Indian infertile males.

Authors:

H. Sharma¹, R. Mavaduru², S. Singh², R. Prasad²; ¹AIIMS Bathinda, Bathinda, India, ²PGIMER Chandigarh, Chandigarh, India

Abstract Body:

Deletion in the long arm of Y chromosome is considered as the most common genetic cause of defective spermatogenesis. However, due to variable environmental influence and genetic factors the frequency of the Y chromosome microdeletion is heterogenous in different population. Further, there is paucity of data pertaining to significant correlation between phenotypic and genotypic profile among Indian fertile males with Y-chromosome microdeletion. Hence, the study was aimed to ascertain the frequency of Y chromosome microdeletion in 292 idiopathic cases of male infertility from northern region of India and an attempt was also made to define the subgroup of patients which are at higher risk of harbouring Y chromosome microdeletion based on their phenotype. Frequency of Y chromosome microdeletion in north Indian infertile males was found to be about 8.5%, with azoospermia factor (AZFc) region as the most susceptible region for microdeletion. Comparatively microdeletion is more common in patients with nonobstructive azoospermia than oligozoospermia (9.2% versus 7.1%). Statistical analysis also revealed that patients with hormonal FSH level between 20 and 40 mIU/mL have more chances of harbouring microdeletion. Hence, we conclude, incidence of Y chromosome microdeletion are more common in northern region of India with AZFc region as most susceptible for deletion. Therefore, all infertile couples specifically those with higher FSH level should be advised for Y chromosome microdeletion screening before undergoing any ART procedure.

Mendelian Phenotypes Posters - Wednesday

PB1842. Functional analysis of *EZH1-A678G* in *Drosophila melanogaster*

Authors:

S. Jangam^{1,2}, L. C. Briere³, K. Jay^{1,2,4}, J. Andrews^{1,2}, M. Walker⁵, F. High⁶, L. Rodan⁷, Undiagnosed Disease Network, H. Bellen^{1,2}, S. Yamamoto^{8,2}, D. Sweetser^{6,3}, M. Wangler^{1,2,4}; ¹Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, ²Jan and Dan Neurological Res. Inst., Texas Children's Hosp., Houston, TX, ³Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA, ⁴Genetics and Genomics Program, Baylor Coll. of Med., Houston, TX, ⁵Dept. of Neurology, Div. of Neurogenetics, Child Neurology, Massachusetts Gen. Hosp., Boston, MA, ⁶Div. of Med. Genetics & Metabolism, Massachusetts Gen. Hosp., Boston, MA, ⁷Dept. of Neurology, Boston Children's Hosp., Boston, MA, ⁸Dept. of Molecular and Human Genetics, Baylor Coll. of Med., HOUSTON, TX

Abstract Body:

Genetic mutations in DNA histone modifiers have been shown to disrupt key signaling pathways leading to developmental disorders. *EZH1* (*Enhancer of Zeste 1, Polycomb Repressive Complex 2 Subunit*), a component of Polycomb Repressive Complex-2 (PRC2), promotes maintenance of embryonic stem cell pluripotency by modifying histones at H3 Lysine27 (H3K27). The methyltransferase activity of *EZH1* containing PRC2 complex suppresses downstream target genes by H3K27-trimethylation (H3K27me3). *EZH1* has not yet been associated with any disorders. Here we report a novel *de novo* variant in *EZH1*, *p.Ala678Gly*, resulting in a novel neurodevelopmental phenotype. The patient, evaluated at 2.5 years of age, has a severe global developmental delay, mixed tone, proximal muscle weakness, and intermittent exotropia. While there is no history of seizures, EEG was indicative of mild diffuse cerebral dysfunction. The patient also has mild short stature with preserved head circumference, small hands and feet, mild dysmorphisms, and hypopigmentation. This variant, *EZH1-A678G*, is in a well-conserved motif, the SET domain, which is required for methyltransferase activity. Human *EZH1* is homologous to the *Drosophila Enhancer of zeste (E(z))* gene, and the residue is conserved throughout the species including flies. To study its functional aspect *in vivo*, we generated transgenic flies expressing wildtype (*E(z)WT*) and the variant (*E(z)-A691G*) under the constitutively active tubulin promoter. The resulting variant flies showed a significant bang-sensitive phenotype similar to seizures in humans. Knowing the methyltransferase activity of *E(z)*, we quantified H3K27me3 in those flies and observed hyper H3K27me3 in the variant when compared to wildtype or control. This indicates a gain-of-function mechanism of the variant. In the presence of one *E(z)* null allele (sensitized background), the wildtype transgene resulted in a reduction in H3K27me3, but the variant did not show a significant change. Complete loss of *E(z)* in the fly is lethal, *E(z)WT* rescued the lethality completely, while *E(z)-A691G* rescued it partially. These data suggest that this variant is dominant-negative gain-of-function in nature. Interestingly, while this variant has never been observed in *EZH1*, the human paralogue, *EZH2*, has the identical amino acid variant *EZH2-A677G*, which also results in hyper H3K27me3, supporting our *Drosophila* studies. In conclusion, the *de novo* incidence and evolutionary constraint of this variant, along with the *in vivo* functional studies strongly suggest a novel syndrome for *EZH1* related disorders.

Mendelian Phenotypes Posters - Thursday

PB1843. Functional characterization of recurrent truncating variant in *UBAPI* associated with hereditary spastic paraplegia.

Authors:

S. Gu¹, N. Ho¹, I-J. Lin¹, K-K. Lee¹, L. Meng²; ¹The Chinese Univ. of Hong Kong, Hong Kong, Hong Kong, ²Baylor Coll. Med., Houston, TX

Abstract Body:

Hereditary spastic paraplegias (HSPs) are a group of genetic neurodegenerative diseases resulting from the axonal degeneration of the corticospinal upper motor neurons. Dismayingly however, the molecular diagnosis of more than half of HSP patients and the pathogenicity mechanisms of most HSP genes remain unknown. Recently, our group and others independently identified a novel gene, *UBAPI* (ubiquitin associated protein 1), as causative for autosomal-dominant HSP via clinical exome sequencing analyses. All affected individuals showed highly comparable clinical presentations of non-syndromic HSP, with almost identical disease onset age of around eight years old. To understand the mechanism underlying *UBAPI*-associated disease, we conducted cellular and model organism studies to authentically reproduce the pathogenicity observed in patients. Specifically, applying CRISPR/Cas9 genome editing, we established human embryonic stem cells (hESCs) and a mouse model harboring a patient-specific frameshift variant that was observed in more than half of *UBAPI*-HSP patients. *UBAPI* encodes a highly conserved and ubiquitously expressed protein. It is a component of the endosome-specific ESCRT-I complex that functions to sort ubiquitinated cargo and to maintain endosomal ubiquitin homeostasis. This two base-pair deletion led to stable expression of a truncated protein, which retained the ESCRT-I binding domain yet lost the ubiquitin interaction domains. We therefore proposed that the truncated protein exert a dominant-negative effect on its normal function, as it could still be recruited by the ESCRT-I complex yet lost the ability to interact with ubiquitinated proteins. Consistent with the proposed mechanism, we observed vesicle accumulation and enriched ubiquitinated proteins in mutant cells comparing to wildtype cells. Additionally, mutant hESCs-derived upper motor neuron organoids demonstrated reduced neurite outgrowth and axon length, resembling the hallmark phenotype in HSP patients. Further, mutant mice exhibited hindlimb motor defects starting from 6 months old, which were illustrated by beam walking and hindlimb clasping tests. Currently, besides identifying and quantifying the accumulated ubiquitinated proteins in mutant cells through mass spectrometry, we are also investigating the distinct pathogenicity of heterogeneity in mouse brains upon *Ubp1* mutation via single-nucleic transcriptome analysis. Our studies will elucidate not only the pathogenicity of *UBAPI*, but also its role in maintaining endosomal dynamics, providing an authentic preclinical model system for future therapeutic studies of HSP.

Mendelian Phenotypes Posters - Wednesday

PB1844. Gaps in the phenotype descriptions of ultra-rare genetic conditions: Systematic review and recommendations

Authors:

A. Almail¹, A. Jamjoom², A. Pan³, N. Jewitt⁴, C. Diskin⁴, D. Baribeau⁵, G. Costain²; ¹Univ. of Toronto, Temerty Faculty of Med., Toronto, ON, Canada, ²The Hosp. for Sick Children, Toronto, ON, Canada, ³Univ. of Toronto, Dept. of Molecular Genetics, Toronto, ON, Canada, ⁴The Hosp. for Sick Children, Dept. of Pediatrics, Toronto, ON, Canada, ⁵The Hosp. for Sick Children, Dept. of Psychiatry, Toronto, ON, Canada

Abstract Body:

Background: Genome-wide sequencing and genetic matchmaker services are propelling a new era of genotype-first ascertainment of novel ultra-rare diseases. The degree to which reported phenotype data address informational priorities for clinicians and families is unclear. We hypothesize that current phenotype descriptions limitedly address questions of adaptive functioning, feeding and growth, medication use, and proxies for quality of life.

Methods: We systematically reviewed the literature to identify reports of novel genetic conditions published from 2017-2021 where ascertainment was genotype-first. Reports were assessed by two independent raters regarding the adequacy of phenotype data provided in these domains: (I) Development, cognition, adaptive functioning, behavior, and mental health; (II) Feeding, growth, and nutrition; (III) Medication use and treatment history; and (IV) Pain, sleep, and quality of life.

Results: In total, 200 of 3243 screened publications met inclusion criteria. Preliminary analysis of the reported phenotype data revealed superficial descriptions and numerous gaps in the four phenotype domains in the majority of publications. Common issues included lack of detail regarding the severity of developmental delays / intellectual and developmental disabilities, use of general descriptions like “feeding difficulties” and “behavior problems”, and little to no information about past treatment trials (e.g., anti-epileptic and psychotropic medications).

Conclusion: Phenotype information relevant to clinical management, genetic counseling, and the stated priorities of patients and families is lacking in many descriptions of new ultra-rare genetic diseases. We propose a checklist to guide phenotype data collection and reporting.

Mendelian Phenotypes Posters - Thursday

PB1845. *GATA3*-related pedigrees showing characteristic audiologic profile and inheritance pattern.

Authors:

B. Kim¹, J. Han^{1,2}, Y-M. Kim¹, B. Choi²; ¹Chungnam Natl. Univ. Coll. of Med./Chungnam Natl. Univ. Sejong Hosp., Sejong, Korea, Republic of, ²Seoul Natl. Univ. Bundang Hosp., Seongnam, Korea, Republic of

Abstract Body:

GATA binding protein 3 (*GATA3*) is a protein encoded by *GATA3* gene, which is associated with autosomal dominantly-inherited Hypoparathyroidism, Deafness, and Renal Dysplasia (HDR) syndrome (MIM no. 146255). The phenotypes of HDR syndrome are known to vary and sometimes symptoms related to hypoparathyroidism and renal disease are subclinical, which makes it challenging to diagnose the syndrome in the patient predominantly presenting with hearing loss. Here, we report three sporadic cases who first presented with asymmetric, low-frequency hearing loss, and eventually are diagnosed as having *GATA3* variants-related HDR syndrome by molecular genetic diagnosis and luciferase assay.

A 14-year-old girl and a 21-year-old man presented with asymmetric moderate degree low-frequency hearing loss. Screening panel of deafness genes followed by exome sequencing revealed two potential candidate variants of *GATA3* (c.404del:p.Pro135Argfs*60 and c.1015T>C:p.Cys339Arg (novel variant) respectively) in each family. Luciferase assay using Wildtype and two *GATA3* variants co-transfected with *KLRC1* promoter into HEK293T cell line, showed reduced luciferase activity in these two variants than wildtype, further confirming the pathogenic potential of the two variants. Another 1-year-old boy was referred for hearing evaluation and asymmetric moderate hearing loss was found, although frequency-specific hearing threshold was not adequately obtained because of young age. Exome sequencing identified c.1099C>T:p.Arg367* of *GATA3* as a causative variant. Segregation study confirmed de novo inheritance pattern in three pedigrees and subsequent laboratory and radiologic evaluation revealed varying degree phenotypes of HDR syndrome in all three patients, which are mostly subclinical, but should be adequately managed.

Taken together, we report three *GATA3* pedigrees, initially presenting with hearing loss, finally diagnosed of HDR syndrome. Luciferase assay assisted proving the pathogenicity of each variant and de novo inheritance pattern and asymmetric, low-frequency audiogram pattern observed in these pedigrees could be a notable clue for further pursuit of *GATA3*-related HDR syndrome. This genetic diagnosis-driven revelation of varying degree symptoms of HDR syndrome should also be noted from clinical perspectives.

Mendelian Phenotypes Posters - Wednesday

PB1846. Genealogy as a predictor of disease progression in patients with myotonic dystrophy type 1: A demonstration of the power of intersectorial research.

Authors:

J. Bouchard¹, C. Moreau¹, L. Gagnon¹, A. Girard², H. Vezina¹, A. Barry¹, C. Gagnon³, É. Duchesne¹, S. Girard⁴, ¹Université of Québec at Chicoutimi, Chicoutimi, QC, Canada, ²Univ. of Quebec in Chicoutimi, Chicoutimi, QC, Canada, ³Univ. of sherbrooke, Chicoutimi, QC, Canada, ⁴Université du Québec à Chicoutimi, Chicoutimi, QC, Canada

Abstract Body:

Background/Objectives: Myotonic dystrophy type 1 (DM1) is an autosomal dominant disease and is the most common form of muscular dystrophy in adults. DM1 is caused by an abnormal repetition of a CTG nucleotide triplet located on the DMPK gene. DM1 is classically categorized into five phenotypes based on the age of onset and the number of CTG repeats. The presence and severity of signs and symptoms, as well as their progression, vary greatly not only between but also within the phenotypes. However, there is a lack of knowledge in identifying the predictors of multisystemic impairments associated with DM1. The objective of this study was to verify if genealogical kinship-based clustering could be used to better understand the severity and progression of physical impairments in DM1. Our research team proposes an innovative method combining a large genealogical dataset with an extensive DM1 patients' clinical collection. **Methods:** The cohort is composed of 200 participants from the Saguenay-Lac-St-Jean region in Quebec who participated in a longitudinal study over 20 years. Our team has collected several clinical measures related to the progression of the disease including grip strength, forced vital capacity, walking speed, balance and upper- and lower-limb maximal muscle strength measurement. We have also conducted a deep characterization of CTG repeat length for each patient including the presence of interruptions. Additionally, we took advantage of the BALSAC population database (based on linked civil and church records) to reconstruct the genealogies of the participants. Genealogical kinship-based clustering was performed at different generations in order to identify individuals and families with high levels of kinship. **Results:** As previously reported, we observed that the CTG repeat number did not correlate strongly with severity. Correlations with muscle impairment measurements were tell us more. Using our deep genealogical records, we were able to identify several clusters of families with higher kinship values. We currently investigate if certain family clusters present different profiles of disease severity, CTG repeats and muscle impairments. Additionally, the genealogical clusters at different generations will be compared with the severity of the disease to verify if they could become a marker for earlier therapies in order to improve the prognosis in DM1. **Conclusion:** We report here one of the first studies that aims to bridge genealogical structures with clinical measures in DM1. This research will increase our understanding of a disease caused by a nucleotide repeat in a population with a strong founder effect.

Mendelian Phenotypes Posters - Wednesday

PB1848. Genetic analysis reveals that GNE Myopathy remains an underdiagnosed neuromuscular disorder

Authors:

F. Rossignol, P. Leoyklang, M. Malicdan, C. Ciccone, Q. Yuan, J. Jang, A. Bowling, N. Carrillo, W. Gahl, M. Huizing; NHGRI, NIH, Bethesda, MD

Abstract Body:

GNE encodes the rate-limiting, bifunctional enzyme of sialic acid biosynthesis, UDP-*N*-acetylglucosamine 2-epimerase/*N*-acetylmannosamine kinase (*GNE*). Bi-allelic variants, mostly missense, underlie recessively inherited *GNE* myopathy, an adult-onset progressive myopathy due to decreased sialylation of muscle glycoconjugates. The recent expansion of molecular testing and inclusion of *GNE* in neuromuscular disease panels greatly increased diagnosis and identification of new *GNE* gene variants. Since the clinical presentation at onset of disease is non-specific and the majority of *GNE* variants are missense, the interpretation of pathogenicity of each variant for a correct diagnosis remains a challenge. To support our *GNE* myopathy natural history study and clinical trial with the sialic acid precursor *N*-acetylmannosamine (ManNAc) (ClinicalTrials.gov: NCT01417533, NCT04231266), we assembled a comprehensive list of 285 *GNE* gene variants associated with *GNE* myopathy reported in the literature to date, including pathogenicity classification according to American College of Medical Genetics (ACMG). We also listed the bi-allelic variants of all reported genotyped *GNE* myopathy patients (1221 cases worldwide). Reported *GNE* variants not associated with *GNE* myopathy, including those causing the dominantly inherited disorder sialuria or those associated with thrombocytopenia, are also discussed, as they may obscure the *GNE* myopathy diagnosis.

Based on allele frequencies in gnomAD, the world-wide prevalence of *GNE* myopathy was estimated to be at least 2.5/1,000,000. This unrecognized high prevalence (~ 20,000 patients worldwide; ~850 patients in USA) confirms suspicions that many patients escape diagnosis. Indeed, our ongoing natural history study revealed significant diagnostic delay (~9 years) after initial symptoms in most patients, due to the rare nature of the disease and the lack of conclusive, inexpensive diagnostic tests. Genetic testing for pathogenic, bi-allelic *GNE* variants ultimately confirms the diagnosis.

GNE myopathy should be considered in any young adult with distal, lower extremity muscle weakness. Delayed diagnosis causes emotional hardship for the patient, postpones proper disease management, and influences eligibility to enroll in clinical trials. Awareness among physicians including neurologists and geneticists for *GNE* myopathy is essential for the identification of new patients, preferably in early stages of disease. This will support understanding early pathomechanisms of the disease and success of ongoing treatment trials.

Mendelian Phenotypes Posters - Thursday

PB1849. Genetic and clinical landscape of childhood cerebellar hypoplasia and atrophy.

Authors:

M. Sakamoto¹, N. Tsuchida^{1,2}, Y. Uchiyama^{1,2}, E. Koshimizu¹, A. Fujita¹, K. Hamanaka¹, K. Misawa¹, S. Miyatake^{1,3}, T. Mizuguchi¹, N. Miyake^{4,1}, N. Matsumoto¹; ¹Dept. of Human Genetics, Yokohama City Univ. Graduate Sch. of Med., Yokohama, Japan, ²Dept. of Rare Disease Genomics, Yokohama City Univ. Hosp., Yokohama, Japan, ³Clinical Genetics Dept., Yokohama City Univ. Hosp., Yokohama, Japan, ⁴Natl. Ctr. for Global Hlth.and Med., Tokyo, Japan

Abstract Body:

[Purpose] Cerebellar hypoplasia and atrophy (CBHA) in children is an extremely heterogeneous group of disorders, though few comprehensive genetic studies have been reported. [Methods] Using exome sequencing, patients with CBHA in 176 families were genetically examined and patients who have disease-causing variants were clinically evaluated. [Results] In 95 of the 176 families (54%), disease-causing variants were identified. After excluding six families unsuitable for further analysis, 47 patients from 41 families were categorized as having specific diseases associated with CBHA, while the remaining 51 patients from 48 families had true CBHA with and without supratentorial lesions (CBHA+S [N = 15] and CBHA-S [N = 36], respectively). In the 48 families, 26 aberrant genes were identified, of which 20 (76.9%) caused disease in a single family each, with long tail distribution. *CACNA1A*, *ITPR1*, and *KIF1A* were the most prevalent genes (8+8+6=22, 45.8%). Of the 26 aberrant genes, 14 were functionally annotated to cerebellar atrophy. CBHA-S was more clinically milder than CBHA+S. Notably, *ARG1* and *FOLR1* variants were identified in two families, for whom medical treatments were available. [Conclusion] This cohort revealed a wide genetic and clinical diversity of CBHA by exome sequencing, which highlights the importance of comprehensive genetic analyses. Furthermore, molecular-based treatment was possible for two families. Acknowledgments: We would like to thank all the following doctors: Sasaki M, Ishiyama A, Komaki H, Saito T, Takeshita E, Shimizu-Motohashi Y, Haginoya K, Kobayashi T, Goto T, Tsuyusaki Y, Iai M, Kurosawa K, Osaka H, Tohyama J, Kobayashi Y, Okamoto N, Suzuki Y, Kumada S, Inoue K, Mashimo H, Arisaka A, Kuki I, Saijo H, Yokochi K, Kato M, Inaba Y, Gomi Y, Saito S, Shirai K, Morimoto M, Izumi Y, Watanabe Y, Nagamitsu S, Sakai Y, Fukumura S, Muramatsu K, Ogata T, Yamada K, Ishigaki K, Hirasawa K, Shimoda K, Akasaka M, Kohashi K, Sakakibara T, Ikuno M, Sugino N, Yonekawa T, Gürsoy S, Cinleti T, Kim CA, Teik KW, Yan CM, Haniffa M.

PB1850. Genetic and phenotypic heterogeneity of childhood-onset hearing loss and implications for the success of cochlear implants.

Authors:

R. Carlson¹, T. Walsh¹, J. Mandell¹, A. Abu Rayyan¹, D. Horn², H. Ou², K. Sie², L. Mancl¹, J. Rubinstein¹, M-C. King¹; ¹Univ. of Washington, Seattle, WA, ²Seattle Children's Hosp., Seattle, WA

Abstract Body:

In the US, most childhood-onset hearing loss is genetic and highly heterogeneous with more than 120 causal genes and thousands of different causal alleles known. Cochlear implants are the management of choice for many children with hearing loss, and their success may be associated with the cause of the hearing loss. In a cohort of 449 children from 406 families treated for hearing loss at Seattle Children's Hospital or the University of Washington between 2019 and 2021, we evaluated the genetic causes of hearing loss and how these causes might contribute to cochlear implant success. Genomic DNA was evaluated by targeted sequencing of 191 genes and by structural variant analysis. Longitudinal audiologic testing was used to evaluate severity and progression of hearing loss, and longitudinal speech perception testing was used to evaluate success of cochlear implants. A genetic cause of hearing loss was found for 53% (213/407) of families, with causal mutations in 49 different genes. Age-specific audioprofiles over time revealed gene-dependent and allele-dependent variation in severity, affected frequencies, and progression with age. Hearing loss was significantly progressive for children with hearing loss due to mutations in *MYO6*, *OTOA*, *SLC26A4*, *TMPPRS3*, or severe loss-of-function mutations in *GJB2*. Cochlear implant success was high overall, with 89% of implanted patients scoring at least 60% on adult-level speech perception tests. Even so, level of success varied significantly by genotype (ANCOVA $P < 0.0001$). Cochlear implants benefitted children with hearing loss regardless of cause, but level of speech perception after implant varied by causal gene. Therefore, management of childhood-onset hearing loss can benefit from cochlear implantation undertaken in the context of genetic diagnosis. Supported by research grants from the Bloedel Foundation, the Ben B. Cheney Foundation, and by NIH/NIDCD 5R01DC011835.

Sci., Mashhad, Iran, Islamic Republic of, ⁹Dept. of Neuromuscular Diseases UCL Queen Square Inst. of Neurology, Univ. Coll. London, London, United Kingdom, ¹⁰Dept. of Med. Genetics, Next Generation Genetic Polyclinic, Mashhad, Iran, Islamic Republic of, ¹¹Ctr. for Inherited Cardiovascular Diseases, Great Ormond Street Hosp. and UCL Inst. of Cardiovascular Sci., Zayed Ctr. for Rare Disease Res., London, United Kingdom

Abstract Body:

Background: Inherited cardiomyopathies are a prevalent cause of heart failure and sudden cardiac death. Both hypertrophic (HCM) and dilated cardiomyopathy (DCM) are genetically heterogeneous and typically present with an autosomal dominant mode of transmission. However, in highly consanguineous populations, such as in the Middle East, there is a burden of autosomal recessive disease variants.

Methods: The study included 9 un-related probands from consanguineous Middle Eastern families presenting with HCM/DCM. Phenotypic assessment and diagnoses were based on cardiological investigations and clinical data, including echocardiography, resting and ambulatory 12-lead electrocardiogram, cardiac catheterization and cardiac MRI. Whole exome sequencing was carried out in the proband followed by bioinformatic and co-segregation analysis to predict the potential pathogenicity of candidate causal variants.

Results: We identified homozygous missense variants in *LDB3*, *TNNI3K*, *DOLK*, *DSP*, *DSC2*, *RBCK1* and *MYH6* linked with a dilated phenotype, in *NRAP* linked with a hypertrophic phenotype, and in *KLHL24* linked with a mixed phenotype of dilated/hypertrophic and non-compaction features. Co-segregation analysis by Sanger sequencing in available family members confirmed autosomal recessive inheritance associated with disease presenting either in early childhood or early adulthood.

Conclusions: Our findings add to the mutational spectrum of recessive cardiomyopathies, supporting inclusion of *KLHL24* and *NRAP* as disease-causing genes for cardiomyopathy. We also provide evidence for novel (recessive) modes of inheritance of well-established genes such as *TNNI3K* and *LDB3*, expanding our knowledge of the clinical heterogeneity of cardiomyopathies. A greater understanding of the genetic causes of cardiomyopathy, particularly in underrepresented populations such as the Middle East, has major implications for diagnosis and screening.

Mendelian Phenotypes Posters - Wednesday

PB1852. Genetic Mapping Identifies A Founder Mutation of *GHRHR* Gene in Pakistani Family with Isolated Growth Hormone Deficiency Type 4

Authors:

M. Khan¹, S. Ahmad², M. Ali², S. Abbas², I. Ahmed¹, S. Nawaz¹, M. Ziab¹, K. Fakhro¹, A. Akil¹; ¹Sidra Med., Doha, Qatar, ²Gomal Univ., D.I.Khan, Pakistan

Abstract Body:

Background Isolated growth hormone deficiency (IGHD) is characterized by growth and developmental failure in children due to disruption of the growth hormone (GH) or growth hormone releasing hormone (GHRHR). Patients with IGHD type IV have short stature, reduced serum growth hormone (GH) levels, and delayed bone age. **Objectives** Genetic mapping of familial IGHD cases to identify the mutation and explore its functional impact through *in silico* approaches. **Methods** In the present study, we ascertained a consanguineous IGHD family comprising of four patients. Clinical and radiological studies of the affected individuals were performed for deep phenotyping of the disease. Whole exome sequencing (WES) and Sanger sequencing was carried out to identify the disease-causing mutation. *In silico* studies involved protein structural modeling, docking and simulation analysis using different computational tools. **Ethical Statement** The study is approved by the ethical review board of Gomal University, D.I.Khan, and patients were enrolled signing the informed written consent. **Result** We investigated the phenotypic spectrum, hormonal profile, and the molecular basis of IGHD4 (MIM# 618157). All affected individuals presented short stature, without any gross skeletal anomalies. Biochemical findings demonstrate a significant reduction in the level of serum growth hormone. Genetic mapping revealed a nonsense mutation [NM_000823:c.G214T:p.(Glu72*)] in the 3rd exon of *GHRHR* gene (MIM#139191). The identified variant segregated in all patients, but it was absent in the normal individuals. The substituted amber codon (UAG) presumably truncates the protein by deleting the C-terminus GPCR domain. The protein modeling studies have shown a drastic effect of this mutation on GHRHR structure and its interaction with growth hormone releasing hormone and thus confirms its involvement in disease etiology. The identified protein truncation mutation (Glu72*) has previously been mapped in three South Asian families, which suggest the founder effect of this mutation in IGHD. **Conclusion:** Our study reports a founder mutation of *GHRHR* gene in an extended consanguineous family, and confirms the body of evidence that p.Glu72* disrupt the receptor protein, affect the hormonal signaling and causes IGHD type IV. Moreover, the deep phenotype analysis, and hormonal profiling will help in establishing the genotype-phenotype correlation.

Mendelian Phenotypes Posters - Thursday

PB1853. Genetic modifiers in Niemann-Pick type C1 disease.

Authors:

D. Sitarska^{1,2}, K. Bodzon^{1,3}, L. Sivitskaya², A. Lugowska¹; ¹Dept. of Genetics, Inst. of Psychiatry and Neurology, Warsaw, Poland, ²Genomed S.A., Warsaw, Poland, ³Dept. of Biology, Univ. of Warsaw, Warsaw, Poland

Abstract Body:

Niemann-Pick disease type C1 (NPC1) is a genetically determined neurodegenerative metabolic disease characterized by the accumulation of non-esterified cholesterol and glycosphingolipids in the lysosomes. It is an autosomal recessive disease that results from pathologic mutations in the *NPC1* gene. NPC1 is exceptionally heterogeneous in age of onset and symptoms, which may vary from perinatal period to adulthood. Similarly, patients' lifespan can range from a few days to even tens of years. Most patients develop hepatosplenomegaly. Among the neurological symptoms the most characteristic are: cerebellar ataxia, dysarthria, dysphagia and developmental delay or progressive dementia. The majority of patients show a characteristic symptom - vertical supranuclear gaze palsy (VSGP). Cataplexy, epileptic seizures and dystonia are also common and psychiatric symptoms, present in patients with late onset of the disease include e.g. psychosis, paranoid delusions or schizophrenia. The severity of the NPC1 disease depends primarily on the type of genetic variants in the *NPC1* gene. However, some patients with the same pathologic mutations display different phenotypes, even within the same family. We hypothesised, that there are some other variants (genetic modifiers) that may suppress or enhance the severity of the disease, resulting in the variability of phenotypic outcomes in NPC1 patients. We performed NGS analyzes in 20 patients with NPC1 of various types. DNA samples were grouped according to the similarity of the genotype. The most frequent variant in our cohort was c.3019C>G p.Pro1007Ala, including 5 unrelated homozygous patients. The age of onset of the first symptoms in these patients ranges from 3 months of age (seizures) to 25 years (VSGP). In order to elucidate the potential influence of molecular background onto the clinical outcome of NPC1 disease, the NGS data were studied and the identified possible modifier genes variants will be presented. This work was supported by National Science Centre (<https://www.ncn.gov.pl>) grant no. 2019/35/N/NZ2/03102.

Mendelian Phenotypes Posters - Wednesday

PB1854*. Genetic modifiers of nutritional status in CF are both unique to CF and shared with the general population

Authors:

H. Ling¹, M. A. Aksit¹, E. W. Pugh¹, R. G. Pace², F. Onchiri³, K. Raraigh¹, F. Wright⁴, A. Faino³, M. Bamshad⁵, R. Gibson³, M. Knowles², Y-H. Zhou⁴, G. Cutting¹, S. Blackman¹; ¹Johns Hopkins Univ., Baltimore, MD, ²Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ³Seattle Children's Hosp., Seattle, WA, ⁴North Carolina State Univ., Raleigh, NC, ⁵Univ. of Washington, Seattle, WA

Abstract Body:

Background: Individuals with cystic fibrosis (CF) often struggle to maintain good nutritional status, and this contributes to lung disease and mortality. Paradoxically, some with CF have obesity. After accounting for CFTR genotype severity, variation in nutritional status (e.g. body mass index, BMI) is largely determined by genes other than *CFTR* (genetic modifiers). We report an initial genome-wide association (GWAS) study for BMI on >4000 individuals with CF in the CF Genome Project (CFGP). **Methods:** Longitudinal height, weight, demographics, and covariates were ascertained from medical records and the CFF Patient Registry 2017. The trait used in the analysis (AvgBMIz) was derived by calculating the average of per-quarter BMI z-scores. GWAS used linear mixed modeling with fixed effect of study site, first 4 principal components, birth cohort, and pancreatic sufficiency (PS) status. Relatedness was modeled as a random effect. **Results:** In an analysis of 4101 CF individuals with severe CFTR genotypes, genome-wide significant association was observed for variants in the *FTO* gene (rs28567725, $P=3.36e-8$; MAF = 0.41) and *ADAMTS5* (rs162500, $P=4.92e-10$; MAF = 0.006, $\beta=-0.7$). The variants in *ADAMTS5* fall on a haplotype that is more common in TOPMed African (MAF = 18.3%) than European (MAF = 0.6%) samples. Among 46 unrelated carriers of a rs162500 minor allele, 28 (61%) were non-EUR vs 4% in the entire CFGP samples. To assess overlap with BMI modifiers in the general population, a polygenic risk score was calculated using 941 variants identified from 700,000 non-CF Europeans (Yengo 2018); this PRS was strongly associated with AvgBMIz ($P=4.9e-30$; $r^2=0.03$). **Conclusions:** Some genetic modifiers of BMI in the CF population are shared with the general population, and others appear unique to CF. *ADAMTS5* variants are not known to be associated with BMI in the general population, but functional studies suggest a role in liver integrity in a mouse model of high-fat diet-induced obesity. Understanding the genetic contributions to BMI in CF can identify mechanisms contributing to undernutrition or obesity in people with CF, who have high metabolic needs and consume high-calorie, high-fat diets. *Supported by CFF CUTTINI8XX1, BAMSHA18XX0, and KNOWLE18XX0.*

Mendelian Phenotypes Posters - Wednesday

PB1855. Genetic underpinnings of moderate to severe hearing loss in singleton individuals born to consanguineous couples in Pakistan

Authors:

H. Khan¹, F. Muzaffar¹, G. H. Seo², S. Naz¹; ¹Sch. of Biological Sci., Univ. of the Punjab, Lahore, Pakistan, ²3Billion inc., Seoul, Korea, Republic of

Abstract Body:

Hearing loss is a common sensory defect which affects over 5% of the world's population. Genetic studies comprising hearing loss in individuals with no previous history of deafness are relatively uncommon in Pakistan. We recruited 22 singletons born to consanguineous couples with no family history of deafness. Audiometry was completed in ambient noise conditions. Exome sequencing was performed on extracted DNA. Most of the participants had non-progressive moderate to severe degree of sensorineural hearing loss. The exome data were filtered and variants with frequency of less than 0.01 in public databases including gnomAD were assessed using automatic variant prioritization system by 3billion and Franklin software. Pathogenicity predictions by multiple software and conservation scores were considered. Analyses revealed both known and novel variants in the samples of the participants. Pathogenic variants in *SLC26A4* were found in nine individuals out of which a single missense variant c.1337A>G:p.(Gln446Arg) was observed in more than half of the participants. Different pathogenic variants of *CDH23* and *OTOF* were identified in two affected individuals each. Homozygous missense, nonsense, and frameshift variants in *CLND14*, *LHFPL5*, *RDX* and *USH1G* were found in samples of four affected individuals while compound heterozygous missense variants in *MYO15A* were identified as the cause of the hearing loss for one participant. Interestingly, a missense variant in *HGF* was identified which was predicted to be pathogenic and could perhaps be the cause of hearing loss of the participant. Previously, only non-coding variants of *HGF* have been implicated in deafness. Exome sequencing failed to pinpoint the cause of hearing loss for three individuals. Our study strengthens the involvement of previously described variants of genes implicated in hearing loss as well as describes novel pathogenic variants in deafness genes. It further suggests that either some deafness genes remain to be identified or the variants were not detected due to limitations of exome sequencing. Whole genome sequencing could be employed in future to detect pathogenic variants in undiagnosed samples.

Mendelian Phenotypes Posters - Thursday

PB1856. Genetics of intellectual disability in pakistani consanguineous families.

Authors:

M. Rasheed¹, V. Khan¹, R. Harripaul², M. Malik¹, M. Zahid¹, Z. Ullah¹, J. Vincent³, S. Leal⁴, M. Ansar⁵; ¹Quaid-i-Azam Univ., Islamabad, Pakistan, ²CAMH, Toronto, ON, Canada, ³Ctr Add/Mental Hlth, Clarke Div, Toronto, ON, Canada, ⁴Columbia Univ., New York, NY, ⁵Quaid-i-Azam Univ, Islamabad, Pakistan

Abstract Body:

Intellectual disability (ID) is a neurodevelopmental disorder which is characterized by less than average intelligence and compromised adaptive behavior. ID affects 1-3% population worldwide and is much prevalent in certain populations. ID is genetically heterogeneous with over 1500 genes currently known and presence of different co-morbidities further adds to the genetic complexity. The present study focused on ten consanguineous families (Family A to J) from Pakistan with autosomal recessive and X linked ID inheritance with an aim to identify underlying genetic causes of the disease. The clinical investigation of the families revealed presence of additional clinical features in some families such as seizures (Family A, B, G), hypotonia (Family A), facial dysmorphism (Family A, C, G, H, J), camptodactyly (Family B), autistic features (Family F), behavioral abnormality (Family A, E, F, H, J), speech impairment (Family A, B, C, D, F, G, H, I), lethargy (Family F, G), microcephaly (Family I), ataxia (Family A, I) and ambulation delay (Family J). The genetic analysis was performed by using genome wide SNP microarray and exome sequencing which helped in the identification of homozygous missense variants in three novel genes, *ZBTB11* (p.H880Q), *ELFN1* (p.P50H) and *CCS* (p.117A), in family A, B and G(b), respectively. *ZBTB11* acts as a transcription factor which is localized in nucleolus and the variant, p.H880Q, identified in family A results in its mislocalization resulting in loss of function. *ELFN1* functions as trans-regulator of *mGluR7* in excitatory post-synaptic sites and *Elfn1* knockout mice exhibits seizures along with hyperactivity and these clinical features were also observed in our patients of family B. In family C and F, novel non-sense homozygous variants were identified in previously known ID genes i.e. *METTL4* (p.R84*) and *C5orf42* (p.Q2871*). In family E and I, a 9 bp and a 4 bp homozygous deletions were identified in *ARX* (p.R483fs*46) and *BCKDK* (p.D216Lfs*65), respectively. In family D, a novel homozygous ~0.2 Mb deletion was identified which resulted in the deletion of exon 6 of *ILIRAPL1*. In family G(a), H and J, recurrent mutations were identified in *GNE* (p.Y156H), *RSRC1* (c.532-1G>A) and *LRP2* (p.D3779N). The *GNE* missense variant, p.Y156H, is previously reported to cause hereditary inclusion body myopathy however, the clinical profile in family G(a) was ID with seizures. These gene mutations are believed to cause ID by disrupting cellular processes such as neuronal functioning (*ELFN1*, *ARX*, *ILIRAPL1*, *C5orf42*, *LRP2*), protein synthesis (*ZBTB11*, *RSRC1*, *METTL4*) and metabolism (*BCKDK*, *GNE*).

Mendelian Phenotypes Posters - Wednesday

PB1857. Genome sequencing identifies coding and non-coding variants in hereditary deafness missed by exome sequencing.

Authors:

M. Ramzan¹, D. Duman², L. C. P. Hendricks¹, M. F. Zafeer¹, G. Bademci¹, M. Tekin¹; ¹Dr. John T. Macdonald Fndn. Dept. of Human Genetics and John P. Hussman Inst. for Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL, ²Univ. of Ankara, Ankara, Turkey

Abstract Body:

The recent implementation of advanced sequencing technologies has significantly contributed to the molecular study of hearing loss. It accelerated the identification of causative variants and allowed the discovery of novel candidate genes involved in the auditory process. In this study, probands of 162 families from different ethnicities, referred with presumably non-syndromic autosomal recessive hearing loss were subjected to Exome Sequencing (ES) after excluding common *GJB2* variants. A total of 69 variants in 26 genes were detected and confirmed with Sanger sequencing which are considered to explain their phenotype. This allowed us to solve only 37% of the cases. Thirty multiplex families which remained unsolved after ES, underwent Genome Sequencing (GS). We solved 21 (70%) of these families after data analysis. In total, 27 variants (14 novel) were identified with GS, of which four are intronic and predicted to be splice disrupting, 13 are missense, nine are leading to frameshifts or stop codons and one was a large deletion in *GJB6*. Six coding variants were missed by ES because of poor coverage and the rest were missed due to insufficient evidence for pathogenicity at the time of ES. Our results suggest that GS can yield improved detection of deafness variants compared to ES.

Mendelian Phenotypes Posters - Thursday

PB1858. Genomic and transcriptomic characterization of a novel *RYR1* variant in the French-Canadian population

Authors:

M. Labrecque^{1,2}, J. Hauteclouque^{1,3}, A. Rihoux^{1,3}, J-D. Brisson^{4,5}, C. Morin⁴, J. Mathieu^{4,5}, A. J. Parker^{1,3}, C-T. E. Nguyen^{3,6}, M. Tétreault^{1,3}; ¹CRCHUM, Montréal, QC, Canada, ²Dept. of Bioinformatics, Université de Montréal, Montréal, QC, Canada, ³Dept. of NeuroSci.s, Université de Montréal, Montréal, QC, Canada, ⁴Neuromuscular Diseases Clinic, Integrated Univ. Hlth.and Social Services Ctr., Saguenay-Lac-Saint-Jean, QC, Canada, ⁵Faculty of Med. and Hlth.Sci., Université de Sherbrooke, Sherbrooke, QC, Canada, ⁶Sainte-Justine Hosp. Ctr., Montréal, QC, Canada

Abstract Body:

Neuromuscular diseases are a group of diseases that affect the muscles, and the main symptom is muscle weakness. Myopathies are a type of neuromuscular diseases that affects the skeletal muscles and lead to a wide range of symptoms. *RYR1* related myopathies (RYR1-RM) are amongst the most common subtypes and is associated with phenotypes ranging from malignant hyperthermia to severe myopathies. The *RYR1* gene which codes for the ryanodine receptor 1 protein plays an important role in contraction of muscles. An uncharacterized mutation, p.E176K, has been identified in 28 individuals from 6 families in Quebec that show an inter- and intra-familial phenotypic variability. Our hypothesis is that the mutation is pathogenic and that an expression profile could explain the heterogeneity observed. To test the pathogenicity of p.E176K, a *C. elegans* model was made using CRISPR-cas9 genome editing. The p.E182K change in *C. elegans* UNC-68 is equivalent to p.E176K in humans. We then evaluated lifespan, reaction to aldicarb and motility in the modified worms. In a pilot project for the study of expression and pathways for RYR1-RM in humans, an RNA-seq pipeline was used on 4 patients with a myopathic phenotype and 2 controls. The RNA was extracted from muscle biopsies and sequenced. The differentially expressed genes (DEGs) were obtained with NOISeq and a gene enrichment exploratory analysis was made with GSEA to find differentially expressed pathways. In the *C. elegans* model, the lifespan of the mutant worms was significantly shorter than wildtype. In the presence of aldicarb, the muscle is not able to relax which eventually lead to paralysis. The paralysis took significantly longer in mutant worms compared to wildtype. For the motility, the mutant worm compared to the wildtype had a significant reduction of thrashing frequency and swim speed. In the exploratory analysis of DEGs in humans we found 36 upregulated genes and 168 downregulated genes, including *RYR1* and *ACHE* (Acetylcholinesterase). Afterwards, we found 32 upregulated pathways, including myogenesis in which *RYR1* and *ACHE* are implicated, and 18 that were downregulated. In the *C. elegans* model, all tests points to the p.E182K mutation being pathogenic which means the homologous p.E176K human mutation is also likely pathogenic. Interestingly, the delayed paralysis in mutant worms when presented with aldicarb shows a defect in synaptic transmission and possibly a lack of acetylcholinesterase that normally allows the muscle to relax. In humans, we also found that *RYR1* and *ACHE* were less expressed in patients, which corroborates the findings in the *C. elegans* model and offer an insight into a possible treatment for RYR1-RM.

Mendelian Phenotypes Posters - Wednesday

PB1859. Genomic ascertainment and reverse phenotyping diabetogenic variants in a phenotypically unselected cohort.

Authors:

C. Wilczewski¹, R. Kumar¹, R. Muniyappa², K. I. Rother³, D. Ng¹, K. Lewis⁴, P. A. Chan¹, H. Shiferaw¹, R. Semple⁵, C. Turner¹, A. Katz¹, L. Biesecker¹; ¹Natl. Human Genome Res. Inst., Bethesda, MD, ²Natl. Inst. of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, ³Eunice Kennedy Shriver Natl. Inst. of Child Hlth. and Human Dev., Bethesda, MD, ⁴NIH, Bethesda, MD, ⁵Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract Body:

Diabetes mellitus is defined simply by hyperglycemia, but is etiologically highly heterogeneous. In some cases, it is caused by monogenic variants in genes involved in insulin release, insulin receptor signaling, or lipodystrophy. As research into the phenotypic consequences of these variants has primarily relied on evaluating clinically affected individuals, our understanding of the phenotypic consequences of these variants in the broader population may be hampered by phenotypic selection bias. We sought to understand the effect of these variants in a phenotypically unselected population by genomically ascertaining individuals heterozygous for predicted deleterious variants in genes associated with metabolic disease, then recalled these individuals to perform reverse phenotyping for diabetes and lipodystrophy. This included collecting medical and family history, physical examination, clinical urine and blood-based laboratory assays, glucose tolerance tests, body fat quantification, and liver MRI. Out of 1514 exome sequencing datasets collected through the ClinSeq study, we identified 19 individuals with variants of interest (6 missense and 13 predicted loss of function) in 14 genes. Hemoglobin A1C levels from electronic health records indicated diabetes in one individual (7.6%) and prediabetes in 12 individuals (5.7-6.4%). Out of eight participants to complete reverse phenotyping, three had been previously diagnosed with type 2 diabetes and one had been diagnosed as prediabetic. Clinical examinations showed two genomically ascertained participants had monogenic diabetes, changing one diagnosis and making one new diagnosis. One participant had diabetes consistent with a previous diagnosis of familial partial lipodystrophy type 3. Five participants had evidence of monogenic impact on metabolism without meeting a diagnosis of diabetes. We highlight one individual harboring an *HNF1A* missense variant (NM_000545.8:c.788G>A, p.Arg263His) previously diagnosed with type 2 diabetes at 31 years old; his diagnosis was subsequently updated to Maturity Onset Diabetes of the Young (MODY). Cascade testing led to a diagnosis of MODY in his daughter. This work demonstrates how genomic ascertainment and reverse phenotyping can interrogate the clinical yield of variants associated with diabetes and lipodystrophy in a phenotypically unselected population, yielding more accurate estimates of variant pathogenicity in the broader population. Ultimately, this informs how large-scale genomic screening can enable precision medicine that impacts treatment and prevention of one of the most common chronic health conditions in the United States.

PB1860. Genomic region identified on chromosome 22 contributing to lymphedema in Phelan-McDermid syndrome

Authors:

S. Sarasua¹, M. Smith¹, C. Rogers², K. Phelan³, L. Boccuto¹; ¹Clemson Univ., Clemson, SC, ²Greenwood Gen Ctr, Greenville, SC, ³Florida Cancer Specialists, Fort Myers, FL

Abstract Body:

Lymphedema can be a painful and disabling co-morbid condition with many genetic syndromes including Phelan-McDermid syndrome (PMS). The cause of lymphedema is often unknown, it can be difficult to treat, and it tends to receive less research attention than other acute conditions. PMS is a rare neurodevelopmental disorder caused by deletions of varying size within chromosome band 22q13 or pathogenic variants of the *SHANK3* gene. The severity and type of clinical phenotypes in PMS are also highly variable. Parents and caregivers of individuals with PMS expressed concern that lymphedema was a problem for many people but had received little research in the PMS research community. Therefore, we sought to assess the prevalence and epidemiology of lymphedema in PMS and investigate genotype-phenotype correlations. To do this we assessed reports from the Phelan-McDermid Syndrome International Registry, now known as the PMS DataHub, on more than 400 individuals with information on this condition. Participants in the registry sample tended to be young with a median age of 7 years (range 1-49). We found a formal diagnosis of lymphedema was present in approximately 5% of people with PMS, with the highest prevalence in those over 18 years of age. Frequently co-occurring with lymphedema were cellulitis, pitting, and swelling in extremities. Lymphedema was more common in those with a deletion on 22q13 compared to a *SHANK3* pathogenic variant. Further, individuals with lymphedema also tended to have larger genomic deletions than those without lymphedema suggesting the contribution of additional gene(s). Therefore, an association analysis was conducted using Plink software which identified a specific genomic region at 22q13.31 with a major candidate gene for lymphedema. The results of this investigation can be used to help patients and families, as well as their treating clinicians, to understand lymphedema as a co-morbid condition and provide direction for targeted therapy research. Understanding the function of the candidate gene will also be useful in better understanding the genetic underpinnings of lymphedema in other genetic conditions. This research highlights the utility of assessing genotype-phenotype correlations in deletion syndromes, the use of large patient registries, and the benefits of patient-oriented approaches to research projects.

PB1861. GGC repeat expansion within *NOTCH2NLC* causes behavioral deficits and neurodegeneration in a mouse model of Neuronal Intranuclear Inclusion.

Authors:

Y. Kang¹, Q. Liu², K. Zhang², Y. Li¹, P. Deng², Y. Li¹, Y. Tian², Q. Sun², Y. Tang², K. Xu², Y. Zhou², J-L. Wang², J. Guo², J-D. Li², K. Xia², Q. Meng³, E. Allen¹, Z. Wen¹, Z. Li⁴, H. Jiang², L. Shen², R. Duan², B. Yao¹, B. Tang², Y. Pan², P. Jin¹; ¹Emory Univ., Atlanta, GA, ²Central South Univ., Changsha, China, ³The First Affiliated Hosp. of Univ. of South China, Hengyang, China, ⁴The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract Body:

GGC repeat expansion within *NOTCH2NLC* gene has been identified as the genetic cause of neuronal intranuclear inclusion disease (NIID). To understand the molecular pathogenesis of NIID, here we establish both a transgenic mouse model and a human neural progenitor cell (hNPC) model. Expression of the *NOTCH2NLC* gene with expanded GGC repeats produces widespread intranuclear and perinuclear polyglycine (polyG), polyalanine (polyA) and polyarginine (polyR) inclusions, leading to severe neurodegeneration, motor dysfunction and cognitive deficits, which faithfully mimics the clinical manifestations and pathological features associated with NIID. Furthermore, conserved alternative splicing events was identified between the NIID mouse and hNPC models, among which are the enrichment of the binding motif of hnRNPM, an RNA-binding protein known as alternative splicing regulator. Expanded *NOTCH2NLC*-polyG and -polyA could interact with and sequester hnRNPM while overexpression of hnRNPM could ameliorate the cellular toxicity. These results together suggest that dysfunction of hnRNPM-mediated splicing could play an important role in the molecular pathogenesis of NIID.

Mendelian Phenotypes Posters - Thursday

PB1862. GWAS of cleft palate trios reveals novel associations and subtype-specific effects.

Authors:

K. Robinson¹, T. Mosley¹, T. H. Beaty², A. Butali³, C. Buxo⁴, G. Shaw⁵, J. Hecht⁶, L. Moreno⁷, J. Murray⁸, H. Brand⁹, S. Weinberg¹⁰, M. Marazita¹¹, E. Leslie¹; ¹Emory Univ., Atlanta, GA, ²Johns Hopkins Univ., Baltimore, MD, ³Univ. of Iowa, Coralville, IA, ⁴Univ. of Puerto Rico, San Juan, PR, ⁵Stanford Univ., Stanford, CA, ⁶Univ Texas McGovern Med Sch, Houston, TX, ⁷Univ Iowa, Iowa City, IA, ⁸U of Iowa, Iowa City, IA, ⁹MGH, Wilmington, MA, ¹⁰Univ of Pittsburgh, Pittsburgh, PA, ¹¹Univ Pittsburgh, Ctr. for Craniofacial and Dental Genetics, Pittsburgh, PA

Abstract Body:

Orofacial clefts (OFCs) are the most common craniofacial birth defects, occurring in approximately 1 in 1000 live births. OFCs are divided into cleft lip with or without cleft palate (CL/P) and cleft palate only (CPO), with CPO accounting for approximately 30% of all OFCs. For several reasons, CPO is considered etiologically distinct from CL/P, one of which includes differences in genetic risk factors. Compared to the dozens of risk loci associated with CL/P, only a few have been identified for CPO via common variant analyses. Historically, genome-wide studies have evaluated CPO as a whole, rather than by heterogeneous subtypes which include a spectrum of clefts affecting the hard and/or soft palate. However, differences in timing of midline fusion and variation in transcriptomic profiles between the anterior hard palate and the posterior soft palate suggest there may be distinct genetic drivers of each CPO subtype. To investigate this further, we sequenced 365 trios with CPO (118 unclassified, 69 hard and soft, 136 soft only, and 42 hard only) followed by transmission disequilibrium tests for genome-wide association in three groups: any cleft palate (ACP, n=365), any cleft of the hard palate (CHP, n=111), and any cleft of the soft palate (CSP, n=205). No SNP achieved genome-wide significance ($p < 5 \times 10^{-8}$), though a total of 39 loci reached suggestive significance ($p < 1 \times 10^{-5}$) in at least one analysis. Interestingly, only three of these loci overlapped (all shared between ACP and CSP), supporting the hypothesis of distinct risk factors for hard versus soft palatal CPO. The most significant locus was identified in the ACP group, and was closest to the gene *HOMER1* ($p = 4.20 \times 10^{-7}$, OR 3.29, 95% CI 2.02-5.36). Although not previously associated with CPO, Homer1 in mice is expressed in developing embryonic craniofacial tissue, especially within the palatal rugae. The top locus for CHP was on 9q33.3 ($p = 4.46 \times 10^{-7}$, OR 15.50, 95% CI 3.71-64.76), a region that when deleted results in a syndrome that often includes craniofacial dysmorphism and/or OFCs. Lastly, the top locus of interest for CSP was closest to *FAM120A* ($p = 2.38 \times 10^{-6}$, OR 5.57, 95% CI 2.49-12.46), a scaffold protein involved in many roles, including cell adhesion and apoptosis. Cumulatively, we have identified several novel risk loci yielding suggestive evidence of association for CPO in this study, and provided the first evidence for subtype-specific genetic variants. To further support these findings, future evaluations will include a replication cohort and functional testing to better characterize the role of these novel associations in CPO.

Mendelian Phenotypes Posters - Wednesday

PB1863*. GWAS of Down Syndrome Associated Atrioventricular Septal Defect identifies three novel loci.

Authors:

E. Feldman¹, D. J. Cutler¹, T. C. Rosser¹, S. B. Wechsler¹, L. Sanclemente², A. Rachubinski³, K. R. Rabin², M. Wagner⁴, B. Gelb⁵, J. M. Espinosa³, P. J. Lupo², S. L. Sherman¹, E. J. Leslie¹; ¹Emory Univ., Atlanta, GA, ²Baylor Coll. of Med., Houston, TX, ³Univ. of Colorado Anschutz Med. Campus, Aurora, CO, ⁴Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH, ⁵Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Congenital heart defects (CHDs) are the most common structural birth defect, affecting 8-10 of every 1000 live births and accounting for 25% of infant mortality. They represent a group of structural anomalies which range in severity some of which are incompatible with life. Atrioventricular septal defect (AVSD) is a form of CHD occurring in 1 in 5 infants with Down syndrome (DS) compared to 1 in 10,000 infants with euploid chromosome constitution. While increased dosage of chromosome 21 genes clearly contributes to this risk for AVSD, trisomy 21 is not sufficient to cause CHD as about 50% of infants with DS have structurally normal hearts. Thus, additional modifying genetic and environmental factors may exist. In order to characterize the genetic architecture of AVSD, we sequenced genomes of a multiethnic set of 1000 infants including 428 cases with DS and AVSD (AVSD+DS) and 572 controls with DS and a structurally normal heart (NH+DS) as part of the Gabriella Miller Kids First Pediatric Research Program and the INCLUDE (INvestigation of Co-occurring conditions across the Lifespan to Understand Down syndrome) Project. We performed a genome-wide association study (GWAS) for common variants (MAF > 0.05) using logistic regression and adjusting for principal components of ancestry. Although no SNP achieved genome-wide significance ($p < 5 \times 10^{-8}$), three loci achieved suggestive significance ($p < 2 \times 10^{-6}$). The most significant locus was on 12q21.2 ($p = 2.22 \times 10^{-7}$, OR 0.55), near *NAV3*. Although not previously associated with CHD in humans, *nav3*^{-/-} mutant zebrafish were recently reported to have severe cardiac malformations. The other two lead SNPs at 13q21.33 ($p = 1.15 \times 10^{-6}$, OR 1.71) and 19q13.3 ($p = 3.41 \times 10^{-7}$, OR 1.98) are located in the vicinity of multiple genes expressed in the heart or associated with heart defects in human and/or animal models. Taken together, we have identified novel loci that have suggestive evidence for association with AVSD in DS. Additional analyses are underway to replicate these findings and to identify rare variants associated with AVSD and CHD in DS. The results from this study will generate new hypotheses about biological pathways associated with abnormal heart development due to trisomy 21.

Mendelian Phenotypes Posters - Thursday

PB1864*. Haploinsufficiency and loss-of-function of LEF-1 cause a novel Mendelian disorder by dysregulating WNT signaling

Abstract Body:

Background: *LEF1* encodes a transcription factor acting downstream of the WNT- β -catenin signaling pathway. It was recently suspected as a candidate for ectodermal dysplasia in 2 individuals carrying 4q35 microdeletions. We recruited a highly diverse cohort of 12 patients from 5 unrelated families segregating de novo, monoallelic and biallelic variants of LEF1 inherited in both autosomal recessive and dominant fashion. All the patients manifested a novel Mendelian disorder, ectodermal dysplasia associated with limb malformations.

Methods: High-throughput sequencing was employed to delineate the genetic underpinnings of the disease. Cellular consequences were characterized by immunofluorescence, immunoblotting, pulldown assays, and/or RNA sequencing.

Results: Monoallelic variants in LEF1 were detected in 11 affected individuals from 4 unrelated families, and a biallelic variant was detected in an affected individual from a consanguineous family. The phenotypic spectrum includes various limb malformations, such as radial ray defects, polydactyly or split hand/foot, and ectodermal dysplasia. Our functional data indicate that 2 molecular mechanisms are at play: haploinsufficiency or loss of DNA binding are responsible for a mild to moderate phenotype, whereas loss of β -catenin binding caused by biallelic variants is associated with a severe phenotype.

Transcriptomic studies reveal an alteration of WNT signaling. Notably, WNT target genes, HOX genes and several long non-coding RNAs were differentially expressed in two of the patient derived fibroblasts.

Conclusion: Our findings establish mono- and biallelic variants in LEF1 as a cause for a novel syndrome comprising limb malformations and ectodermal dysplasia.

Mendelian Phenotypes Posters - Wednesday

PB1865. Haplotype in interleukin 6 is associated with a reduction of blood transfusion events in sickle cell anemia patients.

Authors:

C. Fong¹, E. Portilla², L. Cifuentes³; ¹Univ. Cooperativa de Colombia, Santa Marta, Colombia, ²Univ. de Nariño, Pasto, Colombia, ³Univ. Cooperativa de Colombia, Pasto, Colombia

Abstract Body:

Sickle cell disease (SCD) is the most commonest monogenic disease in the world, it is caused by the presence of hemoglobin S. SCD causes altered red-blood cells and hemolysis which drive to an inflammatory state that induces several symptoms. Interleukin 6 (IL6) is a central cytokine in the inflammatory response and polymorphisms in this gene are associated with susceptibility to inflammatory and autoimmune diseases. This study aimed to identify polymorphic sites in the IL6 gene in the Colombian population and to verify their influence on symptoms or blood transfusion events in SCD patients. We sequenced the promoter and coding region of IL6 in a sample of the Colombian population to identify genetic variants. Then, we collected clinical information from 112 patients with SCD. We identified three polymorphic SNPs (rs1800796, rs2069832, and rs2069849) which were genotyped in SCD patients, with these SNPs haplotypes were built. To evaluate both SNPs and haplotypes association with clinical data a logistic regression was performed. The symptoms more frequent in this population were pain crisis, osteomyelitis, and dactylitis. 77% of patients suffered a blood transfusion. Neither polymorphism was associated with symptoms or blood transfusion. Eight haplotypes were observed, the haplotype CGT showed a protective effect (OR= 0.4, p-value= 0.001) on blood transfusion. Our results show an association between IL6 and the events of blood transfusion, probably caused for a reduction of IL6 expression or a reduced amount of functional protein. The haplotype in this population identified could be used as a predictor of SCD severity.

Mendelian Phenotypes Posters - Thursday

PB1866. Hemizygous CNV in chromosome region Xq23 is associated with a complex psychiatric and bone mineral density disorder.

Authors:

J. Kapalanga¹, T. M. Parikh²; ¹Western Univ./GBHS, Owen Sound, ON, Canada, ²McMaster Univ., Hamilton, ON, Canada

Abstract Body:

The purpose of this report is to highlight that male inheritance of an X chromosomal copy number variant (CNV) from a clinically normal mother should not always be taken as evidence supporting the interpretation that it is benign. The CNV may have no deleterious impact in the heterozygous mother and a pathogenic effect in the nullizygous male offspring. We report on a hemizygous loss of 0.334 Mb copy number variant (CNV) in chromosome region Xq23, in a male proband with a complex behavioural and emotional profile, and a skeletal deformity. A maternal uncle was also found to have a constellation of similar clinical features. Parental studies by region-specific microarray analysis revealed that this CNV was inherited from a clinically normal mother. The deletion involves the entire length of *LUZP4* (leucine zipper protein 4), as well as the loss of the 5'UTR region of *PLS3* (plastin 3, OMIM 300131). The deletions within the 5'UTR of the *PLS3* gene and of the entire *LUZP4* gene, likely impacted gene expression and protein function of these genes in the proband and his uncle. The *LUZP4* hemizygous variants have been reported in two males with autism spectrum disorder (PMID: 23352160). Further *PLS3* is a an OMIM Morbid gene associated with X-linked dominant susceptibility to low mineral density skeletal disorders (BMND 18, OMIM 300910, OMIM 300910). The patient and his uncle have a constellation of social deficits, behavioral, and emotional features observed in patients with autism spectrum disorder. Both also have skeletal abnormalities attributable to low bone mineral density. This suggests that the CNV is pathogenic in males.

Mendelian Phenotypes Posters - Wednesday

PB1867*. Here, There and Everywhere: Characterizing Variability in Approaches to Ascertaining Individuals with Rare Mendelian Disorders from EHRs

Authors:

O. Veatch¹, J. Mathew², S. Rockowitz³, D. Baldrige⁴, A. Wetzel⁵, M. Niarchou⁶, M. Clarke⁷, S. Berger⁸, K. German⁹, S. Shankar¹⁰, P. Shankar¹⁰, J. S. Cohen¹¹, A. Keith⁴, I. Oh⁴, R. Raizada⁷, S. Chopra³, on behalf of the NICHD IDDRC GREATestEHR Working Group; ¹Univ. of Kansas Med. Ctr., Kansas City, KS, ²Univ. of Wisconsin-Madison, Madison, WI, ³Boston Children's Hosp., Brookline, MA, ⁴Washington Univ. in St. Louis, St. Louis, MO, ⁵Univ. of Iowa, Iowa City, IA, ⁶Vanderbilt Univ. Med. Ctr., Nashville, TN, ⁷Albert Einstein Coll. of Med., Bronx, NY, ⁸Children's Natl. Med. Ctr., Washington, DC, ⁹Univ. of Washington, Seattle, WA, ¹⁰MIND Inst. UC Davis, Sacramento, CA, ¹¹Kennedy Krieger Inst., Baltimore, MD

Abstract Body:

A critical step in translational medicine for rare Mendelian disorders is the rapid identification of research-eligible individuals. Liberating genetic testing results from electronic health records (EHRs) offers the opportunity to find potential subjects and assess rich phenotypic and genetic evidence. However, issues related to institutional differences in EHR configurations, lack of diagnostic codes for these disorders, and storage of genetic test results as unstructured text, PDFs or scanned images complicate developing reliable and efficient search strategies. This, in turn, impedes detection of individuals with rare monogenic disorders for clinical research. To identify methods likely to enhance the use of these data for research and clinical purposes, NICHD-supported Intellectual and Developmental Disabilities Research Centers (IDDRCs) formed the Genetic Reports - Enhancing Access to Test results in the Electronic Health Record ("GREATest EHR") Working Group. To move towards more efficient extraction of test results, eleven sites systematically compared the variability in methods and yield in identifying and extracting these data from EHRs. The four broad approaches used were: 1) manual searches, reviews, and extractions, 2) Natural Language Processing (NLP), 3) direct collaborations with genetic testing labs, and 4) incorporating EHR genomics modules being developed to aid with structured data capture. Of the eleven IDDRCs, eight perform searches for any text matching gene names of interest followed by manual review and extraction of data from each record with a gene name match. One site uses NLP trained to accurately recognize phenotype terms reflecting IDs, and manually reviews records within the subset to confirm genetic testing results and manually extract data. Four sites use a custom database developed by an external or in-house genetic testing lab. Four sites are in the process of implementing a genomics module developed by EHR vendors to streamline collection of structured genetic testing data. Strengths and weaknesses were noted for each approach. Notably, all approaches were time and labor intensive, requiring at least some level of manual review. Ongoing work includes evaluating the yield for each approach and developing more automated methods (e.g., optical character recognition, context specific search strategies) to optimize legacy data extraction across sites. The ultimate goals are to develop best practice guidelines to identify subjects eligible for translational research and to support clinical decisions about interpretation, reanalysis, new testing, and management.

Mendelian Phenotypes Posters - Thursday

PB1868. Heterogeneity of Inherited Cone Dysfunction Disorders with Normal Fundus Appearances

Authors:

K. Joo, H. Kim, W. Se Joon, K. Park; Seoul Natl. Univ. Bundang Hosp., Seongnam, Korea, Republic of

Abstract Body:

Purpose: To investigate the clinical and genetic characteristics of inherited cone dysfunction disorders with normal fundus appearances. **Methods:** Twenty-four patients with inherited cone dysfunction disorders with normal fundus appearances were evaluated. Exome sequencing targeting 245 candidate genes of inherited retinal diseases and direct Sanger sequencing were performed. Examinations including best-corrected visual acuities (BCVA), retinal morphologic abnormalities analyzed by spectral-domain optical coherence tomography (SD-OCT), longitudinal reflectivity ellipsoid zone (EZ) intensity ratio and electroretinogram (ERG) were performed. **Results:** The median age at the initial examination (n=24) and the final visit (n=17) were 11 years with a range of 4 to 59 years, and 21 years with a range of 8 to 63 years. Fifteen disease-causing disease variants were identified in fifteen genes, including *RGS9BP*, *RBP3*, *CNGA3*, *GNAT1*, *GNAT2*, *GUCY2D*, *CACNA1F*, *RAB28*, *RPGR1P1*, *PRPH2*, *CDHRI*, *RSI*, *PROM1*, *CNBG3*, and *PDE6B*. There were significant negative correlations between the BCVA and external limiting membrane-retinal pigment epithelium thickness (ERT), EZ intensity ratio at the initial examination ($P = 0.002$, $P < 0.001$), final visit ($P = 0.004$, $P = 0.002$), and the interval changes ($P = 0.006$, $P = 0.003$), respectively. ROC curve values for disease progression parameters of ERT differences were AUC 0.909, $P = 0.007$, and EZ intensity ratio differences were AUC 0.939, $P = 0.004$. **Conclusions:** Inherited cone dysfunction disorders with normal fundus appearances show clinically and genetically heterogeneous features. Retinal morphologic and reflectivity changes are identified in SD-OCT images, correlated to the visual function, and considered as predictive parameters for disease progression.

Mendelian Phenotypes Posters - Wednesday

PB1869. High Molecular Diagnostic Yields and New Phenotypic Expansions Involving Anorectal Malformations

Authors:

R. Belanger Deloge; Baylor Coll. of Med., Houston, TX

Abstract Body:

Evidence suggests that genetic factors contribute to the development of anorectal malformations (ARMs). However, the etiology of the majority of ARMs cases remains unclear. Exome sequencing (ES) may be underutilized in the diagnostic workup of ARMs due to uncertainty regarding its diagnostic yield. In a clinical database of ~17,000 individuals referred for ES, we identified 130 individuals with non-isolated ARMs (ARMs+). A definitive or probable diagnosis was made in 45 of these individuals for a diagnostic yield of 34.6% (45/130). The diagnostic yield of individuals who met criteria for VACTERL association was lower than those who did not (26.8% vs 44.1%; $p=0.0437$), suggesting that non-genetic factors may play an important role in this subset of ARMs+ cases. Within this cohort, we identified two individuals who carried de novo pathogenic frameshift variants in *ADNP*, two individuals who were homozygous for pathogenic variants in *BBS1*, and single individuals with carried pathogenic or likely pathogenic variants in *CREBBP*, *EP300*, *FANCC*, *KDM6A*, *SETD2*, and *SMARCA4*. The association of these genes with ARMs was supported by previously published cases, and their similarity to known ARMs genes as demonstrated using a machine learning algorithm. These data suggest that ES should be considered for all individuals with ARMs+ in whom a molecular diagnosis has not been made, and that ARMs represent a low penetrance phenotype associated with Helsmoortel-van der Aa syndrome, Bardet-Biedl syndrome 1, Rubinstein-Taybi syndromes 1 and 2, Fanconi Anemia group C, Kabuki syndrome 2, *SETD2*-related disorders, and Coffin-Siris syndrome 4.

Ctr., Los Angeles, CA, ⁸Univ CA Irvine, Orange, CA

Abstract Body:

ABSTRACT Background and Objective Missense variants of the valosin-containing protein (*VCP*) gene cause a progressive, autosomal dominant disease termed VCP multisystem proteinopathy (MSP1). The disease is a constellation of clinical features including inclusion body myopathy (IBM), Paget's disease of bone (PDB), frontotemporal dementia (FTD) (IBMPFD) and amyotrophic lateral sclerosis (ALS), typically reported at a frequency of 90%, 42%, 30% and 9% respectively. The Hispanic population is currently underrepresented in previous reports of VCP myopathy. We expand our genotype-phenotype studies in five Hispanic families with the c.476G>A, p.R159H *VCP* variant. Methods We report detailed clinical findings of 11 patients in five Hispanic families with the c.476G>A, p.R159H *VCP* variant. Additionally, we report frequencies of the main manifestations in 39 affected members of the extended family members. We also compared our findings with an existing larger cohort of patients with VCP MSP1. Results FTD was the most prevalent feature reported, particularly frequent in females. PDB was only seen in one patient in contrast to the earlier reported cohorts. The overall frequency of the different manifestations: myopathy, PDB, FTD and ALS in these five families was 39%, 3%, 72% and 8% respectively. The atypical phenotype and later onset of manifestations in these families resulted in a noticeable delay in the diagnosis of VCP disease. Discussion Studying each *VCP* variant in the context of ethnic backgrounds is pivotal in increasing awareness of the variability of VCP-related diseases across different ethnicities, enabling early diagnosis, and understanding the mechanism for these genotype-phenotype variations.

Mendelian Phenotypes Posters - Wednesday

PB1871*. Highly recurrent histone H4 mutations cause a neurodevelopmental disorder

Authors:

L. Bicknell¹, F. Tessadori², K. Duran³, K. Knapp⁴, Histone H4 Clinical Consortium, P. Mace¹, G. van Haaften⁵; ¹Univ. of Otago, Dunedin, Otago, New Zealand, ²Hubrecht Inst.-KNAW, Utrecht, Netherlands, ³Univ. Med. Ctr. Utrecht, Utrecht, Netherlands, ⁴Univ. of Otago, Dunedin, New Zealand, ⁵Univ. Med Ctr. Utrecht, Utrecht, Utrecht, Netherlands

Abstract Body:

Chromatin is essentially an array of nucleosomes, each of which consists of the DNA double-stranded fiber wrapped around a histone octamer. This organization supports cellular processes such as DNA replication, DNA transcription and genome integrity in all eukaryotes. The histone octamer is composed of two each of four different histones, including histone H4. Human histone H4 is encoded by fourteen canonical H4 genes, all of which are independently regulated and differ at the nucleotide level. These 14 genes encode an invariant protein, which is one of the most conserved proteins amongst eukaryotes. Here we present a cohort of 29 subjects with de novo missense variants in six H4 genes (*H4C3*, *H4C4*, *H4C5*, *H4C6*, *H4C9* and *H4C11*) identified by whole exome sequencing and genetic matchmaking. All individuals present with neurodevelopmental features of intellectual disability and motor and/or gross developmental delay, while non-neurological features such as facial dysmorphism, hearing loss and skeletal anomalies are more variable. Ten amino acids are affected, six of which recurrently mutated, and are all located within the H4 core or C-terminal tail. These variants cluster to specific regions of the core H4 globular domain, where protein-protein interactions occur with either other histone subunits or histone chaperones. Intriguingly, no variants were identified in the modification-heavy N-terminal tail of H4. Functional consequences of the identified variants were evaluated in zebrafish embryos, which displayed abnormal general development, defective head organs and reduced body axis length, providing compelling evidence for the causality of the reported disorder(s). While multiple developmental syndromes have been linked to chromatin-associated factors, missense-bearing histone variants (e.g. H3 oncohistones) have only more recently emerged as a major cause of pathogenicity. Our findings establish a broader involvement of H4 variants in developmental syndromes.

Mendelian Phenotypes Posters - Thursday

PB1872. Homozygous *EMCI* variant in four families from the same Kuwaiti tribe with cerebellar atrophy, visual impairment, and psychomotor retardation.

Authors:

M. Alenzi¹, R. Alqusaimi², E. El-anany³, A. Alholle⁴, S. Omar⁴, A. Elmonairy⁴, A. Alahmad⁴, R. Alsafi⁴, H. Alsharhan⁵, L. Bastaki⁴, B. Albash⁴, D. Marafie^{4,5,3}; ¹Farwaniya Hosp., Subah-Alnaser, Kuwait, ²Kuwait Univ., Health Science Center, Kuwait, ³Section of Child Neurology, Dept. of Pediatrics, Adan Hosp., Ministry of Hlth., Hadiya 52700, Kuwait, ⁴Kuwait Med. Genetics Ctr., Ministry of Hlth., Sulaibikhat 80901, Kuwait, ⁵Dept. of Pediatrics, Faculty of Med., Kuwait Univ., P.O. Box 24923, 13110 Safat, Kuwait

Abstract Body:

IntroductionThe subunit 1 of the endoplasmic reticulum (ER)-membrane protein complex is a conserved multi-subunit transmembrane complex. This protein enables energy-independent insertion of newly synthesized membrane proteins into ER membranes, mediating protein folding, phospholipid transfer from ER to mitochondria, and elimination of misfolded proteins. Both monoallelic *de novo* and biallelic *EMCI* variants have been identified to cause cerebellar atrophy, visual impairment, and psychomotor retardation (CAVIPMR) [OMIM # 61687]. Only five families with biallelic *EMCI* variants and CAVIPMR have been reported. Here, we describe four Kuwaiti families from the same tribe, with a homozygous pathogenic missense *EMCI* variant [c.245C>T:p.(Thr82Met)] and CAVIPMR.

MethodsClinical exome sequencing was performed in probands from three families while targeted molecular testing for *EMCI* [c.245C>T:p.(Thr82Met)] variant was performed in the fourth family based on strong clinical suspicion and tribal origin. Sanger sequencing confirmed the variant and segregation with disease in all families.

ResultsSeven individuals from four families affected by homozygous pathogenic *EMCI* variant [c.245C>T:p.(Thr82Met)] were identified. The variant was previously reported pathogenic in a Turkish family with CAVIPMR, and was absent from Kuwait Medical Genetic Centre database thus unlikely representing a population founder allele. The average age at symptom onset was 14.7 weeks, with all families reporting visual abnormalities, hypotonia, and/or global developmental delay (GDD) as the presenting features. Shared clinical features include GDD (7/7), cortical visual impairment (6/6), truncal hypotonia (6/6), failure to thrive (6/6) and hyperreflexia (5/5). Other common features include microcephaly (6/7; 86%), chorea (5/7; 71%), peripheral hypertonia (3/4; 75%), dysmorphism (3/5; 60%) and epilepsy (4/7; 57%). Brain imaging showed cerebellar atrophy in 2/5 (40%) and cerebral atrophy in 1/3 (33%) individuals.

ConclusionThe presence of exact biallelic homozygous *EMCI* variant in four families originating from the same tribe in Kuwait suggests a tribal founder allele. The clinical features herein are consistent with the phenotypic spectrum of *EMCI*-associated CAVIPMR in previous reports. The presence of chorea, first noted here, further expands the phenotypic spectrum. Our findings inform the clinical practice in Kuwait through recommended targeted *EMCI* variant [c.245C>T:p.(Thr82Met)] testing for infants from affected tribe presenting with visual impairment, GDD and hypotonia, and augment global efforts to understand rare Mendelian disorders.

Mendelian Phenotypes Posters - Wednesday

PB1873*. How many diseases can one gene cause: Why mechanism matters for gene curation, variant classification, and clinical management.

Authors:

K. Radtke, M. Rossi, W. Alcaraz, B. Wayburn, D. Thrush, H. Keller, M. Towne, J. Huang; Ambry Genetics, Aliso Viejo, CA

Abstract Body:

It is often thought that pathogenic variants in a gene cause a singular disorder; however, this “one-gene-one-disease” position is not universally true. One gene may cause multiple genetic disorders distinguished by differences in mode of inheritance (MoI), mechanism of disease (MoD), and/or genotype/phenotype correlations. Often, this means a pathogenic variant for one disorder does not cause the other associated disorder(s). An example, loss-of-function (LoF) *KLHL7* variants are associated with autosomal recessive neurodevelopmental disorder (NDD), and dominant negative variants are associated with autosomal dominant retinitis pigmentosa. This creates complexities in variant interpretation, clinical reporting, public variant databases submission, and patient counseling. Curating a combination of gene, MoI, MoD, and clinical presentation is critical for accurate variant classification. While this dilemma is known, the scope has not been thoroughly assessed. We reviewed a large set of NDD genes and all associated disorders. Our analysis did not include clinically distinct disorders with no genotype/phenotype correlation, differences in MoI, or MoD. Genes with more than one genetic disorder were grouped into 4 main categories: - monogenic dosage effect: distinct clinical presentations due to dosage effects (ex. *ATM*) - monogenic multimodal: similar clinical presentation with differences in MoI and MoD (ex. *GRINI*) - allelic: distinct clinical presentations and unique MoD (ex. *SMARCA4*) - unknown: unique clinical presentations but insufficient data about MoD We identified 901 distinct disorders associated with 800 NDD genes (1-4 disorders/gene). 11% (86/800) of genes are associated with >1 genetic disorder, totaling 187 distinct disorders. 2% (14/800) of genes are associated with >2 genetic disorders. These 187 disorders were categorized as: monogenic dosage effect 15%; monogenic multimodal 16%; allelic 50%; unknown 19%. Each of these categories require precise curation and have unique implications on variant interpretation, clinical reports, and patient counseling. Of the 86 genes associated with >1 disorder, we analyzed each disorder’s MoI and MoD. 31% (58/187) have different MoI and 42% (78/187) have different MoD. Further, 28% (53/187) differed in both MoI and MoD. Out of the 187 disorders, 41% (78/187) have a LOF mechanism, and approximately 8% (15/187) have a gain of function mechanism; the remaining 51% of disorders have other or unknown mechanisms. Functional confirmation of non-LoF MoD is highly nuanced but will be critical for accurately defining genetic disorders.

Mendelian Phenotypes Posters - Thursday

PB1874*. Human brains with Tay Sachs disease exhibit altered transcriptomes during fetal development

Authors:

S. Han¹, A. Hirt¹, E-R. Nicoli¹, C. Toro¹, M. Kono², R. L. Proia², C. J. Tiffit¹; ¹Natl. Human Genome Res. Inst., Bethesda, MD, ²Natl. Inst. of Diabetes and Digestive and Kidney Diseases, Bethesda, MD

Abstract Body:

Developing therapy for monogenic disorders requires deep understanding of disease pathogenesis with the ideal goal of compensating for the dysfunctional gene in every relevant cell type and at every time point that the gene is normally expressed. Understanding the temporal expression pattern, and correlating a therapeutic “window of opportunity”, is critical to prevent irreversible consequences. Tay Sachs disease (TSD), a lysosomal storage disorder (LSD) resulting from a deficiency of hexosaminidase A producing storage of GM2 ganglioside, is an appealing candidate for gene transfer therapy. Infants with TSD appear healthy at birth and typically manifest symptoms in the first weeks or months of life, providing a potential therapeutic window before symptom onset. However, accumulation of GM2 ganglioside begins during fetal development, raising the possibility of perturbed development despite the healthy presentation at birth. We confirmed GM2 accumulation in tissues from two 17-week human fetal brains with *HEXA* genotypes consistent with juvenile onset TSD and evaluated the transcriptomes of several brain regions by RNAseq. We found that differentially expressed gene sets were enriched for genes perturbed in neurodegenerative disorders including Alzheimer’s, Parkinson’s, Huntington’s, diseases as well as ALS. Moreover, transcriptomes from all regions of TSD brains appear delayed developmentally as they more closely resemble less differentiated control forebrains rather than the more differentiated regions from which they were sampled. Interestingly, we did not observe upregulation of immune genes, suggesting that the neuroinflammation typical of TSD and many neurodegenerative diseases has not yet begun. And, we did not observe upregulation of lysosomal genes previously noted in postnatal tissues in several LSDs. These data suggest that TSD disrupts normal brain development at least by mid-gestation, even before some of the pathological signs of disease have begun. These findings have obvious implications for gene or cell therapies and their ability to interrupt or correct a disease process that is already in place. The tissues used in this study were from the milder juvenile form of TSD and it is possible that pathology in the more severe infantile form will have even earlier onset and progress more rapidly. Therefore, when designing therapies, it will be important to select appropriate endpoints and, more importantly, set realistic outcome expectations for families even if treatment commences in the first few weeks of life.

Abstract Body:

We report on biallelic homozygous and monoallelic *de-novo* variants in *Slitrk3* (*ST3*) in 3 unrelated families presenting with epileptic encephalopathy associated with a broad neurological involvement characterized by microcephaly, intellectual disability, seizures, and global developmental delay. *ST3* encodes for a transmembrane protein that is involved in controlling neurite outgrowth and inhibitory synapse development and that has an important role in brain function and neurological diseases. Using primary cultures of hippocampal neurons carrying patients' *ST3* variants and in combination with electrophysiology, we demonstrate that recessive variants are loss-of-function alleles. By analyzing the development and phenotype of *ST3* KO (*ST3*^{-/-}) mice, we bring additional evidence of enhanced susceptibility to pentylenetetrazole-induced seizure with the appearance of spontaneous epileptiform EEG, as well as developmental deficits such as higher motor activities and reduced parvalbumin interneurons. Taken together, our results exhibit impaired development of peripheral and central nervous system and support a conserved role of this transmembrane protein in neurological function.

Mendelian Phenotypes Posters - Thursday

PB1876. Hypophosphatemia gene panel sponsored program: a comparison of findings from 2019 through 2022 describing *PHEX* variant landscape and molecular diagnosis of XLH.

Authors:

N. Miller¹, E. Rush^{2,3,4}, K. Dahir⁵, O. K. Japalaghi¹, P. Ramesan¹, J. Yong⁶, H. McLaughlin⁷; ¹Ultragenyx Pharmaceutical Inc, Brisbane, CA, ²Univ. of Missouri – Kansas City Sch. of Med., Kansas City, MO, ³Children's Mercy, Kansas City, MO, ⁴Dept. of Internal Med., Univ. of Kansas Med. Ctr., Kansas City, KS, ⁵Vanderbilt Univ. Med. Ctr., Nashville, TN, ⁶Invitae Corp., San Francisco, CA, ⁷Invitae, South Lyon, MI

Abstract Body:

X-linked hypophosphatemia (XLH), a dominant disorder caused by disease-associated variants in the *PHEX* gene, affects males and females of all ages. Patients with XLH have musculoskeletal phenotypes along with below-normal serum phosphate and elevated serum FGF23. **Methods:** Individuals aged ≥ 6 months with a clinical XLH diagnosis or suspicion of genetic hypophosphatemia, as evidenced by 2 or more clinical signs/symptoms or family history of XLH, are eligible for the no-charge genetic testing program. A next generation sequencing panel with copy number variant (CNV) detection initially included 13 genes: *ALPL*, *CLCN5*, *CYP2R1*, *CYP27B1*, *DMP1*, *ENPP1*, *FAH*, *FAM20C*, *FGF23*, *FGFR1*, *PHEX*, *SLC34A3* and *VDR*. *CTNS*, *GNAS*, *ORCL*, and *SLC34A1* were added in SEP 2020. Variants were interpreted according to the joint consensus from ACMG/AMP using Invitae's interpretation algorithm, Sherlock. Here we compare results from 27 FEB - 2 OCT 2019 (first 31 weeks) with results through 31 MAR 2022 (3 years, 4 weeks). **Results:** 317 unrelated probands were tested as of 2 OCT 2019. 244 probands (77%) had a *PHEX* variant: 216 (88%) pathogenic or likely pathogenic (P/LP) and 28 (11%) variants of uncertain significance (VUS). 122 unique *PHEX* variants (P/LP) were detected: 39 SNV (32%), 29 splicing/intronic (24%), 23 CNV (19%), 23 small deletions (19%), 6 small duplications (5%), and 1 each Alu insertion and complex rearrangement (<1% each). Additional data, including family member testing, clinical information, or family history, resulted in reclassification of 6 VUS to P/LP, impacting 21 individuals. Of the 73 (23%) cases where no *PHEX* P/LP/VUS was found, 7 (10%) had molecular diagnoses in other genes: *ALPL*, *ENPP1*, *FGF23*. As of 30 MAR 2022 the number tested increased to 2188 unrelated probands. 1101 probands (50%) had a *PHEX* variant (1034 [94%] P/LP and 67 [6%] VUS). 406 unique *PHEX* variants (P/LP) were detected with a similar distribution as in 2019. Additional data resulted in 32 VUS being reclassified to P/LP, impacting 107 individuals. Of 1087 (48%) individuals where no *PHEX* P/LP or VUS was found, 200 (18%) had molecular diagnoses in other genes: *ALPL* (166), *CLCN5* (1), *CTNS* (2), *CYP27B1* (9), *CYP2R1* (1), *DMP1* (2), *ENPP1* (1), *FGF23* (10), *GNAS* (1), *ORCL* (2), *SLC34A3* (4), and *CTNS/ALPL* (1). **Conclusions:** We report a 3.3-fold increase in unique *PHEX* P/LP variants since 2019. Variant subtype distribution remains similar. *PHEX* VUS decreased from ~11% in 2019 to ~5% over the same period in 2021. Cascade testing and VUS resolution aids molecular diagnosis of XLH.

Mendelian Phenotypes Posters - Wednesday

PB1877. Identification and Functional Evaluation of Autosomal Recessive Non-Syndromic Hearing Impairment Genes in Rwanda.

Authors:

E. Uwibambe¹, L. Mutesa², A. Wonkam³; ¹Univ. of Rwanda, Kigali city, Rwanda, ²Univ. of Rwanda, Kigali, Kigali City, Rwanda, ³Johns Hopkins Univ. Sch. of Med., Univ Cape Town, Cape Town, South Africa

Abstract Body:

The incidence of hereditary hearing impairment (HI) is higher in developing countries compared to developed countries and more than 120 independent genes have been identified as responsible for almost 50% of profound HI. Nonsyndromic HI is the most common form accounting for 70% of cases of which 80% are autosomal recessive. Reported mutations in GJB2, GJB6, and GJA genes are the most common cause of HI but studies among Cameroonian and South African participants did not identify a significant association, hence the need for further genetic exploration of other responsible genes in the African population. In Rwanda, more than 50% of HI among children has been attributed to hereditary causes but no genetic evidence has been established. This study aims at identifying genes responsible for autosomal recessive non-syndromic hearing impairment (ARNSHI) among the Rwandan population. We will recruit 25 familial cases, 100 isolated cases, and 100 control individuals without HI or a family history of HI. One proband per familial affected family will be recruited together with one unaffected sibling, both parents, and at least one affected relative for blood sampling. Standard audiometry including air and bone conduction will be performed, and clinical history will be assessed to exclude exposure to ototoxic drugs or infections including prenatal exposure. For each family, we will exome-sequence samples of the affected members and use Sanger sequencing to follow up variants segregating in their parents and non-affected sibling, and the controls. At the end of the study, we expect to establish a dataset of genes that cause ARNSHI in Rwanda with possible novel ARNSHI variants that have not yet been found in the African population. This will help to advance the science of HI and establish appropriate medical care including early genetic screening, possible genetic therapies, proper genetic counseling necessary for affected individuals and families as well as plan for prevention and control measures against genetic HI.

Mendelian Phenotypes Posters - Thursday

PB1878. Identification of a novel compound heterozygous mutation in *RyR1* gene in an Indian family affected with congenital myopathy

Authors:

L. Kirola¹, D. Joshi², T. Murayama³, T. Sakurai³, A. Mukherjee¹, M. Mutsuddi¹; ¹Dept. of Molecular and Human Genetics, Inst. of Sci., Banaras Hindu Univ., Varanasi, India, ²Dept. of Neurology Inst. of Med. Sci. Banaras Hindu Univ., Varanasi, India, ³Dept. of Cellular and Molecular Pharmacology, Juntendo Univ. Graduate Sch. of Med., Tokyo, Japan

Abstract Body:

In the ryanodine receptor family (RyR), three genes (*RyR1*, *RyR2*, and *RyR3*) are involved in Ca²⁺ homeostasis, storage, and regulation. The RyR isoforms also play a vital role in extracellular and intracellular calcium signaling in many cell types, including muscles, neurons, and epithelial cells. Mutations in *RyR1* cause a wide range of clinical phenotypes, including several congenital myopathies (CM), central core disease (CCD), and hyperthermia susceptibility. *RyR1*-related CCDs usually show clinical heterogeneity and an early-onset of disease pathogenesis. Here, we present a family that includes unaffected parents and three siblings who are affected with CCD since childhood. The clinical features include lower proximal muscle weakness, difficulties in standing up and climbing, skeletal malformations, and hypotonia since birth. Muscle examinations (e.g., NCV, EMG, and muscle MRI) showed weak muscle intensity and activity. Whole-exome sequencing was performed in all the affected siblings using NovaSeq2000. Bioinformatic analysis and filtering of multiple variants revealed a novel variant in *RyR1*. This compound heterozygous variant (c.A5096G:p.D1699G+c.C5097A:p.D1699E; 13423_13424del:p.K4475Efs*106) has not been reported in public databases and *in silico* analysis predicted the variant to be damaging. Furthermore, this novel variant has segregated within the family and *in silico* protein analysis showed putative changes in the protein activity between the wildtype versus mutant *RyR1*. The functional analysis of the causal *RyR1* variants is being further investigated by our group. This study will help in the prenatal diagnosis of CM in the affected family and will also provide a platform for future therapeutics in *RyR1*-related diseases. Our study will also provide a genotype-phenotype correlation.

Mendelian Phenotypes Posters - Wednesday

PB1879. Identification of a novel pathogenic variant in *HIST1H1E* encoding the H1 histone linker in a patient with a complex phenotype including progeroid feature, intellectual disability and lipodystrophy. Contribution of additional variants to the complex.

Authors:

S. Mellone¹, D. Vurchio², S. Ronzani¹, T. Daffara³, M. Romanisio³, G. Ceccarini⁴, C. Pelosini⁴, F. Santini⁴, F. Prodam³, M. Giordano⁵; ¹Lab. of Genetics, “Maggiore della Carità” Hosp., Novara, Novara, Italy, ²Lab. of Genetics, “Maggiore della Carità” Hosp. and Dept. of Hlth.Sci., Università del Piemonte Orientale, Novara, Novara, Italy, ³Endocrinology Unit and Dept. of Hlth.Sci., Università del Piemonte Orientale, Novara, Novara, Italy, ⁴Obesity and Lipodystrophy Ctr., Endocrinology Unit, Univ. Hosp. of Pisa, Novara, Italy, ⁵Lab. of Genetics, “Maggiore della Carità” Hosp., Novara and Dept. of Hlth.Sci., Università del Piemonte Orientale, Novara, Novara, Italy

Abstract Body:

Here we report a case of an adult patient with type 2 diabetes, hypercholesterolemia that at physical examination presented: progeroid features, prominent forehead, hypertelorism, broad nasal bridge, baldness, hypotricosis, hearing loss and lost teeth at ten years of age. He showed developmental delay and ID, mild atrial septal defect, mild osteoporosis and a monolateral low testis volume, with subclinical hypergonadotroph hypogonadism. The BMI was normal and subcutaneous fat was underrepresented in leg and arms, but increased in the abdomen. Since the abnormal distribution of fat and metabolic alterations at a young age, we suspected a progeroid lipodystrophy syndrome. Leptin (1.9 mcg/L) was quite undetectable and the genes known to cause classical lipodystrophy syndromes were wild type as well as CGH array. A whole genome sequencing (WGS) of the proband and his parents was thus performed revealing a de novo pathogenic frameshift variant in *HIST1H1E*, p.Ser150fs,c.447dupC, encoding the H1 histone linker that acts as a structural component of the chromatin controlling the packaging of DNA, gene expression and DNA replication/repair. Mutations in this gene perturb multiple cellular process resulting in cellular senescence and alteration of genome methylation pattern and are characteristic of Rahman Syndrome, a recently recognized developmental disorder characterized by ID, dysmorphisms and an aging appearance. Variable somatic overgrowth may manifest in early infancy but is not observed in adults that often display decreasing height percentile over time. The WGS analysis also revealed inherited pathogenic variants in the *LDLR* gene explaining hypercholesterolemia, in *OTOGL* responsible for neurosensorial hearing loss and in *FBNI* possibly correlated to the lipodystrophy phenotype. This case represents a complex phenotype that remained without a clinical diagnosis for a long time and that reached a definitive diagnosis on the basis of the results obtained through WGS with at least four genes explaining most of his phenotypic characteristics.

Mendelian Phenotypes Posters - Thursday

PB1880*. Identification of a Novel Therapeutic Target Underlying Atypical Manifestation of Gaucher Disease

Authors:

H. Do¹, S. Kim¹, I. Choi², H. Bae³, G-H. Kim⁴, K. Kyunggon⁵, B. Lee⁶; ¹Asan Inst. for Life Sci., Seoul, Korea, Republic of, ²Asan Med. center, Seoul, Korea, Republic of, ³Med. Genetics Ctr., Asan Med. Ctr. Children's Hosp., Seoul, Korea, Republic of, ⁴Asan Med Ctr, Seoul, Seoul, Korea, Republic of, ⁵Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of, ⁶Asan Med Ctr, Seoul, Korea, Republic of

Abstract Body:

Gaucher disease (GD) is a lysosomal storage disorder caused by glucocerebrosidase 1 (GCase) deficiency. This GCase deficiency leads to accumulating glucosylceramide, glucosylsphingosine (Lyso-Gb1), a deacylated form glucosylceramide in the lysosome of macrophages. Therapeutic unmet needs such as lymphadenopathy and neurological manifestations have been observed despite enzyme replacement therapy (ERT), and the role of Lyso-Gb1 in these manifestations has been poorly understood. In the current study, the patients' lymph nodes, plasma, and fibroblasts were examined by multi-dimensional in vitro and in vivo studies. In a type 3 GD patient with severe mesenteric lymphadenopathy despite ERT, atypical Gaucher-like cells were found with intense Lyso-Gb1 accumulation as well as multinucleation, surrounded by fibrous band-like structures. Detailed immunohistochemistry and tissue proteomic analysis revealed altered complement and subsequent aberrant macrophage M1-M2 polarization underlying this aberrant phenotype. In addition, autophagosome formation was increased in these atypical cells, but the autophagy flux was impaired, resulting in low autolysosome formation and a subsequent severe inflammatory response. Importantly, we observed differential expression of proteins related to endothelial mesenchymal transition, in particular, an altered TGF- β signaling pathway. In line with these observations, TGF- β was increased in the plasma and fibroblasts of patients with type 3 GD, which was reduced by high-dose ambroxol treatment. In conclusion, our study demonstrated that complex molecular pathways underlie the unusual progression of GD, leading to ERT unresponsiveness, and a multi-functional therapeutic approach with combination therapy is required to relieve this devastating process.

Mendelian Phenotypes Posters - Wednesday

PB1881. Identification of a pathogenic gene mutation in Med12

Authors:

G. Serrano Rodriguez¹, A. Lebron², G. Arroyo Figueroa², N. Arciniegas³, S. Carlo⁴, A. Cornier⁵; ¹Ponce Hlth.Sci. Univ., Ponce, PR, ²Univ. of Puerto Rico, San Juan, PR, ³Mayaguez Med. Ctr., Cabo Rojo, PR, ⁴Ponce Hlth.Sci. Univ., Cabo Rojo, PR, ⁵San Jorge Children s Hosp./ Ponce Hlth.Sci. Univ., San Juan, PR

Abstract Body:

This case report presents a 12 year old boy with learning disabilities such as speech delay, fine, gross motor problems, autism, hypotonia, low ear set, and keratoconus. The patient was referred for genetic evaluation that resulted in genetic variants on PRMD5 and a novel pathogenic variant on Med12 p.(Asn1591Ser). The patient mother and sister were also evaluated for the MED12 variation. Med 12 is a component of the multiprotein complex known as Mediator, which is involved in the transcription regulation of several cellular processes. Mutations in different regions of Med 12 are related to x-linked intellectual disability syndromes and other abnormalities cataloged as Med-12 related disorders. We proposed that the variable expressivity observed on Med 12-related disorders is a consequence of allelic heterogeneity supporting a continuum of symptoms instead of different syndromes. New variants on Med12 are continuously broadening its genome architecture and phenotype expression, allowing for better genetic counseling and management of these patients.

Mendelian Phenotypes Posters - Thursday

PB1882. Identification of *INHBA*-related neurodevelopmental disorder

Authors:

Abstract Body:

Activins and Inhibins are composed of homo- and hetero-dimers of beta or alpha inhibin subunits. Beta-A and beta-B subunits, which are encoded by the *INHBA* and *INHBB* genes, can homodimerize to form the activins (Activin AA, AB, or BB); while the alpha subunit, encoded by *INHA*, heterodimerizes with either beta subunit to form inhibins (inhibin A or B). These compounds are part of the TGF-beta superfamily and play critical roles in development. In general, Activin homodimers are antagonized by Inhibin heterodimers. *INHBA* is located at 7p14.1; it has 3 exons and initiation of the beta-A coding sequence begins in exon 2. Mice deficient in the beta-A subunit (*Inhba*-null) have abnormal tooth development as Activin A is thought to regulate keratocyte development. Activin A may be involved in myofibroblast transdifferentiation as well. *Inhba*-null mice develop to term, but die within 24 hours after birth with cleft palate and absent whiskers and lower incisors, suggesting beta-A is involved in craniofacial development as a result of deficiency of either Activin A, AB, or Inhibin A. Ablation of *Inhba* expression in fetal mouse Leydig cells resulted in testis cord dysgenesis due to decreased Sertoli cell proliferation. We have identified 4 unrelated patients with de novo heterozygous variants in *INHBA* via exome sequencing (three missense variants involving residues within the mature domain and prodomain and a nonsense mutation involving the signal sequence). Subjects possessing the three missense variants had similar phenotypes associated with mild/moderate intellectual disability (ID) and primary generalized epilepsy. The subject possessing the nonsense variant phenotype had mild ID without epilepsy and a normal EEG. Dysmorphic facial features included hypertelorism and prominent ear lobes in two of the missense cases. The single male had delayed puberty, and 66% of females had endocrine abnormalities, although stature was normal. Tooth development was not examined in detail. Functional studies of these variants are planned in the future.

Mendelian Phenotypes Posters - Wednesday

PB1883. Identification of molecular causes of recessively inherited ataxic and neuropathic disorders in consanguineous Pakistani families.

Authors:

F. Aslam^{1,2}, M. Wajid³, E. Wohler⁴, N. Sobreira⁴, G. H. Seo⁵, W. Ji², S. Lakhani², S. Naz¹; ¹Univ. of the Punjab, Lahore, Pakistan, ²Yale Univ., New Haven, CT, ³Univ. of Okara, Okara, Pakistan, ⁴John Hopkins Univ., Baltimore, MD, ⁵3billion inc, Seoul, Korea, Republic of

Abstract Body:

Autosomal recessive ataxia is characterized primarily by gait and balance problems. Neuropathy is a condition in which nerve problems are manifested as distal muscle weakness, hand and foot deformities, sensory loss and dysphonia. We recruited seven consanguineous families having patients with symptoms of neuropathy or ataxia for the identification of possible genetic defects underlying their disease conditions. Exome sequencing was completed for multiple individuals from each family. Web-based server wANNOVAR, online Franklin tool and 3billion automated prioritization system were used for data annotation, prioritizing homozygous, exonic and splicing variants with frequency less than 0.01 in all public databases including gnomAD. Conservation of affected amino acids was checked by multiple protein alignments using Clustal Omega. Candidate variants were checked for segregation with the disease phenotype by Sanger sequencing of DNA from all participants. In members of five out of seven families, we identified variants, classified as pathogenic by multiple online prediction tools. These included homozygous nonsense, frameshift and missense variants in four genes: two families with different variants in *GDAP1*, and one family each with variants in *AFG3L2*, *MFSD8* and *SETX*. Variants of *GDAP1* were associated with neuropathic disorder while those of *AFG3L2* and *MFSD8* led to ataxic disorder without neuropathy. *SETX* variant was linked to ataxia with associated neuropathic syndrome. Pathogenic variants in *MFSD8* have been previously associated with childhood onset ceroid neuronal lipofuscinosis that cause vision problems and early death. Patients evaluated in this study reported no vision problems and were alive in their late fifties. No genetic cause was identified in the patients from two families, each having symptoms of ataxia, dysarthria, strabismus and spasticity. However, in one of these two families, we identified a frameshift variant in *ALS2* in one patient, but the same variant was not identified in his affected first cousins. In summary, exome sequencing identified the molecular causes of recessive ataxia or neuropathy in most of the recruited families and has broadened the clinical spectrum of *MFSD8* and mutational spectrum of others.

Mendelian Phenotypes Posters - Thursday

PB1884. Identifying modifier genes in a PIGA-CDG pedigree with reduced penetrance

Authors:

H. Thorpe, B. Pedersen, J. Bonkowsky, A. Quinlan, C. Chow; Univ. of Utah, Salt Lake City, UT

Abstract Body:

Phosphatidylinositol glycan class A (PIGA) encodes the catalytic component of the enzyme in the first step of GPI-anchor biosynthesis. GPI-anchors act as membrane anchors for over 150 proteins involved in signal transduction, immune response, and cellular communication among other functions. Loss of function mutations in *PIGA* lead to PIGA deficiency (PIGA-CDG), an ultra-rare disease, typically presenting with seizures, hypotonia, and neurodevelopmental delays. PIGA deficiency is an X-linked recessive congenital disorder of glycosylation (CDG). We identified two brothers (proband) with PIGA-CDG, presenting with mild developmental delay, epilepsy, and autism. Both probands carry the novel, rare *PIGA*^{S132C} variant, a predicted damaging variant not found in the gnomAD database. Confirming this diagnosis, both probands also show a 50% decrease in GPI-anchor protein on the cell surface. Strikingly, the maternal grandfather and a great uncle both also carry *PIGA*^{S132C}, but neither presents with symptoms associated with PIGA-CDG. We hypothesized that there might be a modifier segregating in the family that contributes to this reduced penetrance. Using whole genome sequencing and pedigree analysis, we identified all the possible susceptibility variants found in the probands and not in carriers and all the possible protective variants found in the carriers and not in the probands. This list of potential candidates included a single, damaging rare variant in two other genes also involved in GPI-anchor biosynthesis, *PIGS* and *DPM1*. To functionally test our predicted modifiers, we are using a *Drosophila* eye-based model of PIGA-CDG. We created double knockdowns of *PIGA* and the candidate modifiers and compared the eye sizes of the double knockdowns to the PIGA eye model and single knockdowns of the candidate modifiers. Functional and genetic analyses in this *Drosophila* model indicates that susceptibility and protective modifier genes are plausible human modifiers and could explain the incomplete penetrance in this family. The identification and study of rare disease modifier genes in human pedigrees may lead to pathways and targets that may be developed into therapies.

Mendelian Phenotypes Posters - Wednesday

PB1885. Identifying phenotypic expansions for congenital diaphragmatic hernia plus (CDH+) using DECIPHER data.

Hosp., Torino, Italy, ¹²Princess Anne Hosp., Southampton, United Kingdom, ¹³Nantes Université, Nantes, France, ¹⁴Univ. Hosp. Leuven–KU Leuven, Leuven, Belgium, ¹⁵Birmingham Women S NHS foundation Trust, Birmingham, IN, United Kingdom

Abstract Body:

Congenital diaphragmatic hernia (CDH) can occur in isolation or in conjunction with other birth defects (CDH+). A molecular etiology can only be identified in a subset of CDH cases. This is due, in part, to an incomplete understanding of the genes that contribute to diaphragm development. Here, we used clinical and molecular data from 36 individuals with CDH+ who are catalogued in the DECIPHER database to identify genes that may play a role in diaphragm development and to discover new phenotypic expansions. Among this group, we identified individuals who carried putatively deleterious sequence or copy number variants affecting *CREBBP*, *SMARCA4*, *UBA2*, and *USP9X*. The role of these genes in diaphragm development was supported by their expression in the developing mouse diaphragm, their similarity to known CDH genes using data from a previously published and validated machine learning algorithm, and/or the presence of CDH in other individuals with their associated genetic disorders. Our results demonstrate how data from DECIPHER, and other public databases, can be used to identify new phenotypic expansions and suggest that *CREBBP*, *SMARCA4*, *UBA2*, and *USP9X* play a role in diaphragm development.

Mendelian Phenotypes Posters - Thursday

PB1886. *In Silico* genomic interrogation reveals 16 autosomal dominant neurodevelopmental candidate genes at 1p13.3

Univ., Jinju, Korea, Korea, Republic of, ¹⁴Dept. of Biological Sci., Kent State Univ., Kent, USA, OH

Abstract Body:

Genome-wide chromosomal microarray is extensively used to detect copy number variations (CNVs), which can explain undiagnosed microdeletion and microduplication syndromes. These small unbalanced chromosomal structural rearrangements ranging from 1 kb to 10 Mb comprise up to 15% of human mutations leading to monogenic or contiguous genomic disorders. Albeit rare, CNVs at 1p13.3 cause a variety of neurodevelopmental disorders (NDDs) including development delay (DD), intellectual disability (ID), autism, epilepsy, and craniofacial anomalies (CFA). Most of the 1p13.3 CNV cases reported in the pre-microarray era encompassed a large number of genes and lacked the demarcating genomic coordinates, hampering the discovery of positional candidate genes within the boundaries. Here, we present four subjects with 1p13.3 microdeletions displaying DD, ID, autism, epilepsy, and CFA. *In-silico* comparative genomic mapping with previous reported three CNV subjects with 22 unreported DECIPHER CNV cases has resulted in the identification of four different sub-genomic loci harboring five positional candidate genes for DD, ID and CFA at 1p13.3. Most of these genes have pathogenic variants reported and their interacting genes are involved in NDDs. RT-qPCR in various human tissues revealed a high expression pattern in the brain and fetal brain, confirming their functional roles in NDDs. Interrogation of variant databases and interacting protein partners led to the identification of another set of 11 potential candidate genes, which might have been disrupted by the position effect of these CNVs at 1p13.3. Our studies define 1p13.3 as a genomic region harboring 16 NDD candidate genes and underscore the critical roles of small CNVs in *in silico* comparative genomic mapping for disease gene discovery. Our candidate genes will help accelerate the isolation of pathogenic heterozygous variants from the whole exome/genome sequencing (WES/WGS) database.

Mendelian Phenotypes Posters - Wednesday

PB1887. Incontinentia pigmenti female with the *IKBKG/NEMO*del4-10 deletion: A mosaic form.

Authors:

M. Ursini¹, E. Spinosa¹, M. Salvia¹, C. Casale¹, A. Pescatore¹, A. Torella^{2,3}, G. Piluso², V. Nigro^{2,3}, V. Piccolo⁴, A. Diociaiuti⁵, M. El Hachem⁵, F. Fusco¹; ¹IGB ABT CNR, Naples, Italy, ²Dept. of Precision Med., Univ. of Campania "Luigi Vanvitelli", Naples, Italy, ³Telethon Inst. of Genetics and Med. (TIGEM), Naples, Italy, ⁴Dermatology Unit, Univ. of Campania Luigi Vanvitelli, Naples, Italy, ⁵Dermatology Unit, Bambino Gesù. Children's Hosp.—IRCCS, Rome, Italy, Rome, Italy

Abstract Body:

Incontinentia pigmenti (IP; OMIM#308300) is an X-linked dominant disease, generally lethal in male, caused by mutations in *IKBKG/NEMO* gene, essential for NF- κ B activation. The IP phenotype is characterized by typical skin lesions and by neuroectodermal defects that contribute to a wide variability of disease severity.

Here we report the case of IP female with neurological and ocular impairment, carrying the recurrent deletion in *IKBKG/NEMO* gene as a somatic mutation. Moreover, the patient showed also a de novo pathogenic variant c.1708_1709del, p.Ser570fs*27 in *MED13L* gene.

The IP locus analysis revealed the presence of de novo *NEMO*del4-10 deletion and excluded the presence of the risk alleles for IP (*MER67*dup, *NEMO*Pdel). Somatic mosaicism was supported by quantitative analysis of the ratio of allele mutated versus wild-type allele in genomic DNA from blood. Consistent with somatic mosaicism, the sample of patient had lower ratios (30 %) of mutant versus wild-type allele compared to the fully heterozygote IP female control.

It has been previously reported that postzygotic/somatic mosaicism for the *IKBKG/NEMO* LoF mutation causes IP in male.

We here report that low level mosaicism for a post-zygotic/somatic *IKBKG/NEMO* mutation causes IP also in female. The somatic *IKBKG/NEMO* mutation in general is not detectable in male peripheral blood while is detectable in female most likely due to X-inactivation. The contribution of constitutive *MED13L* mutation in the female patient (NM_015335.5: c.1708_1709del) will be discussed.

Mendelian Phenotypes Posters - Thursday

PB1888. Integrating Genomic and Phenotypic Analyses of Autonomic Nervous System Dysfunction in a Rare Neurological Disease Cohort

Authors:

E. Rivera-Munoz¹, A. Jolly², H. Du¹, J. R. Lupski¹, J. E. Posey¹, Z. H. Coban-Akdemir³; ¹Baylor Coll. of Med., Houston, TX, ²1 Baylor Plaza, Houston, TX, ³Baylor Coll. of Med.; Human Genetics Ctr., Houston, TX

Abstract Body:

Autonomic nervous system dysfunction or dysautonomia represents a broad group of disorders that includes many diverse phenotypes affecting single - or multiple- organ systems within an affected individual. Many individuals with dysautonomia have neurocardiac involvement characterized by postural orthostatic tachycardia syndrome (POTS), orthostatic hypotension, and vasovagal syncope. Nevertheless, additional features have been described including abnormal temperature regulation, chronic fatigue, gastrointestinal issues, and dysregulation of other involuntary processes regulated by the parasympathetic and sympathetic nervous systems. Autonomic perturbations have multiple known etiologies ranging from aberrant development, adult stem cell maintenance, defects in ion channels, metabolism of neurotransmitters, inflammation, and neurodegeneration. Despite these mechanistic insights, many families with dysautonomia remain without a molecular diagnosis and limited efficacious treatments. Through the Baylor Hopkins Center for Mendelian Genomics (BHCMG) and Baylor College of Medicine Genomic Research to Elucidate the Genetics of Rare (BCM-GREGoR) databases, we have identified 38 unrelated probands and families with exome sequencing (ES) data across a range of clinical phenotypes that are indicative of autonomic nervous system dysfunction. This cohort was reported to have individuals with different organ systems involved including: 60.5% (23/38) cardiovascular, 57.9% (22/38) neurological, 39.5% (15/38) musculoskeletal, 36.8% (14/38) pulmonary, and 26.3% (10/38) gastrointestinal abnormalities. Using a quantitative phenotypic similarity score to compare patients' phenotypes, we have identified subtle phenotypic differences among our cohort, that may potentially inform distinct subgroups of dysautonomia in the context of rare disease. By leveraging existing genomic knowledge sources, we have identified putative candidate, rare variants (MAF \leq 0.1%) predicted to be loss of function in genes with relevant phenotypes in model organisms and the literature (*GXYLT1*, *ATP7B*, *CENPJ*, and *ARG1*). These molecular findings in rare disease may further and more broadly inform autonomic nervous system dysfunction and its clinical presentations beyond neurocardiogenic manifestations. We propose that parallel integration of gene- and phenotype-first analyses offers a productive method for investigation of human disease traits displaying substantial genotypic and phenotypic heterogeneity.

Mendelian Phenotypes Posters - Wednesday

PB1889. Intraflagellar transport protein RABL5/IFT22 is required for normal visual function and retinal photoreceptor survival

Authors:

Y. Yang, Z. Xianjun; UESTC, Chengdu, China

Abstract Body:

Purpose

The outer segment (OS) and inner segment (IS) of retinal photoreceptors are connected by a highly modified connecting cilium, which serves as a conduit to mediate the transport of photopigment molecules to the OS. RABL5/IFT22, a small GTPase-like component of the intraflagellar transport (IFT) complex B, which has been implicated in cilium construction and serves important functions in ciliary cargo selection/transport by recruits the BBSome to basal body. Considering the vital roles of ciliary transport in photoreceptors, we investigated the effect of genetic deletion of *Ift22* on the visual function and pathological changes in mouse.

Methods

We first constructed *Ift22* knockout (KO) mouse model. Electroretinograms (ERGs) were recorded to evaluate the visual function. H&E staining was carried out to verify the loss of rod cells in outer nuclear layer (ONL). To specific investigate the roles of in rod and cone photoreceptors, the conditional *Ift22*-knockout mouse models using the Rho-Cre and HRGP-Cre lines were also generated. Immunofluorescent labeling of several antibodies was performed to reveal detailed pathological alterations caused by *Ift22* deficiency. Transmission electron microscopy (TEM) was also employed to explore the ultrastructural pathological changes. Finally, label-free quantitative proteomics were used to investigate the underlying functional mechanisms behind the retinal pathologies.

Results

IFT22 was abundantly expressed in the retinal photoreceptor layer. ERG recordings manifested a reduction in the amplitudes of a- and b-waves in KO mice. Accordingly, H&E staining revealed a gradual thinning of ONL and shortening of OS in KO mice. Specific depletion of *Ift22* in rod cells causes extensive rod degeneration accompanied with ectopic accumulation of multiple OS proteins in the IS. Likewise, *Ift22* deficiency in cone cells led to the mislocalization of cone opsin and progressive death of cone cells. Mechanistically, label-free quantitative proteomics illustrated that IFT22 depletion resulted in reduced content of multiple phototransduction- and cilium-associated proteins. Western blot further verified that the levels of phototransduction signaling proteins CNGA1, GNAT1 and BBSome components BBS2, BBS4, BBS5 were reduced in *Ift22*-deficient retinas, although both immunostaining and TEM revealed normal cilium organization.

Conclusions

Our data demonstrate that IFT22 plays an important role in maintaining ciliary transport in retinal photoreceptors, and is essential for photoreceptor function and survival.

Mendelian Phenotypes Posters - Thursday

PB1890. Investigating SLC6A1 targeted therapeutics in *Drosophila*.

Authors:

K. Jay¹, K. Pham¹, J. Andrews¹, S. Jangam¹, N. Gogate¹, R. German¹, F. Alavi Naini¹, J. Constantino², H. Dierick¹, H. Bellen¹, M. Wangler¹; ¹Baylor Coll. of Med., Houston, TX, ²Washington Univ., St. Louis, MO

Abstract Body:

Our understanding of the clinical phenotype associated with *SLC6A1* (*Solute Carrier 6, Member 1*) related disorders is rapidly increasing. Patients experience genetic pleiotropy and variable expressivity of symptoms including developmental delay, epilepsy, intellectual disability, motor dysfunction, and autism spectrum disorder. *SLC6A1* encodes the gamma aminobutyric acid (GABA) transporter type 1 (GAT1) protein and contributes to maintaining homeostasis of excitatory and inhibitory neurotransmitters. GAT1 is responsible for the reuptake of the inhibitory neurotransmitter GABA at the synapse which is essential to protect from seizure activity. The most prevalent phenotype of *SLC6A1* patients is pediatric onset absence seizures that progress with age to myoclonic atonic seizures. Seizures are managed with general anti-epileptics, but many patients are not responsive to standard therapeutics. Furthermore, GAT1 is a potential therapeutic target. For this study, we recruited 11 patients through the Brain Gene Registry with *SLC6A1* related disorders. We completed a genotype-phenotype correlative study and identified patients who were responsive and non-responsive to current therapeutics. The average number of therapeutics attempted was 4.6 per patient and several patients experienced exacerbated symptoms or adverse side effects before identifying the most effective treatment. Stronger alleles that impede protein function should result in increased GABA in the presynaptic cleft and increased downstream GABA receptor signaling. I hypothesize increasing activity of the functional GAT1 protein will improve synaptic homeostasis and suppress seizure activity in *SLC6A1* patients. We have characterized loss-of-function phenotypes associated with loss of the *Drosophila* ortholog *Gat*. We found that *Gat* mutant flies are bang sensitive analogous to seizure activity in humans, exhibit motor dysfunction, and have a reduced lifespan. We are currently developing patient specific custom constructs to insert into the *Drosophila* genome to express our variants of interest. Our short-term goal is to evaluate the ability of the variants to rescue loss-of-function phenotypes. Our long-term goal is to identify novel *SLC6A1* modulators and to apply these custom models to predict patient response to therapeutics. Identifying therapeutics that will be most effective in suppressing seizure phenotypes by genotype will eliminate several rounds of trial and error for the patient and result in improved outcome for those living with *SLC6A1* related disorders.

Mendelian Phenotypes Posters - Wednesday

PB1891. Investigating the role of seryl-tRNA synthetase in mitochondrial biology and human recessive disease

Authors:

C. Del Greco, J. Kitzman, A. Antonellis; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Aminoacyl-tRNA synthetases (ARSs) are essential, ubiquitously expressed enzymes that charge tRNA molecules with amino acids in the cytoplasm and mitochondria. All 37 human ARSs are nuclear-encoded and 17 charge tRNA exclusively in the mitochondria to allow for the translation of the thirteen mitochondrial-encoded proteins, which are involved in oxidative phosphorylation. All 17 mitochondrial ARSs have been implicated in human recessive diseases with a broad range of clinical phenotypes that often affect tissues with high energy demands. Mitochondrial seryl-tRNA synthetase (*SARS2*) has been implicated in disease phenotypes including progressive spastic paresis and HUPRA (hyperuricemia, pulmonary hypertension, renal failure in infancy, and alkalosis) syndrome; however, there is no explanation for this clinical variability. Additionally, the number of disease-causing variants is small ($n=6$) and the spectrum of potentially pathogenic *SARS2* variants is incomplete. To address these issues, we will perform a massively parallel assessment of all possible loss-of-function variants in the *SARS2* open reading frame. We generated a Hap1 cell line that contains: (1) a randomly integrated, doxycycline-inducible wild-type copy of *SARS2*; and (2) a 2kb deletion at *SARS2* that ablates gene function. These cells will be transduced with lentiviral cDNA libraries containing all possible *SARS2* variants. Since *SARS2* is an essential enzyme, we will sequence the transduced cDNA from cells in the presence of doxycycline (during expression of the inducible wild-type copy of *SARS2*) and in the absence of doxycycline (in which the variant *SARS2* from the cDNA is the only copy of *SARS2* being expressed). This will allow us to catalog loss-of-function variants by identifying variants that are reduced in the cell population. This comprehensive variant-to-function map will expand the spectrum of potentially pathogenic *SARS2* variants to aid in future diagnosis, and will identify amino acid residues that are important for *SARS2* function.

Mendelian Phenotypes Posters - Thursday

PB1892*. Investigating tissue specific defects in mitochondrial bioenergetics and quality control: new implications for cellular pathogenesis and therapeutic targeting in Barth syndrome

Authors:

O. Sniezek¹, N. Senoo², G. Butschek³, A. Anzmann¹, S. Claypool², H. Vernon¹; ¹Johns Hopkins Sch. of Med., Dept. of Genetic Med., Baltimore, MD, ²Johns Hopkins Sch. of Med., Dept. of Physiology, Baltimore, MD, ³Johns Hopkins Sch. of Publ. Hlth., Dept. of Molecular Microbiol. and Immunology, Baltimore, MD

Abstract Body:

Barth Syndrome (BTHS) is a rare, X-linked disorder caused by defects in the gene TFAZZIN, resulting in defective cardiolipin remodeling. BTHS is clinically characterized by cardiomyopathy, neutropenia, growth defects, and myopathy and in contrast to many mitochondrial disorders, there are limited central nervous system effects. There is a high risk of morbidity and mortality, with no approved disease-specific treatments. Our lab previously identified defects in Complex I of the mitochondrial respiratory chain, and dysregulation of PARL and PGAM5 mediated mitochondrial quality control in a TFAZZIN-KO HEK293 model. However, it is not known why the effects of TFAZZIN, which is ubiquitously expressed, have a tissue-specific pattern of disease expressivity. To understand tissue specific Complex I and mitochondrial quality control defects in BTHS we differentiated TFAZZIN-KO iPSCs into cardiomyocytes (an affected tissue in BTHS) and neurons (a spared tissue in BTHS). To broadly characterize each cell type in an unbiased manner, we first performed RNAseq. This analysis identified cell-type specific dysregulation in pathways related to mitochondrial quality control and metabolism including Wnt signaling, apoptosis, autophagy, and cardiomyocyte-specific dysregulation in glucose metabolism. To illustrate the effects of defective mitochondrial quality control, we next characterized the morphology of each cell type with confocal microscopy. TFAZZIN-KO cardiomyocytes revealed significant morphological abnormalities compared to wild type including decreases in mitochondrial number, area, perimeter, and branching. Importantly, these mitochondrial abnormalities were not found in TFAZZIN-KO undifferentiated cells or neural progenitors. We next investigated bioenergetic phenotypes in each cell type. Oxygen consumption studies showed impaired maximal respiratory capacity in TFAZZIN-KO cardiomyocytes and neurons but less so in undifferentiated cells. The respiratory capacity of wild-type cardiomyocytes was improved by fatty acid supplementation mimicking the cardiac physiological environment; however, that of TFAZZIN-KO cardiomyocytes was further severely impaired. We next plan to study substrate utilization in TFAZZIN-KO neural progenitors to determine if these effects are recapitulated. To understand new directions for potential therapeutic intervention in BTHS, we are currently targeting specific fatty acid pools and early steps in cardiolipin metabolism in cardiomyocytes and neurons with the goal of remediating cellular lipids, mitochondrial morphological defects, and oxygen consumption abnormalities.

Mendelian Phenotypes Posters - Wednesday

PB1893. Investigating variants of uncertain significance in orofacial cleft trios.

Authors:

K. Diaz Perez¹, S. Curtis¹, A. Sanchis-Juan², T. Head¹, S. Ho¹, B. Carter³, T. McHenry⁴, M. Bishop¹, L. Valencia-Ramirez⁵, C. Restrepo⁵, L. Moreno⁶, G. Wehby⁶, T. Beaty⁷, J. Murray⁸, E. Feingold⁴, M. Marazita⁹, D. Cutler¹, M. Epstein¹, H. Brand¹⁰, E. Leslie¹; ¹Emory Univ., Atlanta, GA, ²Broad Inst. of Harvard and MIT, Somerville, MA, ³Agnes Scott Coll., Decatur, GA, ⁴Univ of Pittsburgh, Pittsburgh, PA, ⁵Fundacion Clinica Noel, Medellin, Colombia, ⁶Univ Iowa, Iowa City, IA, ⁷Johns Hopkins Univ, Sch PubHlth, Cockeysville, MD, ⁸U of Iowa, Iowa City, IA, ⁹Univ Pittsburgh, Ctr. for Craniofacial and Dental Genetics, Pittsburgh, PA, ¹⁰Massachusetts Gen. Hosp., Boston, MA

Abstract Body:

Orofacial clefts (OFCs) are common craniofacial birth defects, including cleft lip (CL), cleft lip and palate (CLP), and cleft palate (CP). OFCs are etiologically heterogeneous, and many of the genetic risk factors are not well understood. Recently, we investigated likely pathogenic variants in 503 genes associated with primarily Mendelian OFCs using whole-genome sequencing of 841 OFC cases and 294 controls. We found likely pathogenic variants in 9.16% of cases and only 1.36% of controls ($p < 0.0001$). These likely pathogenic variants in cases were distributed across 40 genes, underscoring the substantial genetic heterogeneity in OFCs. However, most reviewed variants (59.5%) were classified as “variants of uncertain significance” (VUSs) and were more frequent in cases than controls ($p = 0.002$) even though cases and controls had similar distributions of VUSs per person. Overall, VUSs were overwhelmingly missense variants, highlighting the difficulty of assessing pathogenicity for missense variation. Furthermore, we noted a high number of VUSs among cases were in genes highly constrained to missense variation (Genome Aggregation Database (gnomAD) missense Z score ≥ 3.1) ($p = 0.10$). To assess whether individual genes exist with a significant excess of VUSs in cases, we performed gene-based association tests using the Optimal Sequence Kernel Association Test. Overall, we found no single gene with a significant excess of VUSs in cases that could explain the genome-wide burden of VUSs in cases versus controls. However, we found that VUSs in *PRICKLE1* were nominally associated with the risk of OFCs ($p = 0.04$). All other nominally associated genes (e.g., *PHYH*, *SOX9*) showed a higher frequency of VUSs in controls (*PHYH*, $p = 0.03$; *SOX9*, $p = 0.03$). These results remained consistent after removing 81 “solved” individuals with likely pathogenic variants. Stratifying by cleft types identified additional nominal associations, including VUS variants in *GLI3* with CL ($p = 0.009$). *GLI3* VUSs were also identified with individuals with CLP but were not significantly associated. Overall, these data suggest a collective effect of risk variants in various genes among cases, including variants that are not easily classified as pathogenic, and variants in these genes should be subjected to functional validation to determine their true effect. Cumulatively, these results further highlight the etiological heterogeneity of OFCs and provide insight into the role of VUSs in candidate genes for risk to OFCs.

Mendelian Phenotypes Posters - Thursday

PB1894. Isolated acanthosis nigricans in a Mexican girl with a nonsense variant in *FGFR3* gene.

Authors:

M. Abreu González¹, R. Santillán-Martínez¹, L. Hernández Ancheyta¹, Y. Centeno Navarrete², S. Contreras-Capetillo³; ¹Genos Medica, Mexico City, Mexico, ²Hosp. Gen. Agustín O'Horán, Secretaría de Salud de Yucatán,, Yucatán, Mexico, Mexico, ³Centro de Investigaciones Regionales Dr. Hideyo Noguchi, Univ. Autónoma de Yucatán,, Yucatán, Mexico

Abstract Body:

Acanthosis nigricans (AN) is characterized by velvety thickening and hyperpigmented hyperkeratosis of the skin, usually affecting the folds of the neck, armpits, forehead and groin. Syndromic AN has been described with gain of function variants in *FGFR3* (MIM *134934) as part of severe achondroplasia with developmental delay, Crouzon syndrome and hypochondroplasia. The constitutive activation of the *FGFR3*, which are only caused by missense mutations, led to inhibition of chondrocytes growth that produces skeletal anomalies. Meanwhile, the isolated familial acanthosis nigricans (IAN) is originated by mutations with a weak dominant activity in the receptor. Recently, were described two cases of IAN with a nonsense variant in *FGFR3* [Tahara, et al 2021].

In this study we present a female Mexican patient, the only affected in the family, with IAN. On examination at 10 years old she had height (p.75-90) and weight (p.25). The skin was thick and hyperpigmented specially in the jaw, neck and armpits. No skeletal anomalies or neurological defects were detected. Insulin, HOMA, ACTH and 17-hydroxiprogesterone were within normal limits. The skin biopsy was reported as papillomatosis, hyperkeratotic and AN.

A next generation sequencing targeted panel was ordered (Sophia Genetics, CES V2 Panel). The bioinformatics pipeline analysis of the 29 genes associated with AN identified the c.2302G>T (p.Glu768*) pathogenic variant in *FGFR3*, that is predicted to introduce a premature termination codon in the last exon, and it is been suggested that generates a weak constitutive active receptor that correlates with the clinical phenotype of our patient.

Here we described the third case of IAN, the mildest form of the *FGFR3*-related disorders, due to a c.2302G>T (p.Glu768*) in *FGFR3* that expands the phenotype of the type of mutations that could be found in this gene. Patients with IAN, regardless of the presence skeletal alterations, should have a *FGFR3* analysis performed [Hirai, et al 2017].

Mendelian Phenotypes Posters - Wednesday

PB1895. *ITGB8* is a candidate disease gene for autosomal dominant and recessive trait forms of muscular dystrophy and neurological disease

Authors:

S. Barish¹, H. Du², Y. Li¹, J. Fatih¹, D. Calame¹, T. Mitani³, D. Pehlivan¹, J. Lupski¹, J. Posey¹; ¹Baylor Coll. of Med., Houston, TX, ²BCM, Houston, TX, ³Kanagawa Children's Med. Cente, Yokohama, Kanagawa, Japan

Abstract Body:

Integrins are a family of cell adhesion molecules that facilitate cell-cell and cell-extracellular matrix (ECM) contact. Integrins form heterodimers of an alpha and a beta subunit. There are 26 integrins in the human genome (18 alpha, 8 betas), nine of which have been associated with Mendelian conditions. Integrins have primarily associated with skin diseases such as epidermolysis bullosa (MIM #226730) and none have been associated with neurological disease to date. In this study, we identified three unrelated probands with putatively pathogenic variants in *ITGB8*. Two of the probands carry a homozygous missense variant allele, NM_002214.3 c.1846G>A (p.Asp616Asn), that is ultrarare (minor allele frequency < 0.1%) in both control and mixed rare disease populations. These probands present with neurological phenotypes including developmental delay, intellectual disability, microcephaly, and dysmorphic features. The third proband carries a heterozygous putative loss-of-function variant, NM_002214.3 c.1635C>A (p.Y545*) in exon 10/14 that is absent from control populations. This proband presents with facioscapulohumeral muscular dystrophy (FSHD) but analysis of *SMCHD1* and *DNMT3B*, as well as D4Z4 repeat number, did not yield any potential damaging variants to support an FSHD type 1 or type 2 molecular diagnosis. Variants in *ITGB8* were verified in each family via Sanger dideoxy sequencing and segregated in accordance with Mendelian expectations for an autosomal recessive rare disease trait in the first two families. Parental samples for the third family were not available, but the variant was not detected in either the unaffected sibling or child of the proband. *In silico* tools predict *ITGB8* to be intolerant to loss-of-function (pLOEUF = 0.26) and the identified variants are predicted to damage protein function. Together, our data suggest that variants in *ITGB8* are associated with dominant and recessive forms of neurogenetic rare disease trait.

Mendelian Phenotypes Posters - Thursday

PB1896. Joint analysis of de novo mutations in multiple traits and gene-expression data improves statistical power for the prioritization of genes associated with disease

Authors:

T-H. Nguyen, K. Kendler, B. Riley, S-A. Bacanu; Psychiatry Dept., Virginia Commonwealth Univ., Richmond, VA

Abstract Body:

Motivation: De novo mutations from parent-offspring trio data have helped identify risk genes for neuropsychiatric and other disorders. However, for many disorders, only a small number of genes have been discovered. Fortunately, identified genes of multiple disorders are expressed mostly in specific tissues or cell types. Therefore, integrating the gene expression information of the enriched tissues or cell types can increase statistical power. We previously showed that mTADA (multi-trait transmission and de novo association test), which performs a joint analysis of de novo mutations from multiple traits, helps identify additional risk genes. We also showed that integrating gene-sets from gene expression data into this method could improve statistical power. However, the previous approach is not able to jointly analyze multiple tissues/cell types. Here, we propose a flexible approach which integrates both 1) de novo mutations from two traits and 2) the gene-expression information from multiple tissues/cell-types for the prioritization of risk genes.

Results: We tested the new method on simulated data. The new approach performs better than mTADA in the identification of risk genes, especially when enriched tissues are used. We applied the new method to a de novo mutation dataset of 10,012 parent-offspring trios from five disorders. We identified more risk genes than its previous version. For example, by using a threshold of $FDR < 0.05$ in the joint analysis of autism spectrum disorder (ASD) and epileptic encephalopathies (EE): 51 genes were identified by the new approach while only 46 genes were reported by mTADA for ASD.

Availability: The new method is incorporated into our active mTADA R package, which contains various functions for parent-offspring trio analyses.

Mendelian Phenotypes Posters - Wednesday

PB1897. *KIF1A* novel variant p.(Ser887Profs*64) exhibits clinical heterogeneity in a Pakistani family individuals with HSANIIC

Authors:

M. Azam¹, S. Ghafoor¹, M. Rafiq¹, S. Abbas Shah¹, M. Ajmal¹, R. Qamar²; ¹COMSATS Univ. Islamabad, Islamabad, Pakistan, ²Sci. and Technology Sector, ICESCO, Rabat, Morocco, Rabat, Morocco

Abstract Body:

Hereditary sensory and autonomic neuropathies (HSANs) are rare heterogeneous group of neurological disorders caused by peripheral nerve deterioration. The HSANs sub-clinical classes have clinical and genetic overlap which often lead to misdiagnosis. In the present study a Pakistani family with five affected members suffering from neuropathy were genetically analyzed to identify the disease causative element in the family. Genome wide high-density single nucleotide polymorphism (SNP) microarray analysis of DNA samples of five affected and nine healthy members was carried out followed by whole exome sequencing of the proband and an affected sibling. Shared homozygous regions in all affected were identified through homozygosity mapping approach. The largest homozygous region of 14.1Mb shared by the five affected members of the family was identified on chromosome 2. Subsequent exome sequencing identified a novel single nucleotide deletion c.2658del; p.(Ser887Profs*64) in *KIF1A*. Segregation analysis revealed that this mutation was homozygous in all five affected individuals of the family with severe clinical manifestation, while members of the family that were heterozygous carriers shared only abnormal skin features (scaly skin) with the homozygous affected members. A novel frameshift mutation p.(Ser887Profs*64) in *KIF1A* is the potential cause of severe HSANIIC in a Pakistani family along with incomplete penetrance in mutation carriers. We demonstrate that using a combination of different techniques strengthens the gene finding approach along with exact clinical sub categorization in HSAN group of inherited diseases.

Ctr. at Houston, Houston, TX, ¹³Pacific Northwest Res. Inst., Seattle, WA

Abstract Body:

Neurodevelopmental disorders (NDDs) affect >3% of newborns worldwide due to nervous system dysfunction. Driven by the Clan Genomics hypothesis, family-based genomics, and rare variant analyses, the discovery of novel NDD-traits has reached an ‘exponential phase.’ Nevertheless, the mutational mechanisms and perturbations of biological balance underlying this clinically heterogeneous class of disorders remain largely unknown. Here, we performed genomic analyses of a cohort of 150 mostly consanguineous families with NDDs from the Middle East and North Africa (MENA) region. Preliminary data analyses reveal a molecular solved rate of 103/150 (69%) families via exome sequencing and deep clinical phenotyping, including 87/150 (58%) solved by known disease genes/loci and 16/150 (11%) cases solved by proposed candidate genes. Sixty-five distinct genes/loci linked to known NDD traits, including 72 (94%) SNVs/indels and 5 (6%) CNVs. Among 87 families solved with known disease genes/loci, recessive NDD traits driven by autozygosity were found in 73/87 (84%) of families, while 10/87 (12%) families revealed *de novo* dominant NDD traits despite reported parental consanguinity; inherited X-linked hemizygous and compound heterozygous alleles were also observed in 2/87 (2%) families, respectively. The average total absence of heterozygosity, a surrogate measure of runs of homozygosity (ROH) calculated from 30 unrelated families in this cohort, was 313 Mb (range: 118 to 647Mb), and causal autozygous variants fall within ROH blocks in an average of 12.04 Mb (range: 1.2 to 60.5 Mb). For families with a single molecular diagnosis, the total ROH in the MENA cohort is significantly higher than in the previously published TBM2-NDD and Arthrogryposis cohorts (one-way ANOVA, $p < 0.0001$), however, there are no statistical differences in the total ROH among the three cohorts for the families with multi-locus pathogenic variants. Moreover, identifications of candidate genes led to discoveries of multiple novel neurobiological mechanisms such as i) biallelic loss-of-function (LoF) of *LGI3* causing mislocalization of Kv1 channel complexes in juxtaparanode of myelinated peripheral axons, resulting in a novel peripheral nerve hyperexcitability syndrome; ii) LoF mutations in *SLC38A3*, a sodium-coupled neutral amino acid transporter required for the glutamate/GABA homeostasis, cause a novel AR-type of developmental epileptic encephalopathy. Together, family-based genomic analysis on a diverse population accelerates the discoveries of novel NDD genes/loci, serving as an “entry-point” to elucidate unknown neurobiology of disease.

Mendelian Phenotypes Posters - Wednesday

PB1899. Large-scale zebrafish-based functional analysis of genes associated with neurodevelopmental disorders

Authors:

S. Thyme, C. Conklin, W. Gannaway, E. Torija, V. Martina, A. Ginsparg, C. Calhoun, M. Vivian, M. Capps, Thyme Lab Undergraduate Assistants (>5); Univ. of Alabama at Birmingham Med. Sch., Birmingham, AL

Abstract Body:

The goal of the Thyme lab is to uncover the molecular basis for complex neurodevelopmental disorders and discover drug treatments. We use the larval zebrafish model, taking advantage of new high-resolution and large-scale approaches for neural phenotyping and genetic analysis, which we pioneered for analyzing mutants generated with CRISPR/Cas9. Previously, we assessed whole-brain activity, brain morphology, and behavior of zebrafish loss-of-function mutants for orthologs of 132 human schizophrenia-associated genes. This work set the stage for in-depth molecular studies of several mutants with compelling phenotypes and additional screens of genes involved in other disorders. One example of an in-depth study is of the autism- and schizophrenia- associated transcription factor ZNF536, which we have found regulates a completely unstudied putative protease through RNA-seq and genetic interaction data. We have ongoing, unpublished screens for other genes linked to schizophrenia by exome sequencing (7 genes), rare variants linked to childhood-onset schizophrenia (8 genes and 4 patient mutations), and genes directly linked to autism (17 genes and 3 patient mutations) and indirectly through the implicated program of developmentally regulated microexon splicing (43 genes). We have collected whole-brain activity maps and behavioral data for more than 50 mutant lines from these screens. Comparing the phenotypes of truncating mutations to patient-specific mutations has provided insight into the function of these mutations. In parallel to our zebrafish work, we have built a new computational method for in silico drug discovery. This method integrates a knowledge-based approach with the physical energy potential of the Rosetta macromolecular modeling program. Testing several hundred predicted compounds in larval zebrafish is feasible, and many proteins are highly conserved, making it an ideal model for compound screening and testing new tools and methods. Our proposed pipeline of integrating computation, whole-organism screening, and in-depth mechanistic studies promises to yield potentially therapeutic molecules that impact diverse mechanisms underlying neural development and function.

Mendelian Phenotypes Posters - Thursday

PB1900. Leveraging orthogonal sequencing and optical mapping technologies for the precision diagnosis of neurodevelopmental disorders in a Middle Eastern family based cohort.

Authors:

Z. Siddig¹, D. Hammadi¹, A. Nour¹, S. Hassan¹, M. Ghorbani¹, H. Naeem¹, I. Diboun¹, S. Moosa¹, R. Abouelhasan¹, M. Tauro¹, S. Nassar¹, R. Farhad¹, R. Razali², I. Alazwani¹, M. Hashmi¹, R. Mokrab^{1,4,5}; ¹Sidra Med., Doha, Qatar, ²Dept. of BioMed. Sci., Coll. of Hlth.Sci., Qatar Univ., Doha, Qatar, ³Sidra Med., Doha, Qatar, Qatar, ⁴Dept. of Genetic Med., Weill Cornell Med., New York, NY, ⁵Coll. of Hlth.and Life Sci., Hamad Bin Khalifa Univ., Doha, Qatar

Abstract Body:

Establishing genotype-phenotype correlations for neurodevelopmental disorders (NDDs) is a substantial challenge, especially amongst Middle Eastern populations enriched for these conditions due to high level of consanguinity. We implemented a platform integrating data from short and long read WGS, optical mapping and EHRs to diagnose and characterize unresolved pediatric cases with neurodevelopmental disorders in Qatar. In a pilot project, we recruited a cohort with intractable epilepsy or developmental delay with no genetic diagnosis, consisting of 102 families of patients. For these we generated Illumina WGS and PacBio long-read sequencing, from which we obtained high quality SNVs and Indels as well as SV and CNVs respectively. EHRs were collected and mapped to HPO from which the terms global developmental delay, delayed speech, and seizures were found to be most common. Family segregation genomic analysis was done using Congenica© using gene panels from the G2P consortium. Variants were annotated with allele frequency from Qatar Genome Project and other public datasets, as well as pathogenicity predictors including Exomiser and CADD. Candidate disease variants were then prioritized following ACMG guidelines. Using this approach, we analyzed a set of 14 families leading to the shortlisting of 23 variants on 22 genes. Nine genes were known to be implicated in NDDs. Amongst the variants, 9 variants were previously reported including 3 with phenotypes reported as matching the patients'. We report a *de novo* missense variant (chr15:44881558C>A) in *SPG11* in a female patient with spastic tetraplegia, cerebral palsy, global developmental delay, and seizures. *SPG11* is strongly linked to spastic paraplegia in the Decipher Developmental Disorders Genes database. Furthermore, we identified 9 novel variants on known pathogenic genes potential link to patient phenotypes. For instance, we identified a novel *de novo* pathogenic splice donor variant (chr19:13136367G>A) in *NFIX* in a male patient who exhibits symptoms of global developmental delay and tall stature. Known syndrome caused by *NFIX* mutations is Soto's syndrome, characterized by developmental delay and overgrowth (PMID: 25736188).Based on PacBio long read data we identified CNVs across genes and genomic regions known to be linked to NDDs as well as novel regions. For example, we identified an 80.9kbp homozygous deletion at 21q22.12 in a patient who presented with microcephaly and global developmental delay. As we continue to analyze this patient cohort, the results will have significance impact on to the precision diagnosis and understanding of developmental disorders in the Middle East and worldwide.

Mendelian Phenotypes Posters - Wednesday

PB1901*. LIM Homeobox 1 gene variants contribute to Mayer-Rokitansky-Küster-Hauser syndrome

Authors:

D. Kira¹, J. Butler², L. P. Chorich¹, Z. A. Hawkins¹, J. A. Phillips III³, L. C. Layman⁴; ¹Augusta Univ., Augusta, GA, ²Morehouse Sch. of Med., Atlanta, GA, ³Vanderbilt Univ. Med. Ctr., Nashville, TN, ⁴Med Coll GA at Augusta Univ., Augusta, GA

Abstract Body:

Introduction: Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome consists of congenital absence of the uterus and vagina and affects 1/4,500 women. Affected individuals present with normal breast development, primary amenorrhea, and a 46,XX karyotype. The Mullerian aplasia may be isolated (type I) or associated with renal, skeletal, cardiac, and auditory anomalies (type II). The etiology of MRKH largely remains unknown, but multiple reports of familial clustering suggest possible genetic causes. Copy number variants (CNVs) have been reported, including a recurring 1.2 Mb chromosome 17q12 deletion. Interestingly, the LIM Homeobox 1 gene (*LHX1*) locus resides on 17q12 and it encodes the LHX1 transcription factor containing two LIM Zinc finger motifs and one DNA binding domain. LHX1 is important in renal and uterine development in rodents, and is essential for development of Müllerian duct epithelial progenitor cells. **Hypothesis:** Heterozygous deleterious *LHX1* variants including CNVs may cause MRKH. **Method:** gDNAs from 134 individuals with MRKH were analyzed by quantitative PCR (qPCR) to identify potential *LHX1* deletions since DNA sequencing failed to reveal single nucleotide variants. Heterozygous *LHX1* exon 4 deletions were found in gDNAs from 3/134 unrelated individuals. Total RNA was obtained from lymphoblasts from these 3 individuals with MRKH cultured with or without puromycin (a translation inhibitor that suppresses nonsense-mediated decay or NMD). RNAs were subjected to RT-PCR, followed by PCR for exons 3-5 of *LHX1*. PCR products were confirmed, and subjected to colony PCR and Sanger sequencing. **Results:** qPCR of gDNA demonstrated a de novo heterozygous 166 bp *LHX1* deletion (c.676_841del;pV226 Ifs*120) deleting the entire exon 4 sequence in all three patients, which was confirmed by RT-PCR. An intense exon 3-5 band was seen on gel electrophoresis by RT-PCR at differing concentrations of cDNA only with puromycin treatment. Without puromycin, no band was seen with 500ng or 1ug, but demonstrated a faint band with 1.5 and 2ug of cDNA. By colony PCR and sequencing, both the WT and variant were observed. Without puromycin most colonies were variant; with puromycin most colonies were WT. **Conclusion:** Our data indicate that gDNAs of 3/134 persons with MRKH have an *LHX1* exon 4 deletion, which is predicted to disrupt the 3' portion of the DNA binding domain. We hypothesize that these exonic deletions, extend into flanking introns to create, eliminate or activate cryptic splice sites that trigger NMD that leads to their degradation. Our findings provide additional evidence that LHX1 CNVs along with previously reported WNT4 and HNF1B variants contribute to MRKH.

Mendelian Phenotypes Posters - Thursday

PB1902. Lisch epithelial corneal dystrophy is caused by heterozygous loss-of-function variants in *MCOLN1*

Authors:

K. Patterson¹, J. X. Chong¹, D. D. Chung², W. Lisch³, H. Møller⁴, D. Garczarczyk-Asim⁵, E. Dreisler⁶, University of Washington Center for Rare Disease Research, A. J. Aldave⁷, M. Bamshad¹, A. R. Janecke⁸; ¹Univ. of Washington, Seattle, WA, ²Univ. of California, Los Angeles, Los Angeles, CA, ³Univ. Med. Ctr. of the Johannes Gutenberg- Univ. Mainz, Mainz, Germany, ⁴Dept. of Pediatric Ophthalmology, Aarhus Univ. Hosp., Aarhus, Denmark, ⁵Dept. of Pediatrics I, Med. Univ. of Innsbruck, Innsbruck, Austria, ⁶N.Jespersensvej 3, DK-2000 Copenhagen, Frederiksberg, Denmark, ⁷Jules Stein Eye Inst/UCLA, Los Angeles, CA, ⁸Innsbruck Med Univ, Innsbruck, Austria

Abstract Body:

Lisch epithelial corneal dystrophy (LECD) was delineated in 1992 in a large family with diffuse grayish epithelial opacities of the cornea in distinctive radial, feathery or club-shaped patterns. The opacities consisted of crowded, transparent microcysts in retroillumination of the cornea. Light microscopy shows vacuolization of the epithelial cells, particularly in outer layers of the cornea and electron microscopy discloses coalescent intracellular vacuolization of the corneal wing cells. In vivo confocal microscopy shows intraepithelial hyperreflective dystrophic areas containing hyporefective round structures, sharply demarcated from normal epithelial areas. LECD often causes no clinical complaints or causes blurred vision if the pupillary axis is involved. Using a combination of linkage analysis, exome, and genome sequencing in the original family, a second multiplex family, and a cohort of seven unrelated cases, we identified five heterozygous, rare (MAF < 6x10⁻⁵ in gnomAD) variants in *MCOLN1*, explaining 6/9 families. Three variants, c.514C>T (p.Arg172*), c.576C>A (p.Cys192*), and c.406-2A>G are predicted to be loss-of-function and two were missense, c.776T>C (p. Leu259Pro) in a proband and affected father and c.694A>C (p.Thr232Pro), in a proband.

In the homozygous and compound-heterozygous state, three of these variants have been previously reported to cause the rare lysosomal storage disorder mucopolipidosis IV (MLIV) and one meets ACMG Likely Pathogenic criteria. MLIV is characterized by severe psychomotor delay, progressive visual impairment, and achlorhydria, and corneal opacity is considered a hallmark finding. Staining of epithelial cells shows autofluorescent inclusions containing phospholipids, mucopolysaccharides, and gangliosides. *MCOLN1* encodes mucolipin-1, a member of the transient receptor potential (TRP) cation channel family, which is expressed in intracellular membranes. Most molecules trafficked through the lysosomal compartment are delayed in MLIV cells, either due to a primary transport defect, or secondarily because they are prevented from delivery by the excess storage. MLIV impairs vision by a combination of corneal clouding and retinal degeneration leading to severe visual impairment by adolescence.

Based on the overlapping clinical observations of diffuse epithelial inclusions and increased autofluorescence of such cells and material in LECD and MLIV, we conclude that at least some, if not most, carriers of *MCOLN1* loss-of-function mutations present with LECD.

Mendelian Phenotypes Posters - Wednesday

PB1903. Lissencephaly spectrum disorders: Clinical, radiological molecular results of 70 Egyptian families

Authors:

M. Zaki¹, M. Issa¹, H. elbendary¹, K. Rafat¹, J. Gleeson², M. Abdel-Hamid³; ¹Natl. Res. Ctr., Cairo, Egypt, ²Univ California, La Jolla, CA, ³Natl. Res. Ctr., Giza, Egypt

Abstract Body:

Lissencephaly (LIS) encompasses a spectrum of malformations of cortical development due to defective neuronal migration with diverse genetic contextual. Brain magnetic resonance allows the characterization of various anatomic and morphological abnormalities and further radiological-genotype correlations. We studied a cohort of 92 Egyptian patients derived from 70 families with LIS spectrum and microlissencephaly. Based on the radiological classification, target gene sequencing was done for LIS1, DCX, RELN, VLDLR, and LAMB1 genes. For patients with nonspecific neuroradiological patterns, whole-exome sequencing (WES) was performed. The causative mutations were identified in 60 families. LIS1 gene constitute 11.7 % of families followed by RELN and VLDLR, both 11.4% (8F), DCX (7.6%-5F) DYNC1H1(7.6%-5F), KATNB1 (7.6%- 5F), TUBA1A (5.7%-4F), APC2 (5.7%-4F), PIDD1 (4.2%-3F), LAMB1(2.8%-2F), TMTC3 (2.8% 2F), CDK5 (1.4%-1F), ACTG1(1.4%-1F) and MACF1 (1.4%-1F). Ten families (14.2%) remained unsolved. Because of the high consanguinity rate in our community, autosomal recessive linked LIS was prevalent. Novel mutations dominated our study and were significantly present in all families with RLN and VLDLR genes. Interestingly, the novel mutation identified in the MACF1 gene was homozygous. Herein, we present the phenotype and radiological findings of a large series of lissencephaly from the same ethnic group. We expand the mutational spectrum of lissencephaly and point to the predominance of autosomal recessive LIS.

Mendelian Phenotypes Posters - Thursday

PB1904. Local versus systemic control of bone and skeletal muscle mass by targeting components of the transforming growth factor- β signaling pathway using pharmacological and transcriptional approaches.

Authors:

H. Chandok¹, S-J. Lee¹, E. L. Germain-Lee², A. Lehar¹, Y. Liu¹, M. Michaud¹, J. George¹; ¹The Jackson Lab., Farmington, CT, ²Dept. of Pediatrics, Univ. of Connecticut Sch. of Med., Farmington, CT

Abstract Body:

Among the major health challenges for astronauts during prolonged space travel are loss of muscle mass and loss of bone mass. Here, we investigated the effects of targeting the signaling pathway mediated by the secreted signaling molecules, myostatin and activin A, in mice sent to the International Space Station. We show that targeting this signaling pathway has significant beneficial effects in protecting against both muscle and bone loss in microgravity, suggesting that this strategy may be effective in preventing or treating muscle and bone loss not only in astronauts on prolonged missions but also in people with disuse atrophy on Earth in individuals who are bedridden or wheelchair-bound from illness. Here, we used both genetic and pharmacological approaches to investigate the effect of targeting MSTN/activin A signaling in mice that were sent to the International Space Station. *Wild type* mice lost significant muscle and bone mass during the 33 d spent in microgravity. Muscle weights of *Mstn*^{-/-} mice, which are about twice those of *wild type* mice, were largely maintained during spaceflight. Systemic inhibition of MSTN/activin A signaling using a soluble form of the activin type IIB receptor (ACVR2B), which can bind each of these ligands, led to dramatic increases in both muscle and bone mass, with effects being comparable in ground and flight mice. To deepen the understanding, we performed local versus systemic control of bone and skeletal muscle mass by targeting components of the transforming growth factor- β signaling pathway. Using an allelic series corresponding to varying expression levels of endogenous *Fst*, we show that FST acts in an exquisitely dose-dependent manner to regulate both muscle mass and bone density. Moreover, by employing a genetic strategy to target *Fst* expression only in the posterior (caudal) region of the animal, we show that the effects of *Fst* loss are mostly restricted to the posterior region, implying that locally produced FST plays a much more important role than circulating FST with respect to regulation of muscle and bone. Finally, we show that targeting receptors for these ligands specifically in osteoblasts leads to dramatic increases in bone mass, with trabecular bone volume fraction being increased by 12- to 13-fold and bone mineral density being increased by 8- to 9-fold in humeri, femurs, and lumbar vertebrae. These findings demonstrate that bone, like muscle, has an enormous inherent capacity for growth that is normally kept in check by this signaling system and suggest that the extent to which this regulatory mechanism may be used throughout the body to regulate tissue mass may be more significant than previously appreciated.

Mendelian Phenotypes Posters - Wednesday

PB1905*. Long Read Sequencing and Expression Studies of *AHDC1* Deletions in Xia-Gibbs Syndrome Reveal a Novel Genetic Regulatory Mechanism

Authors:

V. Chander^{1,2}, M. Mahmoud^{1,2}, J. Hu^{1,2}, Z. Dardas², C. M. Grochowski², M. Dawood^{1,2}, M. Khayat^{1,2}, H. Li¹, S. Li¹, S. Jhangiani¹, V. Korchina¹, H. Shen¹, G. Weissenberger¹, Q. Gibbs^{1,2}; ¹Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX, ²Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, ³Texas Children's Hosp., Houston, TX, ⁴Dept. of Pediatrics, Baylor Coll. of Med., Houston, TX, ⁵Dept. of Computer Sci., Rice Univ., Houston, TX

Abstract Body:

Xia-Gibbs syndrome (XGS; OMIM: 615829) is a neurodevelopmental disorder (NDD) characterized by delayed motor milestones, speech delay, intellectual disability (ID) and hypotonia. Most individuals molecularly diagnosed with XGS through whole-exome sequencing harbor *de novo* truncating mutations in the AT-Hook DNA Binding Motif Containing 1 gene, *AHDC1*, that are predicted to prematurely terminate translation leading to a truncated protein. Some missense mutations in critical regions of the *AHDC1* protein also lead to XGS. In addition, recent reports of large *de novo* heterozygous deletions that encompass the *AHDC1* gene in individuals with symptoms that overlap those of XGS individuals have been ascribed as diagnostic for the disorder. The evidence that *AHDC1* haploinsufficiency is pathogenic is incomplete; however, primarily since there are usually many flanking genes involved in the contiguous deletion intervals. We analyzed 19 individuals with large (up to 20 Mb) deletions that involve *AHDC1* along with other genes in the region, to dissect genotype-phenotype relationships. We focused on one informative proband, with the smallest known contiguous *AHDC1* deletion of ~350Kb, encompassing eight other genes within chr1p36.11 (*FGR*, *IFI6*, *FAM76A*, *STX12*, *PPP1R8*, *THEMIS2*, *RPA2*, *SMPDL3B*) and terminating within the first intron of *AHDC1*. We identified the breakpoint junctions and resolved the phase of the deletion using a combination of short and long-read sequencing, via the Oxford Nanopore sequencing platform. Molecular characterization and quantification of RNA expression patterns in whole blood revealed that *AHDC1* exhibited a mono-allelic expression pattern, but we observed no deficiency in overall *AHDC1* expression levels, in contrast to the other deleted genes that showed a 50% reduction in mRNA expression. These results suggest that *AHDC1* expression in this individual is being compensated potentially by a novel regulatory mechanism and that some *AHDC1* deletions may be benign, depending on the breakpoints, phasing and molecular status. This knowledge informs how the *AHDC1* gene is regulated and advances understanding of regulatory mechanisms in NDDs.

PB1906. Long term prognosis in two adult patients with malonyl CoA decarboxylase deficiency

Authors:

S. Yano, R. McGowan, K. Moseley; LAC+USC Med Ctr, Keck Sch. of Med, USC, Los Angeles, CA

Abstract Body:

Background: Malonyl-CoA decarboxylase deficiency (Malonic aciduria) is a rare autosomal recessive inborn error of metabolism. Approximately 40 patients, among whom only a few patients were diagnosed by newborn screening (NBS), have been reported. Developmental delay, seizures, hypoglycemia, metabolic acidosis, abnormal brain MRI findings, and cardiomyopathy are frequently associated. Long-term clinical outcomes into adulthood are not well known. *Case reports:* We report on a pair of adult siblings, aged 32y and 24y, with Malonic Aciduria. These patients were diagnosed at age 4y and birth, respectively, based on plasma/urine metabolic analytes with enzymatic confirmation with skin fibroblasts (older sibling: 7% of normal). Treatment includes dietary interventions with a low-fat diet with MCT supplementation and medications with carnitine and an ACE inhibitor. The older sibling had episodes of respiratory distress and an enlarged heart at 4 days of age, hypoglycemia, metabolic acidosis, and seizures (cerebral infarction) at 2 months. This patient has microcephaly and a global developmental delay. Younger sibling has been treated with dietary interventions and medication for cardiomyopathy since early infancy. He has never developed a metabolic decompensation, i.e., hypoglycemia and metabolic acidosis. He does not have microcephaly or seizures but has a mild intellectual disability. He completed college and was employed until recently. Both elder and younger siblings developed hypertriglyceridemia and later hypercholesterolemia at age 25y and 10y, respectively. *Discussion:* Long-term prognosis of patients with Malonic aciduria remains unclear. Since NBS has been introduced, patients with Malonic aciduria can be diagnosed at birth. Malonyl-CoA decarboxylase plays a role in the regulation of fatty acid synthesis and oxidation. Hypertriglyceridemia has not been documented in this condition. The elder and younger siblings developed hypertriglyceridemia and later hypercholesterolemia approximately at age 25y and 10y, respectively. Treatment for hyperlipidemia with an HMG-CoA reductase inhibitor alone may have a potential risk to cause a depletion of free CoA. Further research may look at the benefits of treatment with C7 molecule compared to MCT oil (C8) for the prevention of hyperlipidemia and intellectual disability as well as improvement in cardiomyopathy.

Mendelian Phenotypes Posters - Wednesday

PB1907. Long-term clinical course of Heyn-Sproul-Jackson syndrome.

Authors:

H. Futagawa¹, K. Fukuda¹, H. Yamanaka¹, M. Kuroda¹, S. Ito¹, M. Honda¹, H. Suzuki², M. Yamada², T. Takenouchi², K. Kosaki², H. Yoshihashi¹; ¹Tokyo Metropolitan Children's Med. Ctr., Fuchu, Tokyo, Japan, ²Keio Univ. Sch. of Med., Tokyo, Japan

Abstract Body:

<Introduction> In *DNMT3A*(2q23.3), loss-of-function variant caused Tatton-Brown-Rahman syndrome (MIM#615879) which characterized by overgrowth, intellectual disability and dysmorphic facial features, while gain-of-function variant cause Heyn-Sproul-Jackson syndrome (MIM#618724:HESJAS) which characterized with microcephalic dwarfism and developmental delay (Heyns et al, 2019). Here, we report the oldest patient of HESJAS and add the detailed clinical description. <Patient> 24-year-old woman. She was born at 41 weeks of gestation. Birth weight 2492g (-2.3SD) and head circumference (OFC) 32.5cm (-0.9SD). Developmental milestones achieved hold head up at 3-month, roll over at 5-month, sit without support at 9-month and independent walk at 18-month. At 3-year of age, she was diagnosed developmental delay and included special education support. Visual acuity declined rapidly between the ages of 20 to 22 due to progressive cataract. She does not have other visceral complication. Now, her height, body weight and OFC were 138.2cm (-4.0SD), 45.0kg (-1.8SD) and 49.3cm (-4.8SD), respectively. She employed easy work at welfare facility because of mild intellectual disability. Her dysmorphic features included microcephaly, sparse scalp hair, blepharophimosis, thin upper lip vermilion and brachydactyly. WES (IRUD) revealed de novo pathogenic variant in *DNMT3A* (NM_022552.4:c.916T>C p.Trp306Arg) that was assumed to be gain of function, and a diagnosis of HESJAS was made. <Discussion> Previous reports of HESJAS have been limited to infants (1-4 years of age), with no reports in adults. In previous reports, developmental delay, severe short stature and microcephaly exceeding -4.0 SD were common findings, and this patient had similar features. While the developmental status of present patient was mild, reported patients have moderate to severe. There seemed to be the wide spectrum of the development. The characteristic feature of present patient was the rapid loss of vision acuity in adulthood. According to the research of *Drosophila* which does not have endogenous methylation, induced the expression of *Dnmt3a* into *Drosophila* resulted to microphthalmia or anophthalmia. It is possible that a gain-of-function mutation in the *DNMT3A* may have caused ocular symptoms associated with HESJAS. Further investigation is warranted in future case series. Somatic variants in the *DNMT3A* are known to be associated with hematopoietic disease. In general, the age of onset is middle-aged, and preventive health care regarding tumor development was considered for this patient. <Conclusion> Management of HESJAS in adulthood should anticipate progressive ocular disease.

Mendelian Phenotypes Posters - Thursday

PB1908*. Loss of adipocyte phospholipase gene *PLAAT3* causes lipodystrophy with neurological features due to inactivated arachidonic acid-mediated PPAR γ ; signaling

Abstract Body:

PLAAT3 is a phospholipid modifying enzyme predominantly expressed in white adipose tissue (WAT). It is a candidate drug target as *Plaat3* deficiency in mice protects against picornavirus infection and diet-induced obesity. We identified five patients from three independent consanguineous families, with homozygous loss-of-function mutations in *PLAAT3*, presenting with severe lipodystrophy and neurological features including intellectual disability and a demyelinating peripheral neuropathy. PLAAT3-deficient mice and human WAT showed a failure to liberate arachidonic acid (AA) from membrane phospholipids resulting in an inactive gene network downstream of adipogenesis master regulator and anti-diabetic drug target PPAR γ . CRISPR/Cas9-mediated *PLAAT3*^{-/-} human adipose stem cells displayed insulin resistance and showed a disturbed differentiation characterized by a significant decrease in lipid droplet formation and a downregulation of PPAR γ ; and perilipin. These findings establish PLAAT3 deficiency in humans as a novel type of hereditary lipodystrophy due to an AA- and PPAR γ -dependent defect in WAT differentiation and function.

Mendelian Phenotypes Posters - Wednesday

PB1909*. Loss of C-terminal Mediator Complex subunit-11 impairs fetal brain development and cause severely progressive neurodegeneration

Abstract Body:

The Mediator (MED) is an evolutionarily conserved multi-subunit protein complex that modulates the activity of several transcription factors and different critical components of the overall transcriptional machinery. Individual deficits in subunits part of the MED complex have been implicated in different neurological disorders. Exome or genome sequencing were performed in five unrelated families identified via different research networks and Matchmaker Exchanges. Deep clinical and brain imaging evaluations were performed by clinical pediatric neurologists and neuroradiologists. The functional impact of the candidate variant on both MED11 RNA and protein was assessed by RT-PCR and Western Blotting using fibroblast cell lines derived from one affected individual and controls and by computational approaches. Knockouts in zebrafish were generated by CRISPR/Cas9.

A recurrent, segregating homozygous variant in MED11 (c.325 C>T; p.Arg109Ter) was identified in all seven affected children. The variant results in a premature stop codon and a putative protein lacking the last nine residues of MED11 C-terminal.

The disease is characterized by microcephaly, profound neurodevelopmental impairment, exaggerated startle response, myoclonic seizures, progressive widespread neurodegeneration, and premature death. Functional studies on patient-derived fibroblasts did not show a loss-of-protein-function but rather disruption of the C-terminal of MED11, likely impairing binding to other MED-subunits. A zebrafish knockout model recapitulates key clinical phenotypes (microcephaly, premature death, exaggerated response to light stimuli).

Our results establish MED11 as a novel gene causing a severe neurodegenerative disorder potentially associated with premature death in humans. Loss of the C-terminal of MED subunit 11 may affect its binding efficiency to other MED subunits, thus implicating the MED-complex stability in brain development and 'MEDopathies' in neurodegeneration.

Mendelian Phenotypes Posters - Thursday

PB1910*. Loss of FOCAD, operating in the SKI mRNA surveillance pathway, causes a pediatric syndrome with liver cirrhosis.

Abstract Body:

Cirrhosis is a chronic, life-threatening disease characterized by fibrotic scarring and inflammation that disrupts liver architecture and function. It is typically the result of alcoholism or hepatitis viral infection. In this study we report 14 children from 10 unrelated families presenting with a syndromic form of pediatric liver cirrhosis. By genome/exome sequencing, recessive variants in *FOCAD* were found to segregate with the disease. Zebrafish lacking *focad* phenocopied the human disease, revealing a signature of altered mRNA degradation processes in the liver. Using patient's primary cells and CRISPR/Cas9-mediated inactivation in human hepatic cell lines, we find that FOCAD deficiency compromises the SKI mRNA surveillance pathway by reducing the levels of the RNA helicase SKIC2 and its cofactor SKIC3. FOCAD knockout hepatocytes exhibited lowered albumin expression and signs of persistent injury accompanied by CCL2 overproduction. Our results reveal the importance of FOCAD in maintaining liver homeostasis and disclose a possible therapeutic intervention point via inhibition of the CCL2/CCR2 signalling axis.

Mendelian Phenotypes Posters - Wednesday

PB1911. *LYRM7* mutations causing mitochondrial complex 3 deficiency nuclear type 8 (MC3DN8) in a Five-year-old boy without cavitating leukoencephalopathy

Authors:

R. Alfattal¹, **H. A. Alsharhan**², A. Algaith³, B. Albash⁴, R. M. Elshafie⁵, A. Alshammari⁴, A. Alahmad⁴, F. Dashti⁶, R. Ctr., Faculty of Med., Kuwait Univ., Kuwait City, Kuwait, ⁶Dept. of Radiology, Ibn Sina Hosp., Ministry of Hlth., Shuwaikh, Kuwait, ⁷Dept. of Pediatrics, Adan Hosp., Ministry of Hlth., Hadiya, 52700, Kuwait

Abstract Body:

Abstract: Defects of complex III (CIII) respiratory chain, result in characteristic but rare mitochondrial disorders associated with distinct neuroradiological findings. The underlying molecular defects affecting mitochondrial CIII assembly factors are few and yet to be identified. *LYRM7* assembly factor is required for proper CIII assembly where it acts as a chaperone for the Rieske iron-sulfur (UQCRFS1) protein in the mitochondrial matrix and stabilizing it. We present here the fifteenth individual with *LYRM7*-associated mitochondrial leukoencephalopathy secondary to a previously reported pathogenic homozygous *LYRM7* variant, c.2T>C, p.(p.Met1?). Similar to previously reported individuals, we report a 4-year-old male proband, who presented with recurrent metabolic and lactic acidosis, encephalopathy and myopathy. Further, he has additional, previously unreported features, including acute stroke like episode with bilateral central blindness and optic neuropathy, recurrent hyperglycemia and hypertension associated with metabolic crisis. However, he has no signs of psychomotor regression. He has been stable clinically with residual left-sided blindness, with no more metabolic crises for 2-year-period on mitochondrial cocktail. Although the reported brain MRI findings in other affected individuals are homogenous, it is slightly different in our index, revealing evidence of bilateral almost symmetric multifocal periventricular T2 hyperintensities with hyperintensities of the optic nerves and the optic chiasm but with no cavitation or cystic changes. This report describes new phenotypic and radiological spectrum of *LYRM7*-associated CIII deficiency. It also summarizes the clinical and molecular data of the previously reported individuals to describe the full phenotypic spectrum.

Mendelian Phenotypes Posters - Thursday

PB1912. *MED13L* knockout in cerebral organoids leads to a shifted developmental program through abnormal cis-regulatory element activation

Authors:

J. Ghomid^{1,2}, J. Sige¹, M. Balerdi¹, D. Laboy³, R. Ziffra³, N. Ahituv³; ¹Univ. of Lille, Lille, France, ²Lille Univ. Hosp., Lille, France, ³UCSF, San Francisco, CA

Abstract Body:

The Mediator is a large coregulator complex conserved from yeast to humans. It has emerged as a master coordinator of development and cell lineage determination through interactions with various transcription factors. Pathogenic variants of the gene cause the *MED13L*-syndrome, a neurodevelopmental disorder including intellectual disability. The role of the gene in neurodevelopment is unknown, and the consequences of *MED13L* variants remain to be deciphered.

We developed a *MED13L* ko cerebral-organoid model from hPSc and analyzed, at the single-cell level, the transcriptome (sc-RNAseq) and the chromatin accessibility (scATAC-seq). Sc-RNAseq and ScATAC-seq data analysis show that wt organoids produce cortical neurons, and *MED13L* ko organoids produce only neuroretinal cells. In the *MED13L* ko model, we observed coordinated activation of O5-O7 and O9 *OTX2* CREs as reported in neuroretinal development, while early specific forebrain *OTX2* CREs, AN1, and AN2, were not activated. At *PAX6* locus, we also observed differential expression of the neuroretinal specific CREs HS5, HS3, and HS2, in the ko model.

OTX2 and *PAX6* are early markers of both cerebral cortex and neuroretinal development. We suppose that activation of neuroretinal specific CREs driving expression of both latter genes would explain the downstream upregulation of genes involved in neuroretinal differentiation, including *CRX*, *VSX*, and *USH2A*. These results partially explain the shifted developmental program in ko organoids. Based on these data, *MED13L* is probably critical for proper enhancer activation during the neural induction. Then, neurodevelopmental disorder observed in patients with *MED13L* pathogenic variants is possibly linked to a global neural gene expression misregulation.

Mendelian Phenotypes Posters - Wednesday

PB1913. Metatranscriptomics detects emerging multidrug resistant *Candida auris* in a family with a mild TP63 associated ectodermal dysplasia

Authors:

P. Fortina¹, L. Youssefian¹, J. Park¹, A. Saeidian², F. Palizban³, S. Khodavaisy⁴, J. Uitto¹, H. Vahidnezhad⁵; ¹Thomas Jefferson Univ, Philadelphia, PA, ²Children's Hosp. of Philadelphia, Philadelphia, PA, ³Univ. of Tehran, Tehran, Iran, Tehran, Iran, Islamic Republic of, ⁴Tehran Univ. of Med. Sci., Tehran, Tehran, Iran, Tehran, Iran, Islamic Republic of, ⁵Thomas Jefferson Univ., Philadelphia, PA

Abstract Body:

Tumor protein 63, encoded by TP63, has an essential role in epidermal differentiation and ectodermal development. Autosomal dominant mutations in human TP63 result in several overlapping syndromes, with some established genotype-phenotype correlations based on the protein domain affected. Several groups have linked TP63-associated ectodermal dysplasia (ED) syndromes with varying degrees of immune dysfunction. In this study, we followed the clinical course of a daughter and father who presented with mild ED symptoms, chronic mucocutaneous candidiasis (CMC), recurrent bacterial infections, and equivocal immune function status. Whole-exome sequencing (WES) and whole-transcriptome analysis via RNA sequencing (RNA-Seq) disclosed a recurrent monoallelic mutation in TP63. Additionally, RNA-Seq data was used for detection of non-albicans *Candida* species, *Candida auris* and *Candida parapsilosis*, in CMC lesions of the daughter and father, respectively. Although a strong association between ED and TP63 mutations exists, the mechanism of immune dysregulation remains unclear. Our cases attest to the variable expressivity of TP63-associated disorders and the potential role of TP63 in maintaining immune system integrity. Furthermore, this study represents the first case of CMC caused by the multidrug-resistant pathogen *C. auris* in the context of TP63-associated ED and demonstrates the utility of RNA-Seq for concomitant mutation detection and accurate identification of rare and often misidentified pathogens.

Mendelian Phenotypes Posters - Thursday

PB1914. Metatranscriptomics reveals association of α -, β -, and γ -HPVs with typical epidermodysplasiaverruciformis in a large cohort of patients with CIB1, TMC6, or TMC8 mutations

Authors:

L. Youssefian; Thomas Jefferson Univ, Philadelphia, PA

Abstract Body:

Cutaneous human papillomavirus (HPV) infection typically manifests with isolated warts. However, some patients in familial clustering develop extensive and protracted HPV infections, primarily the β -HPV types 5 and 8, with distinct cutaneous findings. This clinical entity, epidermodysplasia verruciformis (EV), with autosomal recessive inheritance, is characterized by numerous cutaneous flat warts in childhood, which progress into squamous cell carcinomas later in life. The “typical” form of EV, not vulnerable to other infections, is caused by mutations in CIB1, TMC6, or TMC8, which impair keratinocyte-intrinsic immunity to β -HPV infection. Mutations in other genes related to T-cell development or function have been associated with “atypical” EV in patients with other infections. We developed a whole-transcriptome sequencing-based method on RNA isolated from skin biopsies for concomitant detection of viral and human genetic determinants of cutaneous wart lesions in a cohort of 50 EV patients. This method, VirPy, can detect 926 viruses, including more than 400 HPVs, and the corresponding human mutations. Nine distinct mutations in TMC8 (n=2), TMC6 (n= 5) and CIB1 (n=2) in 12 distinct families, including 14 patients were detected. The most predominant HPV in this cohort was HPV14. In addition, the RNA-seq data were examined for variant detection and prioritization, pathogenicity confirmation, and RNA expression profiling. Besides, we identified a total of 20 different HPVs including 16 β -, three α -, and one γ -HPV (HPV128) in a patient with TMC8 mutation. In summary, the utilization of RNA-Seq as a first-tier diagnostic method allowed us to simultaneously profile the transcriptome of the host for mutation detection and explore the consequences of variants of unknown significance as well as profile the cutaneous virome of EV patients.

Mendelian Phenotypes Posters - Wednesday

PB1915. Modeling dystroglycanopathy in zebrafish through CRISPR-Cas9-mediated knockout of *pomgnt2*

Authors:

K. Flannery, N. Battula, B. Karas, K. Terez, M. Manzini; Rutgers Robert Wood Johnson Med. Sch., New Brunswick, NJ

Abstract Body:

Dystroglycanopathies are autosomal recessive neuromuscular disorders characterized by congenital muscular dystrophy (CMD) with brain and/or ocular malformations. These disorders are clinically heterogeneous, ranging from milder limb-girdle muscular dystrophy to Walker Warburg Syndrome, which is the most severe form of CMD leading to childhood lethality. Mutations in 19 genes have been implicated in these diseases all converging on the regulation of glycosylation of the transmembrane glycoprotein alpha-dystroglycan (alpha-DG). Alpha-DG is component of the dystrophin-glycoprotein complex which is critical to connect the actin cytoskeleton to the extracellular matrix in the muscle, eye, brain, and other tissues. One major hurdle in studying the pathogenesis of these genetically heterogeneous disorders is the lack of appropriate models since many of the genes mutated in humans lead to early embryonic lethality in mice. In this study we sought to develop a novel zebrafish model of dystroglycanopathy targeting the glycosyltransferase *Protein O-linked Mannose N-acetylglucosaminyl Transferase 2* (*pomgnt2*) which is mutated in severe CMD. We targeted *pomgnt2* through CRISPR-Cas9 microinjections in zebrafish embryos using two parallel approaches: F0 crispants and stable mutant lines. The crispant approach targets the first few cells after fertilization leading to mosaic larvae with a high degree of somatic mutations and is faster than developing stable mutants. Crispant *pomgnt2* larvae injected with two independent guide RNAs exhibited a spectrum of phenotypes over the first 4 days post fertilization (dpf) similar to previously published morpholino oligonucleotide knockdowns. A large portion of the crispants showed shortened, curved tails with impaired mobility and several had severe nonviable lesions, including underdeveloped head and eyes, severe spinal alterations, and pericardial and yolk sac edema. In parallel, several juvenile F0 zebrafish were outbred to establish multiple stable *pomgnt2* mutant zebrafish lines which can be used alongside crispants for further analyses. We intend to characterize phenotypes, muscle and eye integrity, and brain abnormalities caused by *pomgnt2* loss of function in both crispants and mutants, as well as perform as high-throughput drug screenings of compounds with the potential to ameliorate the effects of *pomgnt2* loss of function.

Mendelian Phenotypes Posters - Thursday

PB1916. Molecular and behavioral characterization of a novel mouse model of Snyder-Robinson Syndrome: A path towards therapeutic development

Authors:

D. Kemaladewi, O. Akinyele, M. Johnson, A. Munir, M. Perez; Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract Body:

The polyamines putrescine, spermidine, and spermine are ubiquitous polycationic molecules crucial for cellular processes such as gene expression, signal transduction, and cell proliferation. Abnormal accumulation of spermidine due to mutations in *SMS* gene, encoding spermine synthase protein, causes Snyder-Robinson syndrome (SRS), a rare X-linked recessive disorder that manifests as mental retardation, thin habitus, and low muscle tone with no available treatments. The development of effective therapy for SRS requires a suitable disease-specific animal model that recapitulates the abnormalities seen in patients.

A novel SRS mouse model carrying a missense mutation in the *Sms* gene, leading to a glycine-to-serine substitution at position 56 (G56S) in the SMS protein, was generated. We aim to study the molecular mechanisms underlying SRS pathogenesis and develop a therapeutic genome editing strategy using the G56S mice. We hypothesize that *Sms* mutations lead to neurological and musculoskeletal pathophysiology in the G56S mice and mimic the disease presentation in SRS patients.

We measured SMS protein expression by western blot and determined polyamine contents using mass spectrometry. We evaluated brain structure using T2-weighted MRI and bone density by micro-CT scan. We carried out a battery of behavioral assays, such as Morris Water Maze, Fear Conditioning, and open field tests to investigate their learning ability and anxiety level. RNA-Sequencing was performed to seek a novel disease pathomechanism in these mice.

We observed a complete loss of SMS protein in the G56S mouse brain, skeletal muscles, and liver, resulting in a significant increase in the spermidine content. In addition, the G56S mice showed a significant reduction in body weight, length, bone density, and behavioral activity towards the center zone of an open field. The mice also exhibit a significant level of anxiety and impaired learning ability compared to the wild type. Furthermore, there were significant volumetric reductions in the hippocampal and amygdala, which further support the neurological pathophysiology in these mice. Transcriptomic analyses reveal downregulation of genes involved in oxidative phosphorylation and EIF2 signaling in the brain, providing the molecular mechanism that can be further exploited for therapy.

Our data indicate that the G56S mouse recapitulates the molecular and phenotypic abnormalities seen in SRS patients. Current experiments focus on rescuing these defects using genetic and pharmacological approaches, which will open the door to future therapeutic interventions for this condition.

Mendelian Phenotypes Posters - Wednesday

PB1917. Molecular and clinical review of 95 Polish pediatric patients with the clinical suspicion of Alport syndrome.

Authors:

P. Halat-Wolska¹, L. Obrycki², E. Ciara¹, M. Pac², K. Gadomska-Prokop², M. Rydzanicz³, P. Stawinski^{1,3,4}, J. Feber⁵, B. Chalupczynska¹, D. Jurkiewicz¹, M. Pelc¹, D. Piekutowska-Abramczuk¹, D. Siestrzykowska¹, D. Wicher¹, K. Chrzanowska¹, R. Ploski³, M. Litwin²; ¹The Children's Mem. Hlth.Inst., Dept. of Med. Genetics, Warsaw, Poland, ²The Children's Mem. Hlth.Inst., Dept. of Nephrology, Warsaw, Poland, ³Warsaw Med. Univ., Dept. of Med. Genetics, Warsaw, Poland, ⁴Inst. of Physiology and Pathology of Hearing, Dept. of Genetics, Warsaw, Poland, ⁵The Children's Hosp. of Eastern Ontario, Div. of Nephrology, Dept. of Pediatrics, Ontario, ON, Canada

Abstract Body:

Introduction: Alport syndrome (AS) is a genetically heterogeneous nephropathy resulting from *COL4A3*, *COL4A4* and *COL4A5* pathogenic changes. AS can be transmitted as X-linked, autosomal recessive (AR) or dominant (AD) difficult to differentiate from benign familial hematuria (BFH). The symptoms vary widely from mild to severe among patients. Because of the significant lifetime risk for kidney failure, hearing and ocular symptoms, an early diagnosis, detailed genotype-phenotype correlation and personalized therapy is crucial. **Materials and Methods:** We examined 95 Polish pediatric patients with suspicion AS by next-generation sequencing (NGS) of glomerulopathy genes panel. **Results:** Clinical diagnosis was confirmed at the molecular level with 81% compliance (n=77). Overall 62 pathogenic/likely pathogenic *COL4A3-5* variants were revealed (known=36, novel=26). About 97% (n=60) of them were SNVs: frameshift, in-frame, missense, nonsense, splice-site and CNVs: deletions of single and six *COL4A5* exons. In 70% (n=54) the inheritance was X-linked *COL4A5*, 21% (n=16) AD AS/BFH and 6% (n=5) AR *COL4A3-4*. We revealed a recurrent *COL4A5* c.1871G>A p.G624D variant, with allele frequency 30% (17/56). Of these, 2 patients carried additional *COL4A3* heterozygous change, resulted in digenic inheritance (3%). Genotypes were compared with the clinical manifestations: renal function, proteinuria, microalbuminuria, hematuria, arterial hypertension, hearing and ocular abnormalities. Microalbuminuria and proteinuria excretion were significantly different between the genotypes. Variant p.G624D gave milder symptoms (older age hematuria, lower microalbuminuria and proteinuria, rare ocular abnormalities) than other *COL4A5* changes. The phenotype of patients with digenic AS did not differ significantly in the study group. Diagnosis age, hypertension, hypertension with >500mg/24h proteinuria, microalbuminuria, ocular symptoms were the predictors of GFR reduction for all patients. **Conclusions:** The differences in AS phenotype occur depending on the genotype. NGS is an effective approach to obtain genetic information, which help to predict the clinical course, especially for patients with mild or atypical phenotype. Also, we broaden the molecular spectrum of AS, which will facilitate future research on the genotype-phenotype correlations. **Partially supported by CMHI M29/18, MEiN 7071/IB/SN/2020 and MEiN 7088/II-KDM/SN/2020**

PB1918. Molecular Genetic Defects of Hereditary Angioedema in Saudi Arabia.

Authors:

H. Alajlan¹, F. Sheikh¹, M. Albanyan¹, H. Alruwaili¹, B. Al-Saud¹, R. Arnaout¹, M. Al-Hamed¹, H. Al-Mousa¹, S. AlShareef¹, A. Alazami²; ¹KING FAISAL SPECIALIST Hosp. AND RESEARCH CENTER, Riyadh, Saudi Arabia, ²King Faisal Specialist Hosp. & Res. Ctr., Riyadh, Saudi Arabia

Abstract Body:

Hereditary Angioedema (HAE) is a rare life threatening inherited disorder characterized by swelling of the larynx, subcutaneous tissues, and the lining of the gut and lungs. These symptoms develop as the result of deficiency or dysfunction of proteins that help to maintain the normal flow of fluids through the capillaries. The mode of inheritance is autosomal dominant. HAE affects approximately 1 in 50,000 individuals, and the main gene linked to pathogenesis is *SERPING1*, which encodes C1 esterase inhibitor (C1-INH). Here we present the clinical and genetic profiles of HAE patients from a single Saudi institution, which is a major national referral center. Fifty-one (51) patients with a diagnosis of HAE were recruited, making this one of the largest cohorts ever studied in the world and the largest ever reported from the Arab world. Clinically, the primary HAE subtype in our cohort was type I, accounting for 76% of our cases. Polymerase chain reaction (PCR) analysis detected three (3) novel frameshift mutations in *SERPING1*, in addition to two (2) novel nonsense mutations. All individuals that tested negative for *SERPING1* by Sanger were evaluated by Multiplex Ligation Dependent Probe Amplification (MLPA). This identified a heterozygous ~900bp deletion affecting *SERPING1* exon 4 in a large multi-generational family. This was the sixth novel mutation uncovered in our study. In total, *SERPING1* mutations were uncovered in 49 patients (96%). The remaining unsolved cases (4%) were screened for *F12*, *PLG*, *ANGPT1*, *MYOF*, *KNG1* and *HS3ST6* but no relevant genetic variants were found.

Mendelian Phenotypes Posters - Wednesday

PB1919*. Molecular insights into the pathogenesis of Chediak-Higashi syndrome and the biology of Lysosomal Trafficking Regulator.

Authors:

M. Morimoto, E-R. Nicoli, C. Kuptanon, J. Serra-Vinardell, P. Sharma, C. Ciccone, M. Huizing, C. Toro, W. A. Gahl, W. J. Inrone, M. C. V. Malicdan; NIH, Bethesda, MD

Abstract Body:

Introduction: Lysosome-related organelles (LROs) are cell type-specific cellular compartments, each with a unique morphology, composition, and function; they contribute to diverse processes such as pigmentation, blood coagulation, immunity, and neurological function. Dysfunction in the biogenesis and trafficking of lysosomes and LROs lead to LRO-related disorders including Chediak-Higashi syndrome (CHS), a rare autosomal recessive disorder characterized by partial oculocutaneous albinism, a bleeding diathesis, immunological dysfunction, and neurological impairment. While CHS was first described in the 1940s and the gene Lysosomal Trafficking Regulator (*LYST*) was implicated as the genetic cause in 1996, molecular insights into how *LYST* deficiency leads to CHS have been elusive. The key challenges include the exceptionally large size of the gene (11.4 kb coding sequence) and protein (429 kDa), and the absence of a validated antibody. **Methods:** To further our understanding of the pathogenesis of CHS and the biology of *LYST*, novel pathogenic *LYST* variants were identified by genomic DNA and cDNA Sanger sequencing within our CHS patient cohort, relative *LYST* mRNA expression was assessed in several cell types by quantitative PCR, and *LYST*-interacting candidates were identified in melanocytes by immunoprecipitation (IP)-mass spectrometry (MS). **Results:** 23 novel pathogenic *LYST* variants were identified in patients with a clinical diagnosis confirmed by the presence of pathognomonic giant intracellular granules. *LYST* mRNA expression varied widely among different cell types; there was no detectable expression in iPSCs, low expression in fibroblasts and iPSC-derived neurons, moderate expression in NK cells, and high expression in melanocytes. CHS patient fibroblasts, NK cells, and melanocytes generally had decreased relative *LYST* mRNA expression. To advance the protein studies of *LYST*, rabbit polyclonal antibodies against 2 *LYST* peptides were developed and tested in parallel with 3 commercially available antibodies. Three of the 5 antibodies exhibited a high molecular weight band that was present in control but absent in CHS patient melanocytes by immunoblot analysis. IP-MS uncovered several novel *LYST*-interacting candidates. **Conclusions:** The identification of novel pathogenic *LYST* variants, the analysis of *LYST* expression among different cell types, including those from patients, and the preliminary detection of *LYST*-interacting proteins will contribute to the earlier diagnosis of CHS patients and serve as the groundwork for understanding the mechanism of disease and the identification of therapeutic targets.

Univ, Portland, OR

Abstract Body:

Background: DExD/H-box RNA helicases are a large paralogous gene family implicated in neurodevelopmental disorders (NDD) and cancer. DExH-box helicase 9, encoded by the gene *DHX9*, is highly expressed in the developing and adult nervous system and regulates functions frequently disrupted in NDD including transcription, triple stranded DNA-RNA hybrids called R-loops, and homologous recombination (HR); yet its function in the neuronal development and homeostasis remains enigmatic.

Methods: To explore *DHX9*'s role in the human nervous system, we performed a primary analysis of >30,000 exomes and genomes and searched GeneMatcher and other NDD cohorts for rare and damaging monoallelic or biallelic *DHX9* variants. *Dhx9*^{-/-} mice were generated using International Mouse Phenotyping Consortium 'knockout first' targeting strategy and underwent detailed phenotypic characterization.

Results: The *DDX-DHX* gene paralogs exhibit a strong correlation between missense and loss-of-function (LoF) constraint in gnomAD. *DHX9* has the highest mutational constraint of all *DDX-DHX* genes (missense Z-score 5.84, LOEUF 0.1). Genomic analyses revealed 17 individuals with qualifying *DHX9* variants and NDDs or axonal Charcot-Marie-Tooth disease (CMT2). 16 variants were identified: 5 LoF and 11 missense including one recurrent variant (NM_001357.5):c.3497G>C; p.(Arg1166Pro). All variants were absent from gnomAD except for c.1417G>A; p.(Val473Ile) (1 heterozygote) in an individual with mild NDD. As *de novo* mutations are a major driver of NDDs, we performed family analysis if parental samples were available (12/17) and found *DHX9* variants occurred *de novo* in all cases. Missense variants clustered in domains required for helicase activity, nucleic acid binding, or nuclear localization. Quantitative HPO analysis supported nascent genotype-phenotype correlations, with LoF variants clustering with mild NDD phenotypes, whereas missense variants within the nuclear localization signal (NLS) cluster with severe NDD. *Dhx9*^{-/-} mice demonstrate neurologic abnormalities including hypoactivity in novel environments, tremor, reduced grip strength and body mass, and sensorineural hearing loss.

Conclusions: These data provide compelling evidence for *DHX9* variation as a cause of autosomal dominant (AD) NDD or CMT2, suggests null alleles result in mild neurologic phenotypes, implicates inappropriate cytoplasmic DHX9 localization as a cause of severe NDD, and dissects the role of DHX9, R-loops, HR, and double-strand DNA break repair in neurodevelopment, neurodegeneration, & genomic stability.

Hosp., Boston, MA, ¹³VUMC, Nashville, TN, ¹⁴Geisinger, Holmen, WI, ¹⁵Natl. Human Genome Res. Inst., Bethesda, MD

Abstract Body:

BACKGROUND: The prevalence and penetrance of actionable pathogenic/likely pathogenic variants detected in a 'genome-first' approach are unclear. We assessed prevalence and penetrance of pathogenic familial hypercholesterolemia (FH) variants and their association with coronary heart disease (CHD) in a multicenter targeted sequencing study. **METHODS:** Adult participants (n=18,544) at 7 sites were enrolled in a prospective cohort study, as part of phase III of the eMERGE network, to study the clinical impact of returning results from targeted sequencing of 68 actionable genes, including *LDLR*, *APOB*, and *PCSK9*. FH variant prevalence and penetrance (defined as LDL-C >155 mg/dl) were estimated after excluding participants enrolled based on hypercholesterolemia. Multivariable logistic regression was used to estimate the odds of CHD compared to age & sex matched controls (5-10 for each case) without FH-associated variants. **RESULTS:** We detected FH associated variants in 160 individuals (mean age 59.81 ± 17.26, 41.3% male). The prevalence of FH-associated pathogenic variants was 1 in 188 (69 of 13,019 unselected participants). The mean LDL-C level was 320 ± 154 mg/dl, and the level was significantly higher (434 ± 133.3 mg/dl) in those with predicted loss of function (pLOF) variants in *LDLR*. Penetrance on average was 87.5%. The presence of an FH variant was associated with CHD (odds ratio [OR] 3.1, 95% confidence interval [CI] 2.1-4.7) and early onset CHD (OR 3.5, 95% CI 2.3-5.4). The magnitude of association was larger for pLOF variants in *LDLR* (OR 9.84, 95% CI 1.8-65.6). **CONCLUSION:** In a multisite cohort of EHR-linked biobanks, monogenic FH was prevalent, penetrant, and associated with the presence of CHD. These results suggest potential utility of sequencing EHR-linked biobanks to detect FH.

Mendelian Phenotypes Posters - Thursday

PB1922. Multi-omic approach identifies a novel non-coding deletion at Xq28 in a patient with X-linked primary immunodeficiency.

Authors:

D. Bonner^{1,2}, M. Frees², L. M. Tulu², A. M. Thomas¹, R. A. Ungar³, P. Goddard³, D. Moslehi¹, J. N. Kohler¹, C. M. Reuter¹, S. Marwaha¹, S. Montgomery³, P. Fisher¹, E. Ashley³, M. T. Wheeler², J. A. Bernstein¹; ¹Stanford Ctr. for Undiagnosed Diseases, Stanford, CA, ²Stanford University, Stanford, CA, ³Stanford Univ., Stanford, CA

Abstract Body:

We evaluated a 2-year-old male with a personal and family history of immunodeficiency at the Stanford Center for Undiagnosed Diseases. He initially presented with low T cell receptor excision circle levels on newborn screening. Further testing revealed near absence of recent thymic emigrants, defects of T cell proliferation and decreased natural killer cell function. He underwent hematopoietic stem cell transplantation at 9 months old. Family history is significant for 7 maternal male relatives who died from infections in childhood in a pattern consistent with X-linked inheritance. Clinical genetic testing including microarray, exome and genome sequencing (GS) and transcriptome sequencing (RNA-seq) were non-diagnostic.

Trio GS data was re-analyzed with a structural variant calling and prioritization pipeline, and results were integrated with expression outliers from trio blood RNA-seq analysis. Re-analysis prioritized a novel hemizygous maternally inherited 2.8kb deletion at Xq28 encompassing a primarily intergenic region upstream of *ARHGAP4* with partial overlap of the 3'UTR of *NAA10*. RNA-seq identified significantly reduced expression of *ARHGAP4* (z-score -8.9) and slightly reduced expression of *NAA10* (z-score -2.0) when compared to 330 controls. We considered this a promising diagnostic candidate as it was the only under-expression outlier that correlated with a rare variant on the X chromosome.

Patients reported with loss-of-function variants in *NAA10* and *ARHGAP4* do not demonstrate susceptibility to infection nor clinical immunodeficiency. A patient with a 34.4kb deletion overlapping with our patient's deletion and a phenotype of immunodeficiency and nephrogenic diabetes insipidus is reported.¹ The authors speculated that this patient's immunodeficiency was caused by loss of the intergenic region between *ARHGAP4* and *NAA10* since it is highly conserved across species and involved in cellular response to hypoxemia. Recently, this intergenic region has also been described to have a regulatory role in chromatin accessibility and transcriptional regulation.

Our patient is the second reported case with loss of the 2.8kb intergenic region between *ARHGAP4* and *NAA10* at Xq28 and primary immunodeficiency, providing further evidence for the locus-disease relationship. Research into the functional and epigenetic consequences of this deletion will clarify the mechanism of disease. Ongoing studies include segregation analysis, methylome sequencing and ATAC-sequencing.

Abstract Body:

Bardet-Biedl syndrome (BBS), is an emblematic ciliopathy hallmarked by pleiotropy, inter- and intra-familial phenotype variability, and extensive genetic heterogeneity. BBS is a rare (~1/140,000 to ~1/160,000 in Europe) autosomal recessive pediatric disorder characterized by progressive retinal degeneration, truncal obesity, polydactyly, cognitive impairment, renal dysfunction, and hypogonadism. Twenty-seven genes implicated in the structure or function of the primary cilium have been implicated in BBS, and explain the molecular basis for ~75-80% of individuals. To investigate the mutational spectrum of BBS in Romania, we ascertained a cohort of twenty-three individuals (17 Eastern European, 5 Romani, and 1 Arab). Following informed consent, we performed proband whole exome sequencing (WES). We prioritized variants using bioinformatic filtering and ranked them according to ACMG guidelines for variant pathogenicity. We detected 17 different putative disease-causing single nucleotide variants or small insertion-deletions and two pathogenic exon disruptive copy number variants in known BBS genes in 17 pedigrees. Segregation analysis was performed in all available family members. Eleven different BBS genes harbored causal lesions, confirming the heterogeneous mutational basis of BBS. The most frequently impacted genes were *BBS12* (35%), followed by *BBS4*, *BBS7*, and *BBS10* (10% each) and *BBS1*, *BBS2*, and *BBS5* (4% each). Notably, homozygous *BBS12* p.Arg355* variants were present in seven pedigrees of both Eastern European and Romani origin (n=3 and n=4, respectively). Among the remaining families, two harbored heterozygous BBS gene changes which did not explain the phenotype, and four were bereft of a likely cause among known BBS genes, or the remainder of the exome. Three families harbored second-site variants in BBS genes. In conclusion, the diagnostic rate in our cohort was 74%, suggesting that the remaining families harbor deep intronic or large structural variants that are intractable to WES. Our data show that although the diagnostic rate of BBS in Romania is consistent with other worldwide cohorts, we observed a unique distribution of causal BBS genes, including an overrepresentation of *BBS12* due to a recurrent nonsense variant, that has important implications for regional diagnostics.

Group), INSERM U1231 GAD Lab., Tassigny, Dijon, France, ²⁵Bioinformatics Competence Ctr., Univ. of Lausanne, Lausanne, Switzerland

Abstract Body:

We previously described the KINSSHIP syndrome, an autosomal dominant disorder associated with *de novo* missense variants in the degnon of *AFF3*, a sequence important for its binding to ubiquitin ligase. The eighteen affected individuals shared a recognizable pattern of anomalies that included intellectual disability (ID), epileptic encephalopathy, mesomelic dysplasia and horseshoe kidney. Mouse knock-ins and overexpression in zebrafish suggested a dominant-negative mode of action and a pathological effect of increasing amount of *AFF3*. Additional screening of ID cohorts identified twelve individuals from eight families who carried truncation or deletions rather than missense. They presented with milder phenotypes suggesting an alternative haploinsufficiency mode of action. Corroboratingly, mouse knockouts display brain malformations with enlarged lateral ventricles and decreased corpus callosum size, neurological and skeletal anomalies including vertebrae fusion and transformation and abnormal skull shape, whereas zebrafish knockdowns presented with circling behaviour and decreased velocity indicative of a broad neurological defect. About a tenth of the fish showed also skeletal malformation, yolk sac enlargement and pericardium edema. Finally, we identified four unrelated ID patients with homozygous or compound heterozygous predicted-to-be deleterious missense variants in *AFF3*. Consistent with causatives, 3D protein modelling of these variants suggested that it cannot be accommodated without affecting the local geometry. *AFF3* encodes a component of the transcriptional super elongation complex that regulates the expression of genes involved in neurogenesis and development. Our data suggest that *AFF3* mutations result in either recessive, dominant-negative or haploinsufficiency phenotypes. Consistent with this hypothesis we found that the three types of variants differently impact cellular transcriptome.

Mendelian Phenotypes Posters - Wednesday

PB1925. Myelomeningocele: targeted search for novel variants in Mexican families.

Authors:

Q. Medina^{1,2}, L. Muñoz¹, Y. Svyryd¹, R. Rebollar², L. Luna¹, A. Aguayo¹, O. Mutchinick¹; ¹Inst. Natl. de Ciencias Médicas y Nutrición Salvador Zubirán, Mexico City, Mexico, ²UNAM, Mexico City, Mexico

Abstract Body:

Introduction. Neural tube closure defects are severe congenital malformations of the central nervous system, the most frequent variety being spina bifida and of this myelomeningocele (MMC). In Mexico, the prevalence of MMC is ~1/1000 live births. They have multifactorial etiology resulting from a polygenic genetic predisposition. Although some risk gene variants (RGV) have been proposed, these are not the same across populations, and the known variants have only explained part of the etiologic fraction of the defect. Next-generation sequencing (NGS) has driven rapid progress in genomic research, allowing the identification of new RGV characteristics of each population.

Objective. To investigate novel RGV by sequencing 11 Candidate Genes (CG) involved in the neural tube development in Mexican nuclear families with MMC.

Materials and Method. The 300 studied trios were recruited from 16 Teleton (CRIT) centers in Mexico. *BMP4*, *FUZ*, *GLI3*, *GPR61*, *PTCHI*, *ITGB1*, *PLXNB2*, *NCAM1*, *ALX1*, *PAX1*, and *TBXT* sequencing was performed at the Research Support Network on a NextSeq500 using an Illumina® panel designed for these CG exome sequencing. The variant calling was performed using the DNA Amplicon platform, and the variant annotation with Variant Effect Predictor. The “novel” variant was defined as a variant not registered in dbSNP, genomeAD v2, or COSV databases. In addition, Sanger sequencing was used to confirm the novel variants. Finally, if inherited from one of the parents, the confirmed ones were looked at in a healthy sibling when available.

Results. Of the 983 variants, 855 had a depth greater than 30. Of these, 299 were present only in the parents, and 556 in cases too. Of these, 78 were novel variants not registered in the reviewed databases, 15/78 were identified in coding or regulation regions, but only seven were confirmed as novel variants by Sanger sequencing. Four missense variants were found in *GLI3* (2), *ITGB1* (1), and *PLXNB2* (1). One donor splicing site variant was also found in the *ITGB1* gene. In addition, two synonymous variants in *FUZ* (1) and *PTCHI* (1) were identified. It is worth mentioning that each confirmed variant was found in 1 family out of the 300 studied; all were inherited but not transmitted to the healthy sibling.

Conclusions. Seven novel not previously reported variants were identified in the myelomeningocele cases, of which 5 have potentially pathogenic consequences in the coding regions of proteins essential in developing the neural tube: *IGBT1*, *GLI3*, and *PLXNB2*. However, functional studies are needed to confirm the risk of these variants for MMC in the Mexican population.

Mendelian Phenotypes Posters - Thursday

PB1926. New *trans*-modifier genes in the most common monogenic eye disorder, ABCA4/Stargardt disease.

Authors:

J. Zernant¹, T. Nagasaki¹, W. Lee¹, P-Y. Su¹, S. H. Tsang¹, G. A. Fishman², R. Allikmets¹; ¹Columbia Univ., New York, NY, ²The Pangere Ctr. for Inherited Retinal Diseases, The Chicago Lighthouse, Chicago, IL

Abstract Body:

Over 1,500 variants in the *ABCA4* locus cause phenotypes ranging from severe, early-onset retinal degeneration to very late-onset maculopathies. The resulting ABCA4/Stargardt disease is the most prevalent Mendelian retinal disorder, although its underlying clinical heterogeneity, including penetrance of many alleles, is not completely understood. We hypothesized that a share of this complexity is explained by variants in other, unlinked loci, i.e. *trans*-modifying genes. We sought to identify these by performing exome sequencing in a large cohort, for a rare disease, of 583 patients and compared variation in 285 genes that have been associated with simple or syndromic retinopathies, to cohorts of ethnically matched controls. We also compared the allele frequencies between three ABCA4 disease subgroups. The strongest association was found with the frequent variant p.Ala96Ser in *RGS9BP*, minor allele frequency (MAF) 0.41 in the patient cohort vs. 0.32 in the control group, $p=2.404E-07$. In the late-onset ABCA4 disease subgroup, defined by the hypomorphic p.Asn1868Ile allele and including the c.4253+43G>A variant, the minor allele frequency for the *PRPH2* haplotype-tagging p.Asp338Gly SNP was 0.14 vs. 0.25 in the remaining cohort, $p=0.0027$. In the disease subgroup, defined by the most frequent pathogenic *ABCA4* variant in patients of European descent, p.Gly1961Glu, *PITPNM3* variant p.Pro17Ser presented with increased MAF=0.17, compared to other patients, MAF=0.11; $p=0.008$. Moderately rare, likely functional, variants, with MAF<0.01 and CADD>20, were enriched in *CEP290* in p.Gly1961Glu patient group, where 10.6% of 151 patients harbored a *CEP290* variant compared to 3.5% in 342 patients with other *ABCA4* pathogenic variants ($p=0.0017$). We identified three additional genes with possible modifying effect on ABCA4 disease. These findings should be replicated in other large ABCA4 disease cohorts and the specific *trans*-modifying effects of these variants/genes on the penetrance, expression and progression of ABCA4 disease have to be elucidated.

Mendelian Phenotypes Posters - Wednesday

PB1927. Novel clinical entity: Autosomal recessive missense *GPC6*-related skeletal dysplasia (ARM-GSD)

Authors:

M. Crenshaw, M. L. Meyers, J. Duis, M. Saenz, E. Elias, K. Brown, V. Slegesky, N. J. L. Meeks; Univ. of Colorado, Aurora, CO

Abstract Body:

Background: Skeletal dysplasias encompass disorders of cartilage or bone with a reported incidence of 1/5,000 (Geister, 2015). *GPC6*, located at chromosomal position 13q32, codes for protein glypican 6, which is part of the proteoglycan family that is linked to glycosylphosphatidylinositol (GPI)-anchored heparan sulfate (OMIM 604404). It assists with membrane translocation, membrane anchoring, and growth factor signal regulation (Capurro, 2017). The only described phenotype associated with this gene is autosomal recessive omodysplasia-1 (OMIM 258315), caused by loss of function variants in *GPC6* (Campos-Xavier, 2009). Patients with omodysplasia-1 have severe short stature (standard deviation range: -3 to -5) with shortening and tapering of the proximal long bones of the upper and lower extremities, creating a club-like appearance; they can also have facial hemangiomas, frontal bossing, low-set ears, flat nasal bridge, anteverted nares, motor delays, and cryptorchidism (Bayat, 2020; Elcioglu, 2004). **Case series:** We report a family with five affected out of nine total siblings who presented with an unspecified skeletal dysplasia with features distinct from omodysplasia-1. The patients' height for age ranged from the 0.18 to 9.54%ile (*Z* scores -2.91 to -1.31). Radiographically, the patients had subtle platyspondyly, bilateral coxa breva, humeri and femoral foreshortening, and ulnae minus deformity (in those with closed epiphyses). One sibling required surgical intervention for bilateral talocalcaneal fibrous coalition, four had ear abnormalities, and two had dental crowding. None of the siblings had cognitive deficits, developmental delays, facial hemangiomas, nor cryptorchidism. All affected individuals were found to have homozygous missense variants in *GPC6*, which segregated with affected individuals in the family. Carrier status was confirmed in both parents. **Conclusion:** The patients presented represent a new clinical entity that we are naming autosomal recessive missense *GPC6*-related skeletal dysplasia (ARM-GSD). The siblings differ from the omodysplasia-1 patients in that their variants are missense versus truncating or partial/full gene deletions in patients with omodysplasia-1. The patients presented do not have as profound short stature nor club-like bone appearance, and they have subtle radiographic findings of the spine and all extremities. Given the molecular and phenotypic differences in patients with omodysplasia-1 and the patients presented, we propose a new skeletal dysplasia syndrome associated with biallelic missense variants in *GPC6*.

Mendelian Phenotypes Posters - Thursday

PB1928. Novel homozygous nonsense mutation of *MLIP* and compensatory alternative splicing in a late-onset distal myopathy.

Authors:

J. Mezreani^{1,2}, S. Audet^{1,2}, F. Martin¹, J. Charbonneau¹, V. Triassi^{1,3}, E. Bareke¹, A. Laplante¹, J. Karamchandani⁴, R. Massie⁴, C. H. Chalk⁴, E. K. O'Ferrall⁴, M. Tetreault^{1,2,3}; ¹CRCHUM, Montreal, QC, Canada, ²Dept. of NeuroSci.s, Univ. of Montreal, Montreal, QC, Canada, ³Dept. of Bioinformatics, Univ. of Montreal, Montreal, QC, Canada, ⁴Montreal Neurological Inst., Montreal, QC, Canada

Abstract Body:

Efficiently establishing diagnoses for myopathy-related patients is a complex task due to the important clinical heterogeneity surrounding these pathologies, and concertedly, their multiple overlapping traits. This highlights the need for implementation of more robust diagnostic methods, such as clinical sequencing, as well as the advancement of research, furthering our understanding and the literature encompassing this group of disease. Despite the growing accessibility of clinical sequencing, functional interpretation of candidate variants remains a major hurdle to molecular diagnostics.

In this study, we aim to describe a new adult-onset myopathy with muscle weakness and hyperCKemia, for which we uncovered a novel homozygous nonsense variant in Muscular *LMNA*-Interacting Protein (*MLIP*). Following inconclusive gene panel testing, RNA-sequencing served as a diagnostic tool for this complex case. On top of variant identification, differential expression analysis revealed a significant downregulation of this gene, which had a surprisingly mild effect on *MLIP* protein expression, as observed through Western Blot. RT-PCR and long-read sequencing (LRS) both support an important transcriptome shift in the patient, where decreased *MLIP* levels are seemingly due to nonsense-mediated decay of transcripts containing the exon 5 mutation. Moreover, a compensatory mechanism upregulates the functionally lacking isoforms, and generates novel transcripts. We suspect this irregular molecular event to play a role in the phenotypes of the patient, for whom an earlier-onset of pathology would have been expected.

To complement this study, an *in vitro* myoblast model, designed with CRISPR/Cas9 genome editing, has been developed by our team. The disease-relevant model will allow further assessment of the functional impact of the variant on a cellular level. In order to better define the molecular role as well as the pathogenic effect of *MLIP*, we aim to investigate multiple processes, such as the proliferation rate, differentiation aptitude, protein localization and partner interactions.

These findings support the recently discovered clinical implications of *MLIP* variants in a pediatric myopathy, highlighting for the first time its relevance in adult-onset cases. These results also underline the power of LRS as a tool for the functional assessment of variants of unknown significance, as well as the definition of accurate isoform profile annotations in a tissue specific manner. Finally, we hope our work will greatly benefit *MLIP* literature in a broader fashion.

Mendelian Phenotypes Posters - Wednesday

PB1929. Novel homozygous variant in *TFAP2B* in a colombian family with Char syndrome and distinctive neurobehavioral features.

Authors:

I. Bernal¹, F. Sir-Mendoza², S. MARADEI ANAYA³; ¹Biotecgen S.A.S, Bogota, Colombia, ²Biotecgen S.A.S, Bogotá, Colombia, ³Biotecgen S.A.S, BOGOTÁ, Colombia

Abstract Body:

Char syndrome is a rare genetic condition with a widely variable phenotype, characterized by unusual faces, patent ductus arteriosus (PDA) and absent or hypoplastic phalanges of the fifth finger. There is no evidence of association with neurodevelopmental involvement such as intellectual disability or autism spectrum disorders. Char syndrome is caused by heterozygous pathogenic variants in the *TFAP2B* gene in an autosomal dominant manner. We described a 13-year-old boy with sleep disorder, multiple craniofacial and limb anomalies, patent ductus arteriosus and Asperger syndrome. He has 11 siblings, three of them with suspicion of an autism spectrum disorder, five with PDA, and six with minor facial anomalies. Additionally, craniofacial anomalies, PDA, polythelia and behavioral disorders were identified in the mother. Trio exome sequencing was performed for the proband, identifying a heterozygous pathogenic variant (NM_003221.4):c.218C>G p.(Pro73Arg), in the *TFAP2B* gene, inherited from the mother. Char syndrome diagnosis was considered for the proband, so we performed an analysis of the variant in other family members, using Sanger sequencing. Four maternal generations were tested, identifying the pathogenic variant in a heterozygous state in five siblings of the proband, his grandfather, one aunt and her two sons, a great aunt and her daughter, and interestingly, we found it to be present in a homozygous state in one sibling of the proband. In conclusion, pathogenic variant c.218C>G p.(Pro73Arg), in the *TFAP2B* gene, was identified in 13 individuals of the same colombian family with a wide variety of signs and symptoms. Neurological or behavioral impairment was observed in all affected patients, ranging from oppositional defiant disorder to Asperger syndrome, findings not previously associated with Char syndrome. The homozygous individual presents a more severe craniofacial deformity and neurological involvement, compared to those heterozygotes, but cardiac and skeletal involvement is similar in both scenarios. To our knowledge, c.218C>G p.(Pro73Arg) variant has not been previously reported in the literature. Although it would be necessary to perform functional studies to better understand if this variant accounts for the observed neurocognitive and behavioral phenotypic landscapes, having found a significant number of affected individuals in the same family manifesting these signs/symptoms is highly suggestive of a possible independent phenotype-genotype correlation, whether it could be part of an alternate phenotype of Char Syndrome or even a different unreported medical condition.

Mendelian Phenotypes Posters - Wednesday

PB1931. Novel locus identification for primary congenital glaucoma in a Pakistani family

Authors:

H. Khan¹, M. Azam², F. Akhtar³, S. Ali², R. Qamar², H. Ayub¹; ¹Pak Austria Fachhochschule: Inst. of Applied Sci. and Technology, Haripur, Pakistan, ²COMSATS Univ. Islamabad, Islamabad, Pakistan, ³Pakistan Inst. of Ophthalmology, Al-Shifa Trust Eye Hosp., Rawalpindi, Pakistan

Abstract Body:

Primary congenital glaucoma (PCG) is an autosomal recessive disorder of the trabecular meshwork & anterior chamber angle of the eye, accounting for up to 18% of childhood blindness around the globe. The prevalence of PCG is continuously rising in Pakistani population, which is attributed to the higher rate of consanguineous marriages. A PCG family of Pakistani origin with two affected & five healthy individuals was studied using different molecular genetic techniques & bioinformatic tools to identify the genetic basis of the disorder in the current family. A 250K array analysis, CA marker analysis & whole exome sequencing was done for the family to identify the disease causative mutation. Selected identified exome variants were subjected to segregation analysis. Though none of the variants segregated with the disease phenotype among the family members but homozygosity mapping revealed a 2 Mb homozygous region common among the affected individuals on chromosome 7 (7q34). CA marker analysis confirmed the segregation of the novel locus with the disease in the family. Thus, in the current study we report the identification of a 2 Mb plausible locus 7q34 to be associated with congenital glaucoma in a Pakistani family.

Mendelian Phenotypes Posters - Thursday

PB1932. Novel variants expand understanding of *PPP1R13L* - related cardio-cutaneous syndrome

Authors:

C. Close¹, K. Anyane-Yeboa²; ¹Div. of Clinical Genetics, Dept. of Pediatrics, Columbia Univ. Med. Ctr., New York City, NY, ²Div. of Clinical Genetics, Dept. of Pediatrics, Columbia Univ. Med. Ctr., New York, NY

Abstract Body:

Pathogenic variants in *PPP1R13L*, encoding iASPP protein, are responsible for an autosomal-recessive cardio-cutaneous syndrome. Previous studies have shown that iASPP function is essential to desmosome regulation and loss of iASPP contributes to a cardio-cutaneous phenotype.

To date, there are 10 families affected by biallelic variants in *PPP1R13L* reported in the literature. Affected individuals have dilated cardiomyopathy (DCM), ichthyosis-like skin findings, woolly hair, dystrophic nails, and wedge-shaped teeth.

Here, we describe a family with atypical features of *PPP1R13L* - related cardio-cutaneous syndrome caused by novel variants. Our patient is an 18-year-old male twin who was born with anal atresia, diagnosed with DCM at age 2, received heart transplant at age 3, and developed steatocystoma papules (SP) at age 12. His twin brother was also born with anal atresia and is identically affected by DCM and SP. They are assumed to be monozygotic. They were born to non-consanguineous parents of Caribbean descent had a sister who died at 21 months from idiopathic cardiac fibrosis.

To date, variants in *KRT17* are the only known genetic cause of steatocystoma multiplex. Sequencing and deletion/duplication analysis of *KRT17* did not reveal any pathogenic variants in our patient. SNP microarray was negative but exome sequencing (ES) with samples from our patient and his mother revealed compound heterozygosity of the variants p.D325Gfs*69 (c.974_1008del) and p.W799* (c.2397 G > A) in *PPP1R13L*. ES did not identify any variants related to anal atresia or cardiomyopathy. The frameshift variant, p.D325Gfs*69, was maternally inherited and is classified as a pathogenic variant as per ACMG recommendations. It is predicted to result in protein truncation or nonsense-mediated decay causing loss of function. The nonsense variant, p.W799*, was not present in the maternal sample and is likely in trans. This variant is interpreted as a likely pathogenic variant as per ACMG recommendations as it is predicted to result in protein truncation. Neither of these variants have been previously reported to our knowledge. Upon receiving these results, genetic testing was recommended for our patient's twin brother and results are pending.

This case marks the first report of SP and anal atresia in a patient with *PPP1R13L* variants. It expands our understanding of *PPP1R13L* function as it suggests a broader phenotypic spectrum than previously appreciated. *PPP1R13L* should be considered when evaluating individuals with SP and conditions known to be caused by abnormal intercellular structures such as DCM and atresia.

Mendelian Phenotypes Posters - Wednesday

PB1933. Novel variants in the *PKD1* and *PKD2* genes in German patients with autosomal dominant polycystic kidney disease

Authors:

R. Zarbock, K. Mayer, M. Scholz, J. Philippou-Massier, K. Hörtnagel, I. Rost; Med.ver Genetics, Ctr. for Human Genetics and Lab. Med. Dr. Klein, Dr. Rost and collea, Martinsried, Germany

Abstract Body:

Background: Autosomal dominant polycystic kidney disease (ADPKD) is a potentially fatal genetic kidney disease with a prevalence of 1:1000. ADPKD accounts for a significant proportion of end-stage renal disease. Most ADPKD patients carry a causative sequence variant in the *PKD1* or *PKD2* gene. The molecular diagnosis of ADPKD is hampered by high allelic heterogeneity and the presence of six highly homologous *PKD1* pseudogenes. To date, the ADPKD variant database lists 1225 different pathogenic variants in *PKD1* and 196 in *PKD2*. In addition, causative variants in *GANAB* and *DNAJB11* have been discovered in rare cases.

Methods: Over a 36-month period, DNA from 119 individuals (61 men, 58 women) with suspected ADPKD was analyzed as part of routine diagnostic testing. Detection of variants was performed by targeted next-generation sequencing of ADPKD genes and, in case of *PKD1*, also by long-range PCR followed by Sanger sequencing. Copy number variations were detected using NGS data and, for *PKD1* and *PKD2*, also by multiplex ligation-dependent probe amplification (MLPA).

Results: A total of 73 variants were identified in 119 patients, corresponding to a detection rate of 61.3%. 65 variants were identified in *PKD1* (89.0%) and 8 in *PKD2* (11.0%). These include 39 novel variants detected in *PKD1* and one novel variant in *PKD2*. No variants were detected in the other ADPKD-associated genes. 40 variants (1 missense, 12 nonsense, 19 frameshift, 5 splice site, and 3 large deletions) were classified as pathogenic according to ACMG guidelines. An additional 12 variants were rated as likely pathogenic (9 missense, 2 splice site, and 1 in-frame deletion). The remaining 21 variants (20 missense and 1 in-frame deletion) were classified as variants of uncertain significance. Truncating variants thus accounted for 52% of all sequence changes found. While the presence of pseudogenes may interfere with NGS, all *PKD1* variants identified by Sanger sequencing were also detected by NGS. However, Sanger sequencing was essential because especially exons 1 and 42 of *PKD1* had poor coverage in some samples.

Conclusions: Our results highlight the high allelic heterogeneity of variants, which is complicated by the presence of variants of uncertain significance. The discovery of 40 previously undescribed variants has significantly expanded the spectrum of known ADPKD causative variants.

Mendelian Phenotypes Posters - Thursday

PB1934. One family, two disorders, three affected: a diagnostic odyssey highlighting the importance of WES as first-tier testing in patients with a specific phenotype but a consanguineous background.

Authors:

N. Alsaleh^{1,2}, M. Alfadhel^{1,3,2}, M. Abothnain^{1,2}, W. Altuwaijri^{4,3,2}, W. Eyaid^{1,3,2}; ¹Genetics and Precision Med. Dept., King Abdullah Specialized Children's Hosp., King Abdulaziz Med. City, Ministry of Natl. Guard-Hlth.Affairs (NGHA), Riyadh, Saudi Arabia, ²King Abdullah Intl. Med. Res. Ctr. (KAIMRC), Riyadh, Saudi Arabia, ³King Saud bin Abdulaziz Univ. for Hlth.Sci., Ministry of Natl. Guard-Hlth.Affairs (NGHA), Riyadh, Saudi Arabia, ⁴Div. of Neurology, Dept. of Pediatrics, King Abdullah Specialized Children Hosp., King Abdulaziz Med. City, Ministry of Natl. Guard-Hlth.Affairs (NGHA), Riyadh, Saudi Arabia

Abstract Body:

Introduction: studies have shown that the diagnostic yield of whole-exome sequencing (WES) compared to multi-gene panels and cytogenetic studies are higher, especially in a consanguineous population. Alstrom syndrome is an autosomal recessive disorder caused by a homozygous variant in *ALMS1*. Characterized by cone-rod dystrophy, obesity, and dilated cardiomyopathy. Ullrich congenital muscular dystrophy is an autosomal recessive disorder caused by a homozygous variant in *COL6A2*. Characterized by congenital hypotonia, hyperlaxity of distal joints and contracture of proximal joints, kyphoscoliosis, and gross motor delay. Here we present a consanguineous family with three affected children and a diagnostic odyssey ended by WES. **Method:** a retrospective chart review of the three affected children was done. Parents are first cousins. Mother had a total of 7 pregnancies, two stillbirth females at term. The first affected child, a male, presented antenatally with decreased fetal movement. At birth, he was hypotonic with abnormal joint extension of the hand and feet. Later he developed gross motor delay, kyphoscoliosis, tracheostomy dependent, failure to thrive, ichthyosis, and dysmorphic features. The second affected child was a female with congenital hypotonia. She had nystagmus, dilated cardiomyopathy, obesity, global developmental delay, joint hypermobility, scoliosis, and bronchial asthma with recurrent pneumothorax. The third affected child, a female, presented with congenital hypotonia. She had global developmental delay, nystagmus, dilated cardiomyopathy, dysmorphic features, obesity, and recurrent pneumothorax. All three children had unremarkable metabolic screening labs, radiological studies, and chromosomal analysis. They all had elevated CK levels. **Results:** Chromosomal microarray for all three affected children was negative except for long stretches of homozygosity. WES for the third affected child reported a homozygous likely pathogenic novel variant in *ALMS1*. Later WES was requested for the first affected child and it reported a homozygous pathogenic variant in *COL6A2*. Targeted gene testing for the second affected child is pending for both *COL6A2* and *ALMS1* variants. **Conclusion:** WES's current availability and somewhat quick turnaround time significantly impacted reaching a diagnosis in a timely manner. Variable expressivity is known in several genetic disorders; however, the presence of a more severe phenotype, especially in patients with consanguineous backgrounds, could be due to a second genetic disorder. Therefore, WES is the most proper first-tier testing, especially in a consanguineous population.

Mendelian Phenotypes Posters - Wednesday

PB1935*. Osteogenically differentiated human fibroblasts - an alternative model to study bone diseases

Authors:

M. Pekkinen^{1,2,3}, S. Pihlström^{4,2}, K. Määttä^{5,2}, R. Mäkitie^{5,2,6}, M. Aronen², O. Mäkitie^{5,2,3,7}; ¹Res. Program for Clinical and Molecular Metabolism, Faculty of Med., Univ. of Helsinki, Helsinki, University of Helsinki, Finland, ²Folkhälsan Res. Ctr., Helsinki, Finland, ³Children's Hosp., Helsinki Univ. Hosp. and Univ. of Helsinki, Helsinki, Finland, ⁴Res. gram for Clinical and Molecular Metabolism, Faculty of Med., Univ. of Helsinki, Helsinki, Finland, ⁵Res. Program for Clinical and Molecular Metabolism, Faculty of Med., Univ. of Helsinki, Helsinki, Finland, ⁶Dept. of Otorhinolaryngology – Head and Neck Surgery, Helsinki Univ. Hosp. and Univ. of Helsinki, Helsinki, Finland, ⁷Dept. of Molecular Med. and Surgery and Ctr. for Molecular Med., Karolinska Inst.t, Stockholm, Sweden

Abstract Body:

Several skeletal disorders exhibit abnormal osteoblast development and function along with mineralization defects, creating a demand for an osteoblastic *in vitro* system. However, native osteoblasts are difficult to isolate from affected patients and problematic to expand *in vitro*. Similar issue concerns bone marrow mesenchymal stem cells (MSCs), the original progenitors of osteoblasts. One potential alternative source of cells that are non-immunogenic, easily expandable and readily available through a minimal invasive harvesting procedure are human dermal fibroblasts. Therefore, we developed an *in vitro* culturing technique to transdifferentiate fibroblasts into osteoblast-like cells. We obtained human fibroblasts from forearm skin biopsy, approved by an ethical committee, and differentiated them into osteoblast-like cells by treating them with β -glycerophosphate, ascorbic acid and dexamethasone. The concentrations and duration of the components varied during the osteogenic treatment. Additionally, we differentiated human commercial MSCs, derived from bone marrow, into osteoblasts and used as a positive control. The osteoblastic phenotype was verified by staining alkaline phosphatase (ALP) and calcium deposits (Alizarin red and von kossa staining), and measuring mRNA and protein levels for specific osteoblastic markers using RNA sequencing and proteomic analysis. After 14 days of treatment, both fibroblasts and MSCs stained positive for ALP together with a significant increase in bone specific ALP compared to untreated cells. At a later time point, both cell types deposited minerals, as confirmed by staining, indicating mineralization. Ingenuity Pathways Analysis of RNA sequencing data from fibroblasts and MSCs showed that the osteoarthritis pathway was activated in both cell lines. Since osteoblasts have an essential role in osteoarthritis, by e.g. producing numerous transcription factors, growth factors, and other molecules involved in osteoarthritis pathogenesis, these data are supportive of osteogenic differentiation. Together, this data indicate that our *in vitro* treatment induces osteoblast-like differentiation in fibroblasts and MSCs, producing an *in vitro* osteoblastic cell system.

Mendelian Phenotypes Posters - Thursday

PB1936. Patients with biallelic GGC repeat expansions in *NOTCH2NLC* exhibiting a typical neuronal intranuclear inclusion disease phenotype

Authors:

S. Kameyama^{1,2}, T. Mizuguchi¹, H. Doi³, S. Koyano⁴, M. Okubo³, M. Tada³, H. Shimizu⁵, H. Fukuda^{1,3}, N. Tsuchida^{1,6}, Y. Uchiyama^{1,6}, E. Koshimizu¹, K. Hamanaka¹, A. Fujita¹, K. Misawa¹, S. Miyatake^{1,7}, K. Kanai⁸, F. Tanaka³, N. Matsumoto¹; ¹Dept. of Human Genetics, Yokohama City Univ. Graduate Sch. of Med., Yokohama, Japan, ²Dept. of Pathology, Keio Univ. Sch. of Med., Tokyo, Japan, ³Dept. of Neurology and Stroke Med., Yokohama City Univ. Graduate Sch. of Med., Yokohama, Japan, ⁴Dept. of Neurology, Yokohama Minami Kyosai Hosp., Yokohama, Japan, ⁵Dept. of Pathology, Brain Res. Inst., Niigata Univ., Niigata, Japan, ⁶Dept. of Rare Disease Genomics, Yokohama City Univ. Hosp., Yokohama, Japan, ⁷Clinical Genetics Dept., Yokohama City Univ. Hosp., Yokohama, Japan, ⁸Dept. of Neurology, Fukushima Med. Univ. Sch. of Med., Fukushima, Japan

Abstract Body:

The genotype-phenotype correlation of *NOTCH2NLC*-related diseases may be attributed to multiple factors such as repeat lengths, epigenetic modification, and repeat motifs. However, the relationship between repeat expansion zygosity and clinical phenotype has not yet been fully elucidated. Here we report two patients with neuronal intranuclear inclusion disease (NIID) harboring the biallelic GGC repeat expansion in *NOTCH2NLC* to uncover the impact of repeat expansion zygosity on the clinical phenotype of *NOTCH2NLC*-related diseases. We recruited two Japanese patients clinically diagnosed with NIID. The genomic DNA of these patients was used for repeat-primed PCR and fluorescent amplicon length PCR (AL-PCR) to screen for the *NOTCH2NLC* repeat expansion. The zygosity of the entire *NOTCH2NLC* GGC repeat expansion and DNA methylation were comprehensively evaluated using Southern blotting and targeted long-read sequencing. As a result, in the AL-PCR, we observed amplicons suggestive of only repeat expansion alleles but not those of the wild-type allele, which indicated the presence of the biallelic repeat expansion in *NOTCH2NLC*. PacBio targeted long-read sequencing revealed that one patient harbored almost the same expanded allele containing GGC repeats in *NOTCH2NLC* ([GGC]₉₅ in the consensus sequence) without a non-expanded allele, which suggested homozygous repeat expansion. The other patient harbored two expanded alleles with different lengths of GGC repeats ([GGC]₆₅[GGA]₂[GGC]₂ or [GGC]₉₉[GGA]₂[GGC]₂ in the consensus sequences), which suggested compound heterozygous repeat expansion. The GGC repeats and the nearest CpG island were hypomethylated in all expanded alleles in both patients. Both patients harboring biallelic GGC repeat expansion showed a typical dementia-dominant NIID phenotype. In conclusion, the biallelic GGC repeat expansion in two typical NIID patients indicated that *NOTCH2NLC*-related diseases can be completely dominant.

Mendelian Phenotypes Posters - Wednesday

PB1937. Patients with primary familial brain calcification due to variants in SLC20A2 are not commonly diagnosed with Parkinson's disease

Authors:

J. B. Chang¹, C. Barnhill¹, J. L. Wenke², G. Nicolas³, H. Shen¹, S-G. Ji¹; ¹BridgeBio Pharma Inc., San Francisco, CA, ²Nashville BioSci.s, Nashville, TN, ³CHU Rouen, Univ. of Rouen Normandie, and Inserm U1245, Rouen, France

Abstract Body:

Primary familial brain calcification (PFBC) is a rare genetic disorder with incomplete penetrance. Clinical phenotypes overlap with that of Parkinson's disease (PD) in some patients. Because diagnoses for the PFBC are extremely uncommon, this raises the question of whether PFBC patients are diagnosed with PD. We sought to gain further clarity on the PFBC phenotype by analyzing patients in Genomics England, the UK Biobank, and BioVU with pathogenic variants in SLC20A2, the most common gene that causes autosomal dominant PFBC (PFBC-SLC20A2). Within a small cohort of PD patients in Genomics England, we were able to identify an enrichment of pathogenic SLC20A2 variants. However, in the UK Biobank, we did not detect a similar association with PD phenotypes. Instead, we did detect an association between patients with pathogenic SLC20A2 variants ($n = 49$) and giant cell arteritis (GCA, $p = 1.2e-5$), a disease that has been linked to calcification. This association was corroborated by a separate cohort of 102 patients with PFBC-SLC20A2, in which 1 patient also was diagnosed with GCA. Finally, within BioVU, we identified 21 PD patients who also presented with calcification in the basal ganglia. Whole exome sequencing of these patients revealed that none of them had pathogenic variants in SLC20A2 or other PFBC genes, whereas sequencing of 8 putative PFBC patients revealed 2 with pathogenic variants in SLC20A2 and another 4 in other PFBC genes. Taken together, our results show that PFBC patients are unlikely to be commonly diagnosed with PD.

Mendelian Phenotypes Posters - Thursday

PB1938. PHACE syndrome: New strategies to identify the disease mechanism for this unsolved recognizable condition

Authors:

A. Cuillerier¹, L. McDonell², T. Hartley^{3,4}, L. de Kock¹, G. Del Gobbo¹, A. White-Brown¹, S. Goobie², T. Balci⁵, L. Chad⁶, S. White⁷, M. Lines⁸, R. Mendoza-Londono⁶, C. Armour⁹, P. Au⁸, K. Kernohan¹⁰, Care4Rare Canada, D. Dymant⁴, K. Boycott⁴; ¹Children's Hosp. of Eastern Ontario Res. Inst., Ottawa, ON, Canada, ²Dalhousie Univ., Halifax, NS, Canada, ³Univ. of Ottawa, Ottawa, ON, Canada, ⁴Children's Hosp. of Eastern Ontario, Ottawa, ON, Canada, ⁵London Hlth.Sci. Ctr., London, ON, Canada, ⁶The Hosp. for Sick Children/ Univ. of Toronto, Toronto, ON, Canada, ⁷Royal's Children Hosp., Victoria, Australia, ⁸Cumming Sch. of Med. / Univ. of Calgary, Calgary, AB, Canada, ⁹Children's Hosp. of Eastern Ontario/Univ. of Ottawa, Ottawa, ON, Canada, ¹⁰Newborn Screening of Ontario / CHEO Res. Inst. (Care4Rare), Ottawa, ON, Canada

Abstract Body:

PHACE syndrome is characterized by **P**osterior fossa brain malformations, segmental facial **H**emangioma, **A**rterial anomalies, **C**ardiac defects, **E**ye anomalies, and sternal clefting or supraumbilical raphe. The hallmark of the disease is the presence of a hemangioma greater than 5cm in diameter of the head, including scalp, which usually leads physicians to a PHACE syndrome diagnosis. Although the exact incidence is unknown, over 250 cases are reported in the literature, and it is suspected that PHACE syndrome is underdiagnosed. Despite tremendous efforts by multiple research groups, the underlying etiology of PHACE syndrome has not been identified. It is hypothesized, however, that the syndrome is due to a somatic mutation, likely in a cancer genetic pathway. In order to elucidate the underlying molecular cause of PHACE syndrome, Care4Rare Canada has gathered a cohort of nine families recruited in Canada, Australia and New Zealand, including a set of discordant monozygotic twins in which one twin presents with PHACE syndrome. We have collected DNA from blood for probands and unaffected relatives, and DNA from saliva, buccal, unaffected and affected lesions from probands when possible. We have one family for which post-mortem samples of arteries, carotid, aorta, cerebellum, heart and skin were collected from the proband and another where we have fresh cardiovascular tissue. We are using multiple technologies and laboratory approaches to investigate multiple types of genetic alterations. Chromosomal microarray yielded no compelling large CNVs. Similarly, exome sequencing (ES) and short-read genome sequencing (GS) identified no compelling SNVs, CNVs, SVs or non-coding DNA variants. Some of the ES and GS data have been shared with the Centers for Mendelian Genomics and combined with hundreds of other existing datasets from PHACE patients in the hopes that a combined reanalysis will be fruitful. Functional studies on patient cell lines, including a targeted expression array and growth assays have similarly yielded no compelling candidates or pathways. Given the unrevealing nature of these previous data, we have moved on to broader approaches. Currently we are analyzing methylation, deep ES data, RNASeq, and long-read GS in multiple families using multiple tissue types, with a particular focus on the analysis of the discordant monozygotic twins. We are hopeful that our multi-omics, multi-tissue, multi-family approach will identify clues to the genetic etiology of PHACE syndrome.

Mendelian Phenotypes Posters - Wednesday

Abstract Body:

MECP2 duplication syndrome (MDS) is a rare neurologic condition found exclusively in males. MDS arises due to increased copies of the Xq28 region including *MECP2*. To date, there are several MDS cohort studies (~50 individuals or less in each) that have reported varying frequency of clinical features but their severity was not fully investigated. In this study, we have enrolled 127 individuals with MDS whose molecular diagnoses were confirmed by routine clinical genetic studies. We performed a comprehensive phenotypic characterization of all clinical features. Fifty-six of 113 cases (50%) experienced complications during pregnancy and delivery. Postnatally, 28/109 (26%) were admitted to the NICU and their stay ranged from two days to 104 days. Congenital hypotonia, one of the defining features of MDS, was present in 64% of the individuals (70/109). Severe to profound neurodevelopmental delay was present in all subjects, with most functioning at a 12 to 18 month developmental level. The gastrointestinal system was the second most common system involved. Chewing and swallowing problems were present in 90% (101/112) and 42% of those were G-tube dependent. Constipation, often requiring suppositories and enemas, was reported in 97/110 (88%) individuals. Recurrent infections were prevalent in majority of the subjects. Pneumonia (73%, N=85/116), upper respiratory infection (79%, N=84/107) and urinary tract infections (38%, N=30/79) were the most reported conditions. Mild dysmorphic features were widely observed (90%, N=65/72). Growth parameters including head circumference were mostly within normal range, with 21.3% microcephalic, 21.3% macrocephalic and the remaining 57% normocephalic. Epilepsy, with an average age of onset of 8.4 years, was a dynamic feature and universally present in all individuals after age 15 years. Most patients' epilepsy became refractory within the first two years after onset, and it is the main cause of regression in MDS individuals. Other relatively less common and less severe clinical features include scoliosis (58%, N=45/77), insomnia (53%, N=52/98), sleep apnea (57%, N=54/94), cryptorchidism (43%, N=45/104), hearing deficit (14%, N=13/94) and eye problems, including refraction errors and strabismus (65%, N=63/97). Our study provides a deeper understanding and characterization of the clinical features in MDS subjects. These results will inform clinicians and families regarding the management of individuals with MDS and will provide an important foundation for basic and clinical research.

Mendelian Phenotypes Posters - Thursday

PB1940. Phenotypic variation of outcomes for tail-domain *KIF5A* related variants.

Authors:

M. Jose¹, M. Sikes², T. Wenger², N. Natarajan², I. Glass³; ¹Univ. of Washington, Seattle, WA, ²Seattle Children's Hosp., Seattle, WA, ³Univ of Washington, Seattle, WA

Abstract Body:

Kinesin family member 5A (*KIF5A*) encodes neural kinesin heavy chain, part of the kinesin super family proteins (KIFs), that are expressed in neurons and play a role in intracellular transport. *KIF5A* motor domain-variants are associated with hereditary spastic paraplegia (HSP) and Charcot-Marie-Tooth 2 (CMT2). *KIF5A* tail-variants predispose to amyotrophic lateral sclerosis (ALS) and neonatal intractable myoclonus (NIM). Thus far, just 3 patients with NIM have been reported. Herein, we report a neonate harboring a tail-domain pathogenic variant demonstrating phenotypic divergence for this subtype of *KIF5A* mutations.

A 6-day-old male infant born to healthy, non-consanguineous parents at 39 +weeks gestation with normal birth indices [OFC 35.5 cm (55th %ile), length of 50.5 cm (63rd %ile), birth weight of 3200g (38th %ile)] was transferred because of hypotonia and poor feeding. Initially stable in room air, intermittent hypothermia and by day 7 nasal cannular oxygen support was required, escalated to HFNC, and NGT feeding. Axial > appendicular hypotonia, upper and lower limb girdle weakness, preserved DTRs, absent startle, symmetric paucity of facial motion/eye opening, absence of fixation, bilateral ptosis, staccato unvarying vocalizations were present. Normal metabolic investigations and MR brain imaging were present. EEG showed non-specific mildly encephalopathic features. He failed the newborn hearing screen on the right ear. Prader-Willi DNA methylation confirmed biparental representation and SNP-microarray did not identify a pathogenic CNV. Emergent trio-exome sequencing revealed a heterozygous de novo tail-domain pathogenic *KIF5A* variant c.2819_2903del (p.S940Ifs*80) and a heterozygous paternally inherited pathogenic variant in *CHRNBI*.

This variant in *KIF5A* results in protein truncation and presumed LOF has not previously been observed. It is located in the C-terminal region of *KIF5A*, consistent with 3 other infants reported to have severe impacts from mutations in this domain of the protein. The 3 previously reported infants with tail-domain heterozygous variants demonstrated intractable myoclonus from birth, hypotonia, hearing loss (1/3), and 2/3 with optic nerve atrophy and developmental delay, with early demise at 3 months and 1 year in 2/3. Our case demonstrates a similar devastating neurological outcome with high dependency needs and minimal developmental progress. However, his phenotype diverges thus far as he lacks myoclonus indicating interpretation of variants in the C-terminal encoding region of *KIF5A* need not necessitate myoclonus to occur to assign pathogenicity.

Mendelian Phenotypes Posters - Wednesday

PB1941. PhenylEc: Novel genotypes and nutritional management in phenylketonuria patients from Ecuador.

Authors:

V. Romero¹, A. Campodonico¹, E. Haro¹, A. Mendoza¹, B. Bahamonde¹, J. Pozo²; ¹Univ. San Francisco de Quito, Quito, Ecuador, ²Univ. Tecnica de Cuenca, Cuenca, Ecuador

Abstract Body:

Phenylketonuria (PKU) is an innate error of metabolism due to an enzymatic deficit to convert the phenylalanine into tyrosine. Without nutritional restriction of phenylalanine foods, it results in irreversible intellectual disability. PKU is part of the neonatal screening in Ecuador, however, genetic tests and nutritional counseling are not publicly available. We characterized the molecular variants of affected individual, compared the frequency to worldwide and to other Latin American countries and modified current Guidelines from other regions to rural areas. We reviewed the medical history of Ecuadorian patients with PKU, correlated genotype-phenotype, allele frequencies from the BioPKU database and modelled the protein for the new detected genotypes. In addition, we performed a systematic literary review in English and Spanish of the nutritional databases available and use the nutritional information to develop a Latin American guideline with products from our region. The most frequent worldwide PAH variants and genotypes were not found in Ecuador. The most frequent alleles in Ecuador included p.Arg252Trp, p.Ser349Pro and c.441+5G>T. p.Arg252Trp/ c.441+5G>T genotype and p.Ser349Pro homozygote were the most frequent genotypes. We reported 5 new genotypes not reported in BioPKU database. The American and European recommendations that cannot be used in developing countries. Therefore, we obtained the nutritional information and phenylalanine and tyrosine concentrations from local products and modified the reported recommendations for developing countries. Ecuador is a country with a mixed population - African, European, and Native American. The low frequency of global variants and high frequency of rare suggest indigenous variants and unique genotype-phenotype in eastern part of South America with low frequency of European variants. This highlights the importance of developing new molecular panels for metabolic disorders to analyze and detect variants found specifically in regions of Latin America. Finally, we developed a Nutritional Guideline for Latin America with local products and more accessible recommendations demonstrating the necessity of additional projects to be done in the region.

Mendelian Phenotypes Posters - Wednesday

PB1942. Polygenic risk scores and protein language models predict phenotype severity in individuals with rare clinical pathogenic variants

Authors:

A. Wei¹, R. Border², M. Udler³, V. Ntranos⁴, N. Brandes⁵, N. Zaitlen¹, V. Arboleda¹; ¹Univ. of California, Los Angeles, Los Angeles, CA, ²Univ. of California Los Angeles, Los Angeles, CA, ³Broad Inst., Boston, MA, ⁴Univ. of California, San Francisco, San Francisco, CA, ⁵Univ. of California, San Francisco, San Francisco, CA

Abstract Body:

Background: As more individuals have their genomes sequenced, pathogenic mutations that were previously believed to be 100% penetrant are being identified in individuals with no apparent clinical disease. For example, familial mutations can have differential clinical manifestations due to a combination of differences in genetic background and environment. The combination of how individual amino acid changes and polygenic background influences penetrance and expressivity of a clinical phenotype are unknown. This project improves upon previous studies by utilizing a cohort with ~3x as many subjects to increase power, calculating polygenic risk scores (PRSs) to study common genetic variation, and applying protein language models to improve annotation of pathogenic variants.

Methods: We analyzed whole exome-sequencing and clinical phenotypes from 200,643 individuals in UK Biobank (UKB) to identify carriers of rare, monogenic variants known to cause three metabolic phenotypes: monogenic maturity onset diabetes of the young (MODY), obesity, and hypercholesterolemia. We calculated PRSs for the associated complex traits of type 2 diabetes, body mass index (BMI), and low-density lipoprotein (LDL) levels for all UKB participants with exome sequencing. Scores predicting how single amino acid changes affected protein function were generated by the ESM1-b protein language model.

Results: The penetrance of these rare pathogenic disease variants in the UKB ranged from 20-53%.

Carriers are at higher risk of developing associated diseases than non-carriers (Bonferroni-corrected, $p < 9e-09$). Compared to non-carriers in the top 1% of common-variant polygenic risk, carriers are at similar or higher risk of developing associated diseases. Interestingly, even within the carriers of familial hypobetalipoproteinemia variants, there is a positive association between carrier LDL levels and LDL PRS and (p -value= $1.36e-05$) suggesting that genetic background influences the expressivity of the monogenic disease variant. Finally, we observe that the BMI of obesity variant carriers varies depending on which monogenic obesity variant is observed; gain-of-function alleles have more positive ESM1-b scores, while loss-of-function variants have more negative scores.

Conclusion: Carriers of monogenic disease rare variants have been treated uniformly as one group; however, we show that PRSs modify the penetrance and expressivity of monogenic disease, highlighting the potential integration of PRSs into genomic medicine.

Mendelian Phenotypes Posters - Wednesday

PB1943. *PPP2R5D*-related Neurodevelopmental Disorder can be inherited from a mildly affected parent.

Authors:

S. Jougheh Doust^{1,2}, E. Fox¹, R. Raja²; ¹Peterborough Regional Hlth.Ctr., Peterborough, ON, Canada, ²Lakeridge Hlth.Oshawa, Oshawa, ON, Canada

Abstract Body:

PPP2R5D-related intellectual disability (MIM#616355; ID39) also known as Jordan's syndrome is a neurodevelopmental disorder characterized by hypotonia, intellectual disability and macrocephaly. The presentation is highly variable. Mild to severe intellectual disability is a major finding. Additional features include seizures and autism. Dysmorphic features may include frontal bossing, down-slanting palpebral fissures and hypertelorism. This is an autosomal dominant condition and almost all reported cases are caused by "de novo" pathogenic mutations in this gene. Here, we report a child with *PPP2RD5*-related ID disorder who inherited the *PPP2RD5*:c.598G>A, p.Glu200Lys, from their mildly affected father. This is a recurrent pathogenic mutation which has always been reported as a de novo mutation in the affected individuals. The child has global developmental delay, macrocephaly(OFC>97th percentile), and hypotonia. Their father also has macrocephaly, mild developmental delay and learning disability. The parent and child share characteristic features including frontal bossing, hypertelorism, down-slanted palpebral fissures, low-set ears, prominent lower jaw, long philtrum, and high arched palate. This case expands our current knowledge about inheritability of this rare neurodevelopmental disorder which previously reported to be caused by de novo mutations in *PPP2RD5* gene.

Mendelian Phenotypes Posters - Thursday

PB1944*. Precision diagnostics for GLUT1 disorder using deep mutational scanning

Authors:

N. Tayebi¹, K. McCall¹, **B. Ricardo**¹, G. Haller², C. Gurnett¹; ¹Washington Univ. in St. Louis, St. Louis, MO, ²Washington Univ. Sch. of Med. in St. Louis, St. Louis, MO

Abstract Body:

Accurate genetic diagnosis is critical, particularly as effective therapies become available for neurological disorders. The accumulation of variants of uncertain significance (VUS) presents a growing crisis that negatively impact the ability to implement precision therapies. The goal of this research is to demonstrate the utility of a growth assay to quantify the functional impact of variants in *SLC2A1*, the gene responsible for GLUT1 deficiency syndrome. The GLUT1 deficiency syndrome encompasses a spectrum of neurological disorders, including early onset seizures with acquired microcephaly and cognitive impairment (classic type), paroxysmal choreoathetosis and dyskinesia, atypical childhood absence epilepsy, alternating hemiplegia, along with many related phenotypes. Because *SLC2A1* is required for growth of HAP1 cells, variants that are deleterious would drop out of the cell populations over time. By sequencing pools of cells at different time points, we can quantitatively determine the impact of variants on cell viability. As proof of principle, we evaluated 58 variants across 3 exons using a growth assay in HAP1 cells. We created a donor library consisting of 22 variants for exon 2, 18 variants for exon 3, and 18 variants for exon 7 in pathogenic, benign, and VUS categories. Variant libraries were introduced into the HAP1-lig4KO cell line using exon specific CRISPR/Cas9. Cell populations were harvested and sequenced at days 5 and 11. Nonsense and known pathogenic variants in all exons dropped out of the population, while known benign variants were not depleted. In addition, *SLC2A1* missense variants identified in the patients with childhood onset epilepsy and mild phenotype had intermediate functional effects in this assay. Our results demonstrate the utility of this assay for generating quantitative functional data for 58 variants in *SLC2A1*. Furthermore, our quantitative functional data correlated with clinical phenotypes, suggesting that it can also be clinically useful for prognosis. Future work is needed to scale the assay such that every possible variant in *SLC2A1* can be quantitatively determined. Functional assays are necessary to improve variant interpretation for neurological disorders and provide important insight into protein structure and function.

Mendelian Phenotypes Posters - Wednesday

PB1945. Pre-clinical studies in induced Pluripotent Stem Cell (iPSC) lines with *SORD* mutations linked to a recessive neuropathy

Authors:

C. Yanick¹, R. Maciel², J. Medina¹, A. Rebelo³, M. Shy⁴, S. Zuchner³, M. Saporta¹; ¹Univ. of Miami Miller Sch. of Med., Miami, FL, ²Univ. of Miami, Miami, FL, ³Univ Miami, Miami, FL, ⁴Univ. of Iowa, Iowa City, IA

Abstract Body:

Introduction: Recently, mutations in the gene coding for sorbitol dehydrogenase (*SORD*) were associated with a new form of recessive inherited neuropathy. To model this CMT type, we took fibroblast samples from patients and reprogrammed them into induced-Pluripotent Stem Cells (iPSCs). We are using these cells to perform assays to assess disease phenotypes and mechanisms as well as evaluate different therapeutic strategies for *SORD* related neuropathy. **Methods:** Fibroblasts were transduced using a Sendai Virus Reprogramming kit to express reprogramming factors. Immunocytochemistry for Oct4, NANOG, and SSEA3 was performed to confirm pluripotency of cells. Immunocytochemistry for HB9, Islet 1 and Beta-Tubulin 3 was performed to confirm differentiation into lower motor neurons. Intracellular sorbitol levels were measured via colorimetric sorbitol kit and mass spectrometry. Flow Cytometry was performed on a FACS-Canto II recording at 20,000 events per sample. **Results:** Previous experiments demonstrated that we successfully generated induced Pluripotent Stem Cell (iPSC) lines from patient fibroblasts with the *SORD* mutations and had been able to reproducibly differentiate them into *SORD* motor neurons. To ensure that we were replicating an important disease phenotype, we measured intracellular sorbitol levels of the *SORD* motor neurons and saw that the intracellular sorbitol levels were elevated compared to control. Preliminary data shows that the motor neurons can accumulate sorbitol from the extracellular environment following incubation in a 200mM sorbitol containing media, as well as release sorbitol following a 48hr withdrawal period. We assessed potential osmotic dysregulation by measuring the size of the neurons using Flow Cytometry and observed no size differences between the *SORD* and control motor neurons. Ongoing and future experiments will look at mechanisms of sorbitol accumulation and release, as well as potential neurodegenerative and mitochondrial phenotypes. **Conclusions:** Our results show that while iPSC-derived *SORD* motor neurons do not display changes in cell size, preliminary data indicates that they can either passively or actively accumulate additional sorbitol when exposed to a hypotonic environment as well as release sorbitol following return to an isotonic media and sorbitol withdrawal. Current experiments are investigating potential mechanisms of sorbitol accumulation and release using small molecule inhibitors. We are also investigating mitochondrial and neurodegenerative cellular phenotypes associated with the *SORD* neuropathy.

Mendelian Phenotypes Posters - Thursday

PB1946. Predictive modeling to define the locus heterogeneity of tRNA synthetase-related peripheral neuropathy.

Authors:

A. Cale, A. Antonellis; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Aminoacyl-tRNA synthetases (ARSs) are ubiquitously expressed, essential enzymes that ligate amino acids to cognate tRNAs in the cytoplasm and mitochondria. Mutations in five ARSs cause autosomal dominant, axonal peripheral neuropathy (i.e., Charcot-Marie-Tooth [CMT] disease). While translation and the integrated stress response have been implicated downstream of CMT-associated ARS variants, a unifying pathological mechanism that explains the locus and allelic heterogeneity has not been identified. Many findings argue against haploinsufficiency as the underlying mechanism, leaving dominant-negative and neomorphic gain-of-function mechanisms as non-mutually exclusive explanations. The majority of CMT-associated ARS alleles cause a loss-of-function effect and all CMT-associated ARSs act as cytoplasmic homodimers; this is consistent with a unifying dominant-negative mechanism. If ARS-associated CMT is caused by a dominant-negative effect, it would be expected that certain variants in any cytoplasmic, dimeric ARS could lead to dominant peripheral neuropathy. To test this, we are employing a predictive modeling strategy that begins with engineering variants in threonyl-tRNA synthetase (*TARSI*), which is a cytoplasmic dimeric ARS that has not been implicated in CMT. We are testing the following panel of *TARSI* missense variants: (a) four reported to be loss-of-function and dominantly lethal in bacteria; (b) one reported to be aminoacylation and editing defective in yeast; and (c) two variants identified in human populations that reside near residues being studied in (a). We tested these variants in a yeast complementation assay, which revealed that all are loss-of-function or hypomorphic alleles. We next tested these variants in an established yeast dominant toxicity assay, where we co-express mutant *TARSI* along with wild-type *TARSI* and assess yeast growth. This experiment revealed at least one dominantly toxic *TARSI* allele that reduces yeast cell growth in the presence of wild-type *TARSI*. Next, we will: (1) develop *C. elegans* and mouse models to assess for motor deficits associated with dominantly-toxic alleles; and (2) identify and introduce dimer-reducing mutations to determine if dimerization is required for any observed neurotoxicity, which would implicate a dominant-negative effect. Successful completion of this study will inform clinicians to screen *TARSI* for pathogenic variants in patients with peripheral neuropathy, and provide insight into the mechanism underlying ARS-associated neuropathy.

Mendelian Phenotypes Posters - Thursday

PB1947*. Probing variants associated with neurodevelopmental disorders by studying social behaviors in *C. elegans*

Authors:

J. Pierce¹, S. Sanchez²; ¹Univ. of Texas, Austin, TX, ²Univ. of Texas at Austin, Austin, TX

Abstract Body:

Neurodevelopmental disorders (ND), including Autism spectrum disorder (ASD), are often typified by defects in social behaviors and sensory integration. The wide variety and severity of ND symptoms is likely explained by mutations in hundreds of genes suspected of causing ND either singly or in combination. So far, only a handful of the genes associated with ASD have been confirmed as causing phenotypes related to ASD in animal models. Even fewer genes have been confirmed as modifying ASD phenotypes in polygenic fashion in these models. Thus, a major goal is to find a convenient way to study which of the hundreds of combinations of mutations in ASD risk genes cause or modify ASD phenotypes singly or in combination. --- To investigate the large numbers of genes and variants associated with ND, we turned to leverage the nematode *C. elegans* as a minimum *in vivo* model to quickly discover genes that cause problems in neurological conditions. We recently discovered that *C. elegans* has conserved versions for 80% of ASD risk genes on the SPARK list. *C. elegans* displays robust social behaviors when feeding and integrates diverse sensory input to make decisions. We found that genetically distinct *C. elegans* strains isolated from around the world display different degrees of social behaviors. Surprisingly, we found that the number and severity of mutations in over 100 orthologs of ASD risk genes significantly correlate with differences in social behaviors across these populations. Conversely, we found that mutations in certain genes implicated in the hypersociality in Williams syndrome correlated with increased social behavior in *C. elegans*. Moreover, we found that mutations in certain ASD risk genes cause social deficits, because we could boost social behaviors by genetically repairing defective ASD risk genes (e.g. Neuroligin, SYNGAP1, and DYRK1A). Together, our results suggest that *C. elegans* can be exploited to study the complex polygenic basis for how risk genes cause and modify phenotypes relevant to ASD and other ND.

Mendelian Phenotypes Posters - Thursday

PB1948. Proposal of intervention of the IL-10 rs1800872 (-592 C>A) as a modulator in the cardiovascular variant of Fabry disease

Authors:

A. Ruiz Ramirez^{1,2}, E. Prado Montes de Oca³, L. E. Figuera^{2,1}; ¹Doctorado en Genética Humana, CUCS, UDG, Guadalajara, Mexico, ²División de Genética, CIBO, IMSS, Guadalajara, Mexico, ³Laboratorio Natl. de Med. Personalizada (LAMPER), Centro de Investigación y Asistencia en Tecnología y Diseño del Estado de Jalisco (CIATEJ), Guadalajara, Mexico

Abstract Body:

Fabry disease (FD) is an X-linked lysosomal storage disorder, caused by mutations in the α -galactosidase A (*GLA*) gene. However, the neuro-cardiac variant of FD is not well characterized at the molecular level, and modifier genes could act as enhancers or suppressors of the severity of symptoms. A profile of increased IL-10 production is frequently seen in many FD patients, and even correlations between *IL10* variant (-819C/T) and the neurological score ($p = 0.03$) of the Mainz Severity Score Index (MSSI) have been reported. Methodology: 6 male and 7 female patients ≥ 18 years with molecularly confirmed FD were included, according to clinical characteristics and cabinet studies, they were classified in severity according to the MSSI. Patients signed informed consent before whole venous blood was withdrawn. DNA isolated was subsequently amplified, with designed primers for amplification for the region near position -592 of the promoter of *IL10* gene. DNA sequencing was performed with Applied Biosystems SeqStudio and analyzed with 4 Peaks software. Results: Of the 13 patients, 61.53% were classified as moderate (score 20-40), 31% as mild (< 20), and 7% as severe (> 40). The main cardiac alterations were short PR (23%), left ventricular hypertrophy LVH (23%), valvular insufficiency (23%), and without cardiac alterations (30%). The main neurological alteration was the presence of acroparesthesia (100%), in second place tinnitus in (76%), and third the presence of fatigue (53%). The promoter for the region near position -592 was analyzed, the presence of the rs1800872 (-592 C/A) was found in six patients. Correlations between *IL10* (-592 C/A) and both total and cardiac MSSI sub-scores ($p = 0.034$ and $p = 0.035$ respectively) were found. Preliminary conclusions: The role that variations in inflammatory and anti-inflammatory genes may be modifying clinical characteristics, has been considered in different diseases, in the case of lysosomal diseases, specifically Gaucher disease is an example where it has been continuously analyzed how modifying genes, epigenetics, and other factors can lose the clear limits between simple and complex inheritance. In FD, *IL10* had previously been associated with the neurological components of the disease, this gene could be influential in the neuro-cardiovascular phenotype and be more determinant of the severity of the disease than previously thought. IL-10 has been studied for its protective effect in periods of ischemia, where it has the ability to eliminate $[Ca^{2+}]$ induced by ischemia. This type of studies will allow a therapeutic approach depending on the genetic variants that are associated with the *GLA* mutation in the future.

Mendelian Phenotypes Posters - Wednesday

PB1949. Pulmonary function and structure in young adults with types III, IV and VI osteogenesis imperfecta.

Authors:

B. Gochuico¹, M. Hossain¹, S. Talvacchio², M. G. Zuo¹, M. Barton³, A. Dang Do², J. C. Marini²; ¹Natl. Human Genome Res. Inst., Bethesda, MD, ²Eunice Kennedy Shriver Natl. Inst. of Child Hlth. and Human Dev., Bethesda, MD, ³Natl. Heart, Lung, and Blood Inst., Bethesda, MD

Abstract Body:

Background: Osteogenesis imperfecta (OI), an inherited disorder characterized by skeletal deformities and bone fragility, is associated with lung disease due to intrinsic and extrinsic pulmonary defects. We aimed to expand the phenotype of lung disease in a cohort of children and young adults with different OI types.

Methods: Subjects with OI types III (n=8), IV (n=21), or VI (n=5) underwent pulmonary function tests (PFTs) and chest computed tomography (CT) scans at the NIH Clinical Center. For PFTs, arm span and ulnar length measurements were used as height surrogates.

Results: Mean age of subjects with OI types III, IV, or VI was 28.1, 25.2, or 14.5 years, respectively. PFT results were similar using arm spans or ulnar lengths as height surrogates. Air flow parameters were significantly lower in OI type III compared to OI type IV or VI. Regression analysis demonstrated that forced expiratory volume in 1-second (FEV1) correlated negatively with age in OI type IV. Lung volume and gas exchange (diffusion capacity) were significantly lower in OI type III compared to OI type IV or VI. Restrictive lung disease was found in 7 of 8 OI type III subjects, and half of OI type IV subjects. Most OI subjects had reduced diffusion capacity. Regression analyses showed that PFTs correlated negatively with Cobb angle in OI subjects. CT scans revealed findings in lung airways, parenchyma, and extrapulmonary tissue. The most common pulmonary finding was bronchial thickening at the level of small bronchi. CT findings including bronchial thickening (100%, 86%, 100%), atelectasis (88%, 43%, 40%), reticulations (50%, 29%, 20%), ground glass opacities (75%, 5%, 0%), pleural thickening (63%, 48%, 20%), and focal regions of emphysema (13%, 19%, 20%) were detected in OI types III, IV, or VI, respectively. Consistent with these diverse lung parenchymal findings, whole lung tissue density was variable in OI subjects.

Conclusions: Pulmonary function or lung structure abnormalities are common in young adults with OI types III, IV, or VI. Utilizing arm spans or ulnar lengths as height surrogates yields similar PFT results. In OI, air flow is reduced, and FEV1 declines with age in OI type IV. Restrictive lung disease is found in young adults with OI type III and half with OI type IV. Severity of lung function abnormalities correlates with severity of scoliosis. Bronchial thickening in small airways is highly prevalent in OI and may be directly related to abnormal collagen or a secondary inflammatory response.

Mendelian Phenotypes Posters - Thursday

PB1950. Rapid Turnover Skeletal Disease from In-frame Tandem Duplication of Exons 4-9 in *TNFRSF11A* Encoding RANK

Authors:

S. Mumm¹, F. Collins², N. Pokhrel³, S. Duan³, M. Huskey³, W. H. McAlister³, D. Sillence⁴, D. Veis¹, M. P. Whyte³; ¹Washington Univ. Sch. of Med.; Shriners Children's, St Louis, MO, ²Royal Prince Alfred Hosp. and Univ. of Sydney Med. Sch., Sydney, Australia, ³Washington Univ. Sch. of Med., St Louis, MO, ⁴Sydney Children's Hosp, Westmead, Westmead, Australia

Abstract Body:

Mendelian disorders featuring rapid bone turnover result from: i) constitutive RANK activation due to mono-allelic in-frame 12, 15, 18, or 27-bp duplication in exon 1 of *TNFRSF11A* encoding RANK's signal peptide and ii) juvenile Paget's disease (JPD) due to bi-allelic deactivating mutations in *TNFRSF11B* encoding osteoprotegerin (OPG) or a single heterozygous missense mutation in *SP7* encoding osterix (OSX). We report rapid turnover skeletal disease in a mother and fetus due to a novel duplication of *TNFRSF11A*. A 38-year-old nonconsanguineous woman wore hearing aids at age 15 months. Brittle teeth were noted at age 3 years. Loss of adult dentition began at age 9 years. At age 10 years, she was not dysmorphic and without bone pain or fractures. Bone scintigraphy showed increased uptake in the long bones, and CT revealed hypoplastic ossicles and semicircular canals, and absent cochleas. Radiographic survey revealed a normal skull, but thickened cortices of tubular bones. Serum alkaline and acid phosphatase were elevated. Tibia and ileum biopsy reportedly showed unremarkable lamellar bone, slightly increased vascularity, numerous osteoblasts, and normal marrow. At age 14 years, she had normal stature, slight knock-knee deformity, and had fractured major limb bones. Calcitonin and bisphosphonate therapy were given. At age 16 years, biopsy of her maxilla and jaw showed irregular woven bone, and marked osteoblastic and osteoclastic activity in a highly cellular fibrovascular stroma. Teeth were eroded and replaced by osteocementum and fibrous tissue. By age 27 years, she was edentulous. At age 30 years, a prominent forehead and nasal bridge, deep-set eyes, and anterior tibial bowing were apparent. Family history was negative for deafness or fractures. Then, ultrasound of her first pregnancy at 18 weeks revealed abnormal fetal bones including angulated femurs. Sanger sequencing was negative for exons and mRNA splice sites of both *TNFRSF11A/B*. However, microarray-based copy number analysis and confirmatory qPCR showed 3 copies of RANK exons 4-9 in the mother and greater than 3 in the fetus. Long-range sequencing delineated an in-frame tandem duplication predicting a RANK fusion protein of one extracellular RANKL-binding domain combined with double intracellular activation domains. Expression of the mother's variant in 293T cells confirmed larger size of RANK protein, and studies are underway to report the mechanism for this unique disorder featuring constitutive RANK activation.

Mendelian Phenotypes Posters - Wednesday

PB1951. Rare *MECP2* variant associated with the development of Rett syndrome: a case report.

Authors:

S. Crescenti, J. Black, N. Dosa, R. Lebel, A. Sakonju; SUNY Upstate Med. Univ., Syracuse, NY

Abstract Body:

Rett syndrome is a rare neurological X-linked genetic disorder involving mutations in the *MECP2* gene that typically manifest as delayed developmental progress, loss of speech and motor skills, repetitive hand movements, and seizures. We describe an eight-year-old female born by vaginal route at 41 weeks to a 21-year-old G2P1 mother and 24-year-old father. The pregnancy was uncomplicated, and the union is not known to be consanguineous. Birth weight was 3.6kg (55th percentile) and length was 53.3cm (75th percentile). Neonatal course was uncomplicated. She smiled at 3 months, rolled over at 6 months, sat alone at 7-8 months, crawled before 12 months, walked at 12 months, and first spoke words at 3.5-4 years. The patient presented with repetitive stereotypic midline hand-wringing movements, seizures, Chiari malformation type I, bilateral intermittent esotropia, ataxia, and segmental syringohydromyelia. She was referred for genetic sequencing and deletion/duplication testing which revealed a heterozygous in-frame deletion (c.918-926del) in the *MECP2* gene resulting in a three-amino acid deletion (p.Lys307-Arg309del). This specific genetic variant has not been reported in the literature but interrupts the Arg309 residue, and other variants with a disruption of this residue have been shown to be pathogenic. This case reveals a novel in-frame pathogenic *MECP2* variant and further suggests that the disruption of Arg309 plays a significant role in the pathogenesis of Rett syndrome. This patient also displays a unique set of clinical characteristics including Chiari malformation type I and syringohydromyelia in addition to typical clinical manifestations of the condition. The combination of these novelties in this case contribute to its genetic and clinical significance.

Mendelian Phenotypes Posters - Thursday

PB1952. Rare variants in syndromic ciliopathy genes as novel causes of isolated renal disease in adults

Authors:

Z. Sentell¹, L. Mougharbel², Z. Nurcombe¹, S. Babayeva², N. Anastasio³, L. Chu², M. Akpa⁴, P. R. Goodyer⁵, E. Torban⁵, T. M. Kitzler⁵; ¹McGill Univ., Montreal, QC, Canada, ²Res. Inst. of the McGill Univ. Hlth.Ctr., Montreal, QC, Canada, ³McGill Univ. Hlth.Ctr., Montreal, QC, Canada, ⁴McGill Univ, Montreal, QC, Canada, ⁵McGill Univ. Hlth.Ctr., Montreal, QC, Canada

Abstract Body:

Background: It is estimated that at least 10% of adult chronic kidney disease (CKD) is genetic. Renal ciliopathies are a frequent genetic cause of end-stage renal disease in the first three decades of life, often as part of a syndromic phenotype. However, their true genetic contribution to adult CKD may be underestimated, as some individuals present with a late-onset non-syndromic phenotype. This phenotypic variability may be due to hypomorphic variants in established ciliopathy genes that are not routinely identified on clinical testing.

Methods: By use of next-generation sequencing technologies we identified rare variants in ciliopathy genes in two adults with isolated CKD. Using functional analysis and patient-derived cell models, we demonstrate a potential causal genotype-phenotype relationship.

Results: Case 1: Compound heterozygous missense variants (p.P168L; p.T2079M) in *C2CD3* were identified in a proband with isolated CKD. Pathogenic variants in *C2CD3* cause oral-facial-digital syndrome XIV (OFD14; OMIM# 615948), but no cases of isolated renal disease were reported. Using patient-derived skin fibroblasts and urinary renal epithelial cells, we show reduced cilia length, impaired sonic hedgehog signalling, and reduced localization of *C2CD3* to the basal body, when compared to healthy control cells. Transcriptional profiling suggests a splice site effect for one of the two variants. Notably, ciliogenesis appeared more severely affected in proband renal cells compared to fibroblasts, suggesting a renal-specific defect. **Case 2:** Pathogenic variants in *CC2D2A* cause at least four different syndromic ciliopathy disorders, but with no reported cases of isolated renal disease. We identified a homozygous nonsense variant (p.R34*) in *CC2D2A* in an adult patient with isolated CKD. Crucially, this variant does not affect all *CC2D2A* protein-coding transcripts. Using public data, we show that transcripts harbouring this variant are predominantly expressed in the kidney, but not in other tissues typically involved in syndromic phenotypes.

Conclusion: Rare variants in syndromic ciliopathy genes are a novel cause of isolated renal disease in adults, potentially due to hypomorphic and renal specific effects. To assess the true genetic contribution to adult CKD detailed functional analysis is required.

Mendelian Phenotypes Posters - Wednesday

PB1953. Rate of Deleterious Copy Number Variants Similar in Early Onset Psychosis and Autism Spectrum Disorders: Implications for Clinical Practice

Authors:

C. Brownstein¹, E. Douard², J. Mollon¹, R. Smith³, M. Hojlo¹, A. Das¹, M. Goldman¹, E. Garvey¹, K. Cabral⁴, J. Li¹, J. Bowen¹, A. Rao¹, C. Genetti⁴, D. Carroll¹, E. Knowles¹, E. Deaso¹, P. Ctr., Montreal, QC, Canada, ¹⁰Université de Montréal, Montreal, QC, Canada, ¹¹CHU Ste justine, Montreal, QC, Canada, ¹²CHU Sainte justine Res. Ctr., Montreal, QC, Canada

Abstract Body:

Objective: Copy number variants (CNVs) are strongly associated with neurodevelopmental and psychotic disorders. Early onset psychotic (EOP) illnesses, where symptoms appear before 18 years of age, are thought to be more strongly influenced by genetic factors than adult-onset psychotic disorders. However, the prevalence and effect of CNVs in EOP is unclear. **Methods.** We documented the prevalence of recurrent CNVs and the functional impact of deletions and duplications genome-wide in 137 children and adolescents with EOP compared to 5,540 individuals with autism spectrum disorders (ASD) and 16,504 population controls. Specifically, we compared the frequency of 47 recurrent CNVs previously associated with neurodevelopmental and neuropsychiatric illnesses in each cohort. Next, CNV risk scores (CRS), indices reflecting the dosage sensitivity for any gene across the genome that is encapsulated in a deletion or duplication separately, were compared between groups. **Results.** Prevalence of recurrent CNVs was higher in EOP than in ASD (OR=2.30, p=0.02) and controls (OR=5.06, p=3x10⁻⁵). However, the difference between the EOP and ASD was attenuated when EOP participants with co-occurring ASD were excluded. CRS was higher in the EOP group when compared to controls for both deletions (OR=1.30, p=9x10⁻⁸) and duplications (OR=1.09, p=0.02). In contrast, the EOP and ASD cohorts did not differ in terms of CRS. **Conclusions.** Given the high frequency of recurrent CNVs in EOP and comparable CRS in the EOP and ASD cohorts, our findings suggest that all children and adolescents with a psychotic diagnosis should undergo genetic screening, as is recommended in ASD.

Mendelian Phenotypes Posters - Thursday

PB1954*. RBM12 Variants Lead to a Novel Neurodevelopmental Syndrome With Atypical Genotype-Phenotype Correlations

Authors:

E. Bhoj, RBM12 Research Consortium; Children`s Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

RBM12 is part of the RNA-binding Motif Protein (RBM) gene family, which are vital for cellular functions such as apoptosis, nonsense mediated decay, and RNA splicing. The related protein RBM10 is the cause for the Mendelian TARP syndrome [OMIM 311900], which results in Talipes equinovarus, Atrial septal defect, Robin sequence, and Persistent left superior vena cava. The function of RBM12 is unknown, but truncating variants in RBM12 have been associated with a polygenic risk for psychiatric conditions and/or mild cognitive impairment. However, there is not a reported Mendelian phenotype associated with variants in *RBM12*. Through gene matchmaking programs, we have connected with 14 individuals from 12 families with heterozygous missense and LOF variants in *RBM12*. We first proposed RBM12 as a novel Mendelian syndrome in 2015, but progress was hampered by the unusual genotype-phenotype correlation that has now been recognized. In review of the patients with RBM12 variants we have connected with, there is a much more severe encephalopathic phenotype in the several patients with missense variants (despite being spread out across the gene beyond on specific domain or active area). The several patients with LOF variants have a much milder phenotype of borderline neurodevelopmental differences, and some are inherited from similarly mildly affected parents. This finding is congruent with what has been previously published on RBM12 LOF variants as a risk factor for psychiatric disease with relatively normal development. Interestingly, the distinctive overlapping facial features (low posterior hairline, epicanthus, deep set eyes, hypertelorism, thick eyebrows, and tubular nose), in both the missense and LOF patients drove the realization that this was a recognizable syndrome. We then recognized there was an enormous degree of variability of the severity of the developmental impairment, but in the opposite direction as expected, with missense variants causing more severe disease than LOF. Therefore, in addition to the description of a novel syndrome, this is an informative example of overcoming unexpected challenges to traditional genetics dogma in collecting patient cohorts through gene matching.

Mendelian Phenotypes Posters - Wednesday

PB1955. Reanalysis of whole exome sequencing data of 50 Iranian families with hereditary hearing loss

Authors:

E. Shokouhian¹, F. Jamshidi¹, M. Mohseni², K. Kahrizi², H. Najmabadi², M. Babanejad¹; ¹Genetics Res. Ctr., Univ. of Social Welfare and Rehabilitation Sci., Tehran, Iran, Tehran, Iran, Islamic Republic of, ²Genetics Res. Ctr., Univ. of Social Welfare and Rehabilitation Sci., Tehran, Iran, Islamic Republic of

Abstract Body:

To date, hearing loss (HL) remains the most common sensory disorder, and in Iran, second to intellectual disability, HL is the most common disability. Over 50% of HL cases are due to genetic factors, of which 70% are non-syndromic. Whole exome sequencing (WES), by covering all the coding regions of the human genome, has facilitated the variant identification process, especially in cases that lack sufficient clinical data. However, the innate inability of WES to read non-coding regions, bioinformatic shortcomings, and human error have limited WES diagnostic yield to 20-60%. Previous studies have shown that because novel disease-gene associations are being discovered, and bioinformatics tools and databases are being updated every year, a periodic 3-5 years follow-up can increase WES diagnostic yield by 15-30%. Here, using a variant calling pipeline with the latest versions of the GATK software package, Picard, and ANNOVAR, we reanalyzed the WES data of 50 Iranian families with hereditary HL. As a result, we were able to identify the mutations that segregated with their respective phenotypes in 10 families (20%), including 8 mutations that were initially missed due to lack of sufficient clinical data (for families with syndromic HL), and the variable expressivity of autosomal dominant hearing loss that had led to misdiagnosing a family with autosomal recessive NSHL. Re-evaluation of their phenotypes led to the identification and segregation of 5 heterozygous mutations (*PAX3*:c.199A>T, *MITF*:c.1198C>T, *MITF*: c.649C>T, *MITF*:c.1189G>T, and *MITF*:c.1069T>C) in families with Waardenburg syndrome, heterozygous *WFS1*: c.2339G>C in a family with Wolfram like syndrome, homozygous *FGF3*: c.45delT in a family with LAMM (Labyrinthine Aplasia, Microtia, and Microdontia) syndrome, and heterozygous *DIAPH1*: c.3610C>T in a family with autosomal dominant NSHL. Compound heterozygous mutations *MYO15A*:c.7788-10A>G/c.10205delC, and *MYO15A*:c.8089-14_8089-1del/c.9572G>A also segregated in two families with autosomal recessive NSHL. Interestingly, the last two families both had splice-altering variants that were initially missed because they were annotated as noncoding. In this study, by including splice prediction tools SpliceAI, MaxEntScan, and dbscSNV in our annotation step we were able to further investigate such variants. Furthermore, this study is still ongoing and more investigations are currently being done. In conclusion, we showed the importance of a comprehensive clinical evaluation for identifying any signs of syndromic deafness, and we pointed out the significance of noncoding and intronic variants that are often neglected.

Mendelian Phenotypes Posters - Thursday

PB1956. Recessive variants in *SLC9A1* cause a syndrome of cerebellar ataxia, amelogenesis imperfecta and variable sensorineural hearing loss.

Authors:

D. Pellerin¹, R. Maroofian¹, L. Fliegel², H. Houlden¹; ¹UCL Queen Square Inst. of Neurology, London, United Kingdom, ²Univ. of Alberta, Edmonton, AB, Canada

Abstract Body:

Background: The *SLC9A1* gene encodes the mammalian Na⁺/H⁺ exchanger isoform 1 (NHE1), a ubiquitously expressed membrane-bound enzyme involved in intracellular pH regulation. Ultra-rare recessive variants in *SLC9A1* have previously been described to cause autosomal recessive spinocerebellar ataxia type 19 (SCAR19) in two families. SCAR19 is characterized by early-onset ataxia and variable hearing loss. *Slc9a1* knockout mice exhibit ataxia, seizure and growth retardation. Here, we report 12 patients with recessive *SLC9A1* variants and a complex syndrome of cerebellar ataxia, amelogenesis imperfecta, developmental delay and variable sensorineural hearing loss.

Methods: Patient phenotyping was performed through serial clinical assessments, dental examinations, audiograms and brain MRI. Candidate variants in *SLC9A1* were first identified by whole-exome sequencing and next characterized *in vitro*. The expression and enzymatic activity of mutant NHE1 proteins were respectively examined by immunoblotting and transient induction with ammonium chloride of transfected NHE1-deficient cells. Intracellular targeting of mutant proteins was assessed by a combination of immunocytochemistry and cell surface biotinylation studies.

Results: We identified 12 patients belonging to eight consanguineous families with homozygous *SLC9A1* variants. Eight novel variants were discovered, including two nonsense, four missense, one frameshift and one splicing variant. Patients presented with moderate to severe cerebellar ataxia from infancy associated with cerebellar atrophy (10/11; 91%) and occasional thinning of the corpus callosum (3/11; 27%) on MRI. In addition to developmental delay, all patients exhibited amelogenesis imperfecta, which had not been previously reported with *SLC9A1* mutations. Sensorineural hearing loss of variable severity was present in nine out of 12 subjects (75%). All identified variants caused lower protein expression, reduced NHE1 enzymatic activity and protein mislocalization.

Conclusion: This study expands the mutational and phenotypic spectrum of SCAR19 and provides functional evidence for the pathogenicity of the newly identified variants. Mutations in *SLC9A1* should be specifically sought for in the presence of early-onset cerebellar ataxia and amelogenesis imperfecta.

Mendelian Phenotypes Posters - Wednesday

PB1957*. Recessive variants in the C-terminal domain of *UFSP2* are associated with severe spondyloepimetaphyseal dysplasia.

Authors:

M. Weisz-Hubshman¹, J. Andrews¹, R. Maroofian², J. Rosenfeld^{1,3}, H. Tajsharghi⁴, E. Karimiani⁵, M. Wangler¹, Y. Bae¹, B. Lee¹; ¹Baylor Coll. of Med., Houston, TX, ²Univ. Coll. London, London, United Kingdom, ³Baylor Genetics, Clinical Diagnostics Lab., Houston, TX, ⁴Sch. of Hlth.Sci., Translational Med., Univ. of Skövde, Skövde, Sweden, ⁵Genetics Res. Ctr., Molecular and Clinical Sci. Inst., St. George's, Univ. of London, London, United Kingdom

Abstract Body:

Chondrodysplasias are rare developmental disorders commonly characterized by cartilage abnormalities with progressive clinical manifestations that significantly impact the patients' quality of life. The genetic causes are variable and can affect extracellular matrix proteins, protein transport, protein processing, and post-translational modifications. Ufmylation is a ubiquitin-like post-translational modification, and its role in chondrogenesis is poorly understood. Variants in *UFSP2* and *DDRKG1*, essential components of the ufmylation process, have been found to cause chondrodysplasia. Autosomal dominant variants in *UFSP2* have been associated with Beukes hip dysplasia with incomplete penetrance and Di Rocco type spondyloepimetaphyseal dysplasia (SEMD). Autosomal recessive variants in the N-terminal domain of *UFSP2* have been recently associated with a neurodevelopmental disorder and epilepsy. Autosomal recessive variants in *DDRKG1* are associated with Shohat type SEMD. We report 3 families with homozygous variants in *UFSP2* (p.D426A, p.N459T) manifesting a severe SEMD phenotype without intellectual disability. Interestingly, all variants associated with skeletal phenotypes reside in the C-terminal domain of the *UFSP2* protein, which harbors the catalytic domain of the cysteine protease. Although the interaction between *DDRKG1* and *UFSP2* is not abrogated by the various disease associated variants *in vitro*, cellular studies suggest protein stability differences between the variants. *Drosophila* studies showed that the newly identified *UFSP2* N459T variant as well as the human wild type *UFSP2* rescue the knock out of the *drosophila* orthologue, suggesting that the variant might be a hypomorph variant. *In vivo*, chondrocyte-specific deletion of *Ddrgk1* in mice showed growth plate disorganization with shortened proliferative zone and enlarged hypertrophic zone that correlated with decreased Sox9 and Col2a1 protein levels and increased Col10a1 expression. Taken together these findings suggest an important role for the ufmylation process in cartilage, and deciphering the mechanism underlying these disorders can contribute significantly to the understanding of post-translational modifications in cartilage development and potentially serve as therapeutic target.

Mendelian Phenotypes Posters - Thursday

PB1958. Reconsidering SIX5 as a monogenic cause for Congenital Anomalies of the Kidney and Urinary Tract (CAKUT) and Branchio-oto-renal syndrome (BOR)

Authors:

J. Chang¹, G. Leone¹, A. Thompson¹, I. Patel¹, L. Woo², C-H. Wu³; ¹Case Western Reserve Univ., Cleveland, OH, ²Univ. Hosp./Case Western Reserve Univ, Cleveland, OH, ³Univ. Hosp./Case Western Reserve Univ, Cleveland Heights, OH

Abstract Body:

Background: Congenital anomalies of the kidneys and urinary tract (CAKUT) are a range of defects that occur during embryonic kidney and genitourinary tract development and are present in half of children born with chronic kidney disease. Branchio-oto-renal syndrome (BOR) is an autosomal dominant condition characterized by branchial defects, otic defects, renal abnormalities, and CAKUT. Both CAKUT and BOR are portrayed with incomplete penetrance and variable expressivity. The EYA1 and SIX5 pathogenic variants have been established as monogenic causes of BOR by Hoskins et al. based on a 2007 study. However, Krug et al. presented their BOR cohort in 2011, and the SIX5 variant was rarely seen and co-existed with EYA1 deletions. Thus, Krug et al. questioned if SIX5 is a causal gene for BOR. We present one case of CAKUT/BOR with a SIX5 variant c.1655C>T (p.T552M) and no EYA1 variant, identified by target resequencing, and lean toward supporting SIX5 pathogenic variant as a monogenic cause of CAKUT/BOR.

Case Presentation: The patient is a 27-year-old female referred to genetics with a past medical history of left solitary kidney, vesicoureteral reflux, VATER syndrome, scoliosis, anal atresia, and chronic kidney disease. Additionally, mild to moderate sensorineural hearing loss was noted in her right ear in 2008. The patient's congenital anomalies are reminiscent of BOR syndrome. Genetic evaluation was performed with target resequencing with a panel of CAKUT genes which identified an HPSE2 variant of c.1768C>A (p.Arg590Ser) heterozygously and a SIX5 variant of c.1655C>T (p.Thr552Met) heterozygously.

Discussion: This SIX5 c.1655C>T (p.T552M) was reported as a causal gene and variant for CAKUT and BOR by Hoskins et al. with a functional study in 2007. Here we report another occurrence of the SIX5 variant c.1655C>T (p.T552M), in conjunction with a wild-type EYA1, occurring in a patient with signs of CAKUT and BOR. We would like to refamiliarize this variant of SIX5 to the medical community again as a potential causal gene and a pathogenic variant of CAKUT and BOR syndrome. Further consideration and establishment of SIX5 variants may be warranted to address the current discrepancy within literature.

Mendelian Phenotypes Posters - Wednesday

PB1959. Report of a novel *LAMB3* variant and an overview of *LAMB3* variants associated with junctional epidermolysis bullosa

Authors:

E. Tan¹, M. J. A. Koh²; ¹KK Women s & Children s Hosp., Singapore, Singapore, ²KK Women's & Children's Hosp., Singapore, Singapore

Abstract Body:

Background: Epidermolysis bullosa (EB) is a group of heterogeneous disorders with considerable overlap in the clinical presentations between the different types. Accurate diagnosis is particularly challenging in younger patients in whom the clinical features have not fully manifested. To date, at least 20 genes have been shown to cause skin fragility. **Case presentation:** The patient is a 26-year-old Chinese female from a non-consanguineous marriage with no family history of blistering skin disorders. She had blisters and erosions at sites of trauma since infancy, involving mainly her trunk and limbs. Her teeth and nails were normal. She was clinically diagnosed as EB Simplex (EBS) but continued to have moderate blistering throughout her childhood, adolescence, and adult life, and was treated with judicious wound care with non-adherent wound dressings. She married and went on to have a normal offspring. **Results:** Sequencing of her germline DNA revealed a heterozygous missense substitution (c.1064G>A:p.Cys355Tyr) affecting a highly conserved amino acid residue, and a single-nucleotide deletion (c.2116del: p.Ile706Ter) that would lead to premature termination of translation. The missense variant is novel while the deletion variant has a low frequency of 0.011 in East Asians. The discovery of two pathogenic variants in *LAMB3* and her mild presentations indicate that she has the generalized intermediate type (non-Herlitz) type of junctional EB (JEB). **Discussion:** JEB is the rarest form of EB caused by biallelic mutations in *LAMB3*. There are 129 unique damaging mutations for *LAMB3* in the Human Gene Mutation Database (HGMD) that are single-nucleotide variants or small insertions/deletions that are associated with JEB. We present the analysis of 157 unrelated reported cases for whom the identity of both alleles and their JEB subtype are known, and correlate their genotypes with the clinical presentations of the different types of JEB.

Mendelian Phenotypes Posters - Thursday

PB1960. Report of *PLP1* Gene Mutation in Pelizaeus-Merzbacher Disease

Authors:

S. Seyedhassani¹, M. Kadkhodazadeh¹, R. Fallah², L. Najafi³; ¹Dr. Seyedhassani Med. Genetic Ctr., Yazd, Yazd, Iran, Islamic Republic of, ²Yazd Shahid Sadughi Med. Univ., Yazd, Yazd, Iran, Islamic Republic of, ³Tehran Azad Univ., Tehran, Iran, Islamic Republic of

Abstract Body:

Introduction: Proteolipid protein I (*PLP1*) gene encodes a transmembrane proteolipid protein is the primary constituent of myelin. This protein may play a role in the compaction, stabilization and development of myelin sheaths, oligodendrocyte and axon. The PLP1-related disorders have included Pelizaeus-Merzbacher disease(PMD) and spastic paraplegia type 2. (PMD) is a progressive and degenerative central nervous system disorder and inherited as X-linked recessive pattern and classify into two types. Their phenotypes can overlap. It is characterized by developmental delay, rotary nystagmus, psychomotor delay, dysarthria, seizures and mental retardation **Case report:** A 2.5 years old boy was referred to genetic center. He was born from non-consanguineous parents and suffering from mental retardation , quadriplegia and developmental delay. He had history of the recurrent seizures since the age of 40 days. Also, he had two brothers with same clinical manifestations that were dead about 3.5 years. **Material and methods:** We did whole exome sequencing and then sanger sequencing for the confirmation of findings. **Result:** A hemizygous c.T137C missense mutation was detected at exon 3 in *PLP1* gene. Confirmation of WES finding showed normal and heterozygous conditions in father and mother respectively. Also, genotype- phenotype correlation was done and the disease confirmed. **Conclusion:** PMD is characterized clinically by nystagmus, spastic quadriplegia, ataxia, and developmental delay. This mutation change the amino acid, leucine to proline and can affect proteolipid protein I structure. Main expression of this gene is in brain. Therefore, cerebral signs and symptoms are significant.

Mendelian Phenotypes Posters - Wednesday

PB1961. Rewiring our understanding of the enteric nervous system: Identification of diverse developmental lineages of enteric neurons and cell-state specific roles in maintenance across aging.

Authors:

J. Slosberg, A. Singh, S. Nagaraj, S. Kulkarni, L. Goff; Johns Hopkins Univ., Baltimore, MD

Abstract Body:

Within the enteric nervous system (ENS), the current understanding of cellular roles and developmental origins has guided the design and interpretation of targeted experiments. However, a comprehensive understanding of the various cell types that make up the postnatal ENS and a consensus about their roles in maintaining proper gut function has not been achieved. This is especially true across conditions and disease-states such as aging. Prior studies in this field have suffered from a bias either due to an assumption of a single developmental lineage for all adult ENS neurons, or a preconceived transcriptional identity to annotate ENS neurons. Thus, by performing single cell transcriptomics on all cells of the murine gut wall, we aimed to conduct an unbiased survey of the diversity of cellular transcriptional states that comprise the murine ENS. During this process, we have identified a previously mischaracterized population of post-natal born enteric neurons derived from the mesoderm. We performed unbiased 10X Genomics-based scRNA-seq analyses of cells from the longitudinal muscle and myenteric plexus (LM-MP) tissue of the gut wall, which contains a large population of ENS cells. We collected tissue from mice of three postnatal ages of Days 10, 20, and 60, to identify three major ENS populations - neural crest-derived neurons (NC-neurons), neural crest-derived glial cells (Neuroglia), and the population of mesoderm-derived neurons (MENS). We validated cell type-specific markers from our scRNA-seq reference by immunohistochemistry and single molecule RNA-FISH in neural crest lineage fate mapping mice. Next, we used unsupervised non-negative matrix factorization to identify gene expression signatures that represent the diversity of cell states in the murine ENS. We then applied a pattern-based projection analysis using the Human Gut Cell Atlas, highlighting the presence of MENS' transcriptional signatures in human gut cells and their relative increase with age. To test the relevance of these distinct ENS cells to human disease, we used an agnostic approach to test pattern- and cell-specific gene expression signatures for their disease-association in summary statistics from more than 80 GWAS studies of relevant phenotypes. By using an unsupervised approach via single cell transcriptomics to correctly identify the true transcriptional and developmental heterogeneity in an important neural tissue, our study provides a framework that can be implemented across multiple tissue and organ types to study the relevance of specific cells and their molecular processes in states of health and disease.

Mendelian Phenotypes Posters - Thursday

PB1962*. *RFC1* expansions in Italian population: Molecular analysis, structure/size determination and clinical features of patients with CANVAS/spectrum phenotypes.

Authors:

D. Di Bella¹, S. Magri¹, E. Sarto¹, M. Corbetta¹, M. Balzo¹, C. Gelleri¹, C. Pisciotto², E. Salsano², D. Pareyson², M. Fichera¹, L. Nanetti¹, C. Mariotti¹, F. Taroni¹; ¹Fondazione IRCCS Istituto Neurologico Carlo Besta, Unit of Med. Genetics and Neurogenetics, Milan, Italy, ²Fondazione IRCCS Istituto Neurologico Carlo Besta, Unit of Rare Neurodegenerative and Neurometabolic Diseases, Milan, Italy

Abstract Body:

A biallelic intronic AAGGG expansion in the *RFC1* gene has been identified as the cause of CANVAS, an adult-onset, slowly progressive neurodegenerative disorder characterised in its full form by a combination of neuropathy, ataxia and vestibular disease. Recently, expansions with alternative sequence conformation have been identified whose pathogenic role remains to be established. This study was aimed: 1) to screen Italian patients with full or partial CANVAS phenotype (n=279) or late-onset (n=216) spinocerebellar ataxia for *RFC1* repeat expansion; 2) to assess the frequency of heterozygous carriers of *RFC1* expansion in a healthy control population; 3) to sequence the expanded region with a long-read NGS approach (LRseq) in order to characterize the composition and length of different repeat conformations and to assess their pathogenic role. The *RFC1* locus was analysed by a PCR encompassing the repeat, followed by fluorescent repeat-primed PCRs (Cortese et al, 2019) detecting different repeat motifs. LRseq of expanded alleles was set up on Oxford Nanopore Technologies (ONT) device, using Cas9-based enrichment of the expanded region (Nakamura et al, 2020). Biallelic *RFC1* expansion was identified in 29% (81/279) probands with a CANVAS/spectrum phenotype, and in 12.5% (27/216) of patients with ataxia. Heterozygous carrier rate was 12% in patients (24/198) and 10% (36/360) in controls. Approx. 5% of alleles showed complex repeat conformations with uncertain pathogenicity. Biallelic *RFC1* expansion accounts for a large proportion of ataxia phenotypes in Italian patients (12-29%) and should always be considered in the diagnostic algorithm of patients with sporadic ataxia, ranking first in late-onset cerebellar and sensory ataxia. Given the high heterozygous carrier rate, *RFC1* expansion might be the most common cause of ataxia in Italian patients. Nanopore LRseq data confirm the complex architecture of the expanded repeat which may have crucial implications for diagnosis and counseling.

Ctr., Holon, Israel, ⁹Dep Med. genetics, Haukeland Univ Hosp., Bergen, Norway, ¹⁰Cook Children's Hosp, Fort Worth, TX, ¹¹Dept. of Biology, Chungnam Natl. Univ., Daejeon,, Korea, Republic of

Abstract Body:

RNF220, a zinc RING finger gene, was identified as a binding partner of ZC4H2, which is a causative gene for Miles-Carpenter syndrome (MCS). MCS is an X-linked intellectual disability (XLID) syndrome characterized by digit contractures, mild spasticity, exotropia along with intellectual disability. As an E3 ubiquitin ligase, RNF220 also bridges the interaction between USP7 and beta-catenin, both of which are mutated in neurodevelopmental disorders. USP7 is an integral component of ubiquitin ligase complex, whereas beta-catenin, encoded by CTNNB1, is the central downstream player in the canonical WNT signaling pathway. Despite these direct physical interactions of RNF220 with the threesome involved in neurodevelopmental disorder, the pathological role of RNF220 in human disease remained unexplored. Here we demonstrate that the knockout of RNF220 in zebrafish exhibits behavioral and ocular phenotypes resulting in the complete loss of V2 interneurons and P2 progenitor domains in the spinal cord and hindbrain. Most persuasively, we identified a dozen heterozygous loss-of-function mutations of *RNF220* in human patients presenting with cognitive impairment and motor defects in gait, speech, and eye movements. These results support the crucial role for RNF220 in the generation of V2 interneurons and this loss-of-function results in a new interneuronopathy with a broad spectrum of neurodevelopmental features.

PB1964*. Rothmund Thomson syndrome with congenital cataracts and severe growth restriction is associated with a not previously described gene in an autosomal recessive inheritance pattern in seven families

Authors:

G. Yamamoto¹, R. Di Lazaro¹, T. da Silva², L. Rocha¹, D. Bartholdi³, A. Schaller³, C. Zweier³, R. S. Honjo⁴, C. Utagawa⁵, C. Steiner⁶, C. A. Kim⁴, M. Passos-Bueno⁷, N. C. Hoch⁸, D. R. Bertola⁹; ¹Inst. da Criança - Univ. of São Paulo, São Paulo, Brazil, ²Inst. de Química - Univ. of São Paulo, São Paulo, Brazil, ³Univ. Hosp. Bern, Bern, Switzerland, ⁴Inst. da Criança - Univ. of Sao Paulo, Sao Paulo, Brazil, ⁵Centro Universitário de Volta Redonda, Volta Redonda, Brazil, ⁶UNICAMP, Campinas, Brazil, ⁷Univ. of Sao Paulo, Sao Paulo, Brazil, ⁸Univ. of São Paulo, São Paulo, Brazil, ⁹Inst. da Criança - Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract Body:

Introduction: Rothmund Thomson syndrome (RTS) is a rare autosomal recessive genodermatosis characterized by poikiloderma, abnormal hair/nails; short stature; eye and skeletal abnormalities. Based on clinical and molecular data, this syndrome is classified in type I, including the presence of cataracts and variants in a recently identified gene (*ANAPCI*) and type II, without cataracts and increased predisposition to cancer, associated with biallelic variants in *RECQL4*. **Methods:** The cohort is comprised of 6 Brazilian probands and a pair of siblings (a boy and a male fetus product of TOP, from Portuguese/Swiss origin). None of the probands had history of consanguinity and all presented a severe, homogeneous phenotype (wide-spread poikiloderma, congenital cataracts, facial dysmorphisms; severe growth restriction with growth hormone deficiency, hypogonadism and skeletal abnormalities). Exome sequencing in the Brazilian individuals failed to show pathogenic variants in the coding regions of *RECQL4* and *ANAPCI*. Different genetic techniques were applied to identify a novel *locus* associated with RTS, which we propose to name type III, including SNP-chip array for linkage analysis, whole-genome sequencing (WGS), as well as functional analysis in patient's fibroblast cultured cells. **Results:** Despite admixed ancestries, linkage analysis identified a heterozygous shared chromosomal region of 8 Mb in chromosome 10q in all Brazilian individuals. WGS of the Brazilian probands identified biallelic variants in a gene within this region, all sharing one deep intronic variant in intron 4 of this gene in *trans* with intragenic deletions or a missense variant. On the non-Brazilian case, WGS disclosed the same intronic variant inherited from the father with Portuguese ancestry and a frameshift variant in *trans*. Functional and cDNA analysis depicted alternative splicing due to the intronic variant and consequent loss of function. **Conclusions:** We have identified biallelic pathogenic variants in a gene not previously described associated with RTS in seven families, all with a shared haplotype from probable Portuguese origin. We propose that RTS with congenital cataracts and severe growth restriction should be classified as RTS type III. //FAPESP 2013/08028-1; CNPq: 303375/2019-1. //We declare no conflicts of interest.

PB1965. Screening for Genetic Modifiers of *MED12/kto* Using Naturally Occurring Variation in *Drosophila melanogaster*

Authors:

K. Bussey, N. O. N. Yepiz, V. Shankar, R. R. H. Anholt, T. F. C. Mackay; Clemson Univ., Greenwood, SC

Abstract Body:

MED12 is a component of the Mediator Complex which regulates gene expression. Mutations in different domains of the *Med12* protein are associated with five rare genetic disorders: FG Syndrome, Ohdo Syndrome, Hardikar Syndrome, Lujan syndrome, and Non-Specific X-Linked Intellectual Disability (XLID). They are characterized by a wide range of effects including intellectual disability, behavioral, and congenital defects. Different individuals with the same *MED12* mutation present with differing severity of symptoms, suggesting the presence of genetic modifiers of *MED12*-related disorders. However, the rarity and diversity of these disorders make identifying the genetic basis of pathogenicity and genetic modifiers challenging in human populations. *Drosophila melanogaster* has a strongly conserved functional ortholog of *MED12*, *kto* (*kto*). Knocking down *kto* expression using RNA interference shows that *kto* affects startle response and sleep and activity traits. We are utilizing natural variation among the fully sequenced inbred lines of the *D. melanogaster* Genetic Reference Panel (DGRP) to identify genetic modifiers altering effects of *kto* mutations. We crossed a CRISPR/Cas9-generated null mutation of *kto* (*kto*-), and a wild type *kto* allele (*kto*+) in the same genetic background, to the DGRP lines, and quantified sleep and activity and startle-induced locomotion in the F1 offspring. We used analysis of variance to estimate the effects of *kto* genotype (G), DGRP line (L) and the genotype by environment interaction (G×L) on these phenotypes. A significant G×L term indicates the presence of modifier loci, (i.e., the effect of *kto* genotype is different across the DGRP lines). We found significant G×L terms for startle behavior ($P = 0.0087$) and night activity bouts, sleep bout lengths, and daytime sleep ($P < 0.001$) with both amelioration or exacerbation of effects in *kto*- relative to *kto*+ genotypes. We can perform genome wide association analyses using the difference in phenotypes between *kto*- and *kto*+ for each DGRP line (significant G×L variance is the same as the variance in this difference) to identify candidate genetic modifiers of *kto*. Identification of top modifier candidates will provide insight into how genetic modifiers may influence the manifestation and severity of *MED12*-related disorders and identify modifiers as potential therapeutic targets.

PB1966. Seizures in a patient with Autosomal recessive Intellectual disability type 5

Authors:

E. Aliu¹, M. Hasan², G. Mainali¹, S. Paudel¹; ¹Penn State Hershey Med. Ctr., Hershey, PA, ²Pennsylvania State Hlth.Coll. of Med., Hershey, PA

Abstract Body:

Autosomal recessive Intellectual disability type 5 (OMIM 61109), is caused by biallelic pathogenic variants in the NSUN2 gene which encodes for a methyltransferase involved in several biological processes, ranging from stress responses to neurodevelopment. NOP2/Sun RNA Methyltransferase 2 (NSUN2) encodes a methyltransferase which is required for splicing at C34 of tRNA Leu (CAA) and C47 and C48 of tRNA-Asp (GTC). A proposed mechanism postulates that the loss of 5-methylcytosine increases the angiogenin-mediated endonucleolytic cleavage of tRNAs, leading to an accumulation of 5' tRNA-derived small RNA fragments causing a decrease in the rate of protein translation which activates stress pathways causing reduced cell size and increased apoptosis of cortical, hippocampal, and striatal neurons. This disorder presents with intellectual disability, facial dysmorphism, juvenile cataracts, chronic nephritis, hearing impairment, seizures, cerebellar atrophy, and microcephaly. To date there have been 25 cases reported caused by NSUN2 deficiency but only one patient had seizures treated with valproic acid. We report a 15-year-old male with a history of autism, and moderate intellectual disability, who presented with seizure-like episodes. These episodes were described as impaired consciousness, drooling, eye deviation, and twitching of the corner of the mouth occurring almost on a daily basis for the past year. Each episode would last from 15-20 minutes which is then followed by sleepiness. He underwent 24 hours ambulatory EEG which showed frequent generalized 1-2.5 Hz spikes and slow-wave discharges and sleep-activated multifocal epileptiform discharges. Work-up was initiated to evaluate the etiology of the seizure. In the past, he had genetic evaluations which were not diagnostic. An Autism/ID Xpanded panel (GeneDx, Bethesda MD), identified a homozygous frameshift (c.560del;p.Pro187Leufs*8) variant, predicted to result in loss of function of NSUN2 gene (NM_017755.5). Parental studies were only done on his mother which confirmed she was a carrier. He was started initially on valproic acid but seizures were not fully controlled. After adding clobazam his seizures are controlled. At baseline, the patient is still non-verbal, ambulates mainly by wheelchair, although can walk some with assistance, has generalized hypertonia, and uses a GT for feeding as he is unable to eat by mouth. In conclusion, we are reporting a new pathogenic variant, a 2nd patient with NSUN2 deficiency who developed seizures in his teens, which suggests that epilepsy is part of the spectrum of this condition although an uncommon one, and a successful regimen to control his seizures.

Mendelian Phenotypes Posters - Wednesday

PB1967*. Sequencing analysis of nonsyndromic cleft lip / palate in Brazilian patients reveals *CTNNA1*, *ESRP1* and *PRICKLE1* as novel candidate genes.

Authors:

L. Brito¹, G. Hsia¹, J. Wang², G. Yamamoto³, S. Ferreira², M. Passos-Bueno²; ¹Inst. of BioSci.s, Univ. of São Paulo, São Paulo, Brazil, ²Inst. of BioSci.s, Univ. of São Paulo, Sao Paulo, Brazil, ³Inst. da Criança - Univ. of São Paulo, São Paulo, Brazil

Abstract Body:

Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is a prevalent birth defect impacting around 1 in 1,000 liveborn children, who frequently face feeding, hearing, speaking and psychological problems. NSCL/P etiology is complex and most cases are sporadic, while 30% of cases are familial and present variable inheritance patterns. The genetic etiology embraces multiple low-effect risk loci, as identified by genome-wide association studies, but also moderate-to-high effect variants, which have been increasingly detected by sequencing approaches, in genes such as *CDH1*, *CTNND1*, *ESRP2* and *ARHGAP29*. We have characterized the landscape of rare pathogenic variants in Brazilian NSCL/P individuals, and preliminary analyses have already implied *CDH1* and *ARHGAP29* as prevalent genes harboring such variants. Here, we present our final results, which included the exome sequencing of 47 NSCL/P probands from familial cases and 49 affected relatives, performed with Illumina HiSeq platform, and the targeted sequencing of 540 probands from familial cases and 56 relatives, for a panel of candidate genes. In this panel, we included key genes involved in the canonical (beta-catenin) or non-canonical (planar cell polarity) Wnt signaling pathways that are expressed during human palate and frontonasal embryogenesis, or that were previously implicated with orofacial clefts in humans or animal models, such as *CDH1*, *CTNNA1*, *CTNNB1*, *CTNND1*, *DVL3*, *ESRP1/2*, *FZD1/2*, *LRP6*, *PRICKLE1/2*, *RHOA*, *SNAIL*, *TGFB1*, *WNT5A*, *WNT10A*, *WNT11* and *ZEB1/2*. Variant prioritization criteria included frequency <0.5% in the gnomAD populations and in the Brazilian variants database ABraOM and CADD score > 20 (i.e., variants assigned in silico to be at the top 1% of human deleterious variants). Among the variants prioritized after both sequencing strategies, we call attention to three probably pathogenic ones located in genes never implicated with NSCL/P in humans to date: a missense variant in *CTNNA1*, a frameshift insertion in *PRICKLE1* and a stopgain variant in *ESRP1*. All these variants showed complete segregation with the phenotype and are potentially disruptive to the protein functions, although functional validation analysis are still ongoing. Additionally, novel and previously reported pathogenic variants were also found in *CDH1* (9 families), *CTNND1* (5 families) and *ARHGAP29* (5 families), which, in conclusion, represent the most common causes of familial NSCL/P in this Brazilian sample (3.2%); most importantly, our work provides the first evidence for the etiological contribution of *CTNNA1*, *ESRP1* and *PRICKLE1* to human NSCL/P.

Mendelian Phenotypes Posters - Thursday

PB1968. Severe ABCA4-retinal dystrophy caused by homozygosity for a novel double mutated allele.

Authors:

S. Aslaksen¹, I. Aukrust², M. Hamre Bu¹, M. Innselset Flydal², C. Bredrup², E. Bratland², P. Knappskog²; ¹Univ. of Bergen, Bergen, Norway, ²Haukeland Univ. Hosp., Bergen, Norway

Abstract Body:

Pathogenic variants in the *ABCA4* gene are the leading cause of vision loss in inherited retinal diseases. More than 1500 diseases-causing variants in *ABCA4* have been reported, giving rise to a heterogeneous clinical spectrum of ABCA4-retinal dystrophies. The range of clinical phenotypes and disease severity is believed to be determined by the patient's genotype defined as the specific combination of pathogenic variants in the *ABCA4* gene. ABCA4-retinal dystrophies are inherited in an autosomal recessive manner, either by homozygous or compound heterozygous variants. Here we report a rare case of severe retinal degeneration caused by *two* homozygous pathogenic variants in *ABCA4* (NM_000350.3) detected by exome sequencing; the most frequent pathogenic variant c.5882G>A p.(Gly1961Glu), associated with mild phenotypes and later disease onset, and c.634C>T p.(Arg212Cys), associated with more severe phenotypes. The patient had normal visual acuity in his early childhood but experienced relatively rapidly reduced visual acuity from the age of 12. Upon examination at 13 years of age, he had best corrected visual acuity (BCVA) od:0.15, os: 0.2 and a red-green color deficit. Bilateral macular atrophy was found, but no pallor of the optic disc. Electroretinogram (ERG) showed severely reduced cone function. This severe phenotype observed in the patient homozygous for a novel double mutated allele indicates a synergistic effect of the two pathogenic variants p.(Gly1961Glu) and p.(Arg212Cys). The impact of this disease-causing variant combination on the functional properties of ABCA4 will be examined in future experiments.

Mendelian Phenotypes Posters - Wednesday

PB1969. Shared and divergent transcriptional dysregulation is present across brain regions and cell types in adult *Chd8* haploinsufficient mice

Authors:

A. Nord, S. Lozano, C. Canales, K. Cichewicz, A. Wade, E. Smith, N. Seban, R. Ortiz, J. Zhu, M. Corea, D. Rahbarian; UC Davis, Davis, CA

Abstract Body:

De novo mutations in the chromatin-remodeling factor *CHD8* (Chromodomain-Helicase DNA-binding protein 8) are strongly associated with autism spectrum disorder (ASD) and more generally with neurodevelopmental disorders (NDDs). Mice with heterozygous germline loss-of-function mutation in *Chd8* exhibit genomic, neuroanatomical, and behavioral pathology. With the goal of identifying the molecular consequences of *Chd8* haploinsufficiency in the postnatal brain across regions and cell types, we used bulk RNA-sequencing in cerebral cortex, hippocampus, and cerebellum, and single nucleus (sn)RNA-seq in the adult cortex to compare wild type and heterozygous *Chd8* mutant mice. We identified differentially-expressed genes (DEGs) that were altered across all three brain regions, as well as region-specific signatures, with the greatest dysregulation identified in the cerebellum. DEG pathways included neuroinflammatory, metabolic, and synaptic processes. We identified a set of genes that were consistently perturbed across brain regions. Male and female DEG signatures showed some differences in DEG pathways and magnitude of effects. Single nuclei resolution experiments revealed transcriptional dysregulation in cortex. We found changes that were present across all neurons, as well as unique signatures within excitatory and inhibitory subsets. Changes in microglia and oligodendrocyte lineages were also identified. Similar to bulk RNA-seq data, males and female mutants had both overlapping and sex-specific DEG signatures. Validation of regional and cell-type specific changes is in progress. Overall, our findings show that decreased *Chd8* dosage alters gene expression in adult brain both via shared pathways, and in region-specific and sex-specific manners, with some transcriptional aberration attributable to specific cell types in the cortex. Our results present a systems-level characterization of molecular and cellular pathways that are disrupted in adult *Chd8* mutant brain, and potentially captures generalizable dysfunction driven by mutation to chromatin-associated NDD risk genes.

Mendelian Phenotypes Posters - Thursday

PB1970. Siblings with hypophosphatemic rickets and homozygous *CYP27B1* variants

Authors:

L. Wang¹, M. Shanmugasundaram¹, E. Cooney^{1,2}, P. Lee^{1,3}; ¹Univ. of Texas Med. Branch, John Sealy Sch. of Med., Galveston, TX, ²Univ. of Texas Med. Branch, Dept. of Pediatrics, Div. of Med. Genetics & Metabolism, Galveston, TX, ³Univ. of Texas Med. Branch, Dept. of Pediatrics, Div. of Endocrinology, Galveston, TX

Abstract Body:

Vitamin D-dependent rickets type 1A (VDDR1A) is a rare autosomal recessive disorder caused by biallelic pathogenic variants in *CYP27B1*, resulting in deficient 1 α -hydroxylation of 25-hydroxyvitamin D (25OHD) to 1,25-dihydroxyvitamin D (1,25(OH)2D). We report siblings presenting with hypophosphatemic rickets and homozygous *CYP27B1* variants. The proband was a 20-month-old Hispanic female presenting with a 2-month history of bilateral wrist swelling, gross motor delays, and deceleration of height from 11% at 11-months-old to 1% at the time of the first encounter. Evaluation showed radiographs consistent with rickets, calcium (Ca) 9.1 mg/dL (RR 8.6-10.6), phosphorus (Phos) 2.8 mg/dL (RR 3.5-6.7), alkaline phosphatase (ALP) 1748 U/L (RR 150-370), 25OHD 46 ng/mL (RR 25-80), 1,25(OH)2D 42.8 pg/mL (RR 19.9-79.3), and parathyroid hormone (PTH) 902.6 pg/mL (RR 12-88). A clinical diagnosis of hypophosphatemic rickets was made. After empiric treatment with calcitriol and phosphate, her Phos, PTH, and ALP normalized and the rickets, growth failure, and developmental delay resolved. The proband's younger brother was a well-appearing 7-month-old with Ca 10.2 mg/dL (RR 7.8-11.2), Phos 3.9 mg/dL (RR 4.5-6.7), ALP 790 U/L (RR 185-430), and mild bone demineralization on skeletal survey. By 13 months, he developed radiographic evidence of rickets. Empiric treatment for hypophosphatemic rickets was started. Whole exome sequencing of both children showed homozygous *CYP27B1* c. 1040T>A (p. Ile347Asn) mutations classified as variant of uncertain significance (VUS). Variants were not found in the genes currently associated with familial hypophosphatemic rickets (*PHEX*, *FGF23*, *KL*, *DMPI*). Mother was heterozygous for the VUS; although father was unavailable, he was presumed an obligate carrier. The VUS is relatively uncommon in population databases (rs556530774, Exome Aggregation Consortium 0.009%). Predictive algorithms (SIFT, PolyPhen-2, Align-GVGD) suggest the VUS is disruptive. The VUS was clinically interpreted in the context of family segregation and *a priori* risk resulting in the decision to use VDDR1A instead of hypophosphatemic rickets as the working diagnosis. Calcitriol was continued. Phos supplementation was discontinued. To date, the children's growth and development have remained appropriate and their labs are within normal limits. In summary, we report an uncommon biallelic *CYP27B1* VUS presenting with hypophosphatemic rickets. This case emphasizes the variable clinical presentation of monogenic rickets and highlights the clinician's duty to interpret VUS within the context of *a priori* risk and family segregation to inform medical management.

Mendelian Phenotypes Posters - Wednesday

PB1971. Six patients with genetic disorders with atypical symptoms: how to perceive them

Authors:

T. Uehara¹, M. Inaba¹, S. Mizuno²; ¹Aichi Developmental Disability Center, Kasugai-city, Japan, ²Aichi Developmental Disability Center, Kasugai, Aichi, Japan

Abstract Body:

[Background] In recent years, methods of genetic analysis, including next-generation sequence, have made remarkable progress. That has contributed to an improvement in the diagnostic rate of undiagnosed patients with rare diseases. Progress of genetic analysis have also helped to elucidate the causes of previously undiagnosed diseases. As a result, many new diseases have been reported in the past few years. A part of diagnosed patients by genetic analysis with rare or novel diseases have atypical or unknown phenotypes. Here we report patients with rare or novel diseases who show atypical or unreported phenotypes. [Methods] We investigated patients with congenital anomaly showing with atypical or previously unreported phenotypes who had visited our clinic in the past year, based on their electronic medical record descriptions. [Results] We identified the following six individuals as having interesting phenotypes. Patient 1 is a 9-year-old girl definitely diagnosed by genetic analysis as Coffin-Siris syndrome. She has had seizures from the age of 7 and is currently on antiepileptic medication. Patient 2 is a 21-year-old boy diagnosed by genetic analysis as DLG3 mutation. He showed postnatal overgrowth. Patient 3 is a 14-year-old boy diagnosed by genetic analysis as CUL3 mutation. He showed macrocephaly (+2SD) and short stature (-2SD). Patient 4 is a 18-year-old boy diagnosed by genetic analysis as CDK19 mutation. He showed extreme growth failure (-7SD) hand flapping, and dysmorphic features. Patient 5 is a 16-year-old boy diagnosed by genetic analysis as ODC1 mutation. He showed premature tooth eruption and retardation of bone age. Patient 6 is a nine-year-old boy diagnosed by genetic analysis as CSTF2 mutation. He showed craniosynostosis. [Discussion] The phenotypes identified by this investigation have not previously been reported in patients with the same disease or were thought to be very rare in the in patients with the same genetic mutation. There are three possible explanations for such cases: 1) they are coincidental complications, 2) they should be considered as phenotypic extensions, or 3) they should be considered as different diseases due to differences in variants, even if the mutated genes are the same. Complications of seizures in CSS patients have been increasingly reported in recent years and may occur more frequently than was initially thought generally. Each phenotypes observed in the remaining five patients are difficult to compare with previous cases, due to new diseases whose reports are still few. It is important to accumulate cases to clarify which of the three patterns is applicable.

Mendelian Phenotypes Posters - Thursday

PB1972. *Slc9a6* mutation causes Purkinje cell loss and ataxia in the *shaker* rat

Authors:

K. Figueroa¹, C. Anderson¹, S. Paul¹, W. Dansithong¹, M. Gandelman¹, D. Scoles², S. M. Pulst¹; ¹Univ. of Utah, Salt Lake City, UT, ²Univ of Utah, Salt Lake City, UT

Abstract Body:

The *shaker* rat carries a spontaneous mutation leading to Purkinje cell (PC) degeneration resulting in body tremor and progressive ataxia. In previous work, we fine-mapped the *shaker* locus to the distal end of the X chromosome. In this current study, we sought to identify the mutation underlying *shaker*, with confirmation through functional complementation. We fine-mapped the *shaker* locus using an F2 hybrid strategy to the distal end of the X chromosome and performed transcriptomic studies to identify deleterious variants. We identified a XM_217630.9 (*Slc9a6*):c.[191_195delinsA] variant in the *Slc9a6* gene segregating with disease that was predicted to generate a truncated sodium-hydrogen exchanger 6 (NHE6) protein, p.(Ala64Glufs*23). Having identified solute carrier family 9 member A6 (*Slc9a6*) as the likely causative gene, we generated an adeno-associated virus (AAV) targeting *Slc9a6* expression to PCs using a mouse L7-6 (L7) promoter. We administered AAVs through intracerebroventricular injection at 5 weeks of age, prior to PC death. We tracked motor ataxia through 25 weeks of age, and following motor experiments, we harvested cerebella for histology and molecular analyses, quantifying mRNA and protein expression of *Slc9a6*/NHE6, as well as several cerebellar health markers. Administration of AAV9-PHP.eB expressing rat *Slc9a6* prior to symptom onset reduced the *shaker* motor, molecular, and cellular phenotypes. Functional complementation restoring an average of ~10% wildtype NHE6 not only reduced motor ataxia, but also significantly increased both mRNA and protein expression of several key cerebellar markers, CALB1, PCP2, and RGS8. In conclusion, *Slc9a6* is mutated in *shaker*. Human *SLC9A6* loss-of-function mutations cause Christianson syndrome, an epileptic encephalopathy. AAV-based gene therapy may be a viable therapeutic strategy for Christianson syndrome, and the *shaker* rat model may aid in therapeutic development.

Mendelian Phenotypes Posters - Wednesday

PB1973. Splicing noise is variable across human introns, tissues and age and modelling its characteristics can improve our understanding of age-related diseases of the human brain.

Authors:

S. Garcia-Ruiz^{1,2}, D. Zhang^{1,2}, R. Reynolds^{1,2}, E. Gustavsson^{1,2}, S. Guelfi², J. Botia^{3,2}, L. Collado Torres⁴, M. Rytén^{5,2}; ¹Dept. of Genetics and Genomic Med. Res. & Teaching, UCL GOS Inst. of Child Hlth., London, United Kingdom, ²Dept. of Neurodegenerative Disease, Queen Square Inst. of Neurology, UCL, London, United Kingdom, ³Dept. of Information and Communications Engineering, Univ. of Murcia, Murcia, Spain, ⁴Lieber Inst. for Brain Dev., Baltimore, MD, ⁵UCL Great Ormond Street Inst. of Child Hlth., London, United Kingdom

Abstract Body:

Alternative splicing is a characteristic of most multi-exonic human genes and is used to generate transcriptomic and proteomic diversity across cells. However, the analysis of RNA-sequencing data from human tissues suggests that this process can be noisy with the consistent identification of reads that cannot be mapped to the known transcriptome. We characterised mis-splicing using RNA-sequencing data from 16,955 samples and 47 human tissues, provided by the Genotype-Tissue Expression Consortium v8, in the process of generating a database of annotated-novel intron pairs which we provide as a web resource (https://rytenlab.com/intron_db/ and https://soniagarcia.ruiz.shinyapps.io/intron_db/; docker image: https://hub.docker.com/repository/docker/soniaruiz/intron_db). We focused on reads mapping with a gapped alignment to the genome that could be assigned to a transcript through sharing of known acceptor or donor splice sites but were absent from annotation. Analysing this data, we found that mis-splicing occurs at significantly higher rates at acceptor versus donor splice sites, that novel donor and acceptor sites are located in close proximity to annotated sites in a pattern consistent with the known molecular architecture of splicing, and that mis-splicing is heterogeneous across introns. We estimated that 63% of mis-splicing events detected would be expected to be deleterious. Using linear regression models, we found that both local sequence information and gene-level features significantly impacted splicing noise. By measuring splicing noise across all human tissues, we showed that the effect of 5'/3' consensus sequence and conservation scores on mis-splicing varied in magnitude across human tissues even for a common set of introns, suggesting that splicing accuracy might be affected by RNA-binding protein (RBP) expression. Consistent with this hypothesis, we found that siRNA knockdown of spliceosomal RBPs generated predictable patterns of increased splicing noise and that significant increases in splicing noise with age correlated with a reduction in RBP expression. Interestingly, the effect of age on RBP expression and splicing noise was most apparent in the human brain, with the most mis-spliced introns being significantly enriched in synaptic genes. Together, our findings suggest that understanding patterns of mis-splicing could provide novel insights into age-related human diseases, particularly of the human brain.

Mendelian Phenotypes Posters - Thursday

Abstract Body:

SRSF1 (also known as ASF/SF2) is an evolutionary conserved non-snRNP splicing protein that belongs to the serine/arginine rich domain (SR) family. It is known to be a master regulator of constitutive and alternative splicing. Through international data sharing, we gathered 16 patients (9 females and 7 males) carrying 14 different germline *SRSF1* variants including frameshift, nonsense, and missense variant alleles, as well as one microdeletion of the region 17q22 that included *SRSF1*. Variants occurred mostly *de novo*, however in one family a germline mosaicism was suspected to explain the recurrence in two siblings, while in another case the inheritance was unknown. Main clinical features included developmental delay (DD), intellectual disability (ID), hypotonia, behavioral disorders, skeletal and cardiac anomalies. Three out of 16 patients showed marfanoid habitus with learning disabilities or ID/DD. *In silico*, missense variants indicated predicted conformational changes of the protein surface. Functional studies supported pathogenicity, as established by *in vivo* splicing assay in *Drosophila*. Eye-specific overexpression of SF2, the *Drosophila* ortholog of SRSF1, induced a severe developmental phenotype due to missplicing of key genes involved in normal eye development. In the current study, we replicated this finding and found that overexpression of the human *SRSF1* was a phenocopy pointing towards functional conservation of SF2 and SRSF1. In addition, similar to previously characterized

ASHG 2022 Annual Meeting Poster Abstracts

splicing-deficient forms of SRSF1, clinical missense variants lost the capacity to cause an eye phenotype proving their loss-of-function nature. Overall, these results indicate that haploinsufficiency of *SRSF1* is responsible for a syndromic neurodevelopmental disorder trait with recurrent marfanoid habitus and ID/DD.

Mendelian Phenotypes Posters - Wednesday

PB1975. Subtle genomic duplication on Chromosome 6: a hypothesis for a causative mechanism

Authors:

A. John¹, R. Collins¹, V. Tonk², L. Nagy¹; ¹Texas Tech Univ. Hlth.Sci. Ctr., Lubbock, TX, ²Texas Tech Univ Hlth Sci Ctr, Lubbock, TX

Abstract Body:

Background: Duplications of Chromosome 6, especially those of the long arm (q), are a very rare genetic condition that can lead to a spectrum of defects. Anomalies include growth restriction, heart and brain defects, various dysmorphic physical features, genitourinary system abnormalities, and developmental delay. **Case Report:** A 15-month-old male presented with failure to thrive, hypertonia, daily emesis, repetitive banging of head against wall, and inconsolable screaming. Confirmatory imaging noted a Chiari I malformation with a pre-syrinx and a tethered cord. The patient was born at 36 weeks without complications during pregnancy or birth and had normal newborn screenings. Congenital defects included hypospadias and 2 small atrial septal defects. His genetic workup revealed a 177kbp duplication of cytogenetic band 6q27 that involved the T gene (OMIM 601397). The parents do not share this duplication. The patient underwent Chiari decompression and filum sectioning that resolved his presenting symptoms. **Conclusion:** To our knowledge, this is the smallest case of a duplication (177 kbp) of Chromosome 6q that led to the wide spectrum of manifestations documented in trisomy 6q. We propose that due to the hypothesized tight communication amongst band regions in chromosome 6q, duplications regardless of size or location can lead to similar manifestations.

Mendelian Phenotypes Posters - Thursday

PB1976. Sunken symptoms of *SRCAP* mutation: A case report of atypical phenotype of Floating Harbor Syndrome

Authors:

N. Nesheiwat¹, W. K. Chung²; ¹Div. of Clinical Genetics, Dept. of Pediatrics, Columbia Univ. Irving Med. Ctr., New York, NY, ²Div. of Molecular Genetics, Dept. of Pediatrics, Columbia Univ. Irving Med. Ctr., New York, NY

Abstract Body:

Floating-Harbor syndrome (FHS) is an autosomal dominant condition characterized by short stature, delayed bone growth, skeletal anomalies, seizures, language impairment, and intellectual disability. Individuals can have distinct facies including deep-set eyes, thin lower lip, triangular-shaped face, and a long broad nose. The *SRCAP* gene encodes for a chromatin-remodeling ATPase, which serves as a co-activator for CREB-binding protein (CREBBP) and CBP-mediated transcription. The CREBBP plays a key role in regulating cell growth and division and is important for normal development. Here we report a 14-year-old female of Ashkenazi Jewish descent with a history of moderate developmental delay, language impairment, amenorrhea, progressive severe sensorineural hearing loss, short stature with poor response to growth hormone therapy over 8 years ($Z = -3.95$), umbilical hernia, and congenital duplicated ureters. Upon examination, she displayed hypernasal speech, broad nose, low-set ears, bilateral clinodactyly, pectus excavatum, and hypotonia. She also had unique findings of the development of severe lower lip angioedema of unknown etiology at 12 years of age and bilateral proptosis. Extensive workup, including multiple biopsies of the lip, have been negative. SNP microarray returned negative. Trio exome sequencing identified a de novo pathogenic c.7330 C>T (p.Arg2444Ter) variant in exon 34 of the *SRCAP* gene.

This nonsense variant is predicted to result in protein truncation, as the last 787 amino acids are lost. Truncating variants in exons 33 and 34 of *SRCAP* are associated with FHS. The p.Arg2444Ter variant has been reported in patients with the characteristic FHS phenotype. The prevalence of FHS is not known, yet seventy-three individuals with heterozygous *SRCAP* pathogenic variants have been reported in the medical literature to date.

In addition to some of previously mentioned classical FHS features, our patient also had atypical findings of lip angioedema, proptosis and sensorineural hearing loss, which are contrasting to typical features of thin lips, deep-set eyes, and conductive hearing loss typically seen in FHS. These unique features have not been previously reported with this condition. There remains the possibility that these are new traits associated with FHS, however secondary causes cannot be ruled out. This suggests the phenotype of the condition is quite variable and our patient's distinct features of proptosis, lower lip angioedema, sensorineural hearing loss further add to the expansion of the clinical spectrum and variable expressivity of FHS. Additional cases will help expand the phenotype and knowledge of this rare disorder.

Mendelian Phenotypes Posters - Wednesday

PB1977. Systematic bioinformatic analysis promotes a missense variant in *XK* as potential cause of X-linked intellectual disability.

Authors:

T. Litster¹, M. Corbett^{1,2}, T. Dudding-Byth³, J. Gecz^{1,2,4}; ¹Univ. of Adelaide, Adelaide, Australia, ²Robinson Res. Inst., Adelaide, Australia, ³Hunter New England Area Hlth.Service, Newcastle, Australia, ⁴South Australian Hlth.and Med. Res. Inst., Adelaide, Australia

Abstract Body:

Despite only making up 5% of the genome, the X chromosome shows enrichment for genes involved in intellectual disability (ID), housing approximately 15% of known ID genes. Despite this enrichment, many cases of ID with a clear X-linked inheritance pattern remain without a genetic diagnosis. These cases provide opportunities to discover novel ID genes and variants on the X chromosome and enhance our understanding of the genetic landscape of ID. One such case is the MRX11 family (Kerr et al. 1992), who present with multiple males affected by mild to moderate, non-syndromic ID. This family has undergone extensive genetic testing and remains unresolved.

Here we applied a systematic bioinformatic analysis pipeline to this family to identify the disease causing variant. Genome-wide linkage analysis defined the linkage interval between rs7067109 and rs5918300 (hg38 chrX:32775936-42171940) with maximum LOD score of 3.34. Analysis of short-read whole genome sequencing data revealed no coding, splicing or regulatory variants predicted to be damaging in known ID genes within this region. RNA-seq data from patient-derived lymphoblastoid cell lines showed no pathogenic aberrant splicing or expression events. Finally, long-read sequencing with Oxford Nanopore using adaptive sampling to enrich for sequences on the X-chromosome revealed no damaging structural variants.

After extensive analysis, only one variant remained that was predicted to be damaging and segregated with disease; NM_021083.4(*XK*): c.872A>G: p.(Asn291Ser). The *XK* protein forms part of the Kell antigen complex on the surface of erythrocytes, and acts as a phospholipid scramblase involved in apoptotic pathways in other cell types. Pathogenic, loss of function variants in *XK* are typically implicated in McLeod Syndrome which is characterised by neuroacanthocystosis (spine-like protrusions that form on erythrocytes) and a late onset neurodegenerative disorder that is distinct from the phenotypes of affected males in the MRX11 family. Therefore, our extensive and systematic bioinformatic analysis, through a process of elimination, has revealed *XK* as a potential novel ID gene with a phenotypic spectrum separate from McLeod syndrome.

Mendelian Phenotypes Posters - Thursday

PB1978*. Systematic identification of disease-causing near-coding variants in 29,759 individuals with rare disease

Authors:

N. Whiffin^{1,2}, A. Martin-Geary², E. Ng², N. Wieder², M. Ferla²; ¹Univ. of Oxford, Oxford, United Kingdom, ²Wellcome Ctr. for Human Genetics, Univ. of Oxford, Oxford, United Kingdom

Abstract Body:

Genomic regions directly adjacent to the protein coding sequence, such as untranslated regions (UTRs) and gene promoters (collectively referred to as ‘near-coding’ regions), are known to play important roles in transcriptional and post-transcriptional gene regulation. Variants that disrupt these elements have been shown to cause severe disease phenotypes. However, these regions are not routinely included in clinical diagnostic pipelines. The extent of ‘missed’ near-coding diagnoses that have the potential to be identified by expanding coding specific pipelines is currently unknown.

Here, we analysed near-coding de novo variants in 12,020 rare disease trios in the Genomics England 100,000 Genomes dataset (GEL). We selected variants within near coding regions of MANE transcripts for genes flagged as potentially involved in each proband’s phenotype (PanelApp - ‘Green genes’), with a dominant mode of inheritance. Rare variants in each region were annotated with UTRannotator, SpliceAI scores, polyA signatures, miRNA binding sites, transcription factor binding sites, and other regulatory features.

We found a total of 480 rare de novo near-coding variants, in dominant genes considered diagnostic for a patient’s phenotype; 58 within 5’ UTR exons; 360 within 3’ UTR exons; 4 within 5’ splice regions (SpliceAI > 0.1); and 58 variants within the gene promoter (based on ENCODE cCREs). Of the 443 individuals with a candidate variant in this group, 361 (81%) do not have a diagnosis linked to a coding variant.

Likely disease-causing near-coding variants included previously identified variants in both *PAX6* and *MEF2C*, along with several novel diagnostic candidates. These include a 5’UTR splice donor variant in *SETD5* in a patient with intellectual disability (SpliceAI=0.97), and a 5’UTR variant that creates an upstream start-codon out-of-frame with the coding sequence of *SLC2A1* in a patient with motor difficulties and abnormal glucose homeostasis. Finally, using matched participants from the GEL cancer cohort as controls we performed burden testing in 29,759 rare disease probands to quantify the enrichment of variants in undiagnosed patients within each of our candidate near-coding elements.

It is common for individuals suffering from rare disease to be faced with, often prolonged diagnostic odysseys. Here, we demonstrate the power of incorporating near-coding regions into existing diagnostic pipelines to uncover additional diagnoses that are missed when using a coding-centric approach.

Mendelian Phenotypes Posters - Wednesday

PB1979. Taking the *CPLANE INTU* the light: further defining the orofacioidigital syndrome phenotype association with biallelic *INTU* alterations.

Authors:

J. Hunter^{1,2}, R. Rushforth^{2,1}, D. Nolan¹, D. Koboldt³, R. Stottmann³, M. Mori¹; ¹Nationwide Children's Hosp., Columbus, OH, ²The Ohio State Univ., Columbus, OH, ³Nationwide Childrens Hosp., Columbus, OH

Abstract Body:

Alterations in the *INTU* gene are provisionally associated with orofacioidigital syndrome XVII (OMIM: 617926, OFD17), short-rib thoracic dysplasia 20 with polydactyly, (OMIM: 617925, SRPS) and possibly nephronophthisis (NPHP). To date, only 4 patients from three families have been reported with an OFD phenotype, two patients with a SRPS phenotype and one patient with a NPHP phenotype. The OFD phenotype appears to consist of growth retardation, facial dysmorphisms, tongue hamartomas, polydactyly, cardiac malformations, and renal malformations. The SRPS phenotype is similar to the OFD phenotype plus short rib thoracic dysplasia and appears to be more severe or even lethal in utero. Finally, a single patient with a rare homozygous missense *INTU* alteration was reported to have only short stature and nephronophthisis. The *INTU* gene codes for the intuned protein, a critical subunit of the *CPLANE* protein complex that is required for proper cilia function and reported phenotypes are consistent with a ciliopathy. We present here a fifth patient with a phenotype consistent with OFD. This male patient presented prenatally with congenital heart defects and was found postnatally to have feeding difficulties, and early growth concerns. He has demonstrated developmental delay including motor and language delay. As with other reported patients, he has tongue hamartomas, bilateral great toe polysyndactyly, and slight facial dysmorphisms. Clinical trio exome sequencing revealed a paternally inherited missense alteration (p.Thr240Ile; c.719C>T) and a maternally inherited truncating alteration (p.Arg572Ter; c.1714C>T) in the *INTU* gene (transcript: NM_015693.4). We are investigating these alterations in an *in vitro* model to further determine their effects on ciliary form and function and confirm the suspected role of *INTU* in ciliopathies. This patient represents only the fifth reported patient with a phenotype consistent with OFD that harbors potentially pathogenic biallelic alterations in *INTU*. This OFD patient, along with *in vitro* and *in vivo* mouse models of disease being studied, will help bring this novel syndrome *INTU* the light and one step closer to clinical validity of the gene-disease relationship.

Abstract Body:

Long QT syndrome (LQTS) is one of the most common inherited arrhythmias and multiple genes have been reported as causative. Presently, genetic diagnosis for LQTS patients is becoming widespread and contributing to implementation of therapies. However, causative genetic mutations cannot be detected in about 20% of patients. To elucidate additional genetic mutations in LQTS, we performed deep-sequencing of previously reported 15 causative and 85 candidate genes for this disorder in 677 Japanese LQTS patients. We performed in-silico filtering of the sequencing data and found 60 novel variants in 40 genes of 71 cases. These variants were predicted to be damaging to coding proteins or to alter the binding affinity of several transcription factors. They might be useful for screening of LQTS patients who had no known genetic factors. In addition, when the mechanisms of these variants in the development of LQTS are revealed, it will be useful for early diagnosis, risk stratification, and selection of treatment.

Abstract Body:

An Xq22.2 region upstream of *PLP1* has been proposed to underly a neurological disease trait when deleted in 46,XX females. Deletion mapping revealed that heterozygous deletions with a smallest region of overlap (SRO) spanning six Xq22.2 genes (*BEX3*, *RAB40A*, *TCEAL4*, *TCEAL3*, *TCEAL1*, *MORF4L2*) associate with an early-onset neurological disease trait (EONDT) consisting of hypotonia, intellectual disability (ID), neurobehavioral abnormalities, and dysmorphic facial features. To date, none of the genes within the smallest region of overlap (SRO) have been associated with monogenic disease. Through local and international collaborations facilitated by GeneMatcher and MatchMaker Exchange, we have identified and herein report seven novel *de novo* variants involving *TCEAL1* in seven unrelated families: three hemizygous truncating alleles; one hemizygous missense allele; one heterozygous *TCEAL1* full gene deletion; one heterozygous contiguous deletion of *TCEAL1*, *TCEAL3*, *TCEAL4*; and one heterozygous frameshift variant allele. Variants were identified through exome or genome sequencing with trio analysis or through chromosomal microarray. Comparison with previously reported Xq22 deletions encompassing *TCEAL1* identified a more-defined novel syndrome consisting of hypotonia,

ASHG 2022 Annual Meeting Poster Abstracts

abnormal gait, developmental delay/intellectual disability especially affecting expressive language, autistic-like behavior, and mildly dysmorphic facial features. Additional features include strabismus, refractive errors, variable nystagmus, gastroesophageal reflux, constipation, dysmotility, recurrent infections, seizures, and structural brain anomalies. An additional maternally inherited hemizygous missense allele of uncertain significance was identified in a male with hypertonia and spasticity without syndromic features. These data provide evidence that *TCEALI* loss-of-function causes a neurological rare disease trait involving significant neurological impairment with features overlapping the EONDT phenotype in females with the Xq22 deletion.

Mendelian Phenotypes Posters - Thursday

PB1982. Temtamy Preaxial Brachydactyly Syndrome: penetrance in heterozygotes for a *CHSY1* missense variant.

Authors:

P. Sabeh¹, M. Valancy^{2,3}, C. Janelle³, P. M. Campeau^{2,3}; ¹Université de Montréal, Montréal, QC, Canada, ²CHU Sainte-Justine, Montréal, QC, Canada, ³Hôpital Shriners, Montréal, QC, Canada

Abstract Body:

Temtamy Preaxial Brachydactyly Syndrome (TPBS) is an autosomal recessive dysostosis. It is characterized by bilateral preaxial brachydactyly with facial dysmorphism, hyperphalangism, developmental delay or intellectual disability, growth retardation, sensorineural hearing loss and dental abnormalities. Loss of function variants in *CHSY1*, encoding a secreted chondroitin glycosyltransferase, cause TPBS by dysregulating NOTCH and BMP signaling. Here, we report partial penetrance in heterozygotes for a *CHSY1* missense variant. A father and his daughter present the same heterozygous variant (NM_014918.5:c.1386A>C, p.Lys462Asn) in the *CHSY1* gene associated with a milder TPBS phenotype, including hallux valgus, brachymetatarsia, mild brachydactyly, significant clinodactyly and limited metacarpophalangeal flexion. They did not have facial dysmorphisms, cognitive involvement, teeth anomalies nor hearing loss. No other variants were identified on a limb anomaly sequencing panel or on exome sequencing. The variant changes a well conserved lysine amino acid residue to an asparagine, thus changing the charge at this position of the glycosyltransferase domain. The variant is absent from gnomAD, and has a CADD score of 23, thus placing it in the top 1% most deleterious variants. In conclusion, we identified a heterozygous missense variant in *CHSY1* which is likely causally related to the hand and feet anomalies dominantly transmitted in this family, suggesting partial penetrance in carriers, a phenomenon noted in other recessive conditions.

Mendelian Phenotypes Posters - Wednesday

PB1983. TGF β signaling is important for spermatogenesis.

Authors:

U. Kumar, Y-C. Shen, C. Sultan, S. Hammoud; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

The process of spermatogenesis requires intricate interactions between the germline and soma (Leydig, Sertoli, and peritubular myoid cells). While many signaling pathways in Leydig and Sertoli cells have been implicated in various aspects in germ cell maintenance and differentiation, relatively little is known about the contribution of peritubular myoid cells (PMC). To investigate possible signaling pathways between PMCs and germ cells, we performed ligand-receptor analysis using our mouse testis scRNA-seq data and identified TGF β 2 and ALK5 as a high confidence ligand receptor pair. TGF β 2 ligand is expressed in PMCs and TGFBR1 receptor (ALK5) is expressed in meiotic and post-meiotic cells. The Myoid-Meiotic cell communication axis was unexpected since these cells are above the blood-testis barrier. To dissect the role of TGF β R signaling in germ cell development, we initially knocked out the ALK5 receptor in differentiating spermatogonia using a Stra8-Cre. The ALK5 conditional knockout mice have 20% lower testis/body weight ratio as compared to ALK5^{+/+} males, suggestive of spermatid cell loss. As expected, no significant difference was noted in the number of undifferentiated (PLZF⁺), differentiating spermatogonia numbers (Stra8⁺), or the number of proliferating STRA8⁺/PLZF⁺ cells in ALK5^{-/-} males, but we did get a significant decrease in the ratio of round to elongating spermatid in the testis. Together, these results suggest that TGF β signaling through the ALK5 receptor in germ cells is important for reproductive fitness and future studies will examine the mechanisms by which TGF β signaling maintains optimal steady state spermatogenesis.

Mendelian Phenotypes Posters - Thursday

PB1984. The benefits and yields of whole exome sequencing data reanalysis in Iranian undiagnosed patients with intellectual disability

Authors:

Z. Fattahi^{1,2}, M. Babanejad¹, F. Peymani¹, F. Ghodrattpour^{1,2}, M. Beheshtian^{1,2}, S. Arjangi¹, M. Mohseni^{1,2}, S. Banihashemi¹, F. Larti¹, K. Kahrizi¹, H. Najmabadi^{1,2}; ¹Genetics Res. Ctr., Univ. of Social Welfare and Rehabilitation Sci., Tehran, Iran, Islamic Republic of, ²Kariminejad-Najmabadi Pathology & Genetics Ctr., Tehran, Iran, Islamic Republic of

Abstract Body:

Nowadays, molecular diagnosis is enhanced by implementing whole-exome sequencing (WES) in studying Mendelian disorders, especially in intellectual disability (ID). Although WES is considered a first-line genetic analysis tool, the diagnostic yield has been still limited to less than 50% in different studies. Over recent years, reanalysis of WES data has allowed genetic diagnosis in patients with negative results from the initial evaluation and has increased the molecular diagnosis in 10-15% of patients. This can be obtained by updates in bioinformatics tools, algorithms, databases, literature, and patient clinical features. Furthermore, simultaneous WES-based detection of CNVs plays an important role as CNVs have a high positive rate with regard to ID. To evaluate the added value of WES reanalysis in molecular diagnosis of autosomal recessive intellectual disability (ARID) in patients with a high rate of consanguineous background, we reanalyzed WES data of 162 negative cases. This cohort was obtained from our previous large-scale study in which whole-exome and whole-genome sequencing had been performed in 404 consanguineous Iranian families with final detection rate of 54%. WES reanalysis was performed by applying the most updated versions of algorithms for variant detection and annotation, as well as WES-based CNV analysis using the GATK GermlineCNVCaller. Thus far, WES reanalysis of all 162 patients has been accomplished, of which the possible causative variant is detected in 17 cases, equal to a 10.5% increase in the detection rate. As the WES-based CNV analysis for all the 162 patients is still in process, we expect to see a higher detection rate in the future. Reanalysis identified pathogenic/likely pathogenic variants in known ID genes (*CDK10*, *ASPM*, *RBMX*, *VARSI*, *MANBA*, and *HSD17B4*) in seven cases. In addition, a duplication on Xq13.2q13.3 in a family with an established X-linked inheritance pattern was detected by linkage analysis and whole-genome sequencing. We also identified the second case with likely pathogenic variants in *FSCN1* and *AGBL2* genes, which were previously reported in similar patients once in the literature. Furthermore, novel candidate genes were detected in six cases: *AKTIP*, *MAZ*, *MIX23*, *SERPINB12*, *CDC25B*, *TTII*, and *GPR126*. Updates in the genetic databases and literature and patients' clinical phenotype were among the main reasons for the ascertained results. In conclusion, this project has shown a 10.5% improvement in detection yield, introduced seven possible novel candidate genes, and provided a second report for the recently identified genes providing a more precise genotype-phenotype correlation.

Mendelian Phenotypes Posters - Wednesday

PB1985. The ClinGen Kidney Disease Clinical Domain Working Group: Defining solutions to the challenge of nephropathy ontology and nomenclature.

Authors:

A. Byrne¹, H. Dziadzio¹, E. Edoh¹, A. Girod¹, R. Webb¹, T. P. Sneddon², M. G. Sampson^{3,4}, A. J. Mallett^{5,6}; ¹Broad Inst. of MIT and Harvard, Cambridge, MA, ²UNC Hlth., Chapel Hill, NC, ³Boston Children's Hosp., Boston, MA, ⁴Harvard Med. Sch., Boston, MA, ⁵Townsville Hosp. and Hlth.Service, Townsville, Australia, ⁶The Univ. of Queensland, Brisbane, Australia

Abstract Body:

Kidney disease affects one in ten people with 10% of affected individuals having a monogenic form. The ClinGen Kidney Disease Clinical Domain Working Group (CDWG) was established in 2019 with the goal of creating a comprehensive, standardized knowledge base defining the clinical validity of gene-disease relationships and expert classifications of variant pathogenicity across the full spectrum of nephropathies in order to improve patient care. The most significant challenge to this goal however, lies in defining the disease entity. For many nephropathies, current disease nomenclature (e.g., OMIM) and ontology (e.g., MonDO) systems do not accurately reflect the underlying biology of a given disorder and are not aligned with contemporary knowledge of disease pathogenesis. Inaccuracies and inconsistencies in disease naming can therefore hinder clinical recognition and impact patients by restricting eligibility and access to appropriate testing, monitoring, and treatment. The ClinGen Kidney Disease CDWG, in coordination with the ClinGen Disease Naming Working Group, are currently working to define consensus recommendations for kidney disease naming, with input from representatives across the global renal community, including clinicians, scientists, and patients. Naming is suggested to follow the general, stepwise system of 'core disease name - gene name', with disease distinguishing phenotype and/or genotype descriptors added where appropriate to differentiate related disorders with well-established differences in e.g., aetiology, presentation, management, or outcome. Implementing these changes across the multiple related, but not interdependent, ontology and nomenclature systems will likely be a challenging undertaking that requires agreement and support from the community, but is one that is expected to have immense benefits in clinical practice.

Mendelian Phenotypes Posters - Wednesday

PB1986. The genetic and phenotypic landscape of *STUB1/TBP*-associated disorders: Two genes and three patterns of inheritance sharing a continuous neurodegenerative phenotypic spectrum.

Authors:

S. Magri¹, L. Nanetti¹, C. Gellera¹, E. Sarto¹, M. Balzo¹, E. Rizzo¹, A. Mongelli¹, G. Di Fede², C. Mariotti¹, D. Di Bella¹, F. Taroni¹; ¹Fondazione IRCCS Istituto Neurologico Carlo Besta, Unit of Med. Genetics and Neurogenetics, Milan, Italy, ²Fondazione IRCCS Istituto Neurologico Carlo Besta, Div. of Neurology 5 and Neuropathology, Milan, Italy

Abstract Body:

Spinocerebellar ataxias type 17 (SCA17) and type 48 (SCA48) are both characterized by cerebellar-cognitive-behavioural features and incomplete penetrance. While SCA17 is caused by a CAG/CAA (polyQ) repeat expansion in the *TBP* gene, with a full penetrance for alleles with >49 repeats and a reduced penetrance for intermediate 41-49 alleles, SCA48 is attributed to heterozygous pathogenic variants in the *STUB1* gene. Notably, biallelic *STUB1* pathogenic variants cause a recessive ataxia (SCAR16) characterized by a SCA17/SCA48-like phenotype which manifests only in homozygotes or compound heterozygotes. We recently demonstrated a digenic inheritance of the *STUB1/TBP* genotype which explains the incomplete penetrance in SCA17 and SCA48, showing that SCA17 is a monogenic disorder for *TBP* expansions with >47 polyQ and a "true digenic" *TBP/STUB1* disorder for intermediate *TBP* alleles (41-46 polyQ) (Genet Med 2022, PMID 34906452). Here, we present new insights to address questions concerning 1) the pathogenic role of "high-normal" 39-40 repeat *TBP* alleles; 2) the discrepancy between the expected genetic prevalence of the *STUB1/TBP* genotype and the reported disease prevalence of *STUB1/TBP* associated-diseases; 3) the phenotypic overlap in monogenic and digenic SCA17, and SCA48. Analysis of 170 index cases with ataxia carrying "high-normal" 39- and 40-repeat *TBP* alleles identified 10 novel families carrying a *STUB1* pathogenic heterozygous variant (5.9%), supporting a pathogenic role for 39-40 alleles, previously considered to be benign. Interestingly, screening of 94 index cases primarily referred for dementia revealed 18 cases with *TBP*₃₉₋₄₀ alleles, indicating a slight enrichment of these "high-normal" alleles in this group of patients. Notably, a *STUB1* pathogenic heterozygous variant was identified in 3 of these cases, suggesting that the *STUB1/TBP* genotype may underlie a wider spectrum of phenotypes. Comparison of clinical and neuroimaging findings reveal that an earlier and more severe cognitive deterioration and a more widespread pattern of cerebellar atrophy characterizes the SCA17^{Digenic} phenotype in comparison with SCA17 monogenic disease. By contrast, the highly homogeneous MRI morphological findings in SCA48/SCA17^{Digenic} and SCAR16 patients strongly emphasizes the existence of a continuous clinical-neuroimaging and genetic spectrum in *STUB1* gene-related disorders. Due to the relatively high frequency of *TBP*₄₀₋₄₆ (f=0.015) and *TBP*₃₉ (f=0.088) alleles, and that of *STUB1* pathogenic variants (f=0.003) in the general population, SCA17^{Digenic} represents a very demanding task for genetic counseling. (Funding: FRRB-CP-20/2018 to FT)

PB1987. The genetic background in a group of 155 Polish pediatric patients with unexplained epilepsy.

Authors:

B. Chalupczynska¹, E. Ciara¹, M. Rydzanicz², P. Stawiński^{1,2}, D. Siestrzykowska¹, P. Halat-Wolska¹, D. Jurkiewicz¹, M. Pelc¹, D. Piekutowska-Abramczuk¹, A. Madej-Pilarczyk¹, D. Wicher¹, R. Płoski², K. Chrzanowska¹; ¹The Children's Mem. Hlth.Inst., Warsaw, Poland, ²Warsaw Med. Univ., Warsaw, Poland

Abstract Body:

Introduction: The studies conducted so far indicate a high clinically and genetically heterogeneous of epilepsy syndromes. A large number of genes, with wide ranging functions, are implicated in their etiology. Next-generation sequencing (NGS) has contributed to the identification of many monogenic epilepsy syndromes and is favoring earlier and more accurate diagnosis in a group of pediatric patients with epilepsy.

Materials and Methods: In the present study, molecular profile analysis of pediatric patients with a variety of epilepsy types was performed using NGS based multi-gene targeted panels, containing the majority of epileptic significant genes or whole-exome sequencing (WES).

Results: Molecular profile analysis was conducted in 155 epileptic patients. A total of 85 pathogenic/likely pathogenic variants in 53 genes were identified, including 32 known and 53 novel alterations. The most commonly mutated was *SCN1A* gene, associated with Dravet syndrome. Sporadically variants in *ALG13*, *AMT*, *ANKRD11*, *ATPIA3*, *CACNA1A*, *CDKL5*, *CHD2*, *CLN6*, *COL4A1*, *CTSD*, *CUX2*, *EFHC1*, *EHMT1*, *FGFR3*, *FLNA*, *GABRA1*, *GABRG2*, *GALC*, *GAMT*, *GRIN2A*, *ITPA*, *KANSL1*, *KCNA2*, *KCND3*, *KCNJ11*, *KCNQ2*, *KMT2D*, *LMBRD2*, *MBD5*, *MECP2*, *PCDH19*, *PIGN*, *POMT2*, *PTCH1*, *RYR2*, *SCN1B*, *SCN2A*, *SCN3A*, *SCN8A*, *SETBP1*, *SLC16A2*, *SMARCA2*, *SMARCB1*, *SMCIA*, *SPTAN1*, *STXBPI*, *SYNI*, *SYNGAP1*, *TPP1*, *TUBA1A*, *TUBB4A*, *WDR45* were identified. The diagnostic yield of the entire study cohort was 45%.

Conclusions: Targeted massively parallel sequencing is an effective diagnostic test for pediatric patients with epilepsy, with over 40% diagnostic efficiency. The *SCN1A* it is the most essential factor in the etiology of epilepsy in the studied group (12%). The remaining genes were observed in single cases, which confirms the high genetic heterogeneity. Patients with earlier seizure onset and drug-resistance epilepsy were the best candidates for testing. Our study contributes to further delineation of the epilepsy molecular profile, and for pediatric patients with epilepsy, genetic diagnosis is important for accurate prognosis and treatment.

Partially supported by CMHI project: M39/2019

Mendelian Phenotypes Posters - Wednesday

PB1988. The genetic landscape of *ATP7B* provides insights into Wilson Disease variant penetrance and prevalence.

Authors:

G. del Angel¹, W. Mowrey¹, J. Bissonette², L. Chunn², M. Kiel², D. Nefcy², S. Wasilewski³, T. Defay¹; ¹Alexion AstraZeneca Rare Disease, Boston, MA, ²Genomenon, Ann Arbor, MI, ³AstraZeneca, Cambridge, United Kingdom

Abstract Body:

Wilson Disease (WD) is a monogenic disorder of copper metabolism caused by biallelic loss-of-function variants in the gene *ATP7B*. A comprehensive understanding of the *ATP7B* genetic landscape is thus required for accurate estimation of WD prevalence and diagnosis rates. The UK Biobank (UKB), a public biomedical database aggregating genetic and clinical data for ~500,000 individuals, enables the discovery of novel *ATP7B* variants and the resolution of ambiguous variant interpretations.

We identified 1,211 protein-altering *ATP7B* variants in UKB Whole-Exome Sequencing (WES), including 37 novel protein-truncating variants. We assessed these variants' pathogenicity using ClinVar and Genomenon's Mastermind. These resources apply ACMG criteria (Richards et al., 2015) to complementary sets of variant data: where ClinVar archives submitted reports of variant clinical significance, Mastermind archives published literature reports of variants. ClinVar and Mastermind identified 140 and 227 variants, respectively, as potentially pathogenic. Subjects biallelic for pathogenic *ATP7B* variants were rare in UKB (0.03%), though subjects diagnosed with disorders of copper metabolism were even more rare (0.003%). We found zero overlap between *ATP7B* biallelic subjects and possible WD cases. Only one subject in UKB had additional diagnoses indicative of WD, including tremor, anemia, and corneal pigmentation. This subject was homozygous for a series of common *ATP7B* polymorphisms, but had no pathogenic variants that were identifiable by WES.

The absence of WD phenotypes in other biallelic subjects were attributable to pathogenic *ATP7B* variants with low-penetrance, or that were in *cis* (and thus not biallelic). The variants c.2972C>T and c.122A>G, identified as low-penetrance by Wallace and Dooley (2020), contributed to 111 of 128 biallelic cases. A variant pair present in another 8 biallelic patients, c.524_525del and c.778dup, was found to be in *cis* as a single pathogenic allele. Excluding these problematic cases left just 9 putative biallelic patients (0.002%) with 13 unique variants. The lack of WD phenotype in these subjects suggests that they may represent additional cases of low-penetrance *ATP7B* variants.

Our findings show that UK Biobank is an important resource for defining the genetic landscape of *ATP7B*, revealing both novel pathogenic variants and low penetrance in variants assumed to be pathogenic. Targeted investigation of these variants will improve our understanding of WD genetics, as well as the quantification of WD prevalence and diagnosis.

This research has been conducted using the UK Biobank Resource under application number 26041.

Mendelian Phenotypes Posters - Thursday

PB1989. The genetic landscape of neurodevelopmental disorders in a large cohort of multiplex consanguineous families from Turkey.

Authors:

A. Reis¹, E. Gümüşlü¹, E. Gümüş², Ö. Öz³, M. Özkan⁴, K. Kararer⁵, A. Ekici⁶, E. Pembegül Yildiz⁷, N. Aydinli⁷, A. Rauch⁸; ¹Friedrich-Alexander-Univ. Erlangen-Nürnberg, Erlangen, Germany, ²Mugla Sitki Kocman Univ., Mugla, Turkey, ³Harran Univ., Sanliurfa, Turkey, ⁴Medeniyet Univ., Istanbul, Turkey, ⁵Pamukkale Univ., Pamukkale, Turkey, ⁶Friedrich-Alexander-Univ. Erlangen-Nürnberg, Erlangen, Germany, ⁷Istanbul Univ. Sch. of Med., Istanbul, Turkey, ⁸Univ Zurich, Schlieren-Zurich, Switzerland

Abstract Body:

Neurodevelopmental disorders (NDDs) are genetically and phenotypically highly heterogeneous. Autosomal recessive (AR) forms are enriched in families from consanguineous marriages, but these families can present all other forms of inheritance, making a diagnosis challenging. In recent years, diagnostic yield increased from 40% to more than 60% in a recent study, with *de novo* and X-linked causes in 8-19% of diagnosed cases.

We now investigated a large cohort of consanguineous families with multiple affected individuals with NDDs in order to investigate the genetic landscape focusing on diagnostic consistency within families, which is commonly assumed in such families. We recruited a total of 183 affected individuals from 82 consanguineous families with two or more children with NDDs through clinical genetic and neuropsychiatric consultations from various academic hospitals in Turkey. Exome sequencing in all affected individuals and their parents allowed identification of pathogenic or likely pathogenic variants for 116 individuals in 85 established or known candidate genes for NDDs. This diagnostic yield of 63% is in line with the most recent report, but was only achieved when also sequencing parents, compared to only 47% when studying affected siblings only. Progress in the field becomes apparent by 8% of diagnoses based on genes published in the last 18 months. In 34 individuals (18.5%) from 23 families, we identified previously described pathogenic variants in 19 genes, indicating a high rate of founder mutations. Similarly to previous studies, we found *de novo* variants and variants in X-linked genes in 19 cases (10%), and in 54 individuals (29.5%) we found multiple molecular NDD diagnoses. Unexpectedly, only in 14 families (17%) our hypothesis of shared homozygous variants among all affected individuals of that family could be confirmed, as most families presented different molecular diagnoses.

Our study shows that multiplex consanguineous families often represent chance familial aggregation of different genetic disorders and modes of inheritance, requiring individual analysis of each affected child and inclusion of parents in the analysis. Only this way, a diagnostic yield of >60% can be achieved. Founder effects with 19% of cases are relatively frequent, a finding that is only now becoming evident given the growing amount of variant data available. Similarly, progress in gene identification now allows detecting multiple molecular diagnoses, which were seen in 30% of cases, a much higher frequency than in individuals from unrelated parents. Further investigation of novel candidate genes is ongoing and will help further increase the diagnostic yield.

Mendelian Phenotypes Posters - Wednesday

PB1990*. The impact of NGS on rare and complex epilepsies: identification of novel causative variants for an efficient diagnostic pathway and personalized treatments

Authors:

C. Gellera¹, B. Castellotti¹, S. Magri¹, G. Messina¹, F. Ragona¹, E. Freri¹, R. Solazzi¹, L. Canafoglia¹, M. Soldovieri², P. Ambrosino³, I. Mosca², M. Tagliatela⁴, F. Taroni¹, J. C. Di Francesco⁵, T. Granata¹; ¹Fondazione IRCCS Istituto Neurologico Carlo Besta, Milan, Italy, ²Univ. of Molise, Campobasso, Italy, ³Univ. of Sannio, Benevento, Italy, ⁴Univ. of Naples Federico II, Naples, Italy, ⁵Università Milano Bicocca, Monza, Italy

Abstract Body:

Epilepsy affects 1% of children and is the most frequent chronic neurological condition in childhood. The etiology remains unknown in 50% of cases, although it has been estimated that the large majority have a genetic determinant. The systematic use of NGS technology has allowed a) to increase the diagnostic rate in patients with rare phenotypes; b) to identify new pathogenetic variants; and c) to describe new related mechanisms. In recent years, the number of genes causative of severe and complex generalized epilepsies and developmental epileptic encephalopathies has increased significantly. We started using targeted gene panels with ≤ 100 genes to the current one with 295 genes. In total, we have analyzed 697 patients from the clinical, instrumental, radiological, and genetic point of view. Our studies led to a molecular diagnosis in 151 patients (22%) (81 carrying class 5 variants, and 70 class 4 variants); while 152 patients (22%) had class 3 (VoUS) variants and 394 patients (56%) did not carry variants of possible pathogenic significance. The most frequently mutated genes encoded channel proteins: 13.4% in SCNs channel genes and 12.7% in KCNs channel genes. Interestingly, 7% of causative identified variants belong to genes coding for SLC family neuronal transporter proteins. Among the 390 negative patients, we selected 37 families for WES analysis (31 sporadic cases, 4 with an autosomal recessive trait and 2 autosomal dominant). We reached a genetic diagnosis in 6 families (16%), 4 sporadic cases, and 2 autosomal recessive families, and we identified variants of possible pathogenic significance and compatible with the patient's phenotype in 4 additional cases (11%). Through in vitro electrophysiological studies in CHO cells, we demonstrated the pathogenic role of some new variants in potassium channel genes and evaluated in vitro the ability of molecules acting on specific channels, such as retigabine or gabapentine (KCNQ2, KCNQ3), quinidine (KCNT1), and fluoxetine (KCNC1) to revert variant-induced channel dysfunction. Notably, in most cases, the use of these drugs in patients carrying specific variants prompts a significant clinical improvement, thereby highlighting the efficacy of this approach for personalized treatment approaches.

PB1991. The mechanism and current concepts and future research direction of rare hereditary disease
White Sponge Nevus

Authors:

W. Cai; Tongji Univ. Sch. of Med., Shanghai, China

Abstract Body:

White sponge nevus (WSN) is an autosomal dominant rare hereditary disease. Keratin 4 (*KRT4*) and Keratin 13 (*KRT13*) gene mutations were involved in the WSN. In this study we will explore the pathogenesis of WSN. We recruited two WSN Chinese families, The mutations of *KRT4* and *KRT13* gene were detected by PCR and direct sequencing. The multiple alignments of *KRT13* from 28 diverse species homology analysis were performed by the ClustalW program. The *KRT13* expression was measured by Real-Time PCR and Western blot analysis. We revealed the pathological pathway of the WSN expression profile by RNA sequencing (RNA-seq). Sequencing analysis revealed two mutations of *KRT13* gene: one mutation was 332T>C (Leu111Pro). Another mutation was 340C>T (Arg114Cys). The sequence of *KRT13* was highly conserved. Real-Time PCR and Western blot analysis results show that *KRT13* expression level is lower in patient but keep almost no change in mRNA level. When treat cells with MG132, *KRT13* protein level was increased and kept almost the same in normal and patient cell. We identified two heritable mutations in the *KRT13* gene, which were associated with the development of WSN. The abnormal degradation of *KRT13* protein of WSN may probably associate with abnormal ubiquitination process. Further RNA-seq analysis suggests that the abnormal degradation of *KRT13* protein of WSN may probably associate with Keratin 7 (*KRT7*) and abnormal ubiquitination process. All the efforts may contribute to the molecular therapy for WSN. Gene-based diagnosis and gene therapy for WSN may become available in the near future while provide reference and instruction for treating other keratin associated diseases.

Mendelian Phenotypes Posters - Thursday

PB1992. The Spectrum of PLEC Sequence Variants and Related Plectinopathies Including Novel Association with Epidermolysis Bullosa Pruriginosa

Authors:

J. Uitto¹, H. Vahidnezhad², L. Youssefian¹, H. Mahmoudi³, A. Saeidian⁴; ¹Thomas Jefferson Univ, Philadelphia, PA, ²Thomas Jefferson Univ., Philadelphia, PA, ³Tehran Univ. of Med. Sci., Tehran, Iran, Tehran, Iran, Islamic Republic of, ⁴Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

Plectin, a cytoskeletal linker and intermediate filament protein ubiquitously expressed in many cell types, is encoded by PLEC. Plectin consists of three main domains that determine its functionality: the Nterminal domain, the rod domain, and the C-terminal domain. Molecular defects in PLEC correlating with the functional aspects lead to a group of rare heritable disorders, plectinopathies. These multisystem disorders include an autosomal dominant form of epidermolysis bullosa simplex (EBS-Ogna), limb girdle muscular dystrophy (LGMD), and an autosomal recessive form of epidermolysis bullosa simplex (EBS), which may associate with muscular dystrophy (EBS-MD), pyloric atresia (EBS-PA), and/or congenital myasthenic syndrome (EBS-MyS). In this study, genotyping of over 800 Iranian patients with epidermolysis bullosa by a gene-targeted sequencing panel or whole-exome sequencing identified 15 patients with disease-causing PLEC variants. Analysis of the clinical spectrum of plectinopathies in our cohort and in the literature indicated a relationship between the variant locations in PLEC and phenotypic manifestations. Most EBS-MD patients are found to have at least one variant in the central rod domain of the plectin and/or the C-terminal domain, whereas EBS, EBS-PA, and EBS-MD typically present with variants outside these domains. In addition, a novel association of a homozygous nonsense variant in PLEC was observed in a patient with EB pruriginosa, MD, and MyS. This study integrated our seven novel PLEC variants with previously published data totaling 115 variants to provide the most complete overview of pathogenic PLEC variants and related disorders.

Mendelian Phenotypes Posters - Wednesday

PB1993. Three cases of (likely) pathogenic *FGF10* variants: Examples of phenotypic variability in Lacrimoauriculodentodigital syndrome.

Authors:

M. Drost, S. Demirdas, S. Kant, M. Wessels, L. Hoefsloot; Dept. of Clinical Genetics, ErasmusMC, Rotterdam, Netherlands

Abstract Body:

Background Lacrimoauriculodentodigital syndrome (LADD) is an autosomal dominant condition caused by germline loss-of-function variants in *FGF10* or by tyrosine kinase domain variants in either *FGFR2* or *FGFR3*. The syndrome is characterized by malformed ears and deafness, various dental and digital anomalies and, specifically for *FGF10*, aplasia of the lacrimal duct and/or gland. Here we present three cases of LADD with great phenotypic variability of this syndrome.

Case presentation **Case 1.** A five-year old girl presented with an accessory auricle, conductive right-sided hearing loss and mixed left-sided hearing loss. Whole exome sequencing (WES) followed by targeted analysis of the LADD genes revealed a variant of uncertain significance, NM_004465.1(*FGF10*):c.232C>A, p.(Arg78Ser). Variant segregation was confirmed in four affected family members, with phenotypes including absence of the nasolacrimal duct and/or unilateral hearing loss. This led to reclassification of the variant to a likely pathogenic variant, confirming LADD diagnosis. **Case 2.** A 21-year old man presented with congenital defects including cholestatic liver disease and dysmorphic features including a broad forehead. WES followed by filtering for genes included in a multiple congenital anomaly panel revealed heterozygosity for two variants in the *ABCB4* gene, confirming a diagnosis of progressive familial intrahepatic cholestasis. WES also revealed a pathogenic variant of maternal origin, NM_004465.1(*FGF10*):c.55del, p.(Cys19Aafs*95). LADD diagnosis was considered an incidental finding in this case, reverse phenotyping of both index and mother revealed only minor features of LADD. **Case 3.** A 2-day old baby presented with an accessory auricle, absence of the nasolacrimal duct and severe hypoplasia of the lungs for which extracorporeal membrane oxygenation was required. The baby died after 2 months. WES followed by filtering for genes included in a multiple congenital anomaly panel revealed a pathogenic variant of paternal origin, NM_004465.1(*FGF10*):c.497C>A, p.(Ser166*). *FGF10* phenotypes combined with neonatal lethal pulmonary hypoplasia were described to be additionally associated with deletions or single-nucleotide variants involving *TBX4* (PMID 30639323), which could not be detected in this case. Absence of the nasolacrimal duct was also found in his father, and family members with LADD were only mildly affected.

Discussion We present three LADD cases with associated inter-and intrafamilial variability. Although this syndrome is inherited in an autosomal dominant fashion, its manifestation can differ greatly, stressing the need for caution in genetic counseling.

Mendelian Phenotypes Posters - Thursday

PB1994. Three new founder Bukharian Jewish mutations in *COL4A4* are causative of autosomal dominant and recessive Alport syndrome

Authors:

M. Levy¹, L. Bazak¹, L. Basel-Salmon², L. Basel-Salmon¹, I. Maya³; ¹The Raphael Recanati Genetic Inst., Rabin Med. Ctr., Petah Tikva, Israel, ²Recanati Genetic Inst., petah tikva, Israel

Abstract Body:

Introduction. *COL4A4* pathogenic variants are causative of collagen IV nephropathy or Alport syndrome, in both autosomal dominant and recessive inheritance patterns. To date, no founder pathogenic variant has been reported in this gene in the Bukharian Jewish population. **Methods.** We reviewed medical records of all individuals with suspected Alport syndrome, referred to genetic counseling in our Nephrology clinic between the years 2012-2022. The molecular basis of Alport syndrome using various molecular methods including linkage analysis, Sanger sequencing and next-generation sequencing was determined. Clinical and molecular characteristics of all families of Bukharian Jewish origin were recorded. **Results.** Molecular diagnosis was confirmed in 20/38 (52.6%) patients and 12/22 (54.5%) families of Bukharian Jewish origin. 20 patients were molecularly diagnosed, with at least one of the following three disease-causing *COL4A4* variants: c.871-6T>C, c.338G<A (p.Gly113Asp) or c.3022G>A (p.Gly1008Arg) was detected. two were obligate carriers. 16 patients were found to be heterozygous, and 6 patients were homozygous or compound heterozygous. Each one of the three variants was detected in more than one unrelated family. At the time of referral to our clinic, all patients had hematuria. Proteinuria has been seen at the earliest age in homozygotes for c.3022G>A variant. End-stage renal disease was diagnosed in one patient at the age of 38 years who was found to be compound heterozygous. Hearing deterioration was detected in 3/8 patients heterozygote for c. 338 G<A variant and appeared as early as the age of 40 years. In our local database, the frequency of the three variants was 1:22 to 1:111. All three variants were classified by all the laboratories performing the analysis and by variant classification tools as variants of uncertain significance (VUS) according to the ACMG guidelines. **Conclusion.** Our results show that currently three VUSs c.3022G>A, c.871-6T>C, and c.338G>A in *COL4A4* gene are common among Jews of Bukharian ancestry and cause Alport syndrome in both dominant and recessive inheritance patterns

Mendelian Phenotypes Posters - Wednesday

PB1995. TMEM161B mediates radial glial scaffolding in neocortical development

Authors:

L. Wang¹, J. Gleeson²; ¹UCSD, San Diego, CA, ²Univ California, La Jolla, CA

Abstract Body:

TMEM161B encodes an evolutionarily conserved widely expressed novel 8-pass transmembrane protein of unknown function in human. Here we identify *TMEM161B* homozygous hypomorphic missense variants in our recessive polymicrogyria cohort. Patients carrying *TMEM161B* mutations exhibit striking neocortical polymicrogyria and intellectual disability. *Tmem161b* knockout mice fail to develop midline hemispheric cleavage, whereas knock-in of patient mutations and patient-derived brain organoids show defects in apical cell polarity and radial glial scaffolding. We found that TMEM161B mediates actin filopodia, functioning upstream of the Rho-GTPase CDC42. Our data reveals the function of TMEM161B in apical polarity regulating radial glial scaffold formation during neocortical development.

Mendelian Phenotypes Posters - Thursday

PB1996*. Toward precision medicine in Neurodevelopmental disability: identifying phenotypic differences in individuals with global developmental delay.

Authors:

T. Cuppens¹, J. Shatto², A-H. Ng², A. Kumar³, M. Leclercq⁴, B. Finlay⁵, J. Zwicker⁵, I. Dunham⁶, A. Droit¹, F. Bolduc⁷; ¹Ctr. de recherche du CHU de Québec - Université Laval, Québec, QC, Canada, ²Univ. of Alberta, Dept. of Pediatrics Neurology, Edmonton, AB, Canada, ³EMBL-EBI, Cambridge, United Kingdom, ⁴Ctr. de recherche du CHU de Québec - Université Laval, Québec, QC, Canada, ⁵Univ. of Calgary, Sch. of Publ. Policy, Calgary, AB, Canada, ⁶European Bioinformatics Inst., Open target and European Molecular Biology Lab., Cambridge, United Kingdom, ⁷Univ Alberta, Edmonton, AB, Canada

Abstract Body:

Introduction: Global developmental delay (GDD) is a neurodevelopmental disorder (NDD) subtype that is often diagnosed at an early age and has a prevalence of up to 3%. Many clinical presentations have been described so far, but mostly in case reports and not on a large scale. The influence of age and sex on the clinical presentation of individuals with GDD has therefore never been described. This limits our ability to take advantage of precision medicine.

Objective: We were interested in determining the most common symptoms, clinical signs, and genes in individuals with GDD, both in the overall cohort and sorted by age and sex.

Methods: Using the largest cohort of individuals with GDD, Deciphering Developmental Disorders (DDD), characterized by a systematic approach, we extracted phenotypic information from 6588 individuals with GDD. We analyzed variability in phenotypic presentation using statistical analysis to identify significant variation based on age and sex.

Results: We observed that some GDD-related phenotypes were more prevalent than others, such as autistic behavior, lack of speech, seizures, strabismus, and constipation. Subsequently, we found significant differences in expressed neurodevelopmental, dysmorphic, neurological, and general phenotypes between different age groups and with sex. For example, at preschool age the prevalence of seizures is lower than in adulthood, increasing from 9.11% to 24.91%. We observed regarding sex, males with GDD had a significantly higher prevalence of autistic traits and autism diagnosis. Microcephaly was more present in females with GDD while macrocephaly was more frequent in males.

Implications: Our study highlights the importance of dissecting phenotypes from large cohort databases to better understand the relationships between phenotype, age, and sex of individuals with GDD in order to develop specific interventions. Indeed, although clinically well-defined, GDD represents a broad spectrum of possible phenotypic manifestations. This study allows us to identify the most common phenotypes, and specific phenotypes according to the patient's age and sex. We hope that our results will prove useful in guiding both clinical practice and the design of future clinical trials for individuals with GDD.

Mendelian Phenotypes Posters - Wednesday

PB1997. Transcriptional response of *Fundulus heteroclitus* embryos exposed to carbaryl

Authors:

O. Torano¹, W. Huang¹, D. Bencic¹, R. Flick¹, B. Clark², A. Biales¹; ¹US Environmental Protection Agency, Durham, NC, ²US Environmental Protection Agency, Narragansett, RI

Abstract Body:

Carbaryl is an acetylcholinesterase inhibitor widely used for pest management in agriculture and landscaping. The breadth and volume of carbaryl use results in frequent contamination of aquatic environments and subsequent aquatic organism exposures. In-vitro studies have demonstrated carbaryl to be acutely toxic with developmental effects on exposed fishes at different life stages. To better understand the molecular responses underlying known adverse outcomes, mRNA-seq was employed to assess the transcriptional response of embryonic *Fundulus heteroclitus* exposed to carbaryl at three different concentrations (100, 1000, and 10,000 µg/L). Embryos (n=20) were exposed to a single dose of carbaryl and allowed to grow for seven days after which they were transferred to clean water and grown an additional three days before samples were collected. The highest-dose exposure was prematurely terminated due to embryo death before the conclusion of the experiment and these embryos were not processed for mRNA analysis. RNA-seq analysis using STAR and RSEM showed that low and medium carbaryl exposures resulted in few differentially expressed genes or isoforms compared to untreated control at a 5% FDR cutoff. However, the Ingenuity Pathway Analysis of top-ranked genes showed significant enrichment of cancer, organismal injury and abnormality, and endocrine system disorder-related genes, and results were consistent between the low and medium doses. In summary, the results suggest that carbaryl may have little or no lasting effects on *F. heteroclitus* at the low and medium doses, though the immediate response is not clear and high-dose exposure is lethal. The lack of response in expression to the low- or medium- dose exposure, but acute toxicity at the high-dose may result from narrow timing of gene expression response and a steep dose-response curve to increasing toxicant concentration.

Mendelian Phenotypes Posters - Thursday

PB1998. Translated mutant *DSPP* mRNA expression level impacts the severity of dentin defects.

Authors:

J-W. Kim¹, Y. Kim¹, Y. Lee¹, H. Zhang², F. Seymen³, M. Koruyucu⁴, S. Bayrak⁵, N. Tuloglu⁵, J. Simmer², J. Hu²; ¹Seoul Natl. Univ. Sch. of Dentistry, Seoul, Korea, Republic of, ²Univ. of Michigan, Ann Arbor, MI, ³Altinbas Univ., Istanbul, Turkey, ⁴Istanbul Univ., Istanbul, Turkey, ⁵Private Practice, Eskisehir, Turkey

Abstract Body:

Hereditary dentin defects are conventionally classified into three types of dentinogenesis imperfecta (DGI) and two types of dentin dysplasia (DD). Mutations in the dentin sialophosphoprotein (*DSPP*) gene have been identified to cause DGI type II, III and DD type II; therefore, these are not three different conditions but allelic disorders. In this study, we recruited three families with varying clinical phenotypes from DGI-III to DD-II and performed mutational analysis by candidate gene analysis or whole exome sequencing. Three novel mutations including a silent mutation (NM_014208.3: c.52-2del, c.135+1G>C and c.135G>A; p.(Gln45=)) were identified, all of which affected pre-mRNA splicing. Comparison of the splicing assay results revealed that the expression level of *DSPP* exon 3 deletion transcript correlated with the severity of the dentin defects. This study did not only expand the mutational spectrum of *DSPP* gene but also advanced our understanding of the molecular pathogenesis impacting the severity of hereditary dentin defects.

Mendelian Phenotypes Posters - Wednesday

PB1999. Truncating variants in *RFC1* cause cerebellar ataxia, neuropathy vestibular areflexia syndrome (CANVAS).

Authors:

S. Das¹, R. Ronco², C. Perini³, R. Curro², N. Dominik², A. Gary¹, M. Delfeld¹, P. Kandikatla¹, J. Chen⁴, C. Gomez¹, J. D. Schmahmann⁴, D. Gosal⁵, H. Houlden², A. Cortese²; ¹Univ. of Chicago, Chicago, IL, ²UCL Queen Square Inst. of Neurology, London, United Kingdom, ³Inst. of Molecular Genetics IGM-CNR "Luigi Luca Cavalli-Sforza", Pavia, Italy, ⁴Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, ⁵Manchester Ctr. for Clinical NeuroSci.s, Salford Royal Hosp., Manchester, United Kingdom

Abstract Body:

Cerebellar Ataxia, Neuropathy and Vestibular Areflexia Syndrome (CANVAS) is an autosomal recessive neurodegenerative disease characterized by adult onset and slowly progressive sensory neuropathy, cerebellar dysfunction, and vestibular impairment. The genetic basis of the disorder has recently been identified to be due to a common biallelic (AAGGG)_n repeat expansion in the second intron of the Replication Factor Complex subunit 1 (*RFC1*). A large percentage of patients with a diagnosis of CANVAS have been shown to have biallelic (AAGGG)_n repeat expansions in the *RFC1* gene. However, a small number of cases with typical CANVAS do not carry the common biallelic repeat expansion. We set out to determine the genetic basis of CANVAS patients who do not harbor the biallelic repeat expansion in *RFC1*. Fifteen individuals diagnosed with CANVAS and carrying only one heterozygous (AAGGG)_n expansion in *RFC1* were selected to test for the presence of a second variant in *RFC1* by either whole genome sequencing or exome sequencing. A truncating variant in the *RFC1* gene was identified in seven patients from five unrelated families with clinically defined CANVAS carrying a heterozygous (AAGGG)_n expansion, which included: c.1267C>T (p.Arg423Ter), c.1739_1740del (p.Lys580SerfsTer9), c.2191del (p.Gly731GlufsTer6) and c.2876del (p.Pro959GlnfsTer24). The truncating variant was identified to be present in *trans* with the (AAGGG)_n expansion in all cases. Patient fibroblasts containing the c.1267C>T (p.Arg423Ter) or c.2191del (p.Gly731GlufsTer6) variants demonstrated nonsense-mediated mRNA decay and reduced RFC1 transcript and protein. This is the first description of truncating variants in the *RFC1* gene in patients with CANVAS and our result expands the genotype spectrum of *RFC1* disease. Full *RFC1* sequencing is recommended in cases affected by typical CANVAS and carrying monoallelic (AAGGG)_n expansions. Our results also shed further light on the pathogenesis of *RFC1* CANVAS as it supports the existence of a loss of function mechanism underlying this complex neurodegenerative condition.

Mendelian Phenotypes Posters - Thursday

PB2000. Tumor burden among members of the DiscovEHR cohort harboring deleterious constitutive variants in *NF1*

Authors:

A. Pemov¹, J. Kim², J. S. Haley³, H. Rao⁴, DiscovEHR Collaboration, D. J. Carey⁵, D. R. Stewart⁶; ¹NIH, NCI, Rockville, MD, ²Natl. Cancer Inst., Rockville, MD, ³Geisinger, Danville, PA, ⁴Geisinger, Danville, PA, ⁵Geisinger Clinic, Danville, PA, ⁶Natl. Cancer Inst., ROCKVILLE, MD

Abstract Body:

Background. Large-scale exome sequencing linked to electronic health records (EHR) and broad ascertainment of participants' clinical phenotypes provides a unique opportunity to investigate genotype-phenotype correlations, improve the estimates of prevalence and penetrance of Mendelian disorders, and ultimately, advance disease prognosis, risk stratification and care for patients. **Methods.** Utilizing a genome-first approach, we examined exomes of 175,449 participants from the DiscovEHR cohort and identified deleterious variants in *NF1*, the causative gene in neurofibromatosis type 1 (NF1). We identified carriers of pathogenic/likely pathogenic (P/LP) variants classified by either ClinVar or InterVar. Additionally, we identified and included all remaining loss-of-function (LoF) variants and large intragenic *NF1* deletions (CNVs) in the analysis. We then examined EHR and tumor registry records for the participants carrying these variants. **Results.** Out of 175,449 participants, we identified 124 who carried P/LP ClinVar/InterVar variants, and 17 who carried large deletions in *NF1*. Thus, the prevalence of *NF1* deleterious variant carriers in this cohort was 1:1,243. Of these 141 carriers, 39 belonged to 19 multiplex pedigrees, with ³2 family members per pedigree sharing a deleterious *NF1* variant. There were 80 participants in the entire cohort, diagnosed with neurofibromatosis type 1 (1:2,193); 58 of them (72.5%) carried a deleterious variant in *NF1*, including 44 P/LP ClinVar, 9 P/LP InterVar and 5 intragenic CNVs. The odds ratio (OR) for association of the NF1 diagnosis with the carrier status of a deleterious *NF1* variant was 5,568 (p-value<10⁻⁵ by Fisher's exact test). As anticipated, we identified elevated ORs for the following malignancies commonly observed in NF1 patients: "peripheral nerves and autonomic nervous system" (OR=381, p-value<10⁻⁵); "spinal cord, cranial nerves and other parts of central nervous system" (OR=46, p-value=10⁻³); "adrenal gland" (OR=33, p-value=10⁻⁴); and "neoplasm of brain" (OR=11, p-value=7x10⁻⁴). For the analysis of blood neoplasms, for which association with NF1 is not well-established, we combined *NF1*-carriers (13/141) and compared them to non-carriers (7,077/175,308) diagnosed with this type of tumors (OR=2.41, p-value=0.008). **Conclusions.** By utilizing a genome-first approach in the DiscovEHR cohort, we confirmed existing tumor associations with NF1 and identified potential novel risks for neoplasms in NF1 patients. Our findings will aid in the disease prognosis, risk stratification and care for the patients.

Mendelian Phenotypes Posters - Wednesday

PB2001. Two novel compound heterozygous variants identified in a new case of classic Donohue syndrome and literature review

Authors:

H. Wang, C. Grossheim, S. Ramanathan, R. Clark; Loma Linda Univ. Sch. of Med., Loma Linda, CA

Abstract Body:

INTRODUCTION: Donohue syndrome (DS, Leprechaunism) is an extremely rare, autosomal recessive disorder caused by a functional defect in insulin receptor (INSR). It is characterized by severe insulin resistance and distinctive facial features. Limited cases have been reported. Here we report a new case with two novel compound heterozygous variants in INSR gene. **CASE DESCRIPTION:** A 48-day old, 36w5d gestation male born vaginally with SGA, coarse features, large nipples, umbilical hernia/mass, large scrotal sac, abdominal distention, and hypoglycemia, transferred from outside hospital. Mother, a G3P2012 ethnically Asian woman, with pregnancy was complicated by gestational diabetes and IUGR. The birth weight was 1450 g (<3rd%ile), length 40.5 cm (<3rd %ile), HC 32 cm (21st %ile). Family history was significant for a previous pregnancy termination for severe IUGR with concern for skeletal dysplasia at 25 weeks' gestation. Consanguinity was denied. Physical exam showed emaciated dysmorphic infant, coarse facies, bulging eyes, thick eyelids, proptosis, infraorbital creases, low set ears with thick and overfolded helices superiorly, broad nose with anteverted nares, open mouth with thick patulous lips, gingival hypertrophy, mild micrognathia, prominent nipples with small white cyst on each nipple, distended abdomen, hypertrichosis and decreased subcutaneous tissue. Echo showed mild dilatation and mild hypertrophy of the right ventricle. Abdominal ultrasound showed early medullary nephrocalcinosis. Chromosome microarray was normal. The clinical picture was consistent with classic Donohue syndrome. *INSR* gene analysis detected two novel variants: c.3792_3793dup (p. Val1265Glufs*16) and c.344_348delinsCCTTG (p. Phe115_Phe116delinsSerLeu) that had not been previously reported. Parental testing revealed biparental inheritance of the variants. The laboratory updated the two variants to likely pathogenic. Therapy with IGF was discussed and patient was transferred to another hospital. **DISCUSSION:** DS has an incidence of 1 in 4 million live births but this may be underreported. Currently 87 variants of the insulin receptor gene in DS have been reported in ClinVar, of which only 19 variants have been classified as pathogenic. This infant has classic features of DS, with two novel compound heterozygous likely pathogenic variants. There is no effective treatment, postprandial hyperglycemia does not respond to insulin or metformin in DS. When hyperglycemia persists, high dose insulin may be needed. Cardiomyopathy can be treated with beta blockers. Recombinant human IGF-1 is being studied; its effectiveness is unclear.

Mendelian Phenotypes Posters - Wednesday

PB2002. Understanding the role of *TTC5* in the developing mouse brain: A novel null *TTC5* mouse model.

Authors:

R. Rushforth^{1,2}, R. Stottmann^{1,2}; ¹Nationwide Children's Hosp., Columbus, OH, ²The Ohio State Univ., Columbus, OH

Abstract Body:

Tubulin autoregulation is a long-known, but poorly understood phenomenon. This is the process regulating tubulin mRNA degradation in direct relation to the amount of tubulin protein in the cell. A recent study proposed that the tetratricopeptide 5 (*TTC5*) gene has a role in mediating tubulin autoregulation with the *TTC5* protein binding the amino terminus of tubulin peptides immediately upon exit from the ribosome. Additionally, eight patients with variants in the *TTC5* gene have been previously identified with a spectrum of shared clinical neurodevelopmental phenotypes including moderate to severe intellectual disability, simplified gyral patterns, and mild ventriculomegaly. One additional patient with bi-allelic variants in *TTC5* has been reported to have a brain malformation resembling a tubulinopathy. Literature describing *TTC5* is limited, and no studies have been done to look at the role of *TTC5* in development. There is no known *in vivo* experimental model. Here we report on a novel *TTC5* null mouse generated in our lab. This mouse contains a ~ 800 bp deletion in the *TTC5* gene, resulting in a total null allele. Homozygous null mutants experience 100% perinatal lethality ~ 24 hours after birth. Structural examination of null embryonic day 18.5 (E18.5) brains show multiple phenotypes including periventricular heterotopia and hippocampal malformations. We therefore hypothesize that total loss of *TTC5* leads to defects in neuronal migration in the developing mouse brain. Further studies are being conducted to understand the molecular mechanism(s) underlying the neuronal migration pattern in *TTC5* null mice. As *TTC5* has been reported to have a role in tubulin autoregulation, and at least one patient presents with a bi-allelic *TTC5* mutation representing a tubulinopathy, we plan to examine the relationship between tubulin and our null mouse model. Using a set of novel epitope tagged alleles of tubulin genes in our lab, we can query multiple loci to understand how loss of *TTC5* specifically affects protein levels of TUBA1A, TUBA1B, TUBA1C, TUBB2A, and TUBB2B. We plan to investigate the relationship between these tubulins and *TTC5* via Western blot analysis as this will provide insight into the proposed cellular relationship between tubulin and *TTC5* in an *in vivo* model.

Mendelian Phenotypes Posters - Thursday

PB2003. Using artificial intelligence driven NGS re-analyses followed by full genome profiling (HiFi-GS) for unsolved pediatric white matter disorders

Authors:

I. Thiffault¹, E. Farrow¹, A. S. A. Cohen¹, T. Zion¹, E. C. Boillat¹, J. J. Johnston¹, S. Younger¹, J. Meas¹, W. Cheung², S. Fournier³, S. Perrier³, T. Truong⁴, G. Evrony⁴, G. Bernard³, T. Pastinen¹; ¹Children's Mercy, Kansas City, MO, ²Children's Mercy, Kansas City, KS, ³Res. Inst. of the McGill Univ. Hlth.Ctr., Montreal, QC, Canada, ⁴New York Univ. Grossman Sch. of Med., New York, NY

Abstract Body:

Leukoencephalopathies are a group of heterogeneous genetic diseases leading to progressive disabilities and often associated with poor prognosis. Collectively, their incidence is ~ 1:7500 births. Although some subtypes of white matter disease (WM) have a high (>70%) diagnostic rate by short-read exome (srES), other forms with more complex presentation (neuro+) remain mostly unsolved even by short-read genome sequencing (srGS). Beyond increased diagnostic yield by AI-driven reanalyses, we hypothesize that variations in “srES/srGS blindspots” (repeat expansions, structural variants (SV), intronic/regulatory variants) account for missed molecular diagnoses. Such variations can be detected by Long-read GS using PacBio Sequel IIe (HiFi-GS). Furthermore, HiFi-GS can be utilized for interrogation of non-coding/regulatory variation via methylation detection as well as RNA (HiFi-IsoSeq) and can overcome limitations of reference genomes by *de novo* assembly. **Methods:** In the context of a collaborative genomic medicine program “Genomic Answers for Kids” with >3800 families with suspected genetic disorders; we have developed one of the largest HiFi-GS data resources by integrating an enhanced HiFi-GS workflow for unsolved pediatric cases (> 1000 samples). We recently demonstrated incorporating SVs accounted for 13% of diagnostic yield. To determine the utility of HiFi-GS in WM diseases, we established a cohort of ~270 patients. All patients entering the program have had srES/srGS performed. Prior deploying HiFi-GS, existing srES/srGS data are systematically reanalyzed by AI-driven methods. **Preliminary results:** As previously reported, subtypes of WM (i.e., hypomyelinating, mitochondrial or metabolic) have a high (70%) diagnostic rate versus neuro+ (22%). In neuro+, we have blended phenotypes among patients with dual diagnoses (8%) and a higher rate of gene discovery (18%). For non-trio cases, if VUS(s) detected by srES/srGS are confirmed *de novo* or *in trans* configuration, the genotype would be diagnostic (18%). As examples of HiFi-GS utility in WM, we solved three unrelated patients by identifying pathogenic variants; *CEP85L* (p.M1?), *TUBB2A* (p.R306H) and a deletion in *AARS2*. These variants were undetected by srES/srGS due to poor coverage or misalignment of homologous sequences. We also identified a private hypermethylated “GCC” expansion in a non-OMIM gene. **Discussion:** We are pursuing full genome profiling of unsolved WM cases by leveraging HiFi-GS, *de novo* assembly, methylation and IsoSeq. Moreover, we are validating the findings in patient derived cells (iPSCs) to systematically study impact in RNA or myelination (oligodendrocytes).

Mendelian Phenotypes Posters - Thursday

PB2004. Using genetic relatedness within biobanks to understand genetic architecture of Retinitis Pigmentosa

Authors:

J. Baker¹, H-H. Chen^{2,3}, M. A. Brantley, Jr.^{4,2}, J. E. Below^{2,3}, D. C. Samuels^{5,6}; ¹Vanderbilt Univ., Nashville, TN, ²Vanderbilt Univ. Med. Ctr., Nashville, TN, ³Vanderbilt Genetics Inst., Nashville, TN, ⁴Vanderbilt Eye Inst., Nashville, TN, ⁵Vanderbilt Univ. Sch. of Med., Nashville, TN, ⁶Dept. of Molecular Physiology & Biophysics, Nashville, TN

Abstract Body:

Background: Retinitis Pigmentosa (RP) is a group of inherited eye diseases that cause progressive degeneration of the rod and cone cells in the retina ultimately leading to vision loss. The genetic architecture of RP has been well characterized with pathogenic mutations identified in more than 100 genes with approximately 10% of these variants falling within the *RHO* gene. Despite the well described genetics of RP and the availability of comprehensive genetic testing, only about 60% of RP cases can be definitively explained by a causal variant. Large biobanks can provide greater insight into this lack of causality, allowing researchers to leverage genetic relatedness and electronic health records (EHR) to identify likely carriers of causal rare variants without the need for large-scale sequencing efforts through detection of genomic segments shared identically-by-descent (IBD) due to recent common ancestry. **Methods and Results:** Pairwise IBD segments longer than 3cM were identified using hap-IBD for 69,819 individuals of European ancestry in Vanderbilt University's biobank, BioVU. We constructed networks of individuals that shared an IBD segment overlapping the *RHO* locus. 16,997 networks were identified using this approach. We identified a cluster enriched for diagnosed RP ($p=1.3e-8$) where 4 of 10 individuals were diagnosed in the EHR as having RP. The individuals in this cluster had a mean age of 51.8 years. To identify potentially causal variants, these 10 individuals were whole exome sequenced and the sequencing results were annotated using wANNOVAR. All 10 individuals were confirmed as carrying a reported pathogenic, autosomal dominant, Pro23His variant, chr3:129528801-C-A within the *RHO* locus. **Conclusions:** Only 4 of the 10 individuals are diagnosed with RP in the EHR suggesting that the variant may exhibit incomplete or age-related penetrance rather than the reported autosomal dominance. Another interpretation of these results is that these individuals may not yet have been diagnosed as having RP due to mild symptoms or they may have been diagnosed outside of Vanderbilt's health system. These results highlight the power of this analysis pipeline for rare variant carrier discovery and assessment of variant effects, with implications for precision medicine and prevention. Our approach affordably and efficiently identifies carriers of Mendelian disease variants in health systems prior to disease onset and in the absence of clinical family history data.

Mendelian Phenotypes Posters - Wednesday

PB2005. Using remote methods to assess communication in Phelan-McDermid Syndrome.

Authors:

S. Quadri Valverde¹, J. Klusek², L. Ward¹, K. Phelan³, C. Rogers⁴, N. Powers⁵, L. Boccutto⁶, S. M. Sarasua¹; ¹Clemson Univ., Clemson, SC, ²Univ. of South Carolina, Columbia, SC, ³Florida Cancer Specialists, Fort Myers, FL, ⁴Greenwood Genetic Ctr., Greenwood, SC, ⁵Prisma Hlth., Greenville, SC, ⁶Clemson Univ., GREENWOOD, SC

Abstract Body:

Phelan-McDermid Syndrome (PMS) is a rare genetic disorder caused by deletions involving the distal long arm of chromosome 22 or by pathogenic variants of the *SHANK3* gene localized to 22q13.3. Although individuals with PMS have reduced speech and language abilities, little research has been directed at profiling the communication abilities in this population. Typical communication assessments require in-person evaluations by speech language pathologists (SLPs) which often requires burdensome or prohibitive travel by patients and their families to centralized research centers. Further, clinical evaluation teams rarely include SLPs and thus omit this critical area or rely on over simplified or proxy measures. The objectives of the present study are threefold. The first is to identify the language and communication profile of school-aged children with PMS using a combination of standardized assessments and semi-formal measures such as direct observation and language sampling by a SLP. A second objective is to identify the genetic contributions to the language and communication profile in individuals with PMS. The final objective is to determine the feasibility of remote data collection for research purposes. The remote aspect of this study is a unique feature that will support increased accessibility to participate in studies for families who do not have sufficient funds to finance travel to a testing site or for vulnerable patient populations considering the COVID-19 pandemic. The methods included recruitment of participants facilitated by the Phelan-McDermid Syndrome Foundation (PMSF) with enrollment of up to 20 school-aged children with PMS. Children and their parents participated in research activities remotely using a video-conferencing platform and mail-in saliva samples. Caregivers were asked to independently complete standardized measures of adaptive behavior and social communication abilities. Direct evaluations were remotely conducted across one to two sessions based on family needs. A SLP observed a ten-minute subject-caregiver interaction to collect a language sample and identify nonverbal expressive/receptive and pragmatic communicative functions, followed by formal standardized assessments. The communication profile was correlated with existing genomic data. We will present our findings on remote data collection methods along with preliminary language assessment outcomes. The results of this pilot study demonstrating the efficacy of our methods to assess communication in PMS may be helpful for future evaluations of individuals with PMS as well as others with genetic disorders involving speech-language phenotypes.

Mendelian Phenotypes Posters - Wednesday

PB2006. Variable expressivity in a four-generation ACDMPV family with a noncoding hypermorphic SNV in *trans* to the frameshifting *FOXF1* variant

Authors:

P. Stankiewicz¹, J. A. Karolak², P. Szafranski¹, T. Gambin³, A. Matsika⁴, S. Mcmanus⁴, H. S. Scott^{5,6,7,8,9}, P. Arts⁵, T. Ha^{5,7}, C. P. Barnett^{10,11}, J. Rodgers^{12,13}, E. Yildiz Bolukbasi¹; ¹Dept. of Molecular & Human Genetics, Baylor Coll. of Med., Houston, TX, ²Chair and Dept. of Genetics and Pharmaceutical Microbiol., Poznan Univ. of Med. Sci., Poznan, Poland, ³Inst. of Computer Sci., Warsaw Univ. of Technology, Warsaw, Poland, ⁴Mater Pathology, Mater Hlth., South Brisbane, Australia, ⁵Dept. of Genetics and Molecular Pathology, Ctr. for Cancer Biology, An alliance between SA Pathology and the Univ. of South Australia, Adelaide, Australia, ⁶UniSA Clinical and Hlth.Sci., Univ. of South Australia, Adelaide, Australia, ⁷ACRF Genomics Facility, Ctr. for Cancer Biology, An alliance between SA Pathology and the Univ. of South Australia, Adelaide, Australia, ⁸Dept. of Genetics and Molecular Pathology, SA Pathology, Adelaide, Australia, ⁹Australian Genomics, Melbourne, Australia, ¹⁰Adelaide Med. Sch., Univ. of Adelaide, Adelaide, Australia, ¹¹Paediatric and Reproductive Genetics Unit, South Australian Clinical Genetics Service, Women's and Children's Hosp., North Adelaide, Australia, ¹²Genetic Hlth. Queensland, Royal Brisbane and Women's Hosp., Brisbane, Australia, ¹³Sch. of Med., The Univ. of Queensland, Brisbane, Australia

Abstract Body:

Heterozygous single nucleotide variants (SNVs) or copy-number variant (CNV) deletions involving *FOXF1* or its distant lung-specific enhancer on chromosome 16q24.1 have been identified in 80-90% of patients with Alveolar capillary dysplasia with misalignment of pulmonary veins (ACDMPV), a lethal neonatal lung developmental disorder. Recently, we showed that rare non-coding regulatory hypermorphic SNVs within the *FOXF1* enhancer on the non-deleted/mutated allele of *FOXF1* (in *trans*) may prevent ACDMPV lethality (PMID: 31686214). Here, we describe a four-generation family with a deceased ACDMPV neonate, her sibling from the electively terminated pregnancy, healthy mother with a history of pulmonary arterial hypertension (PAH), an unaffected aunt, an aunt deceased due to findings consistent with ACDMPV, and a reportedly unaffected grandmother, all with the frameshifting variant c.881_902dup (p.Gly302Profs*46) in *FOXF1*, and a deceased great-grandmother with a history of PAH. Genome sequencing analyses in the proband's unaffected mother revealed a non-coding putative regulatory SNV rs560517434-A within the lung-specific distant *FOXF1* enhancer in *trans* to the *FOXF1* frameshift variant. Functional testing of the rs560517434-A variant using an *in vitro* luciferase reporter assay showed that it increases *FOXF1* promoter activity 10-fold. Our studies further demonstrate that non-coding SNVs in the *FOXF1* enhancer region can rescue the lethal ACDMPV phenotype and support the compound inheritance gene dosage (CIGD) model.

Complex, Lahore, Pakistan, ¹⁵Auditory Dev. and Restoration Program, Natl. Inst. on Deafness and Other Communication Disorders, Bethesda, MD, ¹⁶NIDCD/NIH, Bethesda, MD

Abstract Body:

Deafness and retinal dystrophy are clinically variable and genetically heterogeneous phenotypes. Usher syndrome (USH) is a common cause of deaf-blindness and can be associated with biallelic variants of *MYO7A*, *USH1C*, *CDH23*, *PCDH15*, *SANS*, *USH2A*, *ADGRV1*, *WHRN*, *CLRN1* or *ARSG*. Two small unrelated families segregating deaf-blindness were screened using exome sequencing (ES). However, no pathogenic variants of these genes were detected in affected individuals from these families. In one proband we identified compound heterozygous variants of low-density lipoprotein receptor-related protein 2, *LRP2*, p.(Thr50Ser) and p.(Asn1669Asp). In two deaf-blind sisters of the second family, ES revealed compound heterozygous *LRP2* variants, p.(Tyr3933Cys) and a c.7715+3A>T, which we experimentally confirmed as a splice altering variant. In mouse cochlea, *Lrp2* is expressed most abundantly in stria vascularis marginal cells as shown by smFISH, single-cell RNAseq and single-nucleus RNAseq analyses. These data suggest that a *LRP2* deficiency compromises the endocochlear potential, which facilitates hearing. Damaging *LRP2* variants have been associated with Donnai-Barrow syndrome and other multisystem, highly pleiotropic phenotypes different from the two deaf-blindness phenotypes reported here. Biallelic variants of *LRP2* should be considered in cases with a deaf-blindness phenotype, when a panel of common USH genes does not provide a molecular genetic diagnosis.

Mendelian Phenotypes Posters - Wednesday

Abstract Body:

Introduction: Vici Syndrome (OMIM #242840) is a severe, rare neurodevelopmental disorder with multi-systemic manifestations presenting in infancy, and characterized by agenesis of the corpus callosum, hair and skin hypopigmentation and bilateral cataracts. Additional features include global developmental delay, seizures, progressive microcephaly, failure to thrive, cardiomyopathy and varying degrees of immunodeficiency. First described by Dionisi-Vici and colleagues in 1988, Vici syndrome has been described in less than a hundred individuals worldwide. It is caused by biallelic variants in *EPG5*, resulting in impaired autophagy. *Objective and Methods:* We aimed to characterize the clinical and molecular findings in a series of individuals harboring biallelic *EPG5* variants, recruited from four medical centers in Israel. We further sought to assess the prevalence of the c.1007A>G variant, suggested to be a founder mutation among the Ashkenazi-Jewish population, as well as to utilize a machine learning-based tool to assess facial features typical of Vici syndrome. *Results:* Five previously unreported cases of Vici Syndrome, one of which was diagnosed prenatally with subsequent termination of pregnancy, and a sixth previously-published case, were recruited. Among these four unrelated families, a total of four variants were detected in *EPG5*: two novel variants, c.2554-5A>G and c.1461delC, each considered likely pathogenic; and 2 previously reported variants, c.3447G>A and c.1007A>G, the latter suggested to be an Ashkenazi-Jewish founder mutation. In order to evaluate the carrier rate of the c.1007A>G variant, Next Generation Sequencing (NGS)-based testing was carried out amongst 140,491 individuals from diverse Jewish populations who enrolled in the Dor Yesharim pre-marriage screening program between 2016 and 2021. Of these, 508 carriers were identified, yielding an overall carrier frequency of 0.36% (1 in 276), and a carrier rate of 0.45% (1 in 224) in Ashkenazi Jewish individuals. Finally, based on two-dimensional facial photographs of individuals with Vici syndrome (n=19), a composite facial mask was created using the DeepGestalt algorithm, illustrating facial features typical to the disorder. *Conclusions:* We report a case series of five individuals from four unrelated families, and an additional aborted fetus, affected with Vici syndrome. Our findings contribute to the current knowledge

ASHG 2022 Annual Meeting Poster Abstracts

regarding the molecular basis and phenotypic features of Vici syndrome. Additionally, the deep learning-based facial gestalt adds to the clinician's diagnostic toolbox and may aid in facilitating identification of additional affected individuals.

Mendelian Phenotypes Posters - Thursday

PB2009. Whole exome sequencing identifies novel variants in familial myoclonic epilepsy in Mali.

Authors:

S. Bamba¹, M. Dembele¹, L. Sidibé², W. Ji³, S. Diarra^{4,5}, A. Yalcouyé¹, S. Diallo⁶, A. Maiga¹, O. Traoré¹, C. Guinto¹, G. Landouré¹, S. Lakhani³, The H3Africa Consortium; ¹Univ. of Sci., Techniques and Technologies of Bamako, Bamako, Mali, ²Service de Pédiatrie, CHU Gabriel Touré, Bamako, Mali, ³Yale Univ., New Haven, CT, ⁴NIH, ROCKVILLE, MD, ⁵Pediatric Genomics Discovery Program (PGDP), Yale school of Medecine, New Haven, CT, New Haven, CT, ⁶Service de Neurologie, CHU Gabriel Touré, Bamako, Bamako, Mali

Abstract Body:

Introduction Progressive myoclonus epilepsies (PMEs) are a group of rare hereditary neurological disorders characterized by the recurrent myoclonus seizures, and a progressive neurological and cognitive decline. Several clinical entities and genes are reported worldwide, mostly in population with Caucasian ancestry. However, genetically diagnosed cases are scarce in sub-Saharan African population. Only one case of Lafora disease caused by a novel variant in the *NHLRC1* gene was previously identified in Mali. In this study, we used whole exome sequencing (WES) to identify genetic causes of PME in the Malian population. **Objective:** To clinically characterize patients with PME and identify the underlying genetic defects. **Methods:** Institutional ethical approval was obtained. Proband and their families have been enrolled after an informed written consent. Patients undergone a carefully clinical examination by neurologists, neurogeneticist and pediatrician. Blood chemistries and electroencephalography were performed. DNA was extracted from peripheral blood for WES. Several bioinformatics tools were used to assess deleteriousness of the variants and putative variants were confirmed with Sanger sequencing in all available family members. **Results:** Five patients (4 males and 1 female) from three unrelated families were enrolled. Consanguinity was reported in one family and inheritance pattern was consistent with autosomal recessive in two families and autosomal dominant in one family. Disease started in their first decade and the mean age at diagnosis was 6 years (ranging from one month to 30 years). All patients had myoclonus and tonic and clonic seizures. Furthermore, three different patients presented additional symptoms including a spasm with flexion of upper limbs and a psychological and motor delay. Phenotypes suggested a case of severe neonatal myoclonic epilepsy, dominant adult familial myoclonic epilepsy and Lafora disease, in the respective families. WES identified a novel homozygous missense variant located in the *GRIN1* gene (c.T1703C; p.Leu568Pro) and *NHLRC1* gene (c.T602C; p.Phe201Ser) in two different families. A novel heterozygous missense variant was found in *YEATS2* gene (c.A2963G; p.Lys988Arg) in the dominant family. These variants were predicted to be damaging through several *in silico* prediction tools and are absent from all public SNP databases. **Conclusion:** Our study reports novel findings in patients suffering from myoclonic epilepsy and expands their genetic epidemiology. Including patients with different genetic backgrounds may help uncovering novel clinical and/or genetic entities likely using WES approach.

Mendelian Phenotypes Posters - Wednesday

PB2010. Whole exome sequencing in intellectual disability patients identifies de novo mutations in KCNB1, PPP1R3F, SHANK2, and SYNGAP1 genes

Authors:

A. Alkhateeb, M. Almomani; Jordan Univ. of Sci. and Technology, Irbid, Jordan

Abstract Body:

Intellectual disability etiology still poses a challenge to clinicians and families. Here we aimed to dissect the genes causing intellectual disability in local families. We recruited nine trio families with unexplained intellectual disability, and utilized whole exome sequence to identify causative genes/mutations. Out of nine families, we identified the causative genes in four (44% success rate). Novel and known pathogenic mutations were identified in KCNB1, PPP1R3F, SYNGAP1, and SHANK2. All mutations were de novo. With a highly inbred population it was unexpected to find all our mutations to be de novo representing autosomal dominant inheritance as the major pattern for our sample of unexplained intellectual disability. Our data confirm previous data that de novo mutations in autosomal dominantly expressed genes represent the major cause of unexplained intellectual disability, even in a highly inbred population.

Mendelian Phenotypes Posters - Thursday

PB2011*. Whole exome sequencing reveals known and candidate genes in non-syndromic hearing impairment in Mali

Authors:

A. Yalcouyé^{1,2}, O. Traoré¹, I. Shrauwen³, C. Bope⁴, A. Maiga¹, A. Tamega¹, A. Acharya³, T. Bharadwaj³, C. De Kock², M. Jonas², O. Oluwole², C. Guinto^{1,5}, G. Landoure^{1,5}, S. Leal³, A. Wonkam^{2,6}; ¹Univ. of Sci., Techniques, and Technologies, Bamako, Mali, ²Univ. of Cape Town, Cape Town, South Africa, ³Ctr. for Statistical Genetics, Gertrude H. Sergievsky Ctr., and Dept. of Neurology, Columbia Univ. Med. Ctr., New York, NY, ⁴Dept. of Mathematics and Computer Sci., Faculty of Sci., Univ. of Kinshasa, Kinshasa, Congo, Democratic Republic of the, ⁵Service de Neurologie, CHU Point G, Bamako, Mali, ⁶McKusick-Nathans Inst. of Genetic Med. and Dept. of Genetic Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract Body:

Hearing impairment (HI) is a common burden worldwide, affecting up to 7/1000 living new-borns in developing countries. More than 100 causative genes are reported to date to be associated with non-syndromic (NS) HI. While pathogenic GJB2 variants are prevalent in Europeans, their contribution to HI is nonsignificant in most sub-Saharan African populations. We used Whole Exome Sequencing (WES) to identify causative variants in hearing impaired individuals (N=37) from 12 multiplex and 8 simplex families from Mali segregating NSHI. Nineteen families displayed an autosomal recessive mode of inheritance with nine being consanguineous. One family displayed an autosomal dominant mode of inheritance. Carefully clinical assessment was performed and HI was evaluated using pure tone audiometry. The onset of the disease was prelingual in 94,6% of patients. Putative causal variants identified with WES were validated using Sanger sequencing and segregation was confirmed in family members which has not undergone WES. Bioinformatic tools were used to predict conservation and deleteriousness. Additionally protein modelling was performed. WES identified novel variants in 13 of 16 families (81.2%) in known HI genes. Compound heterozygous variants were found in four families located in OTOGL [c.209-9C>G and c.5685C>A; p.(D1895E)], MYO15A [c.8183G>A; p.(R2728H) and c.9401G>A; p.(R3134Q)], MYO15A [c.6783G>A; p.(W2261X) and c.8548C>T; p.(R2850X)], OTOF [c.1697G>A; p.(R566Q) and c.748C>T; p.(R250W)] genes. In eight families homozygous missense variants were found: CDH23 [c.646C>G; p.(L216V) and c.1353G>T; p.(L451F)], PJKV [c.461T>G; p.(V154G)], PDZD7 [c.1811C>A; p.(P604Q)], OTOF [(c.2154G>A; p.(W718X)], CIB2 [c.409C>T; p.(R137W)], MYO15A [c.9401G>A; p.(R3134Q)], and MYO6 [c.2839C>T; p.(R947X)]. Additionally a homozygous splice variant was found in TMC1 (c.2003+2T>C) in one family. The known variants in the remaining three families included two in MYO15A [c.6331A>T, p.(N2111Y) and c.8158G>A, p.(D2720N)] and one in MYO7A [c.3945C>A; p.(C1315X)] genes. Moreover, four candidate genes were identified including UBF1 [c.58G>A; p.(E20K)], BLM [c.2T>C; p.(M1?)], ZSWIM6 [c.309G>T; p.(E103D)], and ODF3L2 [(c.763G>A; p.(A255T) and c.556G>A; p.(V186M)] in four different families. These variants segregate with the phenotype and were found to be damaging with in silico tools and protein modelling. Functional studies are ongoing to confirm pathogenicity. This study confirms the genetic heterogeneity of the African population and suggests novel gene discovery. The data will contribute to the understanding of the pathobiology of HI, globally

Mendelian Phenotypes Posters - Wednesday

PB2012. Whole exome sequencing will miss Congenital Myotonic Dystrophy in the child on an asymptomatic mother.

Authors:

F. Appiah¹, B. L. Marr², A. Eldokla³, R. R. Lebel⁴, A. Sakonju³; ¹SUNY Upstate Med. Univ., Norton Coll. of Med., Syracuse, NY, ²Crouse Hlth., Syracuse, NY, ³SUNY Upstate Med. Univ., Syracuse, NY, ⁴SUNY Upstate Med Univ, Syracuse, NY

Abstract Body:

Myotonic dystrophy is an autosomal dominant multi-system disorder caused by CTG repeat expansion within the *DMPK1* gene (Dystrophica Myotonia Protein Kinase 1). This male was born to a 25-year-old G2P0010>1011 Puerto Rican mother and 36-year-old father, in a non-consanguineous union, at 39 weeks by cesarean route for fetal distress, after a good prenatal care. The pregnancy was complicated by abnormal ultrasound findings: bilateral club feet and renal abnormalities. Resuscitation in the delivery room was by tactile stimulation with blow by oxygen. Apgar scores were 1, 3 and 3 at 1, 5 and 10 minutes respectively. He was transferred to NICU for respiratory support due to unstable airway. Birth weight was 3.13 kg (32nd percentile), length 52 cm (87th percentile) and head circumference 32.5 cm (6th percentile). Physical exams was significant for profound hypotonia, spontaneous eye opening without any other spontaneous movements, bilateral equinovarus and undescended right testicle. Irregular heart rate was noted and EKG on day 7 showed QT prolongation. Repeat EKG at 2 months showed sinus tachycardia, right ventricular hypertrophy and slight right ventricular conduction delay. Echocardiography showed a small patent ductus arteriosus with left to right shunting. EMG showed abnormalities in nerve conduction, and diffuse discharges consistent with myotonic dystrophy. He had mechanical ventilation for 47 days with brief unsuccessful CPAP trials, and a teach collar placed at 6 weeks. He received Glycopyrrolate for excess secretions, and also Oxcarbazepine. Feeding is by G-tube. Karyotype and FISH were normal (46, XY). Whole Exome Sequencing (WES) revealed heterozygous *NEB* variants of uncertain significance, in trans, but histochemical and electronic microscopic examination of his muscle biopsy did not show nemaline rods. A molecular diagnosis of myotonic dystrophy type 1 was accomplished with over 200 CTG repeats in the *DMPK1* gene. Exact number of repeats is indeterminate. It is important to note that WES may not find triple repeats but rather give a false negative. The EMG was positive for myotonia with complex repetitive discharges. His mother's EMG was also positive for classic electrophysiologic myotonia despite having inconsistent grip myotonia and no percussion myotonia. Thus asymptomatic mothers can give birth to children with severe congenital myotonic dystrophy, and EMG testing can show abnormalities consistent with myotonic dystrophy in children as young as 6 days old.

Mendelian Phenotypes Posters - Thursday

PB2013. Whole genome sequencing identifies biallelic *SCLT1* splice-region variants in a child with a suspected ciliopathy: Delineating the *SCLT1*-related ciliopathy spectrum.

Authors:

E. Gillesse¹, P. Au², F. Bernier³, J. Parboosingh¹, Care4Rare Canada Consortium, R. Lamont³, A. Innes³; ¹Univ. of Calgary, Calgary, AB, Canada, ²Univ. of Calgary, Cumming Sch. of Med., Calgary, AB, Canada, ³Alberta Children's Hosp, Calgary, AB, Canada

Abstract Body:

Ciliopathies are a complex class of disorders that are caused by impaired primary cilia function, often impacting multiple organ systems, and show significant phenotypic and genetic heterogeneity. Sodium channel and clathrin linker 1 (*SCLT1*) is an emerging ciliopathy gene that encodes a known core component of the distal appendages of cilia, which are essential for primary cilium assembly and function. To date, there are a few individuals with pathogenic *SCLT1* variants reported with a wide range of named phenotypes, including oro-facio-digital syndrome type IX, Bardet-Biedl syndrome (BBS), Senior-Løken syndrome (SLS), and non-syndromic retinitis pigmentosa. Despite these reports, no disease association is currently listed for *SCLT1* in databases such as OMIM and the gene is excluded from most commercial gene panels and clinical exome analyses. Here we report a female proband with a phenotype suggesting a ciliopathy most consistent with BBS or SLS who initially underwent a commercial ciliopathy gene panel and clinical exome that were both non-diagnostic. She presented with early onset obesity, developmental delay, nystagmus and severe early onset vision impairment suggestive of Leber congenital amaurosis, and later developed renal failure secondary to nephronophthisis. Whole-genome sequencing (WGS) identified compound heterozygous variants *SCLT1* NM_144643.4: c.1218+3A>T and c.1218+3A>G. Further cDNA analysis showed two mis-spliced transcripts and no wild-type transcripts. The first transcript showed skipping of exon 14, resulting in a 72 bp in-frame deletion (r.1147_1218del: p.(Val383_Met406del)). The second transcript showed skipping of both exons 13 and 14, resulting in a 171bp in-frame deletion (r.1048_1218del: p.(Ala350_Met406del)). Segregation of cDNA from the mother revealed that both variants cause both alternatively spliced transcripts seen in the proband. This is the first report of a variant at the exon 14 - intron 14 boundary leading to skipping of exons 13 and 14. Overall, these findings contribute to the growing evidence that variant location and subsequent impact on *SCLT1* protein function, may influence the burden of an individual's phenotype. This report highlights the utility of WGS in the diagnosis of unsolved patients with genetically heterogeneous conditions, and will present a detailed review of the phenotypes associated with *SCLT1*-related ciliopathies.

Mendelian Phenotypes Posters - Wednesday

PB2014. Whole-Exome Sequencing of a French Canadian Cohort Reveals New Candidate Founder Mutations

Authors:

D. Ashton-Beaucage^{1,2}, G. Gagnon^{3,4}, J-C. Grenier⁵, G. Boucher⁵, D. Taliun^{3,4}, C. Stevens⁶, M. Daly^{7,8,9}, J. G. Hussin^{5,2}, V. Mooser^{3,4}, C. Bhérier^{3,4}, J. D. Rioux^{5,2}; ¹Dept. of Med. Genetics, McGill Univ. Hlth.Ctr., Montreal, QC, Canada, ²Dept. of Med., Université de Montréal, Montreal, QC, Canada, ³Dept. of Human Genetics, Faculty of Med. and Hlth.Sci., McGill Univ., Montreal, QC, Canada, ⁴McGill Genome Ctr., Canada Excellence in Res. Chair in Genomic Med., McGill Univ., Montreal, QC, Canada, ⁵Montreal Heart Inst., Montreal, QC, Canada, ⁶The Broad Inst., Cambridge, MA, ⁷Med. and Population Genetics, Harvard Med. Sch., Cambridge, MA, ⁸Analytical and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA, ⁹Inst. for Molecular Med. Finland (FIMM), Univ. of Helsinki, Helsinki, Finland

Abstract Body:

Mendelian conditions pose a significant burden on public health. In founder populations, the prevalence of some Mendelian disorders is increased, however population-level prevalence data is often fragmentary or lacking. The French Canadian (FC) population of Quebec comprises over 6 million people descending from 8,500 French settlers in the 17th and 18th centuries. To date, extensive genetic research in this population has identified over 30 Mendelian diseases bearing a founder effect signature, yet a comprehensive genome-scale survey of pathogenic variants is still lacking. The availability of whole-exome sequencing (WES) offers an opportunity to fill this gap and provide much needed carrier frequency data which is of fundamental importance to clinical genetics and epidemiology. Here, we estimated the allele frequencies (AF) of ClinVar pathogenic and likely pathogenic (PLP) variants in 1928 unrelated individuals from a case-control cohort of 2,625 participants included in a WES study of Inflammatory Bowel Diseases (IBD) in Quebec. After standard WES variant- and individual-level quality control and exclusion of IBD-associated genes, a total of 1886 PLP variants were identified. We estimated the relative AF enrichment in the FC population by comparing our AFs to non-Finnish Europeans AFs from gnomAD. In doing so, we discovered 157 PLP variants with an AF > 0.001 that were significantly enriched (one-sided Fisher exact test p-value < 0.01). After manual curation, we identified 34 variants with prior evidence of higher frequency and/or specific shared haplotypes, providing further evidence of a FC specific founder effect. Our carrier frequency estimates show high correlation to available neonatal screening data and to previously published estimates. The remaining 122 enriched candidates represent potential novel FC founder effect variants. These notably include variants linked to metabolic disorders (n = 23), neurological conditions (n = 17), eye diseases (n = 8), hearing loss (n = 14), endocrine disorders (n = 7) and cancer predisposition (n = 3). We will present our analysis of these enriched variants focusing on those candidates with the highest potential clinical interest. In summary, we will present the first comprehensive whole-exome evaluation of PLP variants enriched in the FC population. This data will help guide future efforts to extend this approach to a broader spectrum of communities in Quebec and to improve our understanding of these Mendelian conditions in terms of public health, understanding penetrance of enriched variants and disease pathophysiology, and for the discovery and development of innovative therapeutics.

Mendelian Phenotypes Posters - Thursday

PB2015. Whole-exome sequencing of Pakistani consanguineous families identified variants in novel and known genes of severe intellectual disability

Authors:

A. Abdullah¹, M. Asif², M. Anayat¹, Z. Ali³, G. Udin¹, G. Raja¹, M. Hussain²; ¹Univ. Inst. of Biochemistry and Biotechnology (UIBB), PMAS-Arid Agriculture Univ., Rawalpindi, Pakistan, ²Cologne Ctr. for Genomics (CCG), Univ. of Cologne, Faculty of Med. and Univ. Hosp. Cologne, Cologne, Germany, ³Ctr. for Biotechnology and Microbiol., Univ. of Swat, Mingora, Pakistan

Abstract Body:

Background: Intellectual disability (ID) is a condition of significant limitation of cognitive functioning and adaptive behaviour, with 50% of aetiology attributed to genetic predisposition. **Methods:** We recruited four consanguineous Pakistani families manifesting severe ID and developmental delay. The probands were subjected to whole exome sequencing (WES) and variants were further prioritized based on population frequency, predicted pathogenicity and functional relevance. **Results:** The WES data analysis of one of the families identified a homozygous missense variant of *CACTIN* (NM_001080543.1:c.1040A>T;p.(Asp347Val)), co-segregating with the disease phenotype. This variant is absent in gnomAD and 1000 Genomes and predicted to be 'deleterious' by several in silico tools. The gene is highly intolerant to missense and loss of function variants ($Z=3.2$ and $pLOF=0.14$) and has never been implicated in any inherited disorder. Its encoded Cactin which is a critical component of post-catalytic spliceosome that mediates exon ligation by stabilizing the position of the branch helix. *CACTIN* depleted cells show global splicing defects, while its knock down in zebrafish leads to embryonic lethality or extensive dysmorphogenesis. Remaining three families segregated presumably pathogenic novel variants in known ID genes; *MBOAT7* (NM_024298.4:c.757G>A;p.(Glu253Lys)), *CSTF2* (NM_001306206.1:c.445-8C>A) and *TRAPPC9* (NM_001160372.3:c.670delG;p.(Val224Cysfs*13)). **Conclusion:** Our findings indicate that *CACTIN* is novel gene that when disrupted leads to intellectual disability. These also provide additional evidence to the role of *MBOAT7*, *CSTF2* and *TRAPPC9* in causation of ID.

Mendelian Phenotypes Posters - Wednesday

PB2016. Whole-genome sequencing for comprehensive genetic modifier identification in CMT1A

Authors:

I. Xu¹, M. Dohrn¹, M. Danzi¹, M. Reilly², M. Shy³, S. Scherer⁴, Inherited Neuropathy Consortium, S. Zuchner¹; ¹Univ. of Miami, Miami, FL, ²UCL Queen's Square, London, United Kingdom, ³Univ. of Iowa, Iowa City, IA, ⁴Univ. of Pennsylvania, Philadelphia, PA

Abstract Body:

Charcot-Marie-Tooth disease type 1A is caused by identical heterozygous duplications of *PMP22*. However, significant heterogeneity of phenotype severity has been observed in many studies. We hypothesize that genetic modifiers will explain some of the clinical variability in phenotypic expression. In this study, we will use whole-genome sequencing (WGS) as a comprehensive approach to identify genetic modifiers.

To do so, the study design encompasses four steps: 1. statistical analyses to define mild vs. severe phenotypes and conduct sample size estimations; 2. phenotype-based patient selection; 3. whole-genome sequencing; and 4. comprehensive bioinformatic analysis of genetic variant clusters in defined phenotype subsets. For the first step, we have analyzed previously collected clinical data sets retrieved from the RDCRN-INC data base (Inherited Neuropathy Consortium). Phenotype information were available in 2,280 patients out of 1,737 families, all confirmed with CMT1A. Including follow-up, we assessed 13,283 visits in total. To understand not only disease severity at baseline, but phenotype dynamics as well, we analyzed the yearly follow-up data for foot dorsiflexion strength (Medical Research Council Scale, MRC) and CMTES-2 (Charcot-Marie Tooth Examination Score Version 2), which were the two most complete data sets overall. Our results confirmed that both parameters correlate with disease duration and age and therefore represent the natural disease course, as well as a need to define mild and severe CMT1A patients with respect to their age. Our results confirmed that both parameters correlate with disease duration and age and therefore represent the natural disease course. Additionally, progression in CMTES-2 and foot dorsiflexion strength did not correlate with age giving the potential for us to use rapid or stagnant progression as a measure of severity. We decided to combine those two parameters in a minimal dataset, together with information on age at onset, age at examination, gender at birth, and ancestry.

Using this minimal data set, we will select suitable patients from collaborating clinical expert centers. Based on preliminary power analyses, we aim at collecting enough minimal datasets to categorize and select a cohort of 500 mildly and 500 severely affected patients for WGS. Interested colleagues are invited to contact us.

Genetic Therapies Posters - Wednesday

PB2017. A conditional knock-in preclinical mouse model for the *TRPV4* skeletal disorders.

Authors:

L. Nevarez, J. H. Martin, D. Diaz, D. Krakow, D. Cohn; UCLA, Los Angeles, CA

Abstract Body:

TRPV4 is a tetrameric non-selective ion channel that principally transports calcium. The gene is selectively expressed in chondrocytes but is also expressed at lower but biologically significant levels in other tissues, including the lung, bladder, peripheral neurons and endothelial cells. Dominant activating mutations in *TRPV4* result in a spectrum of skeletal dysplasias and peripheral neuropathies. The *TRPV4* skeletal disorders are unified by varying severity of short stature, progressive scoliosis, and shortened long bones. These disorders include brachyolmia, spondylometaphyseal dysplasia Kozlowski type (SMDK), and both non-lethal and perinatal lethal metatropic dysplasia. Missense mutations in each of these phenotypes has established the genetic basis of disease but mechanistic studies have been limited by lack of a viable animal model. In humans, the R594H *TRPV4* mutation has been shown to result in numerous genetically independent cases of SMDK. To better understand the mechanism of disease, we developed a conditional floxed knock-in mouse with the R594H mutation. Midgestational induction of the mutation in chondrocytes using *Col2a1-Cre* resulted in mice with short stature, short tails and long bones, craniofacial abnormalities and an increase cervical angle consistent with scoliosis. Postnatal induction at weaning using *Acan-CreER* and tamoxifen produced mice with short stature, short tails, short long bones and craniofacial findings but without the scoliosis observed in the *Col2a1-Cre* mice. Radiographs identified small epiphyses and widened metaphyses, especially at the proximal tibiae, concordant with the radiographic phenotype in SMDK and the other human *TRPV4* skeletal disorders. Growth plate histology revealed disorganized columns of proliferating chondrocytes, suggesting that the activated, mutant TRPV4 ion channels act at the level of chondrocyte proliferation to inhibit the extent and polarity of endochondral bone formation. Thus, this viable mouse model of the *TRPV4* skeletal disorders has facilitated understanding of the effects of *TRPV4* mutations on skeletal development not previously possible. The mouse will also serve as a preclinical translational model for testing inhibitor treatments to ameliorate disease progression and severity in the *TRPV4* skeletal disorders.

Genetic Therapies Posters - Thursday

PB2018. A cross-species approach using an *in vivo* evaluation platform in mice demonstrates that sequence variation in the human *RABEP2* gene modulates ischemic stroke outcomes.

Authors:

H. Lee¹, D. Marchuk²; ¹Duke Univ. Sch. of Med., Durham, NC, ²Duke Univ Sch. of Med., Durham, NC

Abstract Body:

Ischemic stroke, caused by vessel blockage, results in cerebral infarction; the death of brain tissue. Previously, quantitative trait locus mapping (QTL) of cerebral infarct volume and collateral vessel number identified a single, strong genetic locus regulating both phenotypes. Additional studies identified the causative gene, encoding RAB GTPase Binding Effector Protein 2 (*Rabep2*). However, there is yet no evidence that variation in the human ortholog of this gene plays any role in ischemic stroke outcomes. We established an *in vivo* evaluation platform in mice using adeno-associated virus (AAV) gene replacement and verified that both mouse and human RABEP2 rescue the mouse *Rabep2* KO ischemic stroke volume and collateral vessel phenotypes. Importantly, this cross-species complementation enabled us to experimentally investigate the functional effects of coding sequence variation in the human *RABEP2* gene. We chose four coding variants from the human population that are predicted by multiple *in silico* algorithms to be damaging to RABEP2 function. *In vitro* and *in vivo* analyses verify that all four led to decreased collateral vessel connections and increased infarct volume. Thus, there are naturally occurring loss-of-function alleles. This cross-species approach will expand the number of targets for therapeutics development for ischemic stroke.

Genetic Therapies Posters - Wednesday

PB2019. A drug repurposing screen to identify therapies for the rare disease DPAGT1-CDG

Authors:

H. Dalton, A. Berman, C. Chow; Univ. of Utah, Salt Lake City, UT

Abstract Body:

Glycosylation encompasses a wide class of biological pathways involving co- and post-translational sugar modifications. Mutations in glycosylation genes underlie Congenital Disorders of Glycosylation (CDGs) - ultra-rare disorders that can cause seizures, developmental delay, and early death. There are few treatment options available for CDGs, and small patient populations make clinical trials difficult. Thus, there is a great need for alternative approaches to finding treatments for these rare diseases. One such alternative is the use of drug repurposing screens that utilize libraries of small molecules with established safety profiles in humans, allowing for potentially faster patient turnaround.

DPAGT1-CDG is caused by mutations in the gene *DPAGT1*, which encodes the critical first enzyme for N-linked glycosylation. I created a model of DPAGT1-CDG in *Drosophila* using RNAi against *DPAGT1* in the fly eye to cause a small, rough eye phenotype. Using this model, I can assay for drugs that rescue this phenotype by quantitatively measuring its eye size. To find such therapies, I am performing a repurposing screen using 1,500+ small molecules that are 98% FDA/EMA-approved (Prestwick Chemical Library). Drugs are mixed into fly food, flies are exposed until early adulthood, and adult eye size is compared to control flies. The top candidate drugs that rescue the eye phenotype, resulting in a larger eye, are later validated by dose-response or genetic analyses.

As a pilot screen, I tested 240 drugs for their ability to rescue the DPAGT1-CDG model eye size and identified a 3.8% hit rate ($Z \geq 1.5$). My top candidate drug is bumetanide (+25% eye size, $Z=2.04$), which inhibits the Na-K-Cl cotransporter, NKCC1 (Ncc69 in flies). I genetically validated bumetanide by using RNAi against *NKCC1* which also increased eye size (+12.3%). This suggests that ion flux is important in *DPAGT1* deficiency and that this screen can identify new drugs capable of rescuing this disorder. Other hits of interest include the NSAID antipyrine (+20.5%, $Z=1.62$) and its metabolite 4-hydroxyantipyrine (+19%, $Z=1.51$). As these are metabolically-linked drugs that independently rescued eye size, it suggests the antipyrine pathway, or NSAIDs in general, may be important for rescuing DPAGT1-CDG. Taken together, this pilot screen has already revealed multiple candidate drugs that can rescue this model, and my current hit rate projects identifying 40+ more. I will present data on candidate drugs, their validation, and overlapping mechanisms of action from the full screen. These drugs may represent novel therapeutic options for DPAGT1-CDG.

Genetic Therapies Posters - Wednesday

PB2020. A Phase 1, Open-Label, Dose-Escalation Study to Evaluate the Safety and Efficacy of HMI-103, a One-Time Phenylalanine Hydroxylase Gene-Editing Vector in Adult Participants with Classical PKU Due to PAH Deficiency

Authors:

A. Sandhu, C. Simiele, L. Benard, D. Lamppu, J. Von Stetina, J. Thompson, T. Wright, N. Avila, M. Bailey, O. Francone, A. Seymour, J. Wright, J. Jordan; Homology Med.s, Inc., Bedford, MA

Abstract Body:

Phenylketonuria (PKU) is a rare autosomal-recessive inborn error of metabolism. If left untreated, phenylalanine hydroxylase (PAH) deficiency may result in progressive, irreversible neurological impairment. Neither a phenylalanine (Phe)-restricted diet nor currently available therapeutic treatments address the core biological defect of the disease—the presence of biallelic pathogenic variants in the *PAH* gene. This leaves a significant unmet medical need for patients with PKU due to PAH deficiency. HMI-103 is an investigational gene-editing vector designed to: 1) deliver normal copies of the *PAH* gene to hepatocytes, 2) integrate into target *PAH* locus in the genome via non-nuclease-based AAV-mediated homologous recombination, 3) produce the PAH enzyme (via the dual mechanism of integration via homologous recombination and episomal expression), and 4) restore Phe metabolism. This approach is supported by studies in the *Pah*^{enu2} mouse model in which blood Phe was reduced and maintained in juvenile and adult mice and in partially hepatectomized mice regrown with human hepatocytes. No clinical pathology, necropsy findings, or evidence of germline transmission were observed. The data demonstrated efficacy, integration, specificity for the target locus, and preclinical safety of HMI-103 and support initiation of a clinical trial. This Phase 1, open-label, sequential, dose-escalation study (pheEDIT) will evaluate the safety and efficacy of a one-time, intravenous administration of HMI-103 in adult participants aged 18–55 years with classical PKU due to PAH deficiency who have uncontrolled disease despite standard of care or marketed treatments. Three dose levels of HMI-103 will be investigated, with up to 3 participants for each dose cohort. A maximum of 9 participants will be enrolled in the study. Enrollment will be staggered between participants in a given cohort. To decrease potential for immune-response, pheEDIT will use a prophylactic immunosuppressive regimen consisting of a corticosteroid administered in combination with the T-cell inhibitor tacrolimus. The primary study endpoints include incidence and severity of treatment-emergent adverse events (TEAEs) and AEs of special interest, and the mean percent change from Baseline in plasma Phe concentrations within each dose cohort post administration of HMI-103. These will be assessed through Week 104 plus long-term follow-up. Once positive safety and efficacy results are demonstrated in the adult population, Homology plans to enroll younger participants into future studies.

Genetic Therapies Posters - Thursday

PB2021. A Structural Screen Approach and Molecular Simulation Identifies Potential Ligands Against the K700E Hot Spot Variant and Functional Pockets of SF3B1 to modulate splicing in Myelodysplastic Syndrome.

Authors:

R. Garcia, M. Atis, A. Cox, P. Koduru; UTSW, Dallas, TX

Abstract Body:

Myelodysplastic syndrome (MDS) is a blood disorder characterized by ineffective hematopoiesis and risk of acute myeloid leukemia. In terms of genetic defects, chromosome aberrations are detected in up to 60% of cases, notably chromosome 5 and 7 alterations and complex karyotypes. Somatic variants in several genes have been reported in up to 90% and genes associated with aberrant mRNA splicing are frequently mutated. Of these, SF3B1 is by far the most frequently mutated and these are associated with early clonal events and disease development. Current therapies of MDS involve lenalidomide, hypomethylating agents and regenerative hematopoietic stem cells to deter the effects of blood cytopenia. Recently, potential new therapeutic agents are under investigation. Despite these efforts, there is a need to develop novel therapies that target splicing factor alterations. Thus, the objective of the study is to identify potential small molecule modulators against the frequently mutated RNA splicing factor SF3B1(K700E) and functional allosteric sites by using a molecular structure-based approach and a molecular dynamic simulation. To identify potential SF3B1 modulators, we collected a series of chemical compounds from the Zinc and Enamine database. All compounds were converted to single file formats for screening and docking using Vina. Binding affinity scores generated by Vina less than -7.0 kcal/mol were further evaluated using docking suite Schrodinger. The binding affinity between SF3B1 and small molecule modulators was described by pKd values (> 5 were considered). The KDEEP package was used to generate pKd values and the H3B-8800 compound in phase-1 clinical trials for SF3B1 modulation was used as a control. To validate structure-based modeling, a molecular simulation was then performed using NAMD and VMD. A total of 190,000 compounds from the Zinc-Enamine database were collected. The virtual screen and molecular docking identified 23 compounds with affinity to E622, R625, H662, and E700 in SF3B1 with docking scores less than -7 kcal/mol and binding affinity scores greater or equal to 5. A 20-nanosecond simulation showed strong binding between selected compounds and key amino acid residues, including K700E. Total binding energies between these compounds and key residues ranged from -59.4 to -88.2 kcal/mol. In brief, small molecule modulators show strong binding to SF3B1 suggesting these compounds may be used against cells harboring the K700E variant or to preferentially kill neoplastic cells by targeting functional allosteric sites.

Key words: MDS, molecule modulators, molecular docking, molecular dynamics

Genetic Therapies Posters - Wednesday

PB2022. AAV delivery of *ELP1* exon-specific U1 snRNA rescues retinal degeneration in a mouse model of familial dysautonomia.

Authors:

E. Kirchner¹, A. Chekuri¹, J. Bolduc¹, E. Logan¹, M. Salani¹, A. Krauson¹, L. Vandenberghe², F. Pagani³, S. A. Slangenaupt¹, E. Morini¹; ¹Massachusetts Gen. Hosp., Boston, MA, ²Massachusetts Eye and Ear, Boston, MA, ³ICGEB, Trieste, Italy

Abstract Body:

Familial dysautonomia (FD) is a rare neurodegenerative disease caused by a splicing mutation in the Elongator complex protein 1 gene (*ELP1*). This mutation results in tissue-specific skipping of exon 20 in the mature mRNA transcript leading to reduced levels of ELP1 protein, mainly in the nervous system. FD patients exhibit diminished pain and temperature perception, proprioceptive ataxia, failure of blood pressure regulation, and recurrent hypertensive vomiting. In addition to this complex neurological phenotype, FD patients also have progressive retinal degeneration that severely affects their quality of life. They suffer from optic neuropathy featuring reduction of the retinal nerve fiber layer (RNFL) due to progressive loss of the macular retinal ganglion cells (RGCs). Patients often become visually impaired or legally blind after their third decade of life. Recently, we have shown that our phenotypic mouse model, the *TgFD9; ELP1^{Δ20/flox}* mouse, recapitulates the tissue-specific *ELP1* splicing defect while modeling the selective RGC loss and the optic neuropathy observed in FD patients. To restore correct exon 20 inclusion, we have developed a novel modified *ELP1* exon-specific U1 snRNA (ExSpeU1) that can promote the binding of spliceosomal machinery downstream of the mutated 5' splice site and restore correct splicing. The therapeutic efficacy of our approach in rescuing retinal degeneration was evaluated by intravitreal injection of our FD phenotypic mice with self-complementary adeno-associated vector capsid 2 (scAAV2.ExSpeU1) expressing ExSpeU1. Transduction efficiency in the retina was visualized using immunohistochemistry, and splicing correction was evaluated using RT-PCR. Our results show that intravitreal delivery of scAAV2.ExSpeU1 (1×10^{12} vg/ μ l) efficiently transduces RGCs and significantly improves *ELP1* splicing in the retina of scAAV2.ExSpeU1 injected mice (n=6) (p<0.001). Importantly, using Optical Coherence Tomography (OCT), we have demonstrated that scAAV2.ExSpeU1 injected eyes have increased thickness of RNFL compared to PBS injected eyes. For the first time, our study shows the tremendous therapeutic potential of intravitreal delivery of scAAV2.ExSpeU1 in stopping progressive retinal degeneration and preventing visual decline in FD patients.

Genetic Therapies Posters - Thursday

PB2023. Adjunct treatment with glycogen synthase (GYS1) antisense oligonucleotides and Enzyme replacement therapy (ERT) reduced glycogen in the Pompe disease mouse model

Authors:

V. Kimonis¹, W. Weiss¹, M. Carrer², A. Shmara¹, K. Nguyen¹, C. Cheng¹, L. Hettrick³, A. Watt³, N. Raben⁴, P. Jafar-Nejad³; ¹Univ. of California, Irvine, Irvine, CA, ²Ionis Pharmaceuticals, Inc., Carlsbad, CA, ³Ionis Pharmaceuticals, Carlsbad, CA, ⁴NIH, Bethesda, MD

Abstract Body:

Pompe disease is a progressive myopathy resulting from the deficiency of acid α -glucosidase (GAA). Enzyme replacement therapy (ERT) with recombinant human (rh) GAA works well in alleviating the cardiomyopathy; however, many patients continue to have progressive muscle weakness from muscle glycogen accumulation produced by muscle glycogen synthase (GYS1). Previous studies have provided proof of principle that knockdown of GYS1 mRNA by phosphorodiamidate morpholino oligonucleotide reduced glycogen. To impart specificity for the muscle variant of the enzyme, we tested over 150 antisense oligonucleotides (ASOs) targeting mouse *Gys1* designed and previously screened in vitro and in vivo by Ionis Pharmaceuticals. In this report, we focused on the three lead molecules to identify the most efficacious *Gys1* ASOs in *Gaa*^{-/-} mice. The results from treatment with the three *Gys1* ASOs (16- doses of 25 mg/kg/weekly) identified *Gys1* ASO#3 as the most effective with 100% downregulation of GYS1 protein, and 49% and 33% efficiency in clearing muscle glycogen accumulation in 1-month and 3-month-old *Gaa*^{-/-} Pompe mice respectively. Combination therapy with *Gys1* ASO#3 and ERT further reduced glycogen accumulation and effectively alleviated the massive autophagic buildup in *Gaa*^{-/-} mice quadriceps to wild type mice level. The reversal of lysosomal and autophagic pathologies led to improved muscle function in treated *Gaa*^{-/-} mice. These results provide proof of principle that using GYS1 inhibitors as adjunct therapy with ERT is beneficial and will lead to future clinical trials in patients with Pompe disease.

Genetic Therapies Posters - Thursday

PB2024. An allele- discriminative approach for efficient and specific CRISPR/Cas9 based gene therapy of Late Onset of Alzheimer's disease

Authors:

B. Kantor, J. Rittiner, O. Chiba-Falek; Duke Univ., Durham, NC

Abstract Body:

APOEε4 is well-established genetic risk factor for late onset Alzheimer's disease (LOAD). It has been demonstrated that transcriptional repression stemming from the formation of closed chromatin organization around ApoE loci could play an important role in controlling the levels of APOEε4 gene expression. It also has been shown that reduction of APOEε4 levels may alleviate LOAD pathology. Here, we aimed to develop a novel approach for specific and accurate modulation of APOEε4 gene expression. We took advantage of the engineered VRER-Cas9/gRNA system which specifically and accurately recognized a novel protospacer adjacent motif (PAM) created with SNP-rs429358 T-C which defines APOEε4 haplotype. The system is based on an all-in-one lentiviral vector harboring gRNA/VRER-dCas9-repressor effector. Using this vector, we were able to efficiently and selectively reduce expression of ApoEε4 in vitro, in APOEε4-human induced pluripotent stem cell (hiPSC)-derived excitatory neurons, and in vivo, in mice. The developed epigenome-editing platform highlights the novel approach towards the development of next-generation of gene therapies for LOAD.

Genetic Therapies Posters - Wednesday

PB2025. An allele specific strategy for targeting mutant senataxin in patients with amyotrophic lateral sclerosis type 4

Authors:

C. Grunseich¹, B. Johnson¹, A. Apfel¹, D. Li², K. Fischbeck¹, A. Winkelsas¹, V. Cheung²; ¹NINDS, Bethesda, MD, ²Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Amyotrophic lateral sclerosis type 4 (ALS4) is an autosomal dominant form of motor neuron disease caused by mutations in the senataxin (*SETX*) gene. The onset of ALS4 is often in the teenage years and is characterized by a slowly progressive course. To date, there is no treatment for ALS4; here, we present data from an ongoing natural history study of ALS4 and an RNA-based method to silence the mutant allele of *SETX*. Senataxin is an RNA/DNA helicase that resolves the three-stranded nucleic acid structures called R-loops. We have previously shown that the gain of function senataxin mutations leads to fewer R-loops in ALS4 patients. In a natural history study, we follow ALS4 patients annually to assess their muscle function, strength, and collect skin samples to measure R-loop abundance in fibroblasts. The disease progression is also evaluated by nerve and muscle imaging. The c.1166 T>C (p.Leu389Ser) mutation leads to ALS4 in our patients. We designed a set of siRNAs to target this mutant allele. To assess the efficiency of allele-specific silencing, we measured allele-specific gene and protein expression in cell-based assays. First, we screened for siRNAs in HEK293 cells with a construct containing WT or the Leu389Ser senataxin fused to a Halo epitope tag. We then transfected each of these siRNAs into patients' primary fibroblasts, and two of these siRNAs showed allele-specific knockdown of the mutant *SETX* allele at the transcript and protein levels by approximately 50%. Molecular characterization is now underway. In this presentation, we will describe the disease course of this form of juvenile-onset ALS and data from RNA-based precision treatment.

Genetic Therapies Posters - Thursday

PB2026*. An alternate translational start site allows 5' nonsense variants to escape NMD so that readthrough compound ELX-02 and modulators can restore CFTR function.

Authors:

A. Bowling¹, C. Merlo², G. Lin¹, N. West², S. Patel², G. Cutting¹, N. Sharma¹; ¹Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ²Johns Hopkins Hosp., Baltimore, MD

Abstract Body:

Variants predicted to introduce a premature termination codon (PTC) are targeted for degradation by nonsense mediated mRNA decay (NMD), resulting in unstable mRNA and lack of protein. However, initiation of translation at start sites downstream of 5' nonsense variants can remove exon junction complexes that engage NMD, resulting in stable transcript. Using cystic fibrosis (CF) as a model system, we evaluated whether stable transcript bearing 5' nonsense variants can be targeted by readthrough agents to introduce an alternate amino acid at the PTC, allowing for production of a full-length CFTR protein and augmentation of function with CFTR modulator drugs.

Expression minigenes (EMGs) containing the complete *CFTR* cDNA and select flanking intron sequences were generated bearing variants E60X, L88X, and Y122X. Immunoblotting showed that HEK293 cells transiently expressing E60X and L88X *CFTR*-EMG generated a truncated CFTR-specific core glycosylated product, consistent with downstream translation initiation. Alternative translation initiation methionine at codons 150, 152 and 265 were individually mutated to valine. Substitution of M265 did not affect processing of full-length CFTR, but did cause loss of truncated CFTR protein in cells expressing E60X, L88X, and Y122X *CFTR*-EMGs, indicating that downstream translation initiation is occurring at M265. Substitution of M150 and M152 did not affect production of truncated CFTR protein.

Primary human nasal epithelial (NE) cells from individuals carrying L88X were conditionally reprogrammed and grown at air liquid interface. RT-PCR of WT/L88X NE cells revealed that L88X mRNA is stable and comparable to WT levels. WT/WT NE cells generated CFTR function of $13.1 \pm 1.5 \mu\text{A}/\text{cm}^2$ (n=12). Untreated L88X/F508del NE cells generated 6% of WT/WT function. CFTR modulators restored function to 83% of WT due to recovery of F508del CFTR. CFTR function increased further to 123% of WT when readthrough compound ELX-02 was included, which we attribute to activation of CFTR generated by translational readthrough of L88X-*CFTR* transcripts. Of note, treatment with the classic readthrough compound G418 and modulators did not result in additional recovery of function. Our results demonstrate that nonsense variants that naturally evade NMD via mechanisms such as downstream translation initiation are ideal targets for readthrough therapies.

Genetic Therapies Posters - Wednesday

PB2027*. An *in vivo* screen identifies small molecule modulators of retinitis pigmentosa and the ER stress response

Authors:

K. Hope, A. Berman, C. Chow; Univ. of Utah, Salt Lake City, UT

Abstract Body:

Retinitis pigmentosa (RP) is a common form of retinal degeneration caused by mutations in the *Rhodopsin* gene. Misfolded rhodopsin protein accumulates in the endoplasmic reticulum (ER) and causes ER stress. Cells respond to ER stress by initiating the unfolded protein response (UPR) that upregulates chaperone protein expression, increases the degradation of misfolded proteins, and inhibits protein translation. Failure to effectively manage ER stress and restore homeostasis results in cellular dysfunction and ultimately apoptosis, a process implicated in RP and other human diseases such as Alzheimer's disease (AD), Parkinson's disease (PD), Huntington's disease (HD), and spinocerebellar ataxia-3 (SCA3), among others. Identifying small molecules that modulate ER stress may be effective therapeutics for human diseases caused by misfolded protein accumulation. Here, we used a *Drosophila* model of RP that expresses misfolded rhodopsin protein, Rh1^{G69D}, in the eye. Rh1^{G69D} expression induces chronic ER stress and apoptosis, resulting in photoreceptor neuron loss and reduced eye size. We took a drug repurposing approach and screened 1520 small molecules from the Prestwick Chemical Library, the majority of which are FDA-approved, to identify compounds that modulate photoreceptor neuron death in Rh1^{G69D} expressing flies. ER stress-enhancing compounds may reveal novel ER stress pathways, and compounds that suppress ER stress are potential therapeutic candidates for RP and other diseases with an ER stress component. Our *in vivo* repurposing screen identified multiple classes of drugs that enhance or suppress the degenerate eye phenotype, including compounds acting through monoamine neurotransmitters, antibiotics, sodium channels, and the renin/angiotensin pathway. Using an RNAi approach, we found that knockdown of components of the *Drosophila* renin/angiotensin system restored eye size and suppressed the ER stress-induced phenotype in Rh1^{G69D} expressing flies. We will also present data on whether compounds that rescue cell death in the RP model also rescue disease-associated phenotypes in other *Drosophila* models of protein misfolding diseases, such as AD, HD, and SCA3. This work identified potential therapeutic compounds for RP and possibly other human diseases that result from misfolded protein accumulation and ER stress.

Genetic Therapies Posters - Thursday

PB2028. Antisense oligonucleotide-based exon skipping therapeutic strategy for Cohen syndrome.

Authors:

M. Ansar^{1,2}, F. Vacca³, R. Da Costa¹, H. M. A. Baig^{1,4}, E. Lize^{1,5}, I. Anwar¹, M. Choung¹, P. Tiwari¹, L. Faivre⁵, H. Riezman³; ¹Dept. of Ophthalmology, Univ. of Lausanne, Jules-Gonin Eye Hosp., Fondation Asile des Aveugles, Lausanne, Switzerland, ²Advanced Molecular Genetics and Genomics Disease Res. and Treatment Ctr., Dow Univ. of Hlth.Sci., Karachi, Pakistan, ³Dept. of Biochemistry, NCCR Chemical Biology, Univ. of Geneva, Geneva, Switzerland, ⁴Dept. of Biotechnology, Inst. of Biochemistry, Biotechnology and Bioinformatics, The Islamia Univ. of Bahawalpur, Bahawalpur, Pakistan, ⁵Genetics of Dev.al Disorders Team, INSERM UMR 1231, Univ. of Bourgogne Franche-Comté, Dijon, France

Abstract Body:

Cohen syndrome (CS) is an autosomal recessive disorder caused by biallelic loss-of-function mutations in the *VPS13B* gene. To date, more than 200 causative mutations in around 1000 affected individuals have been reported worldwide. CS is characterized by developmental delay, intellectual disability, metabolic syndrome manifestations and visual impairment due to severe myopia, progressive retinal degeneration, maculopathy, and cataract. Since CS is largely manifested by biallelic null mutations and missense variants are rarely pathogenic ($p=0.005$), it is envisioned that skipping short in-frame exons, lying out of the key functional domains of *VPS13B* would not affect the protein function, alternatively, a partially functional protein could be enough to improve the disease phenotypes. Antisense oligonucleotide (AON)-mediated exon skipping as a therapeutic approach has been extensively studied in the past decade, including for the treatment of retinal and muscular dystrophies. Existing clinical applications of AON-mediated exon skipping in Duchenne muscular dystrophy and Usher syndrome encouraged us to develop a similar approach for CS. We propose a therapeutic strategy based on skipping of in-frame exons carrying loss-of-function variants and develop an *in vitro* cell model to test the effectiveness of this strategy for each in-frame exon of the *VPS13B* gene. AONs were designed, using well-described parameters, to target the predicted enhancer splice sites of each of the 24 in-frame exons of *VPS13B*. Exon skipping efficiency of AONs was optimized in HeLa cells. Exon skipping was monitored and confirmed by RT-PCR and Sanger sequencing of the cDNA. Potential knock-down effects of AONs were ruled out by qPCR quantification of the transcripts and deleterious effects on cell viability with an XTT assay. Overall, 16 out of 24 AONs were efficient enough to induce over 25% skipping of their target exon. The ability of potential AONs to correct the aberrant Golgi morphology of *VPS13B*-deficient cells is currently being tested. For this purpose, HeLa cell lines were produced by introducing indel mutations in each of the 24 in-frame exons using CRISPR/Cas9 technology. Potential AONs will also be tested in available patient-derived fibroblasts for the corresponding exons. A high-throughput microscopy-based assay with an automated phenotypic analysis pipeline was developed which very efficiently discriminates the Golgi morphology of mutant cells.

Genetic Therapies Posters - Thursday

PB2029. Characterization of novel mouse model with 35 bp deletion in *Champ1* gene and exploration of AAV gene therapy to correct syndromes arising from mutations in the *CHAMP1*

Authors:

T. Carneiro¹, M. Bakay¹, B. Strenkowski¹, L. Sertori¹, R. Pellegrino², H. Hakonarson¹; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

Introduction: Chromosome alignment maintaining phosphoprotein 1 (CHAMP1) is crucial for kinetochore-microtubule attachment and for chromosome segregation during mitosis, important process for neurodevelopment. Mutations in *CHAMP1* were recently associated with global developmental delay, Intellectual disability, hypotonia and dysmorphic features. Reported mutations result in a premature stop codon and loss of protein c-terminal region which is essential for CHAMP1 localization and protein function. CHAMP1 is also necessary for the localization and activity of other proteins in mitosis process, such as MAD2L2 and POGZ. Additional studies demonstrated that *CHAMP1* depletion in cell lines resulted in *MCL-1* and *BCL-2* reduce expression, therefore this protein might be crucial for cell survival. We propose a gene therapy treatment using cell line and animal model in order to rescue the phenotype developed due to *CHAMP1* haploinsufficiency. This approach is also a way to acknowledge whether the role of CHAMP1 in cell survival is related to the pathogenesis of intellectual disability, a question that remains unanswered. **Methodology:** To mimic CHAMP1 dysfunction, both cell line and animal model have a deletion in the third exon. The base pair deletion in neuroblastoma cell line (SH-SY5Y) will be reached through CRISPR/SpCas9 (SYNTHEGO[®], Redwood City, CA, USA). Knockout (KO) efficiency will be assessed through DNA sequencing. Cells with *CHAMP1* deletion will be treated with AAV vector (Penn vector Core, University of Pennsylvania, Philadelphia, PA, USA). The Mice model was developed (C57BL/6NCr1-Champ1em1(IMPC)Mbp/Mmucd) using CRISPR/Cas9 gene editing technology in mouse zygotes (Mouse Biology Program, UC Davis, Davis, CA, USA). **Expected Results:** Growth rate, viability, *CHAMP1* gene expression and CHAMP1, MAD2L2, POGZ, BCL-2 and BAX protein expression will be accessed in cells lines knocked out for CHAMP1, untreated and treated with AAV. Furthermore, immunoprecipitation will be held for MAD2L2 and POGZ in both cases. Mice colony is being breed; females presented difficulty in giving birth due to occurrence of dystocia. Wild-type and C57BL/6NCr1-Champ1em1(IMPC)Mbp/Mmucd mice will have behavior and molecular characterization assessed before and after the treatment with AAV through Intra-venous injections. In conclusion, we propose to explore the use of AAV gene therapy to correct phenotype arising from mutations in *CHAMP1* gene in mouse model. We believe that results from this study will be useful and informative in understanding Intellectual disability (ID) - related disorders and in exhibiting the feasibility of gene therapy for ID.

Genetic Therapies Posters - Wednesday

PB2030. Comparison of AAVmyo and MyoAAV as promising vectors to deliver gene therapy in the VCP^{R155H} KI mouse model

Authors:

L. Weiss; Univ. of California, Irvine, Irvine, CA

Abstract Body:

Background and Objective Pathogenic variants in Valosin Containing Protein (*VCP*) gene cause a unique autosomal dominant disease characterized by inclusion body myopathy, Paget disease of bone and frontotemporal dementia (also known as multisystem proteinopathy (MSP)). *VCP* pathogenic variants lead to hyperactive enzymatic activity, suggesting a gain-of-function. Concomitantly, overexpression of *VCP* pathogenic variants in cells dominantly interfere with autophagy and endolysosomal sorting. To ameliorate the gain-of-toxicity of VCP mutant proteins, an ideal approach is to silence the mutant gene in an allele-specific manner and to leave the wildtype allele intact. We therefore propose to silence VCP with strategies such as microRNA, antisense oligonucleotides and CRISPR technology. A limitation, however, is obtaining sufficient expression in muscle to target the VCP mutant allele. Recently AAVmyo and MyoAAV have emerged as promising vectors to deliver gene targeting strategies to muscle tissue. We have performed studies in the VCP KI mouse model to study the efficacy and immunological response to these vectors as a mean to deliver gene modifying strategies in muscle. **Methods** To determine the tropism of the viral vectors through systemic injection, we used C57BL/6 WT and VCP R155H/+ mice at age 6-8-week-old to deliver a single dose of 1×10^{12} and 4×10^{12} vector genomes (vg) of either AAVmyo-CAG-EGFP, MyoAAV4A-pAM-CAG-TdTomato, or AAV9-CAG-EGFP by retro-orbital injection. After 3 weeks of regular monitoring for viability, immunity and signs of toxicity, the mice were sacrificed. All muscle groups in addition to multiple organs were harvested and analyzed to detect EGFP/TdTomato expression to determine muscle tropism. Serum was collected to examine markers of liver, renal and muscle toxicity. **Results** EGFP/TdTomato expression was significantly higher in both doses of AAVmyo and MyoAAV compared to AAV9 in various muscle groups. Our preliminary studies indicated better muscle tropism and less tropism for the liver with MyoAAV deeming it safer and muscle specific. We plan to combine our gene modifying strategies with MyoAAV for future studies in the mutant mice to study the effect on muscle pathology and function. **Discussion** Preliminary results show that using MyoAAV is a promising approach to deliver gene therapy to muscle tissue -a most challenging tissue to target. This leads to an exciting next step of targeting the mutant VCP allele and if needed replacing with WT VCP in the mouse model. If successful, this strategy has great translational potential in correcting disease pathology in VCP and other autosomal dominant disorders.

Genetic Therapies Posters - Thursday

PB2031. Deep phenotyping APOC3 Knockouts in a population with high consanguinity

Authors:

S. Khalid¹, M. Z. Khan², L. Wu³, M. Jahanzaib², S. Saeed², R. Mian², M. Bilal², R. Sultana⁴, S. Abbas⁵, M. Hussain⁶, F-u. Memon⁷, T-u. Salam⁸, M. Ishaq⁴, P. Frossard², A. Rasheed², J. Millar⁹, D. Rader¹⁰, D. Saleheen¹¹; ¹Columbia Univ. Irving Med. Ctr., NY, NY, ²Ctr. for Non-Communicable Diseases, Karachi, Pakistan, ³Univ. of Pennsylvania, PA, PA, ⁴Karachi Inst. of Heart Diseases, Karachi, Pakistan, ⁵Faisalabad Inst. of Cardiology, Faisalabad, Pakistan, ⁶Services Hosp., Lahore, Pakistan, ⁷Red Crescent Inst. of Cardiology, Hyderabad, Pakistan, ⁸Jinnah Hosp., Lahore, Pakistan, ⁹Univ. of Pennsylvania, Philadelphia, PA, ¹⁰Univ of Pennsylvania, Philadelphia, PA, ¹¹Columbia Univ. Irving Med. Ctr., New York, NY

Abstract Body:

Apolipoprotein C-III (APOC3) plays an integral role in the regulation of triglyceride rich lipoproteins, by inhibiting the clearance of triglycerides carried by VLDL and chylomicron remnants in the blood. Prior work has shown that heterozygous loss of function (LOF) carriers of APOC3 have lower triglyceride levels and a lower risk of coronary artery disease (CAD). The quantitative impact of disease risk remains unknown in complete knockouts (KOs). Additionally, the effects and safety implications of complete APOC3 LOF have not been characterized. APOC3 inhibition is an active therapeutic strategy to lower CAD risk; hence these questions have therapeutic relevance.

Among 37,244 unrelated sequenced individuals, including 19,681 cases of myocardial infarction (MI), in the Pakistan Genomic Resource - a biobank with high levels of consanguinity - we identified 207 heterozygous LOF carriers and 14 KOs. As expected, the KOs had undetectable APOC3 levels. We also observed a decrease in plasma triglycerides ($P = 9E-85$), VLDL-C levels ($P = 2E-73$), APOE levels ($P = 5.4E-9$) and an increase in HDL-C levels ($P = 1E-34$) and APOA1 levels ($P = 6E-5$) consistent with a gene-dosage effect. We observed a significant decrease in the risk of MI among heterozygous carriers ($P = 0.01$); however, we did not observe any protection from MI risk in complete KOs. Conversely, we observed a non-significant increase in the risk of MI in complete KOs compared to non-carriers; of the 14 knockouts identified, 9 were found to have MI. The loss of protection against MI could not be explained by the genetic background or by the increase in levels of homozygosity of the KOs. By recalling complete KOs and their family members, we were able to identify and phenotype an additional 33 complete KOs and 152 heterozygotes and assess other safety concerns related to complete APOC3 inhibition (i.e., glucose intolerance, fat content in the liver, etc.). In conclusion, by leveraging a highly consanguineous cohort, we have identified and phenotyped APOC3 KOs that have, hitherto, not been identified elsewhere. We did not observe APOC3 LOF to confer protection in complete KOs and observed other biomarker and phenotypic associations; these findings should inform existing therapeutic programs targeting APOC3.

Genetic Therapies Posters - Wednesday

PB2032. Development of an AAV gene therapy for GNE myopathy: AAV9-CK8e-SV40-*hGNEI-V5* shows robust GNE expression in mouse muscle tissue.

Authors:

K. Koczwara¹, P. Leoyklang², A. Lek³, A. DeSimone¹, S. Mitrani-Rosenbaum⁴, M. Huizing², J. Crudele⁵, M. Lek¹; ¹Yale Univ., New Haven, CT, ²NIH, Bethesda, MD, ³Muscular Dystrophy Association, Chicago, IL, ⁴Hebrew Univ. of Jerusalem, Jerusalem, Israel, ⁵Univ. of Washington, Seattle, WA

Abstract Body:

GNE myopathy is a rare, autosomal recessive disease, leading to progressive skeletal muscle atrophy and weakness in the limbs. Myopathy occurs due to pathogenic mutations in the *GNE* gene, resulting in reduced enzymatic activity of the GNE protein, a bifunctional enzyme involved in the sialic acid biosynthesis pathway. To date, over 250 pathogenic mutations in *GNE* have been reported, making mutation correction a poor therapeutic approach. While oral supplementation of N-acetyl-D-mannosamine (ManNAc), the substance produced by GNE within the sialic acid biosynthesis pathway, may be a viable therapeutic strategy, its efficacy in treating GNE myopathy patients is still being evaluated (ClinicalTrials.gov: NCT04231266). Alternatively, delivery of a fully functional *GNE* gene to muscle tissue should restore proper GNE function, regardless of the particular pathogenic mutation. AAV-based gene delivery has proven successful for the treatment of other genetic neuromuscular diseases, and the relatively small size of the *GNE* coding sequence (<2.2kb) make this approach an attractive treatment strategy for GNE myopathy.

In this study we designed and optimized a robust gene therapy for GNE myopathy. A library of AAV vectors was developed to evaluate changes in GNE expression due to: (1) the promoter used; (2) the inclusion of an intron; (3) the GNE isoform; and (4) the position and type of protein tag. *In vitro* results determined that the CK8e-SV40-*hGNEI-V5* construct resulted in the highest muscle-specific GNE gene and protein expression. This construct was then packaged into AAV9 particles and a biodistribution study was performed in wild type mice to determine the safety and efficiency of GNE expression across a variety of tissues. C57Bl/6 4-week old mice were injected with 1e13 or 5e13 vg/kg AAV9-CK8e-SV40-*hGNEI-V5*, and human *GNE* expression was analyzed at 8-weeks post-injection. Robust, dose-dependent GNE gene and protein expression was observed in a variety of muscle tissues, supporting further investigation of the efficacy of AAV9-CK8e-SV40-*hGNEI-V5* in GNE myopathy cell and mouse models.

Genetic Therapies Posters - Thursday

PB2033. Dkk1 inhibition normalizes limb phenotypes in a mouse model of *Fzd2* associated omodysplasia Robinow syndromes.

Authors:

R. Stottmann^{1,2}, M. Michalski³, R. Liegel⁴, S. Vaidya⁴, E. Bittermann⁴, E. Finnerty⁴, C. Menke⁴, C. Diegel³, Z. Zhong³, B. Willaims³; ¹Nationwide Childrens Hosp., Columbus, OH, ²Ohio State Univ., Columbus, OH, ³Van Andel Res. Inst., Grand Rapids, MI, ⁴Cincinnati Childrens Hosp. Med. Ctr., Cincinnati, OH

Abstract Body:

State of the art genomic approaches have revolutionized our discovery of Mendelian phenotypes but these still are most effective when paired with mechanistic experiments to directly address pathogenicity. Fortunately, revolutionary genome editing approaches have recently made this a significantly more tractable experimental approach. Frizzled-2 (*FZD2*) is a transmembrane receptor mediating the Wnt signaling pathway. We previously identified a pathogenic human variant of *FZD2* (p.W548*) coding for a premature stop and loss of 17 amino acids including a portion of the consensus DISHEVELLED (DVL) binding sequence (KTxxxW) required for Wnt signal transduction. This precise *FZD2* variant and 6 others have since been identified in 14 patients with similar phenotypes and this can now be called *FZD2* associated omodysplasia Robinow Syndrome. Patients with the p.W548* variant exhibited autosomal dominant omodysplasia and incompletely penetrant cleft palate, whereas a previously published deletion of *Fzd2* in mouse exhibited incompletely penetrant (50%) recessive cleft palate. To model the p.W548* variant, we utilized zygote microinjection and i-GONAD-based CRISPR/Cas9-mediated genome editing to generate an allelic series of 3 mouse mutations recapitulating the patient variant or creating a small deletion. Embryos mosaic (50-90%) for humanized p.W553* knock-in exhibited cleft palate, decreased weight, and shortened limbs, consistent with p.W548* patients. Additionally, we generated two germline mouse alleles with small deletions, *Fzd2*^{D3} and *Fzd2*^{D4}. Homozygotes for each allele survive embryonic development at normal ratios but exhibit a >90% penetrant recessive phenotype of cleft palate, a wide/short snout and perinatal lethality. Homozygotes for both alleles also had shorter fore- and hindlimb bones compared to wild-type embryos. Craniofacial tissue isolated from *Fzd2*^{D4} embryos had decreased canonical WNT signaling. In utero treatment with IIC3a (DKK inhibitor) rescued the limb lengths in *Fzd2*^{D4} homozygotes. The in vivo replication of clinical features seen in patients represents an approach which may be used to further investigate the mechanism of the autosomal dominant omodysplasia phenotypes and validates the utility of CRISPR knock-in mice as a tool for demonstrating pathogenicity of human genetic variants. We also present evidence for a potential therapeutic intervention for *FZD2* associated autosomal dominant Robinow Syndrome.

Genetic Therapies Posters - Wednesday

PB2034. Down-regulation of *SCN8A* as treatment for developmental and epileptic encephalopathy

Authors:

W. Yu¹, S. Hill¹, M. Meisler²; ¹Univ. of Michigan, Ann Arbor, MI, ²Univ Michigan, Ann Arbor, MI

Abstract Body:

Developmental and epileptic encephalopathies (DEEs) are rare genetic disorders characterized by refractory seizures, developmental delay, and sudden death. *De novo* mutations of *SCN8A*, encoding the voltage-gated sodium channel Na_v1.6, have been associated with DEE (OMIM #614588). The most common pathogenic mechanism of *SCN8A*-DEE is a gain-of-function mutation causing premature channel opening or impaired channel inactivation. Nav1.6 is localized at the axon initial segment of neurons, where it regulates the initiation of action potentials. GOF mutations in *SCN8A* result in excess neuronal firing of action potentials, leading to seizures. In a mouse model expressing the DEE mutation R1872W, seizures were delayed by intracerebroventricular administration of an *SCN8A* ASO (Lenk et al, Ann. Neurol. 2020). The effect of the gapmer ASO was transient, requiring readministration after 6 weeks. We are evaluating two genetic therapies for longer-lasting effects. An AAV10-shRNA virus down-regulates *Scn8a* expression via RNA interference (Wong et al, Sci. Repts. 2018). Intracerebroventricular injection of the virus at postnatal day 1 prevented the onset of seizures and extended survival of *Scn8a*-DEE mice. The *Scn8a*-shRNA also rescued survival of Dravet Syndrome mice with haploinsufficiency of *Scn1a*. Stereotactic administration of the virus to hippocampus of adult mice resulted in 60% reduction of *Scn8a* transcript, demonstrating the potential for regional application of shRNA therapy. To evaluate the effectiveness of an allele-specific knockout of the mutant allele, we are targeting the mouse N1768D allele, which contains 8 silent substitutions close to the single pathogenic nucleotide substitution. sgRNAs with 3 or 4 nucleotides that are specific for the N1768D allele are being tested in *Scn8a*-N1768D/+ heterozygous mice to determine whether allele-specific inactivation could be an effective treatment for *SCN8A*-DEE.

Supported by NIH R01 NS34509 and the Dravet Syndrome Foundation

Genetic Therapies Posters - Thursday

PB2035. Drug repositioning network in rare and intractable diseases based on drug target gene analyses.

Authors:

R. Sakate, T. Kimura; Natl. Inst.s of BioMed. Innovation, Hlth.and Nutrition, Ibaraki-shi, Osaka, Japan

Abstract Body:

Interest in drug repositioning has been growing because it can help reduce the time, cost, and risk involved in drug developments. We analyzed the drug repositionability among rare and intractable diseases. Drug development for these diseases has been challenging for decades due to the low prevalence and insufficient information. Drug repositioning opportunities lie in identifying promising pairings of already-approved drugs and new therapeutic diseases. We established a systematic approach to identify such pairings. First, we created a list of rare and intractable diseases based on the designated intractable diseases in Japan ("Nanbyo" in Japanese). Second, from clinical trial data worldwide (ClinicalTrials.gov, EU-CTR, ChiCTR, and JPRN), drug development information for the diseases in the list was extracted. Then the extracted drugs were integrated with drug target gene information. As a result, we found that ~1,600 drug repositioning events have been occurring in rare and intractable diseases during the past 20 years. These events also occurred between diseases from different disease groups, such as neuromuscular diseases (multiple sclerosis, etc.) and digestive diseases (Crohn's disease, etc.). We investigated a score to represent a degree of drug repositionability by drug target gene analyses combining other information such as pathways. Drugs and their target genes are keys to explore the repositionable drugs, since sharing drug target genes indicates the common mechanism of drug action between the diseases. Drug repositioning network can be drawn by binding diseases with a positive repositionability score. This network well visualizes promising disease pairs for drug repositioning and facilitates drug development for rare and intractable diseases. This analysis was based on DDrare, the database of drug development for rare diseases (https://ddrare.nibiohn.go.jp/index_e.html).

Genetic Therapies Posters - Wednesday

PB2036. Dynamin-2 interacts with SPEG and its reduction rescues the skeletal myopathy of SPEG-deficient mouse model

Authors:

Q. Li¹, J. Lin¹, J. Widrick¹, S. Luo¹, G. Li², Y. Zhang¹, J. Laporte³, M. Perrella², X. Liu², P. Agrawal⁴; ¹Boston Children's Hosp., Harvard Med. Sch., Boston, MA, ²Brigham and Women's Hosp., Harvard Med. Sch., Boston, MA, ³IGBMC, Illkirch, France, ⁴Boston Children's Hosp., Harvard Med. Sch., Boston, MA

Abstract Body:

Striated preferentially expressed protein kinase (*SPEG*), a myosin light chain kinase, is mutated in centronuclear myopathy (CNM) and/or dilated cardiomyopathy. No precise therapies are available against this disorder, and gene replacement therapy is not a feasible option due to the large size of *SPEG*. We evaluated the potential of dynamin-2 (DNM2) reduction as a therapeutic strategy as it has been shown to revert muscle phenotypes in mouse models of CNM caused by *MTM1*, *DNM2*, and *BIN1* mutations. We determined that *SPEG* interacts with DNM2, and *SPEG* deficiency causes an increase in DNM2 levels. The DNM2 reduction strategy in *Speg*-KO mice was associated with an increase in life span, body weight, and motor performance. Additionally, it normalized the distribution of triadic proteins, triad ultrastructure, and triad number, and restored phosphatidylinositol-3-phosphate levels in *SPEG*-deficient skeletal muscles. While DNM2 reduction rescued the myopathy phenotype, it did not improve cardiac dysfunction, indicating a differential tissue-specific function. Combining DNM2 reduction with other strategies may be needed to target both the cardiac and skeletal defects associated with *SPEG* deficiency. DNM2 reduction should be explored as a therapeutic strategy against other genetic myopathies (and dystrophies) associated with a high level of DNM2. We are utilizing transcriptomic and proteomic approaches to decipher the underlying mechanisms of rescue due to DNM2 reduction.

Genetic Therapies Posters - Thursday

PB2037. ECLIPSE, an automated CRISPR platform for the large-scale generation of cell models for the iPSC Neurodegenerative Disease Initiative (iNDI)

Authors:

P. Deng, A. King, B. Saavedra, M. Morell, A. Chair, D. Sailor, A. G. Gianotti, K. Holden; Synthego, Redwood City, CA

Abstract Body:

The National Institutes of Health led iPSC Neurodegenerative Disease Initiative (iNDI) is the largest iPSC genome engineering project attempted with the goal of generating a widely available and standardized set of diseased cell models for over 100 single nucleotide variants (SNV) mutations associated with Alzheimer's disease and related dementias (ADRD) in isogenic iPSC lines. The standardization of cell models is of vital importance for the generation of reproducible and actionable data in therapeutic development. As part of a multi-institution collaboration, Synthego was selected for the generation of 25 SNVs in the candidate KOLF2.1 iPSC line. Toward these goals, we describe the use of our automated, high throughput CRISPR editing platform, ECLIPSE, for the rapid generation of knock-in iPSC models of ADRD. We leveraged our state-of-the-art knock-in methods and automated pipelines for the design, experimental optimization, and clonal isolation of 23 of the candidate target mutations in iPSCs. For each SNV target, at least 3 clonal homozygous and 6 clonal heterozygous mutation lines were generated for a total of 264 clonal cell lines over a 6-month period. The utilization of automated systems such as our ECLIPSE platform are critical catalysts for the rapid development of relevant cell models in large scale disease initiatives such as iNDI.

Genetic Therapies Posters - Wednesday

PB2038. Effect of respiratory resistance exercise done remotely on respiratory function in individuals with familial myopathy.

Authors:

M. Halseth, R. Mahoney, V. Kimonis; Div. of Genetics and Genomic Med., Dept. of Pediatrics, Univ. of California, Irvine, Irvine, CA

Abstract Body:

The goal of this project is to evaluate the effectiveness of remotely administered respiratory exercise training on lung and respiratory muscle function in patients with familial myopathy as quantified by measuring their maximum inspiratory pressures (MIP, primary outcome) throughout the study. We also measured spirometry, hand dynamometry, and functional rating scale surveys (IBMFRS, ALSFRS) biweekly. The six-minute walk test (6MWT) and timed up-and-go (TUG) measurements were taken monthly. Weeks 0-8 serve as baseline measurements. During weeks 8-40, the subjects performed inspiratory muscle strength training twice a day, 6 days a week starting at 50% inspiratory resistance and building up to 80% of their MIP. On review of the results, MIPs showed a significant average increase of 0.425 cmH₂O every week ($p=0.010$). Spirometry measures showed small non-significant decreases in the exercise phase, consistent with the natural decline of the disease. The ALSFRS survey showed a significant beneficial decrease of 0.042 points per week during the exercise phase ($p=0.001$). No other significant changes were noted, in contrast to the natural decline of this disease. A large benefit shown through the course of this study is the effectiveness of administering this experiment remotely, showing research studies and treatments can be largely accessible to individuals who cannot travel due to expenses, mobility, or life responsibilities. An overall decline would be expected as part of the natural history of the disease, but significant increases in the MIP demonstrate that respiratory resistance exercise is beneficial to individuals with myopathy.

Genetic Therapies Posters - Thursday

PB2039. Efficacy and safety of elamipretide in subjects with primary mitochondrial disease resulting from pathogenic nuclear DNA mutations (nPMD) is investigated through this phase 3 study design.

Authors:

M. Mancuso¹, A. Karaa², **A. Abbruscato**³; ¹Dept. of Clinical and Experimental Med., Neurological Inst., Univ. of Pisa, Pisa, Italy, ²Massachusetts Gen. Hosp., Harvard Med. Sch., Boston, MA, ³Stealth Biotherapeutics, Needham, MA

Abstract Body:

Introduction: Primary mitochondrial disease (PMD) is a group of genetic disorders with underlying disrupted energy metabolism due to impaired oxidative phosphorylation capacity. Although mitochondria are under the dual genetic control of nuclear DNA (nDNA) and mitochondrial DNA (mtDNA), 98% of the mitochondrial proteome is encoded by nDNA. Elamipretide is a novel investigational agent that is being developed for the treatment of a variety of mitochondrial diseases, including PMD. Elamipretide readily penetrates and transiently localizes to the inner mitochondrial membrane where it associates with cardiolipin to improve membrane stability, enhance ATP synthesis, and reduce the production of reactive oxygen species.

Objectives: SPIMD-301 (NCT05162768) is designed to evaluate the efficacy and tolerability of elamipretide in subjects with primary mitochondrial disease resulting from pathogenic nuclear DNA mutations (nPMD).

Methods: SPIMD-301 is a phase 3, randomized, double-blind, placebo-controlled clinical trial consisting of screening (≤ 28 days), treatment (48 weeks), and follow-up (4 weeks). Approximately 130 subjects aged ≥ 18 years and ≤ 70 years with nPMD causing their myopathy will be randomized (1:1) to receive a single daily subcutaneous dose of elamipretide or matching placebo for 48 weeks. The population will consist of 90 subjects who have nPMD associated with pathogenic mutations of the mitochondrial replisome ("replisome-related mutations") for primary analysis and an additional subset of up to 40 subjects who have nPMD associated with other non-replisome-related mutations. Subjects are required to have a diagnosis of nPMD with a predominant clinical manifestation of myopathy, which must include progressive external ophthalmoplegia (PEO) and exercise intolerance and/or skeletal muscle weakness. Subjects must also have genetic confirmation of either nDNA mutation of the mitochondrial replisome or other pathogenic mutations specific to nDNA. The primary efficacy endpoint will be distance walked (meters) on the 6MWT. Biomarkers and pharmacokinetic evaluations will also be explored.

Results: The study has been initiated, with the first site enrollment occurring in November 2021. Further opportunities for enrollment continue in the US and Europe. The estimated completion date is June 2024.

Conclusion: Results will help determine the efficacy and safety of mitochondrial-targeting therapy with elamipretide for the treatment of patients with nPMD.

Genetic Therapies Posters - Wednesday

PB2040. Evaluation of Ataluren efficacy in fibroblasts from Neurofibromatosis Type 1 patients with nonsense mutation

Authors:

S. Kim¹, H. Do², S. Heo¹, J. Kim¹, I. Choi³, H. Bae⁴, G-H. Kim⁵, B. Lee⁶; ¹Asan Med. Ctr., Seoul, Korea, Republic of, ²Asan life Sci. Inst., Seoul, Korea, Republic of, ³Asan Med. center, Seoul, Korea, Republic of, ⁴Med. Genetics Ctr., Asan Med. Ctr. Children's Hosp., Seoul, Korea, Republic of, ⁵Asan Med Ctr, Seoul, Seoul, Korea, Republic of, ⁶Asan Med Ctr, Seoul, Korea, Republic of

Abstract Body:

Neurofibromatosis Type 1 (NF1) is an autosomal dominant human genetic disorder caused by heterogenous mutations on the tumor suppressor gene *NF1*, affecting 1 in 3000 people. Since NF1 regulates cell growth and survival by inhibiting the accumulation of hyperactive RAS (GTP-bound RAS), disruption of NF1 induces cell growth-promoting signals such as MEK-ERK effector pathway. According to our previous data, about 30% patients have nonsense mutations on *NF1* introducing premature termination codon (PTC). Ataluren is a well-characterized small molecule which serves as a nonsense suppressor and has been approved by the European Medicines Agency for the treatment of Duchenne muscular dystrophy (DMD) that is basically produced by PTC in *DMD* gene. Here, we have isolated fibroblasts from 22 Korean patients with nonsense mutation NF1 and evaluated the efficacy of Ataluren treatment. We found that GTP-bound RAS activities were significantly reduced in 5 patients' fibroblasts (23%) after Ataluren treatment. Additionally, the levels of phosphorylated ERK, a downstream effector of the RAS-MEK pathway, decreased in the presence of Ataluren. In conclusion, our finding suggests that Ataluren can be an alternative drug for some patients with nonsense mutation NF1 instead of a standard treatment, MEK inhibitor Selumetinib.

Genetic Therapies Posters - Thursday

PB2041. Generation of eight human induced pluripotent stem cell lines from immortalized lymphoblastoid cells

Authors:

L. Sertori Finoti, C. Hou, L. Matsuoka, M. March, D. Li, H. Hakonarson; Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

In order to accurately study timed events that affect gene activation and repression and investigate the timing and dosage of disease genes related to neuron development, it is preferred to use neurons derived from human induced pluripotent stem cells (iPSCs). We have identified a neurodevelopmental syndrome with *de novo* novel missense variants in *U2AF2*, encoding a core component of U2 snRNP in the spliceosome. However, how these variants lead to neuronal differentiation defects is unknown. To investigate this, we utilized a developmental reprogramming strategy to capture a potential critical early neuronal phenotype. Human iPSCs from Epstein-Barr virus (EBV) immortalized lymphoblastoid cell lines (LCL) were generated from 3 healthy matched controls and 4 patients with c.448C>T mutation and 1 patient with a nonframeshift deletion (K329del). LCLs were reprogrammed using non-integrating Sendai viruses expressing Oct3/4, Sox2, cmyc, and Klf4. iPSCs were free of vectors carrying reprogramming genes at the 13th passage. They were positive for the SSEA4 and OCT4 pluripotency markers verified by immunostaining and expressed the LIN28A, NANOG, and OCT4 markers by qPCR analysis. Each line was assessed as negative for large genomic rearrangement using SNP genotyping array. The iPSC cells haven't shown any discrepancy in their morphology; however, we are expecting to see differences during their neuronal differentiation. The generation of these cell lines will allow us to investigate disease mechanisms and test possible therapeutic approaches.

Genetic Therapies Posters - Wednesday

PB2042. Genetic subgroup learnings is presented from the MMPOWER-3 trial: elamipretide improves six-minute walk test in individuals with mtDNA replisome disorders.

Authors:

A. Karaa¹, M. Mancuso², B. H. Cohen³, M. J. Falk⁴, A. Goldstein⁴, M. K. Koenig⁵, M. Hirano⁶, J. Vissing⁷, **A. Sullivan**⁸; ¹Genetics Unit, Massachusetts Gen. Hosp., Boston, MA, ²Univ. of Pisa, Pisa, Italy, ³Akron Children's Hosp., Akron, OH, ⁴Mitochondrial Med. Frontier Program, Div. of Human Genetics, Dept. of Pediatrics, Children's Hosp. of Philadelphia and Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA, ⁵Dept. of Pediatrics, Ctr. for the Treatment of Pediatric Neurodegenerative Disease, Univ. of Texas McGovern Med. Sch., Houston, TX, ⁶Neuromuscular Div., Columbia Univ Med Ctr, New York, NY, ⁷Copenhagen Neuromuscular Ctr., Rigshosp. et Univ. of Copenhagen, Copenhagen, Denmark, ⁸Stealth Biotherapeutics, Needham, MA

Abstract Body:

Introduction: Primary mitochondrial myopathy (PMM) is a group of genetic disorders of the mitochondria, adversely affecting predominantly skeletal muscle, leading to decline in quality of life. The mitochondria-targeting peptide elamipretide was recently assessed in a Phase 3, randomized, double-blind, placebo-controlled clinical trial for the treatment of subjects (N=218) with PMM (MMPOWER-3). Subjects had a variety of pathogenic variants in either nuclear (nDNA) or mitochondrial DNA (mtDNA) genes that caused their myopathy. The trial did not meet the primary endpoints in the highly heterogeneous study cohort. Here, we report results of genetic subgroup, post-hoc analyses subsequently performed on the per protocol population.

Methods: Using the MMPOWER-3 per protocol population, elamipretide effects on change from baseline in the six-minute walk test (6MWT) were examined as a function of gene variants.

Results: Individuals with primary mtDNA pathogenic mutations represented 74% of the trial population. Elamipretide showed no significant effects on 6MWT in these subjects when compared to placebo. Placebo-randomized subjects with the MT-TL1 pathogenic variant (~33% of mtDNA cohort) increased 42.4±13.4 meters (m) in 6MWT at week 24. After 24 weeks of elamipretide, subjects with nDNA gene mutations walked significantly farther than placebo counterparts (25.5±8.0 versus 0.3±7.7 m; p<0.05). The majority of the nDNA cohort was comprised of subjects with pathogenic variants in genes required for mtDNA genome maintenance (the mtDNA replisome, n=51 subjects). 6MWT at week 24 in subjects with replisome mutations changed 25.2±8.7 m with elamipretide versus 2.0±8.6 m in placebo (P<0.05), an effect even more prominent in individuals with progressive external ophthalmoplegia (PEO; n=32), with elamipretide-treated subjects walking 37.3±10.7 m versus -8.0±9.5 m in placebo at 24 weeks (P<0.05). Pharmacokinetic analyses in the nDNA cohort showed a positive correlation between plasma elamipretide concentration and 6MWT improvement.

Conclusions: The subgroup analysis demonstrated that 6MWT in the mtDNA cohort was confounded by a 'placebo effect', disproportionately driven by subjects with MT-TL1 pathogenic variants. The MMPOWER-3 basket trial design introduced significant heterogeneity and highlights the importance of considering genetic subgroups in developing future trials and treatments for individuals with PMM. The observation of improvement in 6MWT in the nDNA cohort with replisome disorders is encouraging, and future studies are planned to explore the efficacy of elamipretide in this population.

Genetic Therapies Posters - Thursday

PB2043. Genome-wide CRISPR/Cas9 Screening Reveals ATR as a Therapeutic Target That Overcomes Osteosarcoma Chemoresistance.

Authors:

S. Tang¹, P. H. Pandya², X. Wu¹, R. D. Roberts¹, K. E. Pollok², L. Li¹; ¹The Ohio State Univ., COLUMBUS, OH, ²Indiana Univ., Bloomington, IN

Abstract Body:

Osteosarcoma is the most common primary bone malignancy exhibiting remarkable histologic diversity and genetic heterogeneity. Despite extensive research efforts, the treatment and survival outcomes for osteosarcoma patients have stagnated over the past 30 years. The complex nature of osteosarcoma has confounded study of chemo-resistance mechanisms and identification of novel target. As an ideal new strategy to address the genetic complexity and drug-resistance in osteosarcoma, genome-wide CRISPR/Cas9 screen was conducted in one osteosarcoma cell line, SaOS2, parallel with RNA-sequencing in different conditions (control, Cisplatin, Doxorubicin), followed by gene essentiality score calculation. Cisplatin and Doxorubicin combination is among those commonly used as first-line therapies for osteosarcoma treatment. The objective of our studies is to bring forth new perspectives in target identification and chemo-resistance study for osteosarcoma. The gene targets and pathways that become more essential for osteosarcoma cell proliferation in the presence of chemo drugs were revealed. Drugs specific for some of these targets could then be added to the established regimens to overcome existing drug resistance. On the other hand, the genes that become less essential after treatment could provide additional chemo-resistant mechanisms. Multiple gene targets were identified in the screen. Among these, we've successfully identified and validated Berzosertib, an ataxia telangiectasia and Rad3-related protein kinase inhibitor (ATRi), as a synergistic lethality partner to Cisplatin in vitro for osteosarcoma treatment. Efficacy and safety measurement of Berzosertib and Cisplatin combination therapy in a cell-line xenograft mouse model and in several patient-derived xenograft models is in progress and expected to be finished before September.

Genetic Therapies Posters - Wednesday

PB2044. Genotyping analysis in patients with retinitis pigmentosa due to mutations in the *RHO*, *PDE6A*, or *PDE6B* gene: the PHENOROD2 study.

Authors:

D. Chung¹, L. Blouin², A. Celle², A. Le Meur², S. Mohand-Saïd³, J-A. Sahel⁴, C. Zeitz⁵, I. Audo⁶; ¹SparingVision, Philadelphia, PA, ²SparingVision, Paris, France, ³Inst. de la Vision, Paris, France, ⁴Dept. of Ophthalmology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA, ⁵Sorbonne Université, INSERM, CNRS, Inst. de la Vision, Paris, France, ⁶UMR S 968 INSERM, Paris, France

Abstract Body:

Retinitis pigmentosa (RP) is a rare rod-cone dystrophy (RCD) in which rod photoreceptors progressively degenerate, subsequently triggering the degeneration of cone photoreceptors. Clinical symptoms start with night blindness, followed by slow constriction of the visual field causing tunnel vision and eventually legal blindness. With over 70 different genes implicated, RCDs form a heterogeneous group of poorly characterized inherited retinal disorders.

PHENOROD2 is an ongoing prospective, multicentric, natural history study documenting functional and structural changes in patients with RP due to mutations in *RHO*, *PDE6A*, or *PDE6B*. An interim analysis was performed in the first 44 patients enrolled at the national reference center for rare diseases (REFERET) of the *Centre Hospitalier National d'Ophthalmologie des Quinze-Vingts* (Paris, France).

Genotyping data were collected from the medical records of patients enrolled in PHENOROD2.

Out of 44 patients, 33 (75%) carried a monoallelic variant in the *RHO* gene, and 11 (25%) carried a biallelic variant in either the *PDE6A* gene (n=7, 16%) or the *PDE6B* gene (n=4, 9%). Segregation analysis was performed in all but one patient with autosomal recessive RP

(i.e., *PDE6A* and *PDE6B* patients). A total of 14 unique variants were identified in the 33 *RHO* patients, 9 unique variants in the 7 *PDE6A* patients, and 7 unique variants in the 4 *PDE6B* patients. The majority of disease variants were missense mutations: 94% in *RHO* patients, 50% in *PDE6A* patients, and 38% in *PDE6B* patients. The most common missense variants were p.(Pro347Leu) and p.(Arg135Trp) each found in 5 (15%) *RHO* patients, and p.(Gln569Lys) found in 3 (21%) *PDE6A* carriers. The only patient with homozygous variants carried biallelic missense variants p.(Arg100His) in the *PDE6B* gene.

Further assessment is ongoing on the full cohort of PHENOROD2 that included a total of 82 patients. The prospective analysis of disease progression in these RP patients could allow for genotype-phenotype correlations.

Genetic Therapies Posters - Thursday

PB2045. Harmonization of phenotype ontologies and identification of novel gene/drug-disease associations with Natural Language Processing

Authors:

I. Melas, L. Middleton, M. Tadeja, A. O'Neill, A. Harper, D. Vitsios; AstraZeneca, Cambridge, United Kingdom

Abstract Body:

Integration of data from multiple resources and ontologies around genotypes and phenotypes is a key challenge in life sciences aiming to bridge the gap between basic and clinical research. This integration is obstructed by the use of different nomenclatures in different consortia, initiatives and healthcare systems. Projects such as the Monarch Initiative have achieved the streamlined curation for a number of such ontologies, employing both computational methods and manual curation. Nevertheless, mapping diseases and phenotypes across ontologies remains a daunting task.

Herein, we leverage several ad-hoc frameworks, such as word embeddings and the Monarch dataset, that address the mapping of terms across ontologies and augment on these to provide a universal mapping framework. We use the BioWordVec word2vec embeddings, pre-trained on the entire PubMed corpus, to construct vector representations of free text terms. BioWordVec captures the meaning behind these terms and embeds them in a latent (250-dimensional) space, so that terms with similar semantic context are mapped closer together in the latent space. To improve these semantic mappings, we use Elasticsearch to look up the PubMed corpus for each query term and retrieve extracts around them from all relevant papers. This allows us to construct augmented embedding representations for each query term (e.g. a phenotype or disease) that better capture their biological context.

Moreover, we leverage the curated mappings from Monarch to train a supervised learning model capable of identifying novel associations between phenotypes. This framework combines the power of BioWordVec embeddings with expertly curated mappings from Monarch to infer the biological semantic similarity in any pair of disease/ontology terms. A Deep Neural Net trained to distinguish between true and false (random) associations achieved an AUC of 0.79 (5-fold Cross-Validation). Remarkably, the trained classifier is powerful enough to identify associations spanning across different biological layers, i.e. disease to gene (AUC = 0.75) and disease to drug (ROC AUC = 0.79) associations (OpenTargets derived associations were used as a training dataset in this case). Additionally, we trained a universal classifier on all association types together (i.e. disease to disease/gene/drug associations) achieving a comparable performance with the specialized models, albeit slightly lower (AUCs = 0.76, 0.74, 0.76 respectively). Finally, we accompany our work with a web resource providing both unsupervised and supervised learnt mappings between various disease ontologies, genes and/or drugs.

Genetic Therapies Posters - Wednesday

PB2046. Harnessing the power of natural variations of the human genome to support the discovery of new therapeutics: A systematic review

Authors:

K. Trajanoska^{1,2}, C. Bhérier^{1,2}, D. Taliun^{1,2}, B. Richards^{1,3}, V. Mooser^{1,2}; ¹McGill Univ., Montreal, QC, Canada, ²Canada Excellence Res. Chair in Genomic Med., McGill Univ., Montréal, QC, Canada, ³Lady Davis Inst., Jewish Gen. Hosp., McGill Univ., Montréal, QC, Canada

Abstract Body:

Rationale: The massive investments made in human genetics and genomics over the past decades were anticipated to result in many innovative and impactful therapies or new indications for existing drugs. Has this expectation been met for non-cancer drugs? Twenty years after publication of the first human genome, we considered this question legitimate and the answer critical to guide future investments in the field. **Methods:** We defined as “genetically-driven” those targets for which human germline genetic associations were judged to be sufficiently informative to support a new drug discovery campaign, resulting in regulatory approval of the therapeutic (or new indication). We restricted our analysis to FDA- or EMA-approved therapeutics and excluded cancer drugs, hormonal therapies, vaccines, and antimicrobials. We then applied this definition to a search in PubMed which we complemented with information from the Orphan Drug Designations and Approvals database. All articles were screened first at the title/abstract level and at a full-text stage. **Results:** We identified 31 drug targets that met our definition of being genetically-driven. This corresponds to ~6% of the ~500 human targets of FDA-approved non-cancer drugs. The 31 underlying germline genetic associations led to the development and approval of new therapies for rare (n=27), common (n=3), and both rare and common (n=1, i.e., PCSK9 inhibitors) disorders. Most drugs indicated for rare diseases compensate for disease-causing loss-of-function or misfolding variants in the target gene whereas, in contrast, the 4 genetically-driven drugs for common conditions mimic the disease-protective effects of rare loss-of-function variants found in diverse populations. Most (18/31) genetically-driven targets are in the metabolic area. Only five genetically-driven drugs so far are small molecules, whereas the remaining drugs have onerous cost of goods. In addition, we identified 7 marketed drugs approved (n = 4) or under development (n = 3) for genetically-driven repurposed indication. **Conclusion:** Our systematic review confirms that drug discovery is starting to harvest the fruits of genetics. A wealth of new therapeutics are anticipated to be tested in humans within the next few years. For genomics to be successfully embedded in drug development will require access to a new generation of large, diverse, disease-based cohorts of properly consented, well-phenotyped participants.

Genetic Therapies Posters - Thursday

PB2047. Implementing a Genetics-First Strategy in Clinical Development for Rare Brain Diseases

Authors:

A. Mitchell, C. Paisan-Ruiz, C. Gubbels, C. Whelan, V. Nguyen, T. Cochrane, L. Gedney, S. Fradette, H. Runz; Biogen, Cambridge, MA

Abstract Body:

Biogen's clinical pipeline programs span seven broad therapeutic areas, working across the human lifespan, from neonates to the elderly. Biogen's programs are increasingly focused on rare diseases and genetically-defined subsets of common diseases. These types of programs require extra support from Clinical Genetics, particularly in the development of patient identification strategies.

The strategies for trial site selection and patient recruitment that have previously worked well are insufficient for ultra-rare diseases, for genetically defined subsets of common disease, and for pre-symptomatic mutation carriers of these diseases.

We approach patient recruitment for each specialized trial from many different angles. Depending on availability, we may leverage sponsored genetic testing panels, networks of genetic counselors and other medical providers, patient databases and outreach programs through clinical genetic testing providers, large scale population and disease-specific genotyping initiatives, academic collaborations, and cohorts that may recall participants by genotype. We may do outreach through patient advocacy groups or sponsor a new patient advocacy group, if none exists. We are increasingly turning to natural history studies for trial-ready cohorts, particularly for indications for which there is no current treatment. Here, we highlight three examples of patient identification strategy for three, very different Biogen programs: an ultra-rare indication, a genetically-defined subset of a common, complex disease, and a study of pre-symptomatic mutation carriers.

As the number of clinical programs with genetic inclusion criteria continues to increase, patient identification challenges will continue to grow. Continued success will require multiple, simultaneous efforts, extensive preparation, and - most importantly - support from every level and every department in the company.

Genetic Therapies Posters - Wednesday

PB2048. Interrogation of the role of androgens and their antagonists in the pathogenesis and treatment of Vascular Ehlers-Danlos Syndrome.

Authors:

E. Juzwiak^{1,2}, C. Bowen^{1,2}, A. Zeng^{1,2}, H. Dietz^{1,2}; ¹Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ²Howard Hughes Med. Inst., Chevy Chase, MD

Abstract Body:

There are currently no therapeutic strategies to prevent spontaneous aortic rupture and premature death in patients with Vascular Ehlers-Danlos Syndrome. Male patients with VEDS are at an increased risk for catastrophic arterial rupture during puberty compared to females. Our VEDS mouse model (Col3a1^{G938D/+}) recapitulates this pubertal sexual dimorphism, with 44% vs. 69% survival of males vs. females at 60 days of age, respectively. We hypothesized that pathogenesis of vascular rupture in VEDS involved modulation of the PKC/ERK signaling axis by androgens. Androgens are hormones that increase during puberty and are higher in males during puberty. They can bind to the androgen receptor (AR) and influence both gene expression and molecular signaling. We therefore had incentive to understand the potential mechanisms by which androgen receptor antagonists might contribute to protection from arterial events. We treated Col3a1^{G938D/+} mice with the selective AR antagonist (ARa) bicalutamide, the dual ARa and mineralocorticoid receptor antagonist (MRa) spironolactone, or the selective MRa eplerenone from the time of weaning until 60 days of age. To ensure these small molecules are acting through the AR to modulate VEDS pathogenesis, we also crossed an AR conditional (floxed) allele to Col3a1^{G938D/+} mice that globally express Cre recombinase. We observed that male Col3a1^{G938D/+} AR null mice have improved survival compared to untreated Col3a1^{G938D/+} mice at 60 days (68% vs. 44%), a protective performance mimicked by treatment with bicalutamide (65% survival). Immunoblot analysis of descending aortic lysates shows that AR blockade, either chemical or genetic, normalizes activation of the PKC/ERK axis. Taken together, these data suggest that AR signaling contributes to vascular disease in Col3a1^{G938D/+} mice. Notably, male Col3a1^{G938D/+} mice treated with the dual ARa/MRa spironolactone showed the best performance (87% survival at 60 days). Use of the selective MRa eplerenone afforded intermediate protection, approaching that of spironolactone (81% male survival at 60 days) in selected contexts. Identical trends were observed in female Col3a1^{G938D/+} mice. These data document that both AR and MR signaling are determinants of outcome in Col3a1^{G938D/+} mice and highlight the therapeutic potential of isolated MR antagonism that should maintain normal sexual development.

Genetic Therapies Posters - Thursday

PB2049. Learnings from a randomized clinical trial with ARID1B patients

Authors:

P. J. van der Sluijs¹, K. Safai Pour², C. Berends², R. G. J. Zuiker², G. W. E. Santen¹; ¹Leiden Univ. Med. Ctr. (LUMC), Leiden, Netherlands, ²Ctr. for Human Drug Res. (CHDR), Leiden, Netherlands

Abstract Body:

Background: Few clinical trials target patients with intellectual disability (ID). However, this is likely to change due to accelerating gene discovery and the increasing knowledge about underlying mechanisms. We initiated a randomized, double-blind, placebo-controlled, two-way crossover study evaluating the effect of clonazepam in patients with an ARID1B-related disability. Here we report our experiences and describe potential challenges while conducting a clinical trial with participants with an intellectual disability or developmental delay. **Results:** We approached 47 patients: 23 of these were eligible and willing to participate (figure 1). Eventually, 16 patients were randomized over two study treatment periods. Initially, we planned to conduct the whole study in a single phase in 2021. Since the inclusion rate initially lagged, we allowed other study groups for a second phase in early 2022. Finally, 10 patients were included in the first phase and 6 in the second. Two patients initially declined but eventually participated in the second phase because we could report limited side effects. One participant dropped out on day 4 of the first treatment period because of increased anxiety possible related to clonazepam. **Conclusion:** Even though we had many potential participants, we struggled to achieve sufficient enrolment. The leading cause was that parents were afraid of side effects. Interestingly, our drop-out rate during the study was low, indicating that our patients were highly motivated. We recommend involving parents in the study design and adding multiple moments of inclusion so that experiences of the first testing period, for example, side effects, can be used to inform parents in subsequent testing periods.

Genetic Therapies Posters - Wednesday

PB2050. Leveraging Machine Learning to Improve Guide RNA Design for Efficient and Selective ADAR-Mediated RNA Editing

Authors:

Y. Jiang, B. Banjanin, L. Guo, L. Bagepalli, K. Rupp, Y. Savva, B. Booth, A. Briggs, R. Hause; Shape Therapeutics, Seattle, WA

Abstract Body:

Therapeutic RNA editing by redirecting natural ADAR enzymes offers promise as a safe method of gene therapy without risk of DNA damage or dependency on the delivery of non-human proteins. However, ADAR enzymes are inherently promiscuous, and deterministic rules for how different guide RNA (gRNA) sequences recruit ADAR and influence editing efficiency and specificity remain poorly understood. We demonstrate a successful application of machine learning coupled with a novel high throughput screening (HTS) and validation platform to identify deterministic gRNA features that improve ADAR-mediated RNA editing efficiency and specificity. Our approach explores the enormous gRNA design space to propose highly efficient and specific gRNAs that validate experimentally. We further propose novel machine learning approaches to expand modeling gRNA performances for additional targets.

The RNAfix® platform generates gRNAs that direct natural ADAR enzymes to therapeutically-relevant sites in the transcriptome to correct G->A mutations, control splicing, or modulate protein expression and function. To empirically determine the rules affecting on-target ADAR-mediated RNA editing, we constructed a HTS platform that assesses up to 500,000 structurally unique gRNAs against any clinically relevant target sequence. We used convolutional neural networks (CNN) to model gRNA performances using primary gRNA sequences as inputs and achieved high predictive accuracy for ADAR1 and ADAR2 editing. Input optimization successfully generated novel gRNA designs that outperformed any gRNA from the original HTS and exhibited primary and secondary sequence diversity that expanded vastly from the original HTS screen.

We have successfully established a robust pipeline for integrating supervised learning into our HTS design for each target. However, the ultimate goal of de novo, in silico design requires identifying generalizable rules that predict gRNA editing outcomes across multiple targets. To this end, we derived secondary structural features across gRNAs to model gRNA editing performance using gradient boosted decision trees that identify important structural features to prioritize for future HTS. We also extended CNN models towards better generalizability by fine tuning several novel transformer-based architectures that incorporate global dependencies of RNA sequence and secondary structure space across multiple candidate therapeutic targets. These developments rapidly shorten gRNA discovery timelines through in silico gRNA design for any number of common or rare genetic diseases.

Genetic Therapies Posters - Thursday

PB2051. Localization of KK13 peptide and their potential against ALS.

Authors:

A. Bhuiyan¹, S. Asakawa¹, N. Bailey Kobayashi², T. Yoshida²; ¹The Univ. of Tokyo, Tokyo, Japan, ²Inst. for Advanced Sci., Toagosei Co., Ltd., Tsukuba 300-2611, Japan

Abstract Body:

Amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) are a kind of neurodegenerative disease that is caused by expansion of the hexanucleotide repeat (GGGGCC) in the non-coding region of the C9orf72 gene. Three possible disease mechanisms have been hypothesized - DNA level: reduced levels of C9orf72 transcription (haploinsufficiency), RNA level: formation of toxic RNA foci and sequestration of RNA-binding proteins (RNA toxicity), and protein level: accumulation of the dipeptide repeat protein (DRP) generated by RAN (repeat-associated non-ATG) translation. Among the six DPR proteins, highly basic poly-PR (proline-arginine) was reported to show cytotoxicity and localization at the nucleolus. A novel polypeptide, KK13 was also shown to be located at the nucleolus, showing the possibility of antagonizing poly-PR was demonstrated. To examine the potential of the KK13 peptide as a therapeutic agent, a vector encoding 100 poly-PR repeats under dsRed was constructed. The poly-PR gene expression and their nuclear localization were observed. The KK13 peptide as a potential material against poly-PR dipeptide will be examined.

Genetic Therapies Posters - Wednesday

PB2052*. Long-term efficacy and safety of elamipretide in patients with Barth syndrome is presented through the 192-week open-label extension results of TAZPOWER.

Authors:

H. Vernon¹, W. R. Thompson², R. Manuel¹, A. Abbruscato³, J. Carr³, B. Hornby⁴, **J. Campbell⁵**; ¹Dept. of Genetic Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ²Dept. of Pediatric Cardiology, Taussig Heart Ctr., Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ³Stealth BioTherapeutics, Inc., Needham, MA, ⁴Dept. of Physical Therapy, Johns Hopkins Univ. Sch. of Med., Baltimore, MD, ⁵Stealth Biotherapeutics, Needham, MA

Abstract Body:

Introduction: Barth Syndrome (BTHS) is a rare mitochondrial disorder characterized by cardiomyopathy, skeletal myopathy, neutropenia, growth abnormalities, and shortened lifespan. BTHS is caused by defects in TAZ, the gene encoding for tafazzin, which is an acyltransferase involved in the final remodeling step to mature cardiolipin, an essential component of mitochondrial function. Elamipretide readily penetrates and transiently localizes to the inner mitochondrial membrane where it associates with cardiolipin to improve membrane stability, enhance ATP synthesis, and reduce the production of reactive oxygen species. This study evaluated the long-term efficacy and safety of elamipretide during the open-label extension (OLE) of the TAZPOWER trial conducted in patients with BTHS.

Methods: TAZPOWER was a 28-week randomized, double-blind, placebo-controlled crossover trial with a 168-week OLE. Patients aged ≥ 12 years with genetically confirmed BTHS received elamipretide 40mg subcutaneously daily or matching placebo for 12 weeks with a 4-week washout between treatments. Patients who entered the OLE continued on long-term elamipretide. The primary outcome measures were the 6-minute walk test (6MWT) and Total Fatigue score on the BarTH Syndrome Symptom Assessment (BTHS-SA). Secondary outcomes included muscle strength by hand-held dynamometry (HHD), Five Times Sit to Stand (5XSST), and SWAY Application Balance assessment.

Results: Ten patients entered the OLE with 8 reaching the week 168 visit and 3 of the 8 patients completed the week 192 visit. Significant improvements on the 6MWT were seen at all timepoints throughout the OLE with cumulative 96.1 meters (w168, $p=0.003$) and 122.7 meters (w192, $p=0.009$) of improvement. Mean BTHS-SA Total Fatigue scores were decreased from baseline at the start of the OLE and maintained below baseline at all OLE timepoints through week 192. An overall increase in the mean muscle strength by HHD from baseline was noted for all subjects over time. The mean changes from baseline were statistically significant at all OLE visits ($p < 0.05$). There was overall decrease in the mean 5XSST time observed for all subjects over time. An overall increase in the mean SWAY balance score was observed for all subjects over time, with statistical significance ($p < 0.05$) at visit weeks 24, 48, 72 and 168.

Conclusion: Long-term therapy with elamipretide was associated with improvements in functional assessments. These results suggest that elamipretide may improve the natural history of BTHS which is usually associated with a progressively deteriorating physical function parameters.

Genetic Therapies Posters - Thursday

PB2053. New class of anaplerotic compounds ameliorates substantial loss of lysine succinylation in propionyl-CoA carboxylase deficient cells

Authors:

A-W. Mohsen¹, A. Karunanidh¹, B. Seminotti¹, C. Van't Land¹, J. Vockley²; ¹Univ. of Pittsburgh, Pittsburgh, PA, ²UPMC Children's Hosp. of Pittsburgh and Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract Body:

Background: Propionic acidemia (PA) is an autosomal recessive metabolic disorder caused by deficiency of propionyl-CoA carboxylase (PCC), a mitochondrial enzyme that catalyzes conversion of propionyl-CoA to *S*-methylmalonyl-CoA. The current treatment approach is to control metabolic episodes of acidosis, hypoglycemia, and hyperammonemia. Propionyl-CoA is a common catabolic product of Val, Ile, Met, Thr, and odd-chain and branched-chain fatty acids. While excess propionyl-CoA inhibits *N*-acetylglutamate synthetase causing hyperammonemia, its thiolysis introduces toxic levels of propionic acid and its derivatives and depletion of its downstream pathway product, succinyl-CoA. Succinyl-CoA's depletion disrupts the structure/function of 1200 mitochondrial proteins modulated by Lys succinylation/desuccinylation including various Krebs cycle enzymes. We are developing a new class of compounds that address the underlying cause of PA namely the depletion of succinyl-CoA and accumulation of toxic propionic acid and its derivatives. **Methods:** Histological sections from liver of a PA patient were stained with hematoxylin and eosin to assess cell morphology. Immunofluorescence (IF) staining with antisuccinyllysine and antipropionyllysine antibodies was used to examine Lys succinylation and propionylation. Cultured HEK293 *PCCA*^{-/-} cells were treated with compound PMA010 for 72 hours and Lys succinylation and propionylation was evaluated by IF staining. Propionic acid derivatives were measured in cell culture media using tandem mass spectroscopy. **Results:** Concurrent with changes in hepatocytes' morphology, PA liver tissue IF staining showed substantial loss of Lys succinylation and gain in Lys propionylation compared to control tissue. In HEK293 *PCCA*^{-/-} cells, the loss of antisuccinyllysine staining intensity was corrected with the PMA010 treatment to levels similar to those observed in the parent HEK293 cells. Propionylcarnitine, propionylglycine, and hydroxypropionylglycine measured in the HEK293 *PCCA*^{-/-} cell culture media containing the PMA010 were decreased by 59, 40, and 80%, respectively, compared to their levels in media of cells without the compound. **Conclusions:** Results confirm the substantial decrease in Lys succinylation in patient liver and in HEK293 *PCCA*^{-/-} cells similar to what we previously reported in patient fibroblasts. Restoring Lys succinylation to normal in HEK293 *PCCA*^{-/-} cells and the decrease in propionic acid derivatives in the media identify PMA010 as a promising compound to further optimize its effectiveness in treating PA.

Genetic Therapies Posters - Wednesday

PB2054*. Novel ASO based treatment shows promise in treating CMT2S, preclinical data

Authors:

B. Przychodzen, S. Smieszek; Vanda Pharmaceuticals, Washington, DC

Abstract Body:

Charcot Marie Tooth type 2S (OMIM 616155), is an autosomal recessive type of CMT, an inherited peripheral neuropathy. Rare variants in immunoglobulin mu-binding protein 2 (IGHMBP2) have been shown to cause CMT Type II. These have been shown to result in abnormal RNA processing which likely leads to alpha-motor neuron degeneration. CMT2S is primarily characterized by distal muscle atrophy, weakness with areflexia, and relatively minor sensory involvement. Cassini et al., 2019 reported a patient whose suspected diagnosis was CMT. Whole-genome sequencing has revealed paternally inherited cryptic splice site variant (inherited non-coding variant (c.1235 + 894 C>A) deep in intron 8). RT-PCR analysis was consistent with activation of the cryptic splice site. Bidirectional sequencing of cDNA derived from the patient's cells identified both ends of the splicing alteration. The abnormal transcript was shown to undergo nonsense-mediated decay (NMD), resulting in haploinsufficiency. The objective of this study was to target IGHMBP2 - specifically cryptic splice site variant with a novel ASO designed to avoid NMD. We have obtained patient's fibroblast cell line and confirmed the variant with WGS, furthermore, we also confirmed NMD induced by cryptic splicing. We designed an ASO targeting specifically deep in intron 8 (c.1235 + 894 C>A). The ASO was 19mer targeting the sequence around CACTTCCAC(A)GGGGGAAGA. Analysis of the area of interest led to the design of several ASOs. These were further screened and prioritized based on optimal in silico binding affinity. CMT Type II patient-derived fibroblast cells underwent ASO treatment (10uM) and incubation. Successful cellular entry of the ASO was confirmed with flow cytometry (fluorescein labeled ASO (GFP+ 99.8%)). Upon treatment with ASO we have observed a significant increase (~30% increase) of the IGHMBP2 protein levels in the oligo-treated samples as compared to control (WB antibody Sigma SAB2106426). Additionally, qPCR results confirmed an increased ratio of restored WT transcript to cryptic exon-containing transcript (~1.3-fold). Furthermore, the ASO was shown to have limited off-target effects in silico. While the improved clinical formulation of the tested ASO may be necessary, the current preclinical data are supportive of a potentially efficacious treatment increasing the IGHMBP2 protein levels. The N-of-1 precision medicine approach may prove instrumental to the design of treatments for this highly diverse genetic disorder. This case exemplifies the shifting boundaries with rapid WGS-based clinical diagnoses coupled with the rapid design of personalized ASO-based therapeutics.

Genetic Therapies Posters - Thursday

PB2055. Novel siRNA-based therapeutic approach for Megacystis Microcolon Intestinal Hypoperistalsis Syndrome (MMIHS).

Authors:

I. Baldini, R. Ottalevi, P. Ebadi, N. Sabatini, A. Infascelli, G. Valoti, P. Graziani, M. Masciovecchio, C. Ciace, D. Clementoni, A. Lo Iacono, G. Iodice, M. Luciano, J. Caceres, R. Paone; Dante Labs, L'Aquila, Italy

Abstract Body:

Rationale MMIHS is a rare and severe form of functional intestinal obstruction in the newborn characterized by megacystis, microcolon, and intestinal dysmotility. A classic feature of MMIHS is represented by *ACTG2* mutations that can be both inherited in an autosomal dominant manner or occur as *de novo* events during oogenesis, spermatogenesis, or early embryonic development. *ACTG2* encodes γ -2 enteric actin and its mutations disrupt actin polymerization leading to impaired contraction of intestinal smooth muscle cells. Even though survival has improved in recent years, MMIHS is a condition that requires invasive palliative treatments. To meet the need for therapeutic approaches targeting the underlying cause of the disease, we designed a group of therapeutic siRNA to specifically target the *ACTG2* mutant allele, with no effect on the wild type (WT). **Methods** Whole genome sequencing (WGS) was performed to identify *ACTG2* mutations. DNA was isolated from chorionic tissue of a 13th week pregnant patient presenting an echography with alteration of gut and bladder of the newborn and sequenced on Illumina Novaseq6000. Variant analysis was performed using Variant Call Files (VCFs) computed with DRAGEN (Illumina) on the human reference genome GRCh37 and the pathogenic variant was identified with EXTENSA™ software. A Machine Learning (ML) software, fed with siRNA silencing information retrieved from experimental data, has been used as prediction tool for the identification of siRNAs with the most discriminatory power between *ACTG2*^{mutant} and *ACTG2*^{WT} mRNA. *In vitro* preclinical studies have been performed on HEK293 cells to evaluate the specific silencing of the *ACTG2*^{mutant} mRNA and to test the reduction of its expression in an efficient and highly specific manner. **Results** Upon identification of the pathogenic *ACTG2* variant, NM_001615.3:c.532C>T (NP_001606.1:p.Arg178Cys), we have predicted 8 siRNAs specific and effective for R178C-*ACTG2* mutation. Preliminary data suggest that our selected siRNA specifically target the *ACTG2*^{mutant} mRNA and reduce the expression of mutant γ -2 enteric actin while showing no effect on *ACTG2*^{WT}, thus enabling a condition of haplosufficiency. **Conclusions** Our study proposes a therapeutic approach based on siRNA as a novel treatment for MMIHS, identified siRNA sequences as good candidates for the development of a new drug and underscore a translational impact for future strategy to cure this disease. Further studies are necessary to verify that the observed reduced expression of mutant γ -2 actin prevents disease progression and to urgently translate these results into benefits for patients.

Genetic Therapies Posters - Wednesday

PB2056*. Personalized RNA interference approach as a nanotherapy for Crouzon syndrome: design of allele-specific siRNAs targeting FGFR2 mutant allele delivered by recombinant human nanoferritin.

Authors:

F. Tiberio¹, M. Salvati¹, L. Di Pietro¹, G. Tamburrini², P. Ceci³, E. Falvo³, L. Massimi², G. Tisci⁴, O. Parolini¹, A. Arcovito¹, W. Lattanzi¹; ¹Università Cattolica del Sacro Cuore, Rome, Italy, ²Fondazione Policlinico Univ.rio Agostino Gemelli, Rome, Italy, ³Consiglio Nazionale delle Ricerche, Rome, Italy, ⁴Università La Sapienza, Rome, Italy

Abstract Body:

Objective: Crouzon syndrome (CS) is a rare genetic disorder presenting with complex craniofacial malformations mainly due to the premature fusion of skull sutures. CS is caused by missense heterozygous gain-of-function mutations in the *Fibroblast Growth Factor Receptor 2 (FGFR2)* gene, which lead to constitutive activation of the receptor and of its downstream cascade. Currently the treatment is based on multiple surgeries to release the skull constraint that impairs brain growth. Post-surgical relapses occur in up to 40% cases requiring further operations associated with severe morbidities. The aim of this project is to develop a noninvasive therapy for CS using allele-specific siRNAs targeting the mutant *FGFR2* allele, delivered by recombinant human ferritin (HFt) as a highly biocompatible nanocarrier. This strategy is intended to restore FGFR2 signaling, thus hampering the aberrant FGFR2-induced osteogenesis and the subsequent premature suture fusion. **Methods:** Calvarial mesenchymal stromal cells (CMSCs) were isolated from calvarial tissue collected as surgical waste from *FGFR2* mutation-positive CS patients. A set of siRNA specifically targeting the mutant *FGFR2*-alleles of each patient enrolled was designed and tested in patient cells. The efficiency of each siRNA was evaluated through real time PCR. The expression of the receptor of ferritin *CD71* was investigated using real time PCR. CMSCs were incubated with fluorescein isothiocyanate-labeled HFt and the cellular uptake of the construct was analysed using fluorescence microscopy. Lastly, siRNAs have been encapsulated within ferritin cavity performing pH-dependent procedure and HFt-siRNAs complexes were tested in CMSCs using Incucyte Live-cells analysis system. **Results:** Gene expression analysis allowed identifying specific siRNAs with differential knockdown efficiency between wild-type and mutant *FGFR2* alleles in CMSCs derived from CS patients. In addition, expression analysis revealed that *CD71* was up-regulated during osteogenic differentiation of CMSCs. Fluorescence microscopy showed an efficient internalization of HFt within CMSCs cytoplasm. Preliminary results with HFt-based nanoparticles showed so far that, though siRNAs can be encapsulated in HFt, their intracellular trafficking is poorly detectable. **Conclusions:** Our data suggested that allele-specific *FGFR2* knockdown by siRNA represents a desirable strategy to silence *FGFR2* mutant allele in CS patients. We also demonstrated that HFt is suitable for delivery in CMSC. Future studies aim to optimize the intracellular trafficking and siRNAs release upon HFt internalization.

Genetic Therapies Posters - Thursday

PB2057. Pre-clinical antisense oligonucleotide treatment of CMT2E in a human induced pluripotent stem cell (iPSC)-derived motor neuron model.

Authors:

J. Medina¹, A. Rebelo², C. Yanick³, E. Jacobs⁴, S. Zuchner², M. Saporta⁵; ¹Univ. of Miami Miller Sch. of Med., MIAMI, FL, ²Univ Miami, Miami, FL, ³Univ. of Miami Miller Sch. of Med., Miami, FL, ⁴Univ. of Miami, Maimi, FL, ⁵Univ. of Miami, Miami, FL

Abstract Body:

Charcot-Marie-Tooth disease type 2E is caused by mutations in *NEFL* encoding neurofilament light chain (NFL), an integral component of the axonal cytoskeleton. Previous studies have established intracellular toxic NFL-positive aggregates in motor neurons. Increased levels of plasma and CSF NFL have been described as biomarkers for CMT2E. Our study aims to develop a genetic treatment strategy to prevent NFL aggregate formation and decrease NFL supernatant, a hallmark of axonal degeneration. Genetic treatments in dominant diseases have thus far proven challenging. Seven antisense oligonucleotides (ASOs) were developed spanning the allele-specific targetable region surrounding a missense mutation (p.N98S) in the *NEFL* gene. ASOs were designed with 2'-O-methyl modifications flanking 4 base pairs on each end with phosphorothioate modifications between all 18 base pairs to enable RNase H binding and clearance of the p.N98S mRNA transcripts. Stable transduction of Lenti-X 293T cell lines were produced with lentiviral vectors encoding wild type and mutant *NEFL* to assess the ASO allele-specific knockdown ability of all seven ASOs. ASO treatment of transduced Lenti-X 293T cells led to an allele specific knockdown of NFL in a human cell model confirmed via western blot at the protein level. We are currently investigating ASO efficacy in iPSC-derived 2D motor neurons and 3D neurospheres from CMT2E individuals and controls. To further assess allele specificity and potential off-target effects, we will be conducting allele-specific RT-PCR using iPSC-derived 2D motor neurons. To explore reversal of pathomechanistic changes observed, we will also be conducting post-treatment co-immunoprecipitation of NFL and known binding partners required for endogenous NFL-dynamics. Our results suggest a viable genetic targeting strategy for a therapeutic application in this autosomal dominant disease. Optimizing this approach in patient derived pre-clinical iPSC studies is a key strategy under FDA rules to design early human trials.

Genetic Therapies Posters - Wednesday

PB2058*. RNA editing of founder nonsense mutations causing inherited retinal diseases using site-directed endogenous adenosine deaminase acting on RNA.

Authors:

D. Sharon¹, N. Schneider¹, R. Steinberg², J. Valensi¹, A. Eylon², E. Banin¹, E. Levanon², S. Ben-Aroya²; ¹Hadassah Hebrew Univ Med. Ctr., Jerusalem, Israel, ²Faculty of Life Sci., Bar-Ilan Univ., Ramat Gan, Israel

Abstract Body:

Purpose: Targeted RNA editing utilizing the ubiquitous human adenosine deaminase acting on RNA (ADAR) enzyme is a possible new genetic therapeutic approach for the treatment of inherited retinal diseases (IRDs). Utilizing guideRNA (gRNA) to recruit the endogenously expressed ADAR enzyme to a mutated RNA and facilitating the deamination of a specific adenosine to inosine (read as a guanine by the ribosome), allows for the correction of mRNA transcripts in a transient and tunable manner. According to our recent analyses, 40% of single nucleotide variants (SNVs)-causing IRDs are candidates for ADAR-directed editing. Our aim is to design and test gRNAs that induce targeted ADAR editing for 3 common Israeli mutations causing IRDs: *TRPM1*- p.K294*, *FAM161A*- p.R523*, and *KIZ*- p.R76*. **Methods:** After determining Israeli IRD candidate mutations, we used a yeast model to identify candidate gRNAs for these mutations by measuring yeast survival and percent editing in next generation sequencing (NGS). Effective gRNA sequences were then assessed for appropriate chemical modifications and produced as single-stranded RNAs. We developed a fluorescence-expressing plasmid reporter system for ADAR editing by inserting a gene cassette harboring a nonsense mutation in between mCherry and EGFP, and subsequently transfected these plasmids into HeLa cells to test the candidate gRNAs. Successful editing of target gene RNA fragments produced by the reporter plasmid is measured through fluorescent microscopy, Sanger sequencing, and NGS. **Results:** Our yeast model identified three possible gRNAs, one for each candidate mutation previously mentioned. In this yeast model, the gRNAs targeting mutations in *TRPM1*, *FAM161A*, and *KIZ* showed 9%, 1%, and 0.03% editing respectively of a relevant nucleotide flanking each mutation. Using our reporter system in HeLa cells, we found that the gRNA complementary to the target *TRPM1* mutation induced RNA editing levels in our system of up to 55% in Sanger sequencing, 40% in NGS, and the treated cells expressed both mCherry and EGFP. Due to sequence constraints in *FAM161A* and *KIZ*, lower editing levels were obtained- up to 5% and 10% respectively. Off-target edited bases were observed in the vicinity of the *KIZ* edited base, while practically no off-targets were detected in the vicinity of the two other studied mutations. **Conclusions:** Targeted RNA editing utilizing the ADAR enzyme could be a useful novel form of genetic therapy due to its ability to edit SNVs in a tunable manner. Next steps include applying this technology to the appropriate knock-in mouse models and retinal organoids and studying editing efficiency on missense mutations.

Genetic Therapies Posters - Thursday

PB2059. Sustained efficacy and safety up to 3.5 years in adults with glycogen storage disease type Ia (GSDIa): results from a phase 1/2 clinical trial of DTX401, an AAV8-mediated, liver-directed gene therapy.

Authors:

J. Mitchell¹, R. Riba-Wolman², D. Rodriguez-Buritica³, A. Ahmad⁴, M. Couce Pico⁵, T. Derks⁶, D. Weinstein², D. Mitragotri⁷, V. Valayannopoulos⁷, E. Crombez⁷; ¹Montreal Children's Hosp., Montreal, QC, Canada, ²Univ. of Connecticut, Farmington, CT, ³Univ. of Texas McGovern Med. Sch., Houston, TX, ⁴Univ. of Michigan, Ann Arbor, MI, ⁵Hosp. Clínico Univ.rio de Santiago de Compostela, Santiago de Compostela, Spain, ⁶Univ. of Groningen, Groningen, Netherlands, ⁷Ultragenyx Pharmaceutical Inc., Cambridge, MA

Abstract Body:

Background: Glycogen storage disease type Ia (GSDIa) results from a deficiency of glucose 6-phosphatase (G6Pase) which is essential for glycogenolysis and gluconeogenesis. DTX401 is an investigational adeno-associated virus serotype 8 (AAV8) vector expressing the human *G6PC* gene under transcriptional control of the native promoter. **Methods:** This global, open-label, phase 1/2, dose escalation gene therapy trial (NCT03517085) is evaluating the safety and efficacy of a single DTX401 intravenous infusion in adults with GSDIa. Three patients in Cohort 1 received DTX401 2.0×10^{12} genome copies (GC)/kg, and three patients each in Cohorts 2, 3, and 4 received 6.0×10^{12} GC/kg. Cohort 4 includes a prophylactic steroid regimen to prevent transaminase elevation. **Results:** In the 12 patients enrolled in Cohorts 1 through 4, mean (SD [range]) total daily cornstarch intake reduction from baseline to Week 52 was 70.0% (23.1 [28-100%]), $p < 0.0001$. From baseline to last available timepoint (~3.5 years for three patients), mean (SD [range]) total daily cornstarch intake reduction was 73.8% (23.5 [29-100%]), $p < 0.0001$. From Cohort 3 onward, continuous glucose monitoring was implemented. In Cohort 3, the average percentage of time in euglycemia (blood glucose range of 60 mg/dL to 120 mg/dL) from Baseline to Weeks 77 to 80 increased 14%, despite a reduction in average cornstarch intake of 65%. In Cohort 4, the average percentage of time in euglycemia from Baseline to Weeks 49 to 52 remained stable (+0.5%), despite a reduction in average cornstarch intake of 51%. At Week 52 exit interviews, patients reported more energy and stamina, better mental clarity, improved glycemic control independent of cornstarch, improved sleep quality, and improvements in health-related quality of life related to cornstarch intake reduction. Patient Global Impression of Change scores at the Week 52 visit indicated that 67% of patients (n=9) felt their disease was moderately or much improved since the start of the study. All serious adverse events (Grade 1 or Grade 2: n=17; Grade 3: n=2) were classified as serious due to hospitalizations and were determined to be unrelated to study drug by both the investigator and study sponsor; all resolved. No dose-limiting toxicities were reported. **Conclusions:** DTX401 showed a positive efficacy and tolerability profile in all treated patients at Week 52 that was sustained for up to 3.5 years in patients enrolled in Cohort 1. Patients in all cohorts showed a significant reduction in cornstarch needs from baseline to Week 52 that was sustained to the last available timepoint. Additional glycemic control, fasting time, and health-related quality of life data will be reported.

Genetic Therapies Posters - Wednesday

PB2060*. Testing gene therapy for achromatopsia-like visual deficits in nonhuman primates affected by naturally occurring missense mutations in *PDE6C*

Authors:

J. Rogers¹, A. Moshiri², J. Stout¹, S. Thomasy², R. Chen¹; ¹Baylor Coll. of Med., Houston, TX, ²Univ. of California, Davis, Davis, CA

Abstract Body:

Various forms of inherited retinal disease disrupt the function of cone photoreceptors and thus affect both high acuity vision and perception of color. Many photoreceptor disorders are due to mutations in a single gene and are therefore candidates for gene therapy. Phosphodiesterase 6C (*PDE6C*) is a gene known to cause one form of cone-specific visual system dysfunction: achromatopsia. Patients with damaging mutations in *PDE6C* exhibit loss of cone photoreceptor mediated signaling and thus lose color vision and macula-dependent high-resolution vision as well as becoming photophobic due to dependence on rod photoreceptors. We have previously reported that at the California National Primate Research Center, we identified a series of rhesus macaques (*Macaca mulatta*) that displayed evidence of photophobia and apparently diminished visual system function. Whole genome sequencing showed that the two initial probands were both homozygous for an amino acid change affecting the catalytic domain of the PDE6C protein. *In vitro* assays of enzyme function demonstrated that the amino acid change (R565Q) significantly reduces enzymatic function and thus is expected to have profound effects on cone photoreceptor activity. Electroretinograms confirmed loss of cone photoreceptor signaling and retention of normal rod function. We have now, in unpublished work, tested an adenovirus-associated viral vector (AAV5) that contains the macaque *PDE6C* gene driven by the cone specific 1.7-kb L-opsin promoter. Subretinal injection of this construct into two normal control animals showed no serious adverse reaction. We next injected one eye each of two affected macaques with the *PDE6C*-carrying AAV5, one at low dose (1.5 E10 vg/eye) and one with a higher dose (1.5 E11 vg/eye). One month after injection the animal receiving the high dose of gene therapy showed marked improvement of cone photoreceptor function in the treated eye, as measured by photopic single flash and flicker electroretinogram, with no change in contralateral control eye. Six weeks after injection the injected eye showed significant rescue of signal using multifocal ERG, markedly different from the control eye. These results provide initial evidence for feasibility of gene therapy as treatment for achromatopsia due to *PDE6C* deficit. A breeding program is actively producing additional macaque carriers of this mutation in order to facilitate further studies. In parallel we are developing stem cell derived retinal organoids to compare the efficacy of gene therapy versus cell-based replacement therapy.

Genetic Therapies Posters - Thursday

PB2061. The Jackson Laboratory Center for Precision Genetics: Preclinical research for rare diseases

Authors:

C. Lutz¹, S. Murray², K. Snow¹, S. Kneeland¹, A. Zuberi¹; ¹The Jackson Lab., Bar Harbor, ME, ²Jackson Lab., Bar Harbor, ME

Abstract Body:

There are more than 7,000 known rare disease that affect more than 350 million people worldwide. The majority of rare diseases affect children, many of which do not survive to reach their fifth birthday. There are currently no FDA approved drugs for more than 95% of all rare disease. However, the landscape for rare disease is changing. Advances in high-throughput sequencing technology has accelerated the pace of novel disease allele discovery and improved the time to diagnosis for patients. Further, advances in genomic medicine, such as gene replacement, antisense oligonucleotides and genome editing have opened new doors in treatments for rare diseases. This progress has revealed a new bottleneck and challenge: the growing need for experimental systems to validate discoveries, interrogate biological mechanisms, and provide platforms for preclinical development. The mouse is an ideal model system as it recapitulates key features of human disease, and advances in genome engineering technology has enabled the rapid and efficient generation of sophisticated alleles. To fill this gap in experimental models and to facilitate research that will lead to therapeutic advancements in rare disease, the overarching goal of The Jackson Laboratory Center for Precision Genetics (JCPG) is to deliver a comprehensive animal model development pipeline to the rare disease community. Our team works with patient based organizations and clinical investigators to identify unmet need for model systems and engineer precise human disease-relevant alleles in mice. We extensively characterize these mouse models to demonstrate the key disease-relevant phenotypes and establish the line as a suitable model of disease. Finally, the JCPG can perform testing of novel therapeutic efficacy testing in the mouse models that can inform clinical trials in terms of target tissues, dose, timing of treatment and biomarker analysis. For more information on nominations, visit our website at <https://www.jax.org/research-and-faculty/research-centers/precision-genetics-center>

Genetic Therapies Posters - Wednesday

PB2062. Two years of venglustat combined with imiglucerase shows continued positive effects on neurological features and brain connectivity in adults with Gaucher disease type 3

Authors:

I. Batsu¹, **R. Zheng**², P. Minini³, D. Cherkasov³, D. Scott⁴, O. Goker-Alpan⁵, J. Hennermann⁶, K. Sakurai⁷, T. Cox⁸; ¹Sanofi, Bridgewater, NJ, ²Sanofi, Cambridge, MA, ³Sanofi, Chilly Mazarin, France, ⁴Clario, San Mateo, CA, ⁵Lysosomal & Rare Disorders Res. and Treatment Ctr., Fairfax, VA, ⁶Univ. Med. Ctr. Mainz, Ctr. for Pediatric and Adolescent Med., Mainz, Germany, ⁷The Jikei Univ. Sch. of Med., Dept. of Pediatrics, Tokyo, Japan, ⁸Univ. of Cambridge, Dept. of Med., Cambridge, United Kingdom

Abstract Body:

Background: Venglustat is a brain-penetrant glucosylceramide synthase inhibitor under investigation for treatment of Gaucher disease type 3 (GD3). After 1 year of venglustat + imiglucerase treatment in the Phase 2 LEAP trial (NCT02843035/Sanofi), target venglustat concentrations were maintained in CSF, and median glucosylceramide and glucosylsphingosine in plasma and CSF decreased markedly with favorable safety and tolerability. Ataxia scores improved, brain volume increased in patients with adequate venglustat exposure, and fMRI showed stronger connectivity between brain regions at Weeks 26/52 in relation to baseline.

Aims: Evaluate 2-year treatment outcomes in the LEAP trial.

Methods: The Phase 2 LEAP trial evaluated oral venglustat (15-mg daily) + intravenous imiglucerase (usual dose) in 11 adults with GD3 who had received ERT for ≥ 3 years and achieved non-neurological therapeutic goals before enrollment. Primary endpoints were safety, tolerability, and changes in glucosylceramide (GL-1) and glucosylsphingosine concentrations in CSF during 1 year of treatment. Secondary endpoints included plasma biomarkers, neurological assessments, volumetric and functional brain MRI, and systemic disease measures. All patients continued treatment for an additional year; 9 patients are currently in study.

Results: There were no deaths or adverse events leading to study discontinuation. Systemic manifestations remained stable. One patient had low-to-undetectable venglustat exposure after Week 26; although the cause was undetermined, non-adherence could not be ruled out. In all patients, a decrease in plasma GL-1 at 1 year continued at 2 years [median (IQR) % change from baseline: -78% (72-84) to -80% (79-85)] and sustained decreases in plasma glucosylsphingosine were observed from 1 year to 2 years [median (IQR) % change from baseline: -56% (41-60) to -56% (45-70)]. On the Scale for Assessment and Rating of Ataxia score, 91% of patients improved or had no worsening at 1 and 2 years. Brain atrophy on MRI in 10 patients had partially reversed from baseline to year 1 but markedly declined in the patient without sustained exposure to venglustat. In the remaining patients who were restudied at 104 weeks, mean brain volume remained stable, and connectivity across key brain regions (resting state networks) on functional MRI showed additive connectivity enhancement in year 2 between RSNs 1, 2 and 3 with RSN 8 among patients with venglustat exposure.

Conclusions: During two years of treatment, venglustat + imiglucerase treatment showed favorable safety and tolerability outcomes and salutary neurological improvements were maintained.

Genetic Therapies Posters - Thursday

PB2063. Venglustat, a novel, investigational, brain-penetrant glucosylceramide synthase inhibitor, for Gaucher disease type 3: phase 3 LEAP2MONO trial design

Authors:

W. Heine¹, I. Batsu², P. Minini³, D. Cherkasov³; ¹Sanofi, Cambridge, MA, ²Sanofi, Bridgewater, NJ, ³Sanofi, Chilly Mazarin, France

Abstract Body:

Background: Venglustat is a novel, small-molecule, brain-penetrant glucosylceramide synthase inhibitor under investigation as a disease-modifying therapy for Gaucher disease type 3 (GD3). Imiglucerase enzyme replacement therapy (ERT) ameliorates hematologic, visceral, and bone manifestations of GD3; however, there is currently no treatment for the neurologic manifestations. After one year of venglustat+imiglucerase in the Phase 2 LEAP trial (NCT02843035/Sanofi), venglustat concentration was maintained in CSF, median glucosylceramide and glucosylsphingosine in CSF decreased markedly, and potential to ameliorate neurological manifestations was demonstrated. **Aims:** Describe the design of the LEAP2MONO study of venglustat monotherapy for GD3. **Methods:** LEAP2MONO is a Phase 3, randomized, double-blind, trial evaluating efficacy and safety of venglustat vs imiglucerase in adults and children ≥ 12 years with GD3 who have reached therapeutic goals with ERT. Patients will be randomized to receive either once-daily oral venglustat with biweekly placebo infusions or biweekly imiglucerase infusions with once-daily oral placebo for 52 weeks (primary analysis period). Venglustat patients who meet prespecified criteria for decline in GD status can receive ERT rescue therapy. After Week 52, all patients will receive venglustat for 52 weeks (extended treatment period). Safety follow-up will continue through 30-37 days after last treatment. Enrollment is planned for 40 participants, including ≈ 10 pediatric participants. Primary endpoints are change from baseline to Week 52 on the Scale for Assessment and Rating of Ataxia modified total score and the Repeatable Battery for the Assessment of Neuropsychological Status total scale index score. Secondary endpoints include safety, tolerability, and changes from baseline in spleen volume, liver volume, hemoglobin, and platelets. Exploratory endpoints include changes from baseline in glucosylceramide and glucosylsphingosine in plasma and CSF, venglustat pharmacokinetics, and patient-reported outcomes. This study will evaluate whether the effects of venglustat monotherapy translate to clinical benefit on neurological manifestations with maintenance of systemic disease stability in GD3 patients.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2064. A novel human mitochondrial donating cell type promotes maturation of GV oocytes

Authors:

T. Lee¹, Y. Chan¹, T. Li¹, H. Chan¹, Q. Lian²; ¹The Chinese Univ. of Hong Kong, Hong Kong, China, ²Hong Kong Univ., Hong Kong, China

Abstract Body:

Delayed marriage and parenthood have been increasingly common and have become a global issue, causing a significant increase of advanced maternal age (AMA) mothers. Aging leads to the qualitative and quantitative decline of oocytes, which translates to poor embryo development and available mature oocytes for IVF. Currently, there is no proven solution to rescue or increase the number of usable mature oocytes in ART procedure. We recently developed a method to increase the number of mature (MII) oocytes through *in vitro* maturation of immature (GV) oocytes with mesenchymal stem cells (MSCs). This novel non-invasive method allows producing more mature (MII) oocytes for IVF and improves the quality. We demonstrated Green fluorescence Protein (GFP)-labelled mitochondria were transferred to mouse oocytes via tunneling nanotubes (TNT). Here we show an alternative non-stem cell human cell source that can serve similar mitochondria donating function as MSCs. Our results revealed that MSC-mediated mitochondrial transfer can improve mitochondrial function and the average maturation rate of GV oocytes by 38% and 243% respectively. The study thus provides a foundation for creating more usable oocytes for ART procedure.

Funding: The work is supported by Hong Kong Research Grant Council (GRF project no. 14111320).

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2065. Assessing the accuracy of variant detection and coverage bias in mitochondrial DNA (mtDNA) after whole genome amplification of single fibroblast cells with known mtDNA heteroplasmic mutations to effectively optimize preimplantation genetic testing of mtDNA related disorders.

Authors:

A. Novoselska^{1,2}, A. Aggarwal¹, R. Antes¹, Y. S. S. Kwok^{1,2}, M. Ho¹, M. Ho¹, C. Librach^{1,2,3,4,5}, S. Madjunkova^{1,6}; ¹CReATe Fertility Ctr., Toronto, ON, Canada, ²Dept. of Physiology, Univ. of Toronto, Toronto, ON, Canada, ³Dept. of Obstetrics and Gynecology, Univ. of Toronto, Toronto, ON, Canada, ⁴Inst. of Med. Sci., Univ. of Toronto, Toronto, ON, Canada, ⁵Sunnybrook Res. Inst., Toronto, ON, Canada, ⁶Dept. of Lab. Med. and Pathobiology, Univ. of Toronto, Toronto, ON, Canada

Abstract Body:

Objectives: Knowledge regarding maternal transmission of mtDNA heteroplasmy (het) to preimplantation embryos is lacking due to the technical bias of whole genome amplification (WGA), which is necessary to obtain enough DNA from 5-10 trophoblast (TE) biopsied cells during preimplantation genetic testing (PGT). WGA can introduce uneven coverage bias and false positive single-nucleotide changes (SNVs) in genomic DNA, which can lead to inaccurate detection of variants. Our aim was to assess and compare technical bias between two widely used WGA platforms, REPLI-g (RPG) (QIAGEN) and SurePlex (SPX) (Illumina), using two different fibroblast cell lines with known mtDNA levels at specific loci. We also aimed to compare the accuracy of het levels detection with these platforms to the known het levels.

Materials and Methods: We used two different fibroblast cell lines with known het levels: F49 - 95% het at m.8993T>C and F101 - 40% het at m.10191T>C in the mtDNA. DNA was extracted from 1.7×10^6 cells from F49 and from F101 using DNeasy Kit (QIAGEN) to represent the unamplified (UA) source of DNA (n=2). Three technical replicates of 10 single cells from each line were collected for both platforms to represent the mock TE DNA source (n=12). For complete mtDNA enrichment, DNA Prep with Enrichment (Illumina) was performed during library prep using custom probes (Twist Bioscience). Sequencing was performed with NextSeq550 (Illumina) and data analysis with the DRAGEN Enrichment (Illumina) analysis pipeline.

Results: All samples were sequenced at an average (av.) depth of 2971x. The av. het level detected at m.8993T>C for RPG (60%) and for SPX (54%) was similar, but significantly lower than the 95% known het ($p < 0.05$). At m.10191T>C, the av. het levels for RPG (34%) and SPX (30%) were comparable, but significantly lower than the 40% known het ($p < 0.05$). A total of 28 variants were detected in UA-F101, 38 in WGA F101, 10 in UA-F49 and 30 in WGA F49. The concordance of variants between RPG and SPX was 92% for F101 and 77% for F49. Between UA and RPG, variant concordance was 93% for F101 and 91% for F49. Between SPX and UA reference, the concordance was 83% for F101 and 78% for F49. Both WGA kits had allele dropout occurring at 2 positions (m.4769 and m.8860) for both cell lines, and amplification bias occurred at 8 positions only for F49.

Conclusions: Whole genome amplification by RPG or SPX, as used in PGT, has relatively high reproducibility for amplification of mtDNA. Both WGA kits have skewed het detection which should be assessed individually for specific variants to limit misinterpretation of PGT for mtDNA mutations.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2066. Assessing the magnitude of clinical utility of preconception expanded carrier screening for prevention of neurodevelopmental disorders

Authors:

P. Boonsawat¹, A. Horn^{1,2}, K. Steindl¹, A. Baumer¹, P. Joset³, D. Kraemer¹, A. Bahr¹, I. Ivanovski¹, E. Cabello¹, M. Papik¹, M. Zweier¹, B. Oneda¹, P. Sirleto¹, T. Burkhardt⁴, H. Sticht², A. Rauch^{1,5}; ¹Inst. of Med. Genetics, Schlieren-Zürich, Switzerland, ²Inst. of Biochemistry, Erlangen, Germany, ³Med. Genetics, Basel, Switzerland, ⁴Univ. Hosp. Zurich, Zurich, Switzerland, ⁵Univ. Children's Hosp. Zurich, Zurich, Switzerland

Abstract Body:

The magnitude of clinical utility of preconception expanded carrier screening (ECS) concerning its potential to reduce the risk of affected offspring, especially those with disabling neurodevelopmental disorders (NDDs), is unknown. Since determination of such risk-reduction potential in general populations would require huge cohort numbers and long-term follow-up data, we retrospectively studied the parental samples of a cohort of children with disabling NDDs, who previously had undergone extensive diagnostic work-up. To this end, we used exome sequencing data from 700 parents of children with NDD and blindly screened for carrier-alleles in up to 3,046 recessive/X-linked genes. Depending on variant pathogenicity thresholds and gene content, risk-reduction potential for NDD was up to 43.5% in consanguineous, and 5.1% in nonconsanguineous couples. This risk-reduction potential was compromised by underestimation of pathogenicity of missense variants in 16 couples due to non-automatable criteria not available for the screening set-up, which corresponds to a false-negative ECS rate of 4.6%. Furthermore, un-investigated inherited copy-number variants and compound heterozygosity of one inherited and one de novo variant that was not detectable by carrier screening (0.9% each) also mitigated the risk-reduction potential. Adherence to the ACMG recommendations of restricting ECS to genes with high carrier frequency for nonconsanguineous couples would not detect diagnoses in 9 couples, which accounted for more than 50% of the detectable inherited NDD-risk in this group. While such guidelines, as well as most previous studies focused on restricted gene lists of supposed moderate to severe disease genes, screening of, for instance, 1,300 genes, listed as severe by the Mackenzie's Mission Project in 2020, would have missed ~30% of our recessive diagnoses. Thus, for optimized clinical utility of ECS, screening in recessive/X-linked genes regardless of their frequency (ACMG Tier-4) and sensible pathogenicity thresholds should be considered for all couples seeking ECS. We therefore suggest a feasible approach for improved variant classification in carrier screening resulting in high sensitivity without compromising specificity. Taken together, our findings revealed the magnitude of utility of preconception ECS for NDD-risk in relation to parental consanguinity, screened gene content and pathogenicity assessment, and will inform genetic counselling in reproductive medicine.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2067. Assisted reproductive technology and DNA methylation at imprinted genes

Authors:

R. Lyle^{1,2}, Y. Lee³, C. Page^{4,5}, H. E. Nustad^{6,7}, P. Magnus⁷, S. E. Håberg⁷; ¹Oslo Univ. Hosp., Oslo, Norway, ²Norwegian Institution of Publ. Hlth., Oslo, Norway, ³Norwegian Inst. of Publ. Hlth., Oslo, Norway, ⁴Univ. of Oslo, Oslo, Norway, ⁵Norwegian Inst. of Publ. Hlth., Oslo, Norway, ⁶Deepinsight, Oslo, Norway, ⁷Norwegian Inst. of Publ. Hlth., Oslo, Norway

Abstract Body:

Assisted reproductive technology (ART) use is increasing, and around 8 million children have been conceived using ART. As more women postpone childbearing, and egg freezing is becoming more socially acceptable, this increase is expected to continue. ART is associated with several adverse pregnancy outcomes, with implications for childhood and adult health. The impact of ART on long-term health is not clear. Some studies have suggested an influence on neurodevelopment, cardiovascular function, metabolism, growth and malignancies. However, it is unclear whether the differences observed in ART conceived children are caused by the ART procedure itself or by underlying factors associated with parental subfertility.

Epigenetic mechanisms regulate gene activity, cell function, and development. DNA methylation, the attachment of a methyl group to a cytosine preceding a guanine base (CpG), is an epigenetic mechanism essential for normal embryonic development. ART involves the manipulation and culturing of embryos during a period that coincides with extensive genome-wide epigenetic remodeling. It is therefore plausible that ART procedures alter the fetal epigenome, potentially perturbing development and thereby influencing later health. So far, there is limited and inconsistent evidence for ART-induced DNA methylation changes, with the exception of findings in imprinting disorders.

Genomic imprinting is an epigenetic phenomenon that results in parent-of-origin gene expression. Imprinting is regulated by DNA methylation at both primary imprinting control regions (ICRs), which are inherited from the parental gametes and are not changed during epigenetic remodelling, and secondary differentially methylated regions (DMRs), which are reestablished during early development. It is thus important to distinguish between ICRs and DMRs when considering the effects of ART.

To investigate if ART perturbs DNA methylation at imprinted loci, we measured DNA methylation (Illumina EPIC array) in trios of 962 ART and 983 naturally conceived newborns (5835 samples total) from the Norwegian Mother, Father and Child Cohort study (MoBa). Using trios allows us to address the potential influence of underlying parental subfertility on newborn DNA methylation. Here we show that ART conceived newborns display differences in DNA methylation at certain imprinted genes.

Associations persist after controlling for parents' DNA methylation, and are not explained by parental subfertility.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2068. Capacity Building: Exploring the Use of Newborn Screening Data to Understand Neurodevelopmental Outcomes

Authors:

Z. Talebizadeh¹, J. Taylor², G. Tona³, Y. Unnikumar⁴, K. Chan⁵, A. Brower⁶; ¹ACMG, Overland Park, KS, ²American Coll. of Med. Genetics and Genomics, Baltimore, MD, ³NBSTRN, Bethesda, MD, ⁴American Coll. of Genetics and Genomics, Silver Spring, MD, ⁵American Coll. of Med. Genetics and Genomics, Bethesda, MD, ⁶American Coll. of Med. Genetics and Genomics, Dakota Dunes, SD

Abstract Body:

Introduction: Newborn screening (NBS) is the largest public health genetic program with 3.8 million newborns screened for up to 81 genetic conditions each year. Many of these conditions have comorbidities, including autism, intellectual and/or developmental disabilities (IDD), and these comorbidities impact health outcomes across the lifespan. The majority of screened conditions are inborn errors of metabolism (IEM), frequently associated with IDD and/or neurological problems. The Longitudinal Pediatric Data Resource (LPDR) is one of the data tools developed by the Newborn Screening Translational Research Network. The LPDR captures, stores, analyzes, visualizes, and shares genomic and phenotypic data over the lifespan of NBS identified newborns to facilitate understanding of genetic disease and to assess the impact of early identification and treatment. Data deposited in the LPDR is available for secondary use by the research community. We undertook an effort to 1) evaluate the analytical utility of the existing data to comprehend neurodevelopmental trajectories, and to 2) prioritize question-answer sets for developing further common data elements (CDEs) for metabolic disorders. **Methods:** We examined health information from a completed, 10-year natural history study of IEMs, called Inborn Errors of Metabolism Collaborative. We extracted data elements related to either neurodevelopmental status or the associated clinical symptoms. A mixed methods approach (data mining as well as community-based participatory approach, focus group, and systematic reviews) was used to conduct statistical power analysis and a feasibility assessment, including identification of needs and priorities. **Results:** We will describe a strategy roadmap for utilizing the NBS system to understand neurodevelopmental outcomes, by outlining 1) aggregated data points from completed studies within the LPDR, 2) developed CDEs including branching logic to facilitate future data collection and analytical utility, and 3) identified barriers, facilitators, and motivators along with suggested recommendations. **Conclusion:** The present study provides a new capacity assessment of this unique public health system from the standpoint of understanding neurodevelopmental outcomes. Documenting behavioral and neurodevelopmental status of participants in long-term follow up NBS studies, using consensus-based codes and standards, would expand the utility of the LPDR datasets for use by the research community. Findings from this capacity building project can inform future efforts toward advancing research infrastructure for this established public health program.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2069. Cell free fetal (cff) DNA assessment using Y- chromosome specific sequences and amplicon NGS of targeted SNPs for possible implementation in non-invasive prenatal testing of common chromosomal aneuploidies

Authors:

R. Vodicka, J. Bohmova, R. Vrtel, M. Prochazka; Univesity Hosp. Olomouc, Olomouc, Czech Republic

Abstract Body:

Non-invasive prenatal testing belongs to the main in the field of prenatal diagnostics of common aneuploidies. Assessment of the fetal fraction is an important part of the entire test procedure. This study aims to assess the fetal fraction using Y-specific sequences in the created NGS panel of single-nucleotide polymorphisms (SNP) and to estimate the possibilities of using this panel for the NIPT. Particularly, we focused on the coverage analysis of 8 SNPs (rs9786043; rs13305774; rs9786562; rs72617693; rs61797733; rs3853054; rs3900; rs57351463) from the Y chromosome to assess and estimate the total amount of reads originated from cffDNA. The study included 17 samples of DNA isolated from maternal plasma of pregnant women with male fetuses from 13 to 17 weeks of pregnancy. Using a database of human genetic variants and polymorphisms from the UCSC genome browser there was designed *in-silico* set of probes targeting in population common SNPs polymorphisms from chromosomes 13, 18, 21, X, Y and from the reference chromosomes. A total of 408 SNPs have been proposed, with respect that the length of the amplicon should be around 100bp. The design was done and evaluated using Ion AmpliSeq Designer. Of the 408 SNPs, a total of 317 polymorphisms from which 8 is from the Y chromosome, 42 from the X chromosome, 72 from chromosome 21, 78 from chromosome 18, 89 from chromosome 13 and 28 from the others (chr1; chr2; chr4; chr5 ; chr6; chr8; chr10; chr12; chr14; chr16; chr17; chr19; chr20; chr22) could be used for in vitro amplification and NGS sequencing. Particular NGS libraries was carried out using the Ion Chef™ device and the Ion 510™/520™/530™ Kit-Chef kit, which provides automatic library preparation, templating and the chip loading. The Ion 540 chip was used for sequencing on Ion S5™ System. The quality of the sequencing data, mapping and analysis of the coverage, was carried out using Torrent Suite software. The total number of reads ranged from 1291449 to 3166718 (average 2377876) per sample. The average number of reads (excluding Y-specific) per SNP ranged from 4179 to 10245 (average 7264). The average number of Y chromosome specific reads per SNP was used as fetal DNA predictor. The total number of cffDNA reads so were estimated from 4 000 to 263 000 (median/average is 73 000/93 000). A number of mapping reads, after appropriate analysis parameters setting that include rich GC amplicon filtration and for particular SNP, the coefficients of amplification robustness and reliability, could be sufficient to reliably distinguish the most common trisomic pregnancies. The study was supported by Ministry of Health, Czech Republic - conceptual development of research organization (FNOI, 00098892)

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2070. Cell-informed atlas of gene, isoform, and splicing regulation in the developing human brain identifies candidate causal variants for neuropsychiatric GWAS

Authors:

Sch., McLean, Belmont, NY, ⁶Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Genome-wide association studies (GWAS) have identified hundreds of loci associated with neurodevelopmental psychiatric disorders, yet our understanding of the risk genes and mechanisms underlying these associations remains very limited. Strong enrichment for psychiatric genetic risk loci among fetal brain regulatory elements has prompted several recent efforts to characterize gene expression regulation in the developing human brain through expression quantitative trait loci (eQTL) for integration with GWAS. Yet, previous integrative efforts have been hindered by the small scale of individual studies, and lack of investigation of alternative splicing and cell-type-specific mechanisms. Here, we uniformly process and systematically mega-analyze gene-, isoform-, and splicing-QTLs, as well as cell-type-specific QTLs from 9 deconvoluted cell-types, in the developing human brain across 654 donors spanning 4-39 post-conception weeks (PCW). We identified 17,847 genes harboring a significant QTL, including 2,095 (11.7%) with QTLs detectable only in a cell-type-specific context. Network-based integration of fetal single-cell chromatin accessibility further mapped 18.4% of eQTL-containing genes to specific cell types. Leveraging this resource to gain mechanistic insight into neuropsychiatric disorders, we performed joint statistical fine-mapping of fetal brain QTLs with summary statistics from five neuropsychiatric GWAS, including schizophrenia (SCZ), autism spectrum disorder (ASD), bipolar disorder (BIP), attention deficit hyperactivity disorder (ADHD), and major depressive disorder (MDD). From a total of 485 genome-wide significant loci across these 5 traits, we were able to successfully account for 214 unique loci (44.1%) with a significant GWAS-QTL colocalization (CLPP > 0.01) in our fetal brain functional genomics reference panel. Of these, 95, 137, and 140 colocalizations were captured by eQTLs, isoQTLs, and sQTLs, respectively, highlighting the important contributions of alternative splicing to psychiatric genetic risk mechanisms. Cell-type-specific eQTLs further identified 121 colocalized GWAS loci, including 39 not captured from bulk-tissue eQTLs. Newly prioritized candidate risk genes overlap with orthogonal results from rare-variant sequencing studies of developmental disorders, such as *SP4* and *ASH1L* in SCZ. Altogether, this work provides a comprehensive view of genetic regulation in the developing human brain and demonstrates the importance of developmental context, cell-type specificity, and splicing/isoform regulation when prioritizing candidate mechanisms underlying GWAS variants.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2071. Characterization of the prenatal presentation of novel truncating variants in *ANKRD11*.

Authors:

J. Van Ziffle¹, B. R. Lianoglou¹, U. Hodoglugil², W. Devine¹, P-M. Martin¹, J. Shieh³, A. Slavotinek⁴, T. Sparks¹, M. Norton³; ¹Univ. of California, San Francisco, San Francisco, CA, ²UCSF, San Francisco, CA, ³Univ. of California San Francisco, San Francisco, CA, ⁴Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract Body:

KBG syndrome has been described primarily in the pediatric setting, associated with inactivating variants in *ANKRD11*. Characteristic postnatal features of KBG syndrome are developmental delay, intellectual disability, behavioral abnormalities, macrodontia, and characteristic facial features. Skeletal anomalies, short stature, early feeding difficulties, hearing loss, brain malformations and seizures have also been reported. The prenatal phenotype is not well understood aside from growth deficiency. We describe six cases diagnosed in a single institution, three diagnosed prenatally and the remaining at 10, 12 and 21 years of age. The prenatal cases were identified by exome sequencing (ES) referred for abnormalities on routine prenatal imaging. All three cases were found to have *de novo* truncating variants in *ANKRD11*. Case 1 was a male fetus with complete atrioventricular septal defect and coarctation of the aorta. Case 2 was a female fetus with pericardial effusion and elevated MCA Doppler suggesting fetal anemia. Periumbilical blood sampling was performed and confirmed anemia (hematocrit: 24%), followed by red blood cell transfusion at 22 weeks. Case 3 presented with congenital diaphragmatic hernia. The pediatric cases in our cohort were reported to have unremarkable prenatal structural imaging and birth history. Case 4, diagnosed at age 21, presented at age 3 with speech delay, intellectual disability, facial features, short stature and a positive family history for intellectual disability. Cases 5 and 6 are siblings; case 5 was diagnosed at age 10, with initial presentation at age 2 including speech and developmental delays, seizures, aplasia cutis, mild facial dysmorphism; case 6, diagnosed at age 12, presented with speech and developmental delay, non-union of the right tibia after recurrent fractures, right lower limb hemihypertrophy, demineralization of femurs, and bilateral dacryostenosis. These findings expand our understanding of the heterogeneous presentation of KBG. While the postnatal cases presented uniformly with developmental delays, the prenatal cases all had abnormal prenatal imaging including structural or physiologic differences not well described as a part of *ANKRD11*-associated KBG, although the prenatal congenital heart condition is likely related. It remains uncertain if the other prenatal cases represent phenotype expansion or incidental findings. For the postnatal cases, the diagnosis was made 8 and 18 years after the initial parental concern. This report demonstrates the value of ES to identify rare genetic diagnosis in cases of non-specific findings in the prenatal and postnatal period.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2073*. Comprehensive preimplantation genetic testing for monogenetic disorders (PGT-M) and aneuploidy (PGT-A) using whole genome sequencing and haplotyping

Authors:

S. Chen¹, R. Abramov¹, R. Antes¹, M. Madjunkov^{1,2}, C. Librach^{1,2,3,4,5}, S. Madjunkova^{1,6}; ¹CReATe Fertility Ctr., Toronto, ON, Canada, ²Dept. of Obstetrics and Gynecology, Univ. of Toronto, Toronto, ON, Canada, ³Dept. of Physiology, Univ. of Toronto, Toronto, ON, Canada, ⁴Inst. of Med. Sci., Univ. of Toronto, Toronto, ON, Canada, ⁵Sunnybrook Res. Inst., Toronto, ON, Canada, ⁶Dept. of Lab. Med. and Pathobiology, Univ. of Toronto, Toronto, ON, Canada

Abstract Body:

Introduction: Wider use of expanded carrier screening, genetic diagnostic tests, improved awareness and higher utilization of in vitro fertilization (IVF) have increased demand for preimplantation genetic testing for monogenetic disorders (PGT-M), as a therapeutic alternative to invasive prenatal tests; not only for common severe childhood and rare disorders, but for serious and mild late onset disorders, including for variants of unknown significance. This requires adaptation of generic genome wide approaches to complement or eventually replace targeted disease-specific PGT-M assays and add the PGT-A testing as a first-tier test. We aimed to evaluate concurrent use of genome wide haplotyping and disease specific assays for PGT-M and high resolution PGT-A in an unselected patient population at risk for monogenetic disorders. **Methods:** 104 couples at risk for monogenetic disorders were analyzed at the CReATe Genetic Laboratory, Toronto, Canada. For each couple DNA from oocyte and sperm provider, related family member/s and whole genome amplified (WGA) DNA (REPLI-g, WGA Kit, Qiagen) from a single trophectoderm (TE) biopsy of embryos created through IVF were used. For PGT-M whole genome SNParray typing (Karyomapping, Illumina, CA) and STR analysis were used to obtain parental haplotypes and Sanger sequencing was used for specific direct variant analysis. PGT-A was performed using Illumina library prep and sequencing on NextSeq 550. The Nxclinical (BioDiscovery) and BlueFuse Multi (Illumina) softwares were used for data analysis. **Results:** 948 embryos, from 144 IVF cycles were analyzed for 53 unique genes (14 cancer predisposing genes, 20 autosomal recessive and 19 dominant) and total of 240 variants. PGT-A analysis showed 32.7% aneuploidy, 9.7% mosaicism and 57.6% euploidy. Euploid and mosaic embryos were tested with Karyomapping that had an average case call rate of 92%, and an average Allele Drop Out rate of 2.7%. Recombination events in 3% of cases prevented assignment of haplotype. The distribution for both recessive and dominant disorders was in Mendelian order. Direct mutation testing was obtained for all samples and was 100% concordant with the predicted haplotypes. In cases with no predicted haplotype, direct testing established the PGT-M diagnosis. To date 45 live births confirmed the PGT-M diagnosis. **Conclusion:** Karyomapping is effective as a generic haplotyping platform, with low risk of undetected recombination events in the genomic region of interest. Simultaneous PGT-A and PGT-M with optional direct variant testing provides optimal patient management that can significantly reduce the time to pregnancy in couples at risk for inherited disorders.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2074. Contribution of BBS9 isoforms to the etiopathogenesis of non-syndromic craniosynostosis

Authors:

D. Sibilia¹, E. Lo Cascio¹, L. Di Pietro¹, A. Vita¹, G. Tamburrini², L. Massimi², O. Parolini¹, A. Arcovito¹, W. Lattanzi¹; ¹Università Cattolica del Sacro Cuore, Rome, Italy, ²Fondazione Policlinico Univ.rio Agostino Gemelli, Rome, Italy

Abstract Body:

Background. Skull development relies on the presence of calvarial mesenchymal stromal cells (CMSCs) residing in the cranial sutures. Congenital alterations that hamper CMSC homeostasis lead to premature suture ossification, causing craniofacial malformations in infants, known as craniosynostosis (CS; affecting 1/2000-2500 newborns). In particular, non-syndromic CS (NCS) are the most prevalent forms (75-80% cases) and have a poorly clarified etiopathogenesis. Nevertheless, a number of osteogenic and developmental molecular pathways have been reported to be impaired in NCS, few of them localizing at the primary cilium, a membrane organelle involved in mechanotransduction and cell-to-cell signaling. The BBSome is a multimeric protein complex that localizes at the primary cilium and translocates cargo proteins throughout this organelle; among its subunits, BBS9 is crucial for the BBSome assembly and integrity. Recent evidence suggested an implication of BBS9 in NCS: i) *BBS9* gene was associated as a susceptible locus for NCS in a GWAS; ii) our group found an overexpression of some BBS9 splice isoform-specific exons in prematurely fused sutures of NCS patients. Our hypothesis is that the BBS9 implied isoforms may lack of the C-term region required for the BBSome assembly with the overexpressed exons falling in the N-term and central regions. **Aims.** Based on this background, our aim is to identify the overexpressed BBS9 isoforms in NCS during the osteogenic process. **Methods.** We used an *in vitro* model of N-CMSCs (from unfused sutures) and P-CMSCs (from fused sutures) isolated from surgical wastes from cranioplastic surgery on NCS pediatric patients. We evaluated BBS9 differential expression during osteogenic differentiation of CMSCs using qPCR and WB techniques. **Results.** Even though the *in silico* model of the BBSome containing a BBS9 isoform lacking of the C-term region showed an impairment in the whole BBSome stability, the transcript level analysis showed a similar expression trend of all the isoforms between N- and P- cells, both in proliferative and osteogenic medium. On the contrary, protein analysis corroborated with the previous results: BBS9 protein is overexpressed in P-CMSC compared to N-CMSC upon osteogenic induction. **Conclusions and future studies.** BBS9 protein isoform expression seems to vary quite reproducibly during osteogenic differentiation of CMSCs and shows a differential trend in N-versus-P cells. Further ongoing studies are aimed to identify the primary structure of selected isoforms and to confirm their role in the BBSome assembly, hence to define their contribution in NCS onset.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2075. *De novo* mutations disturb early brain development more frequently than common variants in schizophrenia

Authors:

T. Itai¹, P. Jia¹, Y. Dai¹, J. Chen², X. Chen¹, Z. Zhao¹; ¹The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, ²Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract Body:

Schizophrenia (SCZ) is a neuropsychiatric disease with high heritability. The genetic etiology of SCZ is heterogeneous, consisting of common variants and rare variants, some of which occur *de novo* (DNM). Although a few thousand DNMs have been identified, there is limited knowledge of how they function in SCZ etiology. We compared temporal and cell-type expression data in SCZ associated genes with common variants and DNMs. We collected 2636 DNMs in 2263 genes across 3477 SCZ patients (SCZ-DNMs). Since statistical enrichment tests failed to extract a sufficient number of DNM genes for downstream analyses, we curated two gene lists based on priori knowledge. The first list had 106 genes (SCZ-neuroGenes) from SCZ-DNMs that are intolerant to loss-of-function and missense DNMs and are neurologically essential. The second list had 52 genes (SCZ-moduleGenes) derived from network analyses of SCZ-DNMs with MAGI and GeneMANIA. We used 120 genes (SCZ-commonGenes) from a recent GWAS study. To compare gene expression between pre-/postnatal stages, we used BrainSpan and BrainCloud datasets with a linear model. To quantify the involvement of each gene in prenatal brain development, we calculated a fetal effect score (FES), which is defined as $-\beta/se$, where β is the linear model's coefficient for *stage* (pre- or postnatal) and *se* is the standard error of β . SCZ-neuroGenes and SCZ-moduleGenes were highly expressed in the prenatal stage and had higher FESs than SCZ-commonGenes. The average FESs for SCZ-commonGenes, SCZ -neuroGenes, SCZ -moduleGenes were -0.8, 4.8, 12.7 respectively in the whole brain, that for the dorsolateral prefrontal cortex were -0.5, 0.9, 3.5, and for hippocampus were -0.3, 0.8, 3.0. For cell-type expression analysis, we calculated the specificity indexes (SIs) using single-cell expression data from cerebral cortices in humans and mice. In human data, SCZ-neuroGenes and SCZ-moduleGenes had higher SIs in fetal replicating cells than that in the SCZ-commonGenes (the median SIs for SCZ-commonGenes, SCZ -neuroGenes, SCZ -moduleGenes were 0.04, 0.08, 0.15). In mouse data, SCZ-neuroGenes and SCZ-moduleGenes had higher SIs in undifferentiated cell types. The median SIs for SCZ-commonGenes, SCZ -neuroGenes, SCZ -moduleGenes were 0.013, 0.024, 0.027 for dopaminergic neuroblasts, that for neural progenitors were 0.017, 0.029, 0.040, and for neuroblasts were 0.022, 0.030, 0.032. Our results showed that SCZ-neuroGenes and SCZ-moduleGenes are expressed in an earlier period and fetal-specific cell types than SCZ-commonGenes, suggesting that expression patterns in specific cell types in early fetal stages have significant impacts on the risk of SCZ.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2076. Developmental programming of vitamin b12 deficiency model in zebrafish

Authors:

A. Verma, S. S. Nongmaithem, M. Challapalli, S. Ramachandran, G. R. Chandak; CSIR-CCMB, Hyderabad, India

Abstract Body:

Vitamin B12 (B12) is one of the key co-factors in One-Carbon Metabolism (OCM) pathway which influences various biological processes including DNA synthesis, amino acid homeostasis, epigenetic regulation, and redox defense. We have shown earlier that B12 deficiency leading to an altered OCM is highly prevalent in the Indian population and is associated with low birth weight and development defects including neural tube defects, congenital malformations, etc. Zebrafish have been used as a tractable model to study embryonic development due to their ability to produce large clutches of *ex utero* developing optically transparent embryos. Transcobalamin 2 (*tcn2*) is the only known B12 transporter in zebrafish and has a similar structure and B12-binding affinity with human TCN2. This study aimed to understand the role of B12 in early fetal developmental programming by generating a zebrafish model of B12 deficiency using the CRISPR-Cas9 system. We generated two *tcn2* knockout (KO) alleles by targeting the exon 7 resulting in premature stop codons at the end of exon 7. Complete disruption of *tcn2* in the zebrafish was established by qRT-PCR and immunoblotting. The F2 generation *tcn2*^{-/-} zebrafish grew normally and did not show any overt phenotype. However, in the F3 generation, nearly 70% of *tcn2*^{-/-} fish died during embryonic development. Majority of *tcn2*^{-/-} embryos showed delayed somitogenesis as compared to WT embryos, remained largely unhatched, and showed pericardial edema, curved or deformed tails, abnormal yolk extension, and yolk sac edema. These phenotypes in F3 were partially ameliorated by the addition of 10 μM B12 (cyanocobalamin) to the embryo water throughout the developmental stages. We performed RNA sequencing analysis at one-cell stage in KO and wild type (WT) and at 24 hpf stage in three groups - KO, KO treated with B12 (KO_B12), and WT to identify differentially expressed genes (DEGs) between these groups. The gene set enrichment analysis of the DEGs showed changes in key pathways including cell cycle, MAPK signaling, calcium signaling, cellular senescence, apoptosis, etc. The opposite direction of the effect of majority of DEGs between KO/WT and KO_B12/WT indicates their potential role in the rescue of *tcn2*^{-/-} phenotype by B12 treatment. Our study on the *tcn2*^{-/-} zebrafish model delineates the importance of B12 in different developmental stages. At a molecular level, we report B12 deficiency-mediated dysregulation of several developmental processes which may explain its role in various human phenotypes. Survival of nearly 1/3rd of *tcn2*^{-/-} embryos in the F3 generation suggests a possible novel mechanism of B12 transport and needs to be investigated further.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2077. Developmental trajectory analysis of differentiating mouse sensory interneurons to further improve stem-cell differentiation protocols.

Authors:

E. Heinrichs^{1,2,3}, S. Gupta^{1,3}, R. Kawaguchi⁴, B. Novitch^{1,3}, S. Butler^{1,3}; ¹UCLA Neurobiology, Los Angeles, CA, ²UCLA Human Genetics, Los Angeles, CA, ³Eli and Edythe Broad Ctr. of Regenerative Med. and Stem Cell Res. at UCLA, Los Angeles, CA, ⁴UCLA Psychiatry, Los Angeles, CA

Abstract Body:

The developing dorsal spinal cord is populated with different classes of interneurons that integrate and relay sensory information including pain, itch, touch and heat. Loss of these modalities can be emotionally and physically devastating for patients. However, current research seeking to regenerate the spinal cord has focused on the recovery of coordinated movement, rather than somatosensation. Nonetheless, a full recovery from spinal cord injuries will require the restoration of both motor and sensory function. Towards this goal, we have recently published directed differentiation protocols capable of making heterogenous dorsal interneuron (dI) populations. While these protocols are a key step forward, protocols that direct individual dI types have remained elusive. Here we present further analysis of our published mouse dI differentiation single cell transcriptomic dataset to provide new insights into the genetic factors driving the early stages of dI differentiation. Using a combination of Seurat and Monocle3 packages in R, we plot the developmental trajectories of differentiating dIs and perform pseudotemporal analyses to identify candidate genes that direct specific developmental bifurcations. Analyses of known marker genes show that dorsal progenitor expression peaks at lower pseudotime values than post-mitotic dI genes, validating the approach. By examining differential gene expression between trajectories, we have identified novel marker genes including *Smoc1*, which is highly temporally restricted to the earliest stages of dI5 differentiation. We have also observed novel developmental hierarchies by plotting these trajectories in three-dimensional UMAP space. Specifically, dI1 and dI5 bifurcate to become distinct populations very early during the differentiation process, while dI2-dI4 have a common origin, and only become different from each other later in differentiation. Collectively, these results reveal the developmental logic by which spinal somatosensory neurons are generated, which can be recapitulated in vitro using pluripotent stem cells to enable disease modeling and therapeutic discovery.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2078. Discordances among NIPT, QF-PCR and cytogenetic results in prenatal cases.

Authors:

F. Thuriot^{1,2}, A. Gomez^{1,2}, S. Farhan^{1,2}, A. Ruchon^{1,2}, G. Tchakarska^{1,2}, J. Lavoie^{1,2,3}; ¹Dept. of Human Genetics, McGill Univ., Montreal, QC, Canada, ²McGill Univ. Hlth.Ctr., Montreal, QC, Canada, ³Dept. of Pathology, McGill Univ., Montreal, QC, Canada

Abstract Body:

Non-invasive prenatal testing (NIPT) is being increasingly used as a first-tier screening test in Canada and around the world. However, despite the advantages of NIPT, it is not a diagnostic test and invasive prenatal testing must be used to confirm all cases of screen positive NIPT results. Quantitative fluorescent polymerase chain reaction (QF-PCR) can be used as a rapid aneuploidy detection test. Based on these results and depending on the clinical indication, chromosomal microarray (CMA) and karyotype analysis may be ordered.

Here, a few prenatal cases where discordances have been observed among NIPT, QF-PCR and cytogenetic testing (CMA and/or karyotype) will be illustrated.

The first case showed a NIPT result of monosomy X. QF-PCR was performed on the amniotic fluid and chromosome Y material was detected. Karyotype analysis was subsequently performed to further characterize these findings. A mosaic karyotype with a cell line with a pseudodicentric chromosome Y and a cell line with a 45,X karyotype was detected. The second case had a normal QF-PCR result; however, given the abnormal ultrasound findings, CMA was ordered and a partial terminal deletion of the long arm of chromosome 13 was observed. Importantly, the QF-PCR markers present in the long arm of chromosome 13 were non-informative as only one peak corresponding to the mother's genotype was present. The third case had an elevated risk for trisomy 18 with NIPT. QF-PCR results were inconclusive because of maternal cell contamination. Karyotype analysis was subsequently performed on the amniotic fluid and a mosaic karyotype including a cell line with an isochromosome 18p was detected. Fluorescent in situ hybridization (FISH) studies later confirmed the results.

These few cases demonstrated that despite the high accuracy of these tests, discrepancies can occur due to technical and/or biological limitations. A standardized and comprehensive testing algorithm is therefore needed to ensure that the appropriate testing takes place.

Despite a universal healthcare system in Canada, disparities in prenatal testing algorithms are apparent. National consensus on how the different genetic tests should be utilized in the prenatal setting is needed.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2079. DNA damage and antioxidant capacity as prenatal markers of placental epigenetic aging clock.

Authors:

F. Tekola-Ayele¹, C. Zhang², R. Biedrzycki³, K. Grantz¹, J. Grewal¹; ¹NIH, Bethesda, MD, ²Natl. Univ. of Singapore, Queenstown, Singapore, ³Glotech, Inc, Bethesda, MD

Abstract Body:

Accelerated aging of the placenta determined by epigenetic clocks in delivered placenta samples has been linked to obstetric and fetal complications such as preterm birth, fetal growth restriction, and preeclampsia. Therefore, identifying non-invasive prenatal markers of placental epigenetic aging holds a potential for developing diagnostics before onset of adverse clinical outcomes, but such data are scarce. The goal of the present study was to examine whether longitudinally measured 8-hydroxydeoxyguanosine (8-OHdG; a DNA damage marker) and total antioxidant capacity (TAC; a measure of cumulative antioxidant defense) in maternal plasma during pregnancy are associated with epigenetic aging of placenta. Maternal blood samples were collected during pregnancy at four consecutive research visits (10-14, 15-26, 23-31, and 33-39 gestational weeks) as part of the NICHD Fetal Growth Studies. 8-OHdG and TAC were measured in plasma (n=301), and the ratio of 8-OHdG and TAC was computed to estimate the degree of DNA damage relative to total antioxidant capacity. Epigenetic age of delivered placenta was estimated using previously developed clocks that use 62 and 396 methylation CpG sites (Clock62 and Clock396). Placental age acceleration was defined to be the residual upon regressing estimated epigenetic age on gestational age at delivery. The association of 8-OHdG, TAC, and 8-OHdG/TAC ratio with placental age acceleration was tested using covariate-adjusted linear regression models, with interaction terms between each biomarker and maternal age and between each biomarker and gestational week at blood draw. As gestation advanced, 8-OHdG showed a rise (18% rise in mean 8-OHdG from 89.6 to 105.5 nM between 10 to 40 gestation weeks), whereas TAC declined (6% decline from 89.5 to 83.7 nM). Higher 8-OHdG/TAC ratio was associated with increased placental age acceleration (Clock62 adjusted- β (S.E.) = -0.55 (0.29) per each SD increase in 8-OHdG/TAC ratio; P=0.049), whereas higher TAC was associated with lower placental age acceleration (Clock62 adjusted- β (S.E.) = -0.61 (0.25) per each SD increase in TAC; P=0.01). These data suggest that circulating levels of maternal DNA damage that outweigh antioxidant buffer during pregnancy may be one mechanism related to accelerated aging of placenta. The potential value of these biomarkers as a non-invasive monitoring tool for early detection of placental epigenetic aging and pregnancy complications warrants future studies.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2080. Down Syndrome therapeutics: The integrated stress response and restoration of protein synthesis.

Authors:

J. Korenberg, M. Gandelman; Univ. of Utah, Salt Lake City, UT

Abstract Body:

Neuronal protein synthesis is essential for learning and memory, and its attenuation caused by the activation of the integrated stress response (ISR), triggered by phosphorylation of eIF2 α has been found to have a role in DS and Alzheimer's disease, among others. Downstream increase of the transcription factor ATF4 is the main effector of the ISR. ATF4 then coordinates a transcriptional program that promotes cell survival during acute stress, although it has the potential of becoming maladaptive under severe or chronic stress conditions. Initial reports have found activation of the ISR in the hippocampus of Ts65Dn mice and in post-mortem brain tissues from patients with DS but the causes, consequences and druggability of the ISR in DS remain largely unexplored.

We utilized skin fibroblasts derived from identical twins discordant for DS to study activation of the ISR and protein synthesis rates. We found elevated levels of phosphorylated eIF2 α in DS fibroblasts, associated with downstream activation of ATF4 and a decrease in protein synthesis rates. Because DYRK1a is located in a chromosome region associated with deficits of learning and memory and has a role in translational control, we investigated whether its knockdown would prevent activation of the ISR and restore protein synthesis. We found that DYRK1a/dyrk1a levels were increased in DS fibroblasts as expected, and its knockdown decreased p-eif2 α and ATF4 levels, but protein synthesis was not restored. We next utilized ISRIB and trazadone, known modulators of the ISR, and found that both successfully increased protein synthesis rates in DS fibroblasts, indicating these drugs hold potential for reversing alterations at the cellular level that can lead to cognitive and memory deficits. In conclusion skin fibroblasts from twins discordant for DS recapitulate DS brain ISR activation and decreased protein synthesis that is not restored by rescue of DYRK1a but is restored by ISR inhibitors. The results also provide a cellular druggable mechanism for the multiple effects of Dyrk1a in DS. Finally, this establishes individuals' cell lines as a valuable model for studying individuals' ISR, for testing interventions, and for personalized treatment to reverse alterations at the cellular level that can lead to cognitive and memory deficits in DS.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2081. Explore SOX9 haploinsufficiency in neural stem cells.

Authors:

S. Chan, Z. Wang, K. Miu, H. Cheung, W-Y. Chan; The Chinese Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract Body:

Campomelic dysplasia (CD) is a rare congenital disease caused by *SOX9* haploinsufficiency and only 5-10% of patients survived. Complications of CD patients include sex reversal, abnormal development of the skeletal system, and mild to moderate learning difficulties. *SOX9* is a relatively well-known gene in skeletal and gonadal development and has recently been associated with cancer as a metastasis marker, it also induces neural stem cells (NSC) and mediates neurogenic-to-gliogenic cell fate switch in the central nervous system (CNS). However, the underlying mechanism of *SOX9*'s role in the NSC induction remains unclear.

With CRISPR/Cas9 techniques, a *SOX9* edited hiPS cell line was generated according to the medical literature of a CD patient. The cells were differentiated into NSC. qPCR result suggested that loss of *SOX9* altered the expressions of key genes, such as *SOX1*, *SOX2*, *Nestin*, and *PAX6*, in iPSC-derived NSC. Further analysis was performed by stranded-specific RNA sequencing. Based on the transcriptome level, several pathways such as MAPK, p53, and Wnt signaling pathways were found altered in NSC. Further analysis including western blot, immunostaining, and qPCR analysis will be performed to validate RNA sequencing results. NSC functions, such as neurogenesis and gliogenesis, and conductivity of the resulting neurons will also be tested by continuous differentiation and high-density microelectrode array analysis. Collectively, the current study aims to identify the *SOX9*'s role in NSC and the subsequent effect in the CNS to explain the learning difficulties reported in CD patients.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2082. Exploring roles of distal enhancers in *SOX9* haploinsufficiency in sex determination

Authors:

F. Ou¹, H-C. Suen¹, H. Sun², Z. Wang¹, K. Miu¹, P. Shi², J. Liao¹, W-Y. Chan¹; ¹The Chinese Univ. of Hong Kong, Hong Kong, China, ²City Univ. of Hong Kong, Hong Kong, China

Abstract Body:

Disorders of sex development (DSD) are congenital anomalies involving discordance between genotype to phenotype in gender identity. People with DSD suffer from ambiguous genitalia, impaired steroid hormone production, reduced or null fertility, and partial to complete sex reversal. Various mutations of the dosage-sensitive haploinsufficient *SOX9* gene (sex-determining region Y-related high-mobility group box 9) were identified in male to female sex reversal patients. *SOX9* regulates the production of the anti-Müllerian hormone (AMH) in Sertoli cells to inhibit the creation of a female reproductive system in an XY embryo. A single copy of the wild-type allele of the heterozygous *SOX9* is insufficient to maintain normal male reproductive tract development. Duplication and deletion of distal enhancers of *SOX9* found in DSD patients suggest the potential roles of enhancers in *SOX9* haploinsufficiency in sex determination. But the underlying genetic mechanism of the haploinsufficiency is still largely unknown. With the advances in high throughput sequencing, gene editing technologies, stem cell, and spatial ncRNA assay, we aim to decipher the chromatin topological interaction complex at *Sox9* enhancers across the sexual developmental time window and elucidate the functional roles of the enhancer complex in *Sox9* haploinsufficiency. Interactions between enhancers, promoters, and cell type-specific transcription factors will be identified by CAPTURE. By integrating scRNA-Seq and scATAC-Seq data, we have profiled temporal chromatin landscapes across gonadal somatic cell types during sex development and identified 3 putative distal enhancers of *Sox9*. The dynamic expression of non-coding enhancer RNA (eRNA) that may involve in the topological interaction for *Sox9* transcription dosage regulation will be further evaluated with a newly developed spatial ncRNA assay on fresh mouse gonads. Co-localization of protein complexes and eRNA would be validated by conducting rISH-PLA. Human iPSC models with disruption to components of the enhancer complex will be differentiated to Sertoli cells for validation. Our project will provide a valuable prototype for studying haploinsufficiency from 3D chromatin topological interactions and non-coding RNA regulation.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2083. Fetal genetic autopsy: A five-year retrospective audit monocentric audit

Authors:

Hosp., AP-HP, Kremlin Bicêtre, France, ⁸Inserm and Univ. Paris Saclay, Kremlin Bicetre, France

Abstract Body:

Normal 0 21 false false false FR X-NONE X-NONE /* Style Definitions */ table.MsoNormalTable {mso-style-name:"Tableau Normal"; mso-tstyle-rowband-size:0; mso-tstyle-colband-size:0; mso-style-noshow:yes; mso-style-priority:99; mso-style-parent:""; mso-padding-alt:0cm 5.4pt 0cm 5.4pt; mso-para-margin-top:0cm; mso-para-margin-right:0cm; mso-para-margin-bottom:10.0pt; mso-para-margin-left:0cm; line-height:115%; mso-pagination:widow-orphan; font-size:11.0pt; font-family:"Calibri",sans-serif; mso-ascii-font-family:Calibri; mso-ascii-theme-font:minor-latin; mso-hansi-font-family:Calibri; mso-hansi-theme-font:minor-latin; mso-fareast-language:EN-US;} **Objectives** To assess the efficiency and the pertinence of oriented genetic fetopathological examinations at a tertiary maternity laboratory. We were particularly interested in the rate of new macroscopic and/or microscopic data brought up by fetal and placental examinations (re)orienting further molecular studies to come. Additionally, the feasibility and the results of genetic post-natal tests performed during fetopathological examinations. **Methods** We conducted a 5-year retrospective audit that included 1710 fetuses and their placentas. All of these cases were referred to the foetopathology laboratory Antoine Beclere, APHP, Paris Saclay University Hospital, between January 2013 and December 2017, including medical terminations (TOPs), stillbirths and miscarriages. **Results** In 51.8% of the reports the fetopathological examination added an important finding (ie considerably modifying a final diagnosis), which was missing on the prenatal follow-up. Among those, the highest level of the new data was observed in the deceased newborns: 69.7%, and 48.3% in TOPs. The non-systematic, hence examination-oriented postnatal karyotypes and aCGH sample requests resulted in 9.2% and 25.9% of pathological results respectively. The highest level of aneuploidies was observed in stillbirths (54.2%), while the aCGH was most frequently unbalanced in TOPs (83.3%). The global failure rate of karyotypes and aCGH performed after fetopathological examinations was respectively 31.7% and 15.1%. Furthermore, the predictive factors of these failures on fetal /placental tissue in immediate post-natal collection are discussed to enhance the yield of better results in the future. An accurate diagnosis following fetopathological examinations and genomic tests directed by the fetopathological team was established in 51.2% of the cases: 69.9% in the cohorte of miscarriages, 56.2% among TOPs, ad 42.2% in stillbirths.

PB2084. Gaucher disease: systematic review.

Authors:

G. Gómez¹, H. Giron Osorio¹, L. Moreno Giraldo²; ¹Univ. Santiago de Cali, palmira, Colombia, ²Univ. del Valle, cali, Colombia

Abstract Body:

Abstract: An updated bibliographic review on Gaucher disease is carried out, in which emphasis is placed on its recognition as an orphan disease for Colombia, due to its low prevalence, chronicity, high complexity, burden of morbidity and mortality and importance of early diagnosis in order to establish timely, targeted treatments that impact its natural history. Are addressed aspects Historical, epidemiological, clinical, genetic-hereditary, pathophysiological, diagnostic, therapeutic, follow-up guidelines, ethical and legal framework relevant to understanding of disease. In addition, the clinical spectrum of the pathology is thoroughly described, recognizing the multisystemic nature and the wide variability of phenotype, and possible correlations with the genotype, highlighting the importance of the implementation of public health strategies for the early identification of this pathology either through the implementation of neonatal screening, creation of diagnostic-therapeutic algorithms, routes of action, education on red flag signs and symptoms, as well as recognizing the importance of genetic counseling as a key prevention mechanism in the disease. **Methods and materials:** A systematic review was carried out. The bibliographic search was carried out in English and Spanish and included scientific reference articles on Gaucher disease dating from the year 2015-2022, from the databases: PUBMED, MEDLINE, SCIENCEDIRECT, GOOGLE SCHOLAR, where the search for keywords: Gaucher Disease, Sphingolipidosis, orphan disease, neonatal screening, lysosomal storage diseases, errores innatos del metabolismo Inborn Errors of metabolism. **Conclusion:** There are currently a large number of therapeutic alternatives available that, when used in the initial stages, could have repercussions on the natural history of the disease and on the patient's prognosis, hence the importance of knowledge of GD by health personnel, recognizing the character multisystemic disease and the wide variability of the phenotype, and possible correlations with the genotype, in addition to the importance of implementing public health strategies for the early identification of this pathology, therapeutic algorithms and care routes.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2085. Genetic Characterization of VACTERL Association-Like Congenital Malformations

Authors:

H. Pang, M. Hsieh, W. Shi, B. Sapkota, S. Li, D. DeMarzo, Y. Enchautegui-Colon, A. C. Tsai; Univ. of Oklahoma Hlth.Sci. Ctr., Oklahoma City, OK

Abstract Body:

VACTERL association is a nonrandom occurrence of multiple congenital abnormalities, including vertebral defects, anal atresia, cardiac defects, tracheal-esophageal fistula, renal and radial abnormalities, and limb malformations. Evidence has shown that genetic and epigenetic factors, teratogenic influences, and maternal medical conditions may contribute to VACTERL association. In particular, blastocyst developmental field defect and mutations in heterogeneous genes associated with early organogenesis (e.g. genes involving Sonic Hedgehog (SHH) and NOTCH signaling) may contribute to clinical features of VACTERL association. A few monogenic genetic disorders like Fanconi anemia and CHARGE syndrome also have overlapping features with VACTERL association; pathogenic variants in genes related to these conditions have been found in some patients. Our studies used conventional cytogenetics, chromosomal microarray analysis (CMA), and next-generation sequencing (NGS) to identify possible etiologies for 23 pediatric patients presenting with clinical features of VACTERL association. FISH studies, karyotypes, or both methods were also performed on 14 patients to identify chromosomal abnormalities, to which none were detected. In addition, CMA was performed on 19 patient samples, revealing changes in three patients— a 1q21.1 duplication in the first, 7q31.3 deletion in the second, and a 1.4 Mb 17p12 deletion in the third. The 17p12 deletion was consistent with the patient's clinical diagnosis of hereditary neuropathy with liability to pressure palsies. NGS (exome slicing and/or whole-exome sequencing) was also performed on all 23 patient samples. NGS detected pathogenic variants in the *SALL1*, *GDF1*, and *CHD7* genes in 3 (13%) patients. These findings indicated the presence of monogenic genetic disorders with similar features to VACTERL association. 14 (60%) patients possessed variants of uncertain significance (VUSs) in multiple genes, including *ZIC3*, *SALL4*, *RECQL4*, *CHD7*, *FGF8*, *HAAO*, *FANCD2*, and *FANCI*. Notably, identical 18-bp deletions in *FGF8* were found in two unrelated patients. Different VUSs in *ZIC3* and *FANCD2* were also detected in more than one patient. Exome slicing was ordered for 6 (26%) remaining patients who presented with no reportable sequence variants. Our results showed that multiple genes may play a role in developing VACTERL association. Genetic testing, especially NGS, should be routinely used to identify underlying causes in patients displaying features of VACTERL. Overall, our results expand the list of genes that may contribute to developing the clinical features of VACTERL.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2086*. Genetic deconvolution of fetal and maternal cell-free DNA in maternal plasma enables next generation non-invasive prenatal screening

Authors:

J. Zhang^{1,2}, J. Li^{2,3}, C. Xu¹, H-F. Huang¹; ¹Fudan Univ., Shanghai, China, ²BioBiggen, Beijing, China, ³Heristar, Houston, TX

Abstract Body:

Current non-invasive prenatal screening (NIPS) tests analyze circulating fetal cell-free DNA (cfDNA) in maternal peripheral blood for selected chromosomal abnormalities. Many genetic disorders are refractory to NIPS largely because the maternal genetic material constitutes most of the total cfDNA present in the maternal plasma which hinders the detection of fetus-specific genetic variants. The inability to reconcile different genetic cues in a single NIPS assay prevents its expansion for the concurrent screening of different types of genetic disorders and improvements on test performance. In this study, we developed an innovative sequencing method, termed Coordinative Allele-aware Target Enrichment Sequencing (COATE-seq), followed by multidimensional genomic analyses of sequencing read-depth, allelic fraction, and linked single nucleotide polymorphisms (SNPs), to accurately separate the fetal genome from maternal background. Analytical confounders including multiple gestations, maternal copy number variations and absence of heterozygosity were successfully recognized and precluded for fetal variant analyses. In addition, fetus-specific genomic characteristics, including the cfDNA fragment length, meiotic error origins, meiotic recombination, and the recombination breakpoints were identified which reinforced the fetal variant assessment. In 1,129 qualified pregnancies tested, 54 fetal aneuploidies, eight microdeletions/microduplications and eight monogenic variants were detected with 100% sensitivity and 99.3% specificity. Importantly, using the comprehensive cfDNA genomic analytical tools developed, we found that 60.3% of aneuploidy samples had aberrant meiotic recombination providing important insights into the mechanism underlying meiotic non-disjunctions. To the best of our knowledge, this is the first report on aneuploidies associated with aberrant homologous recombination identified by cfDNA studies. Altogether, we show that the genetic deconvolution of the fetal and maternal cfDNA enables thorough and accurate delineation of fetal genome which paves the way for the next-generation prenatal screening of essentially all types of human genetic disorders.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2087. Genetic determinants of gestational length in Indian women: A two-stage genome-wide association study.

Authors:

E. Bhattacharjee¹, *. Ayushi², GARBH-Ini study group, R. Thiruvengadam^{2,3}, S. Bhatnagar², P. P. Majumder¹, A. Maitra¹; ¹Natl. Inst. of BioMed. Genomics, Kalyani, India, ²Translational Hlth.Sci. and Technology Inst., Faridabad, India, ³Pondicherry Inst. of Med. Sci., Puducherry, India

Abstract Body:

Background: Preterm birth (PTB), a major public-health burden globally, is associated with high neonatal and infant mortality and long-term health problems. LICs and LMICs contribute more than 60% of PTBs annually; India accounts for 23.4% of PTBs. Although genomic factors enhance PTB risk, estimates of genomic risk factors in Indian and other South Asian women are unavailable. **Hypothesis:** Maternal genotypes at specific loci are associated with gestational length (GL), the determinant of PTB.

Methods: We genotyped 6211 women enrolled in a prospective pregnancy cohort, GARBH-Ini, developed by us in Haryana, India, using Global Screening Array v3.0 with multi-disease drop-in panel (0.7M loci). The study participants, each with spontaneous singleton live birth, after quality control, were randomly grouped into two equal subgroups for discovery and validation. After adjusting the GL (weeks) for maternal age, BMI, parity and occupation, genotype association testing was performed using linear regression. SNPs found to be significantly associated in discovery subgroup were retested for association in the validation subgroup.

Results: Three SNPs were discovered to be significantly associated with GL, of which, rs67151250, an intronic SNP in *ARHGAP26* in chromosome 5, was validated. Population substructure was not detected ($\lambda = 1.02$). Phasing and imputation of chromosome 5 using data of 1000 Genomes Phase 3 and Genome Asia Pilot project as reference, led to the discovery and validation of additional 6 intronic SNPs in *ARHGAP26*. Joint analysis revealed, rs67151250 and the 6 imputed SNPs were associated with GL at the genome-wide significance level ($p < 5e-8$). TT genotype at rs67151250 lowered GL compared to CC and CT (Kruskal-Wallis $p = 0.0057$; Wilcoxon p : TT vs CC = 0.0043, TT vs CT = 0.0021, CC vs CT = 0.16), which we further confirmed by testing under a recessive model ($p = 1.7e-8$, Beta = -2.09, 95% CI = -2.81 to -1.36). Moreover, logistic regression under recessive model, revealed association of the T allele at rs67151250 with PTB ($p = 2.8e-6$, OR = 6.76, 95% CI = 3.04 - 15.03). *ARHGAP26* is a Rho-GTPase that inhibits RHOA. GTP-bound RHOA was previously reported to be significantly increased in the myometrium of preterm delivering women compared to those delivering at term and possibly results in early activation of myometrial contraction.

Conclusion: This first report on genetic determinants of gestational length from South Asia, identified novel maternal *ARHGAP26* variants that provided new insights into susceptibility to PTB. This may help in the identification of women at-risk for PTB and implementation of measures to prevent PTB, thus reducing public health burden.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2088*. Genome-wide analysis of preeclampsia identifies novel loci and loci previously associated with blood pressure traits.

Authors:

Zhang^{12,11}, B. Namjou-Khales¹³, I. Holm¹⁴, T. Edwards², D. R. Velez-Edwards²; ¹Vanderbilt Univ., Nashville, TN, ²Vanderbilt Univ. Med. Ctr., Nashville, TN, ³Univ. of Pennsylvania, Philadelphia, PA, ⁴Univ Washington Med Ctr., Seattle, WA, ⁵Univ. of Washington, Seattle, WA, ⁶Kaiser Permanente of Washington, Seattle, WA, ⁷Northwestern Univ., Chicago, IL, ⁸Mayo Clinic, Rochester, MN, ⁹Columbia Univ., New York, NY, ¹⁰US Dept. of VA, Cincinnati, OH, ¹¹Geisinger Genomic Med. Inst., Danville, PA, ¹²Princeton Univ., Princeton, NJ, ¹³CCHMC, Cincinnati, OH, ¹⁴Boston Children's Hosp., Boston, MA

Abstract Body:

Preeclampsia (PE) is a hypertensive disorder of pregnancy, characterized by new-onset high blood pressure, proteinuria, or signs of organ damage occurring after 20 weeks of pregnancy. This condition affects approximately 5% to 7% of pregnant women worldwide and is a leading cause of maternal morbidity and mortality. PE is also associated with subsequent adverse health outcomes, including long-term increased risk of cardiovascular disease. Greater understanding of genetic susceptibility to PE is needed. To this end, we conducted a cross-ancestry meta-analysis of new and publicly available PE genome-wide association study (GWAS) summary statistics. We incorporated previously published summary statistics (from BioBankJapan, UKBiobank, and FinnGen [Sakaue et al]) in addition to unpublished data from two electronic health record biobanks, BioVU and eMERGE. In total, we utilized data from 355,858 individuals (3,398 cases and 352,460 controls). We conducted a fixed effects meta-analysis with genomic control and a minor allele filter (MAF > 0.01), consistent across datasets. Prior to filtering, 563 of 30,088,180 SNP associations were initially statistically significant ($p < 5 \times 10^{-08}$). After, 15 of 20,500,321 SNP associations were statistically significant ($p < 5 \times 10^{-08}$). Of these 15 SNPs, 8 were mapped to distinct genes in dbSNP, some of which had been previously associated with related phenotypes such as pulse pressure and cardiovascular disease. The lowest p-value SNP was rs74958360, located in *GLYAT* ($p = 6.23 \times 10^{-10}$). An additional significant SNP was rs6748519, located in an intergenic region approximately 5 kb upstream of *QPCT* ($p = 2.93 \times 10^{-08}$). This tag SNP notably represents a region on chromosome 2 displaying linkage disequilibrium, presenting an opportunity for further association mapping. Enrichment analysis of loci achieving suggestive significance ($p < 5 \times 10^{-05}$, 1652 loci representing 544 unique genes) revealed an over-representation of ontology terms relating to the molecular function “calcium ion binding” (2.68-fold enrichment, $p = 3.64 \times 10^{-04}$) and to the cellular component “perikaryon” (5.18-fold enrichment, $p = 9.40 \times 10^{-04}$), among others. Through this work we have identified several SNPs warranting further investigation, adding to a growing body of knowledge surrounding the genetic risk of PE.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2089. Heteroplasmy dynamics and segregation in pre-implantation embryos: Rare insights from complete mitochondrial genome sequencing of clinical trophectoderm biopsy

Authors:

A. Aggarwal¹, A. Novoselska², R. Antes¹, C. Librach², S. Madjunkova²; ¹CReATe Fertility Ctr., Toronto, ON, Canada, ²Univ. of Toronto, CReATe Fertility Ctr., Toronto, ON, Canada

Abstract Body:

Objective: Heteroplasmy (Het) is cellular coexistence of mutated and normal mtDNA copies. Knowledge of maternal transmission of Het through early embryo development and its effects on human embryo is limited, due to restricted availability of human embryos for research and recent advancements in technology for low DNA input genomic analysis. Whole genome amplification (WGA) is integral to preimplantation genetic testing (PGT); however, it may introduce sequence errors and coverage bias, leading to false detection of low-level Mt-Het. We optimized analysis of human embryonic mtDNA from a trophectoderm (TE) biopsy and determined a threshold for detection of Het. Our objective here was to study patterns of heteroplasmic variation and transmission at the embryonic and fetal stage of early development employing the developed pipeline. **Materials & Methods:** We studied 43 samples from 11 cases, analyzing 20 maternal to embryo and 12 maternal to fetal transmissions. Each case included maternal DNA (blood), embryonic DNA (WGA from TE biopsy of blastocysts undergoing PGT), and fetal DNA of miscarried embryos (product of conception tissue). Illumina DNA Prep with Enrichment using whole MtDNA probe capture by ligation (Twist Biosciences) and Next Seq 550 was used for data generation. Optimized Het detection threshold of 5% was applied for variant analysis. **Results:** Mt-genome was sequenced at mean depth ~4300x (100% at 50x). 951 variants were identified at 249 sites. From 138 unique sites, 35 segregated in multiple cases which included haplogroup markers and ancestral variants. Based on gene length, D-loop and protein coding regions had more variants than expected ($p < 0.01$). 112 heteroplasmies (<80%, >5%) at 62 sites were identified. Changes in allele frequency between maternal and fetal tissues followed a normal distribution with mean=0. A weaker correlation of variant allele frequency between sibling embryos ($r=0.78$) than between a mother and fetus ($r=0.81$) was identified. We found a germline bottleneck of 18 Mt-units. We identified two variants: c.4216T>C and c.15928G>A, associated with repeated miscarriage on MitoMap. **Conclusions:** Our optimized pipeline allowed detection of low Het variants (>5%) in human embryonic mtDNA. High variant frequency present in the embryonic mt-genome is transmitted through a severe germline bottleneck of 18 Mt-units. The correlation data is suggestive of a potential germline bottleneck after the divergence of oocyte lineages. We are expanding the analysis on a larger sample size (~500 embryos). These findings may have key implications for understanding variants in early embryos and their significance in human embryo development.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2090. High-risk *APOLI* genotypes and infant growth restriction associations in Black women affected by preeclampsia.

Authors:

R. Durodoye¹, T. Azhibekov², A. Miller¹, R. Davis³, L. Bruggeman⁴, S. Williams¹; ¹Case Western Reserve Univ., Cleveland, OH, ²Metro Hlth.Med. Ctr., Cleveland, OH, ³Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN, ⁴Cleveland Clinic, Cleveland, OH

Abstract Body:

Background

Preeclampsia (PE) is a multisystem hypertensive disorder of pregnancy contributing to disproportionately higher maternal mortality rates in Black women in the United States. Evidence indicates that risk variants for the gene Apolipoprotein L1 (*APOLI*) (termed G1 and G2) associate with elevated PE risk, a higher prevalence of preterm birth, and low birth weight in specific infant populations carrying high-risk (two *APOLI* risk variants) genotypes. These two variants are found almost exclusively in populations of sub-Saharan African descent. The mode of inheritance and associations between these variants and clinical outcomes remain unclear and understudied in this population.

Methods

We harmonized data from the University of Tennessee CANDLE database and the Ohio March of Dimes database to conduct an unmatched case-control study of 1,361 Black women consisting of PE cases (both term and preterm) and 893 term uncomplicated births as controls. This analysis was designed to (1) clarify the inheritance model for *APOLI*-associated PE risk using logistic regression modeling and (2) determine how *APOLI* genotypes affect infant health outcomes.

Results

After adjustments for study location, both the recessive (OR 1.8, 95% CI: 1.1, 2.8) and additive (OR 1.3, 95% CI: 1.0, 1.7) inheritance models associated significantly with PE risk, but only in cases with preterm delivery. PE term cases showed significantly lower birth weights compared to controls ($p < 0.0001$). All control infants (low- and high-risk genotypes), and low-risk genotype term cases showed positive associations between birth weight and gestational age (all $p < 0.0001$), but there was no association observed in high-risk genotype term PE cases. Additionally, term cases with high-risk genotypes were over three times more likely to be small for gestational age compared to term cases with low-risk genotypes (OR 3.5, 95% CI: 1.2, 10.3).

Conclusion

These findings indicate that high-risk *APOLI* genotypes contribute to phenotypes of placental insufficiency and altered fetal growth. Our data best fit a recessive model of PE risk, although the additive model was also significant. These findings underscore the heterogeneity of PE phenotype and the importance of *APOLI* risk variants in conditions that exhibit higher morbidity and mortality in Black women in the United States.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2091. Host genomics and human milk exposure are associated with sex-specific changes in the gut microbiota of infants with asthma in the CHILD Cohort Study.

Authors:

S. A. Stickley¹, Z. Y. Fang¹, A. Ambalavanan¹, Y. Zhang², C. Petersen^{3,4}, D. Dai^{3,4}, B. Robertson⁵, C. Yonemitsu⁵, P. J. Mandhane⁶, E. Simons⁷, T. J. Moraes⁸, M. R. Sears⁹, S. E. Inst. and British Columbia Children's Hosp., Vancouver, BC, Canada, ⁵Dept. of Pediatrics and Larsson-Rosenquist Fndn. Mother-Milk-Infant Ctr. of Res. Excellence (MOMI CORE), Univ. of California San Diego, La Jolla, CA, ⁶Dept. of Pediatrics, Univ. of Alberta, Edmonton, AB, Canada, ⁷ Dept. of Pediatrics and Child Hlth., Univ. of Manitoba, Winnipeg, MB, Canada, ⁸ Dept. of Pediatrics, Hosp. for Sick Children and Univ. of Toronto, Toronto, ON, Canada, ⁹Dept. of Med., McMaster Univ., Hamilton, ON, Canada, ¹⁰Manitoba Interdisciplinary Lactation Ctr. (MILC), Children's Hosp. Res. Inst. of Manitoba, Winnipeg, MB, Canada

Abstract Body:

Asthma is the most prevalent chronic disease among children and a leading cause of hospitalizations and school absenteeism, with higher prevalence in males than females during childhood. Although numerous risk factors have been reported for this multifactorial condition, the mechanisms underlying the sex-specific differences in asthma remain poorly understood. Previous studies suggest that the early-life gut microbiota may play a crucial role in asthma pathogenesis through bidirectional crosstalk along the gut-lung axis, however, more research is needed to investigate the role of sex differences. In this study, we integrate host genomics and early-life exposures, such as breastfeeding practices and human milk composition, to study sex-specific effects on the gut microbiota and susceptibility to asthma and recurrent wheeze. Specifically, we leverage existing datasets from the CHILD Cohort Study, including gut microbiota sequenced using 16S rRNA from stool samples collected at two ages: 3 months (N=747) and 1 year (N=766). We also utilize genomic profiles obtained from the Illumina HumanCoreExome Bead Chip, breastfeeding practices reported by repeated questionnaires, and quantifications of the 19 most abundant human milk oligosaccharides (HMOs) from breastmilk samples collected 3-4 months postpartum using high-performance liquid chromatography. Using generalized linear models, we identified that increased abundance of *Bifidobacterium longum* in males at 3 months was associated with decreased risk of recurrent wheeze (ages 2-5 years; P=0.013). *B. longum* was also found to be increased at 3 months in males who were breastfed at the hospital compared to those who were not (P=4.0×10⁻³). In addition, increased abundance of *Klebsiella oxytoca* at 1 year was associated with increased risk of asthma (diagnosed by age 5) in both males and females (P=0.026, 0.045). Our genome-wide association study of *K. oxytoca* at 1 year identified associations with single nucleotide polymorphisms on Chromosome 20 in females only (rs12481476, P=2.4×10⁻⁹). Furthermore, *K. oxytoca* abundance was increased in males with high genetic risk of recurrent wheeze when they were exposed to increased concentrations of the HMO fucosyllacto-N-hexaose in human milk (P=0.036). Our findings suggest that host genomics and exposure to human milk impact the infant gut microbiota, which in turn may influence asthma and wheeze susceptibility in a sex-specific manner. A better understanding of the sex-specific differences in gut dysbiosis and asthma may help identify early-life biomarkers, preventative strategies, and therapeutic targets.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2092. Human engineered heart tissues uncover *MYH7* alleles associated with a frail sarcomere and ventricular noncompaction

Authors:

T. Monroe, D. Fullenkamp, M. Roy-Puckelwartz, E. McNally, L. Castillo; Northwestern Univ., Chicago, IL

Abstract Body:

Background: Pleiotropy, wherein genetic variation in the same gene can cause multiple phenotypes, is a feature of some inherited cardiomyopathies. *MYH7* variants most commonly associate with hypertrophic cardiomyopathy (HCM) and are less commonly found in dilated cardiomyopathy (DCM). Most recently, studies from large human cohorts as well as individual families indicate *MYH7* truncations and missense variants disrupting the first 600 amino acids of the beta myosin heavy chain head also associate with left ventricular noncompaction cardiomyopathy (LVNC). During heart development, the left ventricle normally loses its trabecular invaginations due to proliferation of the compact cardiomyocyte (CM) layer and concomitant quiescence of the trabecular layer. Deficient compact CM proliferation or excessive trabecular CM proliferation converge on a similar presentation, collectively referred to as noncompaction. We hypothesized that reduced contractility from specific *MYH7* head domain missense or truncating variants disrupts cardiomyocyte terminal maturation, leading to excessive trabeculation.

Results: We identified N-terminal variant carriers who had LVNC often in the setting of dilated cardiomyopathy, similar to what has been described with *MYH7* truncations. We engineered *MYH7* truncations in human induced pluripotent stem cells (hiPSCs) which were differentiated into cardiomyocytes and engineered heart tissues (EHTs) to model the developing heart. In EHTs with *MYH7* truncations contractility was reduced by 50%, EHT size was increased by 17%, and CM proliferation was increased by 40% in EHTs heterozygous for *MYH7* truncations (N=6 each).

Conclusions: Heterozygous truncation of *MYH7* results in impaired differentiation, reduced contractility, and decreased compaction in engineered heart tissues, and these findings are consistent with phenotypes that produce LVNC. We propose a general model where diminished contractility delays sarcomere maturation, extending the proliferation time of trabecular cardiomyocytes and resulting in excessive trabeculae.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2093. Identifying genes associated with preeclampsia using whole exome sequencing data from participants in the Penn Medicine BioBank.

Authors:

B. Xiao¹, S. Lee², Y. Jung², S. Verma¹, Regeneron Genetics Center, Penn Medicine BioBank, M. D. Ritchie¹, D. Kim¹; ¹Univ. of Pennsylvania, Philadelphia, PA, ²Seoul Natl. Univ. Coll. of Med., Seoul, Korea, Republic of

Abstract Body:

Preeclampsia is a complex hypertensive disorder that affects women during pregnancy and is a leading cause of maternal and infant mortality. The heritability of preeclampsia from the maternal side has been estimated to be around 35%, a percentage suggesting that genetic factors play key roles in preeclampsia risk. However, common variants do not predict preeclampsia risk well by themselves. There have been few studies examining the contribution of rare variants to preeclampsia risk in larger cohorts, and there are no widely accepted risk genes for preeclampsia. Thus, we used SAIGE-GENE+ to conduct a gene burden rare variant analysis for preeclampsia from whole exome sequencing data from 3006 participants (905 cases, 2101 controls) in the Penn Medicine BioBank (PMBB), using different binning strategies to define rare variants (varying minor allele frequency (MAF) threshold and annotating variants by functional importance). We also analyzed the effects of rare variants in European (342 cases, 900 controls) and African (490 cases, 963 controls) ancestry participants. Numerous genes were significantly ($p \leq 0.05$) associated with preeclampsia, although none were significant after Bonferroni correction. The top genes associated with preeclampsia varied depending on the binning strategy and the ancestry of the participants. Some genes found to be most associated with preeclampsia showed high gene expression in preeclampsia or pregnancy-related tissues from the Genotype-Tissue Expression project. For example, SPON2, which was associated with preeclampsia when using rare missense variants in European ancestry participants, was more highly expressed in tissues from the cervix and uterus. FADS3 was also associated with preeclampsia when using all rare variants with $MAF < 0.01$ in African ancestry participants and showed higher expression in tissues from arteries. Other genes, such as PON1 and MDH2, have been linked to preeclampsia in previous studies. To test the predictive power of rare variants for preeclampsia, we divided PMBB into training and validation datasets randomly multiple times. In the training dataset, we used rare predicted loss-of-function (pLOF) variants to identify genes most associated with preeclampsia. In the validation set, we generated polygenic rare variant scores by summing the number of top associated genes that contained pLOFs. Adding the rare variant score to a model predicting preeclampsia using only common variants (polygenic risk scores) increased the AUC from an average of 0.554 to 0.572. Future work will focus on replication of these results in other cohorts to better identify genes truly associated with preeclampsia.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2094. Improving rare conditions diagnostic rates by standardizing practice and offering preclinical testing.

Authors:

E. Delot^{1,2}, S. Bhattacharya¹, D. A. Spencer¹, H. Barseghyan¹, E. Vilain^{1,2}, The DSD-Translational Research Network (DSD-TRN); ¹Children's Natl. Res. and Innovation Campus, Washington, DC, ²George Washington Univ., Washington, DC

Abstract Body:

Background: Differences of Sex Development (DSD) are an umbrella of conditions with overlapping phenotypes and a multitude of demonstrated etiology. As a result accurate diagnosis is rarely achieved in clinical practice, resulting in less than optimal outcomes for patients. With currently 14 sites in the US, the DSD-Translational Research Network (DSD-TRN) seeks to standardize practice across providers in all clinical disciplines, with emphasis on early diagnosis prior to management decision-making. The DSD-TRN provides standardized forms to support the network's standard of care and CME-accredited clinical case conferences, documents team activity, and supports a registry and biobank for translational and genomics research. **Methods:** Analysis of registry data and clinic activity reports. Biobank samples were subjected to exome or genome sequencing or reanalysis (on the Franklin platform) and to optical genome mapping (OGM, Bionano platform). **Results:** At least 43 different etiologies were reported, with a diagnostic yield of 43%, achieved through either endocrine (9%) or genetic (26% sex chromosome aneuploidies, 9% autosomal deletions, 56% single gene) testing. Diagnostic yield varied greatly by clinical site. Undiagnosed biobank samples contributed to the delineation of the new genitourinary and/or brain malformation syndrome (GUBS, OMIM #618820). Short-read sequencing identified 23 new diagnoses, including 4 in very established DSD genes (*AR*, *SRD5A2*) missed by clinical panel testing, allowing disambiguation of conditions with similar phenotypes but very different management. Manual analysis of genome sequence BAM files revealed a compound heterozygous 6.5 kb single-exon deletion in *LHCGR* (complementing a missense variant), missed by automated algorithms. In a proof of concept project, OGM was able to diagnose 7 classic DSD chromosomal etiologies, including 45,X/46,XY mosaics. OGM also uncovered additional complexity not reported by clinical testing. For example a 9p terminal deletion identified by microarray was revealed to be a translocation, exchanging telomeric regions between 9p and 5p, with loss of material on both chromosomes. OGM was also able to distinguish between different sizes of Y chromosome translocations to the X chromosome in 46,XX testicular DSD. Resolution was however insufficient to disambiguate the rearrangements at the *CYP21A2* locus implicated in Congenital Adrenal Hypoplasia. **Conclusions:** Combining systematic short read sequencing and optical mapping facilitate the diagnostic of DSD, and needs to be accompanied by a prioritization of genetic testing at each clinical site.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2095. Investigating uptake and impact of genetic and genomic evaluation following a perinatal demise.

Authors:

E. D'Orazio¹, K. Hall¹, V. E. Kimonis^{1,2,3}, F. Quintero-Rivera^{3,1}; ¹Div. of Genetics and Genomic Med., Dept. of Pediatrics, UC Irvine, Irvine, CA, ²Dept. of Neurology, UC Irvine, Irvine, CA, ³Dept. of Pathology & Lab. Med., UC Irvine, Irvine, CA

Abstract Body:

Despite public health efforts to mitigate stillbirth and neonatal death over the 20th and 21st centuries, the rate of decline in perinatal death has plateaued. Genetic etiologies, especially those implicated in undiagnosed causes of perinatal death, are thought to contribute to this trend. Ample literature has investigated the diagnostic yield of genetic testing in the case of stillbirth and neonatal demise. However, little research has explored the frequency of involvement of trained genetics specialists, such as medical geneticists and genetic counselors, in perinatal death cases from prenatal ascertainment of anomalies to demise. The current study examined retrospective demographic and clinical data from 111 perinatal demise cases and their gestational parents associated with attendance and uptake of prenatal genetic counseling, post-delivery genetics consult, genetic/genomic testing, and autopsy investigation at a large university-affiliated medical center between November 1st, 2017, and December 1st, 2021. Furthermore, this study investigated the potential diagnostic yield of genetic testing in the presence and absence of genetics specialist involvement providing evaluation and testing recommendations. Finally, this study appraised the degree of patient education in genetic post-counseling documented by genetics specialists versus non-genetics specialists. Through univariate analysis, genetic specialist involvement in perinatal cases was found to be associated with significant increases in genetic testing uptake ($p=0.007$), abnormal genetic testing results ($p<0.001$), positive results and results of uncertain significance that have a potential to contribute to disease), and increased degree of documentation of patient education outcomes through genetic post-test counseling compared to those services rendered by non-genetics providers ($p<0.001$). The findings of this study underscore the importance of active integration of genetics healthcare professionals into the process of perinatal postmortem investigation and allocating the practice of genetics evaluation and genetic testing selection to healthcare professionals with relevant genetics training.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2096. Knowledge and attitude of pregnant women in the Kingdom of Saudi Arabia toward Noninvasive prenatal testing: A single center study

Authors:

M. Akiel; King Saud bin Abdulaziz for Hlth.Sci. (KSAU-HS), Riyadh, Saudi Arabia

Abstract Body:

Background: Non-invasive prenatal testing (NIPT) is a screening tool for chromosomal aneuploidies. Prior knowledge of NIPT is an inherent factor in the decision-making process. We assessed the knowledge and attitude of pregnant women related to prenatal testing with a particular focus on NIPT. **Methods:** A prospective cross-sectional study, using a culturally validated questionnaire, was conducted with 342 pregnant women of whom 74.9% consented for prenatal screening. Mean age and gestational weeks \pm standard deviation was 31 ± 5 and 26 ± 11 , respectively. **Results:** A positive/very positive attitude was observed to ultrasound, followed by FCT, NIPT and lastly to CVS. More than half of the participants (56.1%) had no previous knowledge of NIPT. A reaching significance association was detected between education and knowledge of NIPT. Significant association was detected between risk for aneuploidy and knowledge of NIPT. The majority (74%) indicated their willingness to perform the test. The effect and value of society on the pregnant women to make a decision regarding NIPT was negligible. **Conclusion:** The pregnant women in the current study displayed a lack of knowledge and awareness regarding prenatal screening, particularly the NIPT. We recommend that pregnant women receive adequate counseling regarding prenatal screening to increase their awareness and knowledge of prenatal testing, including NIPT.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2097. Large-scale genome-wide association study meta-analysis of Hyperemesis Gravidarum confirms the nausea and vomiting hormone gene *GDF15* is the greatest genetic risk factor and identifies additional risk loci

Authors:

M. Fejzo¹, P. Mullin¹, N. Pujol Gualdo², T. Laisk², E. Biobank Research Team², K. W. MacGibbon³, X. Wang¹, N. Mancuso¹; ¹Univ. of Southern California, Los Angeles, CA, ²Estonian Genome Ctr., Inst. of Genomics, Univ. of Tartu, Tartu, Estonia, ³Hyperemesis Ed. and Res. Fndn., Clackamas, OR

Abstract Body:

Most women experience nausea and vomiting of pregnancy and 18% require medication. The most severe form, Hyperemesis Gravidarum (HG), occurs in 2% of pregnancies and is associated with weight-loss and undernutrition. HG accounts for ~400,000 emergency department visits in the US annually and can cause serious maternal morbidity, suicidal ideation and PTSD. HG is associated with increased risk of preterm birth, neurodevelopmental delay, and autism. It is highly heritable. Herein we report results from the largest ever genome-wide association study (GWAS) of HG, comprised of 7,197 cases and 178,953 controls. We performed a meta-analysis of 4 independent studies: a multi-ancestry whole-exome sequencing study of 926 HG cases and 660 controls from the US, a GWAS of 23andMe customers of European descent comparing 1,306 cases to 15,756 controls with no NVP, an Estonian Biobank GWAS of 3,536 cases and 32,113 controls, and a FinnGen GWAS of 1,429 cases with excessive vomiting during pregnancy and 130,424 controls. We identified genome-wide significant ($P < 5E^{-8}$) variants at *GDF15* (rs1058587, $P = 1.745E^{-26}$), *IGFBP7* (rs4865233, $P = 2.737E^{-12}$), and *PGR* (rs10895102, $P = 5.11E^{-10}$), replicating our previous studies of HG. Of note, all 3 genes are known to be activated in early pregnancy, consistent with a putative role in HG risk. FUMA analysis suggests possible enrichment in stomach. Genetic loci in hCG and its receptor, were not associated with HG in any of the 4 studies, nor the meta-analysis, providing no support for the historical hypothesis that the pregnancy hormone is the cause. Future research efforts should focus on the genes identified in this study, which implicates the nausea/vomiting hormone *GDF15*-the most significant locus in all 4 cohorts- as well as the placenta and appetite protein *IGFBP7* and the progesterone receptor *PGR*. Replication studies are needed to confirm whether additional novel variants in/near genes that were significant using a relaxed P -value threshold of 5×10^{-6} in individual cohorts (ie *GDF15* co-receptor gene *RET* in the Estonian GWAS and the thyroid stimulating hormone receptor gene *TSHR* in the Finnish GWAS) are valid associations and/or generalizable to other populations. Overall, this study contributes to our understanding of the biology of nausea and vomiting and may provide new treatment avenues. Of note, drugs targeting the *GDF15* pathway have shown great promise in mitigating weight loss, loss of appetite, and vomiting in animal models and are currently in clinical trials in cancer cachexia, a disease with similar symptoms to HG. The strong link to this pathway in HG suggests these drugs, if safe, may hold great promise for treating HG in the future.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2098. Lethal genes and Mendelian disorders

Authors:

P. Cacheiro, A. Retnakumar, D. Smedley; Queen Mary Univ. of London, London, United Kingdom

Abstract Body:

Essential genes can be defined as those required for organism development. Existing resources that collect and characterise these genes are based on either cell proliferation assays, viability in model organisms, intolerance to variation metrics or predicted lethal genes. Resources like the Online Mendelian Inheritance in Man (OMIM) and the Human Phenotype Ontology (HPO) document phenotypic annotations for Mendelian disorders, yet the evidence on prenatal/neonatal lethal phenotypes is either limited or not easy to retrieve.

Here we queried OMIM for terms related to lethality and classified all Mendelian genes into lethality categories according to the earliest age of death reported using HPO age of death terms, from prenatal death to death in adulthood and non-lethal genes. We also explored how these categories correlate with evidence on mouse viability from the International Mouse Phenotyping Consortium.

After manual curation and exclusion of ambiguous entries, we found that 56% (1955/3517) of OMIM genes are not associated with disorders with clinical records of lethality, 33% (1174/3517) are only associated to disorders with records of lethal phenotypes, and 11% (388/3517) are linked to both lethal and non-lethal phenotypes. With regards to lethality categories, 917 genes, that represent 59% of all lethal genes and 26% of all disease genes, have records of prenatal, neonatal or infant death (pre-infant-lethal) as opposed to post-infant-lethal, where the earliest reported age of death ranges from childhood to adulthood. By associated mode of inheritance, 76% (695/917) of pre-infant-lethal genes are autosomal recessive, compared to 62% (402/645) of post-infant-lethal genes and 52% (1012/1955) of non-lethal genes. When we explored data on viability for the corresponding mouse orthologs - assessed at weaning for the homozygous knockouts - 75% of the pre-infant-lethal genes are lethal/subviable in the mouse, being this percentage similar for the other two groups, 52% and 50% respectively. The former percentage is slightly higher (82%) if we exclude infant death records. Further investigation of the abnormal phenotypes identified in these viable lines could help explain this discrepancy.

Monogenic forms of this extreme phenotype are likely underrepresented in current disease databases. Given the increasing number of prenatal and molecular autopsy sequencing studies, an additional literature search for prenatal and perinatal lethal phenotypes identified 94 novel genes with candidate pathogenic variants. We are currently building a Lethality Gene Portal to catalogue and showcase human lethal genes and support fetal sequencing studies.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2099. Leveraging duplex DNA sequencing to investigate germline mutation rates in the context of sperm selection and paternal age.

Authors:

J. Kunisaki¹, S. Lulla¹, K. Aston¹, J. Hotaling², A. Quinlan¹; ¹Univ. of Utah, Salt Lake City, UT, ²Univ. of Utah Sch. of Med., Salt Lake City, UT

Abstract Body:

BACKGROUND: Germline de novo mutations drive human evolution and underlie human disease. Their rates, patterns, and underlying mechanisms are therefore essential to understand. Work from our group and others have genome sequenced blood from parent-child trios to find that the male contributes 80% of transmissible mutations with an average paternal germline mutation rate of $\sim 0.9 \times 10^{-8}$. However, pedigree analyses study mutations solely from sperm capable of facilitating normal child development: thus, the unbiased germline mutation rate is unknown. To overcome this survivorship bias, one must examine a bulk sperm population comprised of reproductively “fit” and “unfit” gametes which accumulate DNMs amidst continuous cell division of spermatogonial stem cells (SSCs).

METHODS: We hypothesize the germline mutation rate in bulk sperm would be greater than pedigree-derived estimates, reflecting the continuous division of SSCs in a man's lifetime. To test this, we used targeted TwinStrand Duplex Sequencing to analyze low-frequency mutations in bulk sperm across 93 genes involved in spermatogenesis and DNA repair. This technology distinguishes true mutations as those present on complementary DNA strands from errors that arise on single strands. The resulting per-base error rate falls from 1/1000 to 1/100,000,000. We applied TwinStrand Duplex Sequencing to cross-sectional (single timepoint, n=26) and longitudinal (multiple timepoints, n=9) bulk sperm samples from normozoospermic men (sperm concentration ≥ 30 M/mL of ejaculate) aged between 24 to 68 years.

RESULTS: Our sequencing of bulk sperm supports the hypothesis that pedigree estimates of male germline mutation rates suffer from a survivorship bias. We observe an order of magnitude higher mutation rate (1.2×10^{-7}) and an increase of 8 mutations/year in bulk sperm. We also measured elevated pathogenic mutation rates in paternal age effect genes ($p=0.0029$), including BRAF and KRAS, which drive spermatogenesis and autosomal dominant Mendelian diseases such as Noonan syndrome. More broadly, we observe a pathogenic mutation rate of 5.9×10^{-9} across all genes, with such mutations accumulating at a rate of 0.4 pathogenic mutations/year. Further, we find that an average of 6.25% of mutations are clonal (i.e., present in more than one SSC), and 7% of clonal mutations are pathogenic. Such clonal mutations confer a lifelong risk for the transmission of deleterious mutations.

CONCLUSIONS: The observed differences in germline mutation rates between bulk sperm and pedigree studies suggest positive and/or negative selective forces act upon human sperm during fertilization and/or embryogenesis.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2100*. Metabolomic analysis reveals altered omega-6 fatty acid processing as a marker of *FMRI* premutation carriers with FXPOI compared to premutation carriers without ovarian insufficiency

Authors:

E. Allen¹, K. Shelly¹, D. Nelson², P. Jin³; ¹Emory Univ., Atlanta, GA, ²Baylor Coll. of Med., Houston, TX, ³Emory Univ Sch Med, Atlanta, GA

Abstract Body:

Fragile X-associated Primary Ovarian Insufficiency (FXPOI) is the clinical diagnosis given to roughly 20% of women who carry an *FMRI* premutation (PM) allele. This disorder is caused by the expansion of a CGG-repeat tract in the 5' untranslated region (UTR) of the *FMRI* gene to 55-200 repeats. Studies of FXPOI are limited by the availability of primary tissue and sufficient patient numbers who meet the clinical criteria of elevated FSH levels and cessation of menses for 4-6 months prior to age 40. We performed non-targeted metabolomic profiling of patient plasma by LC/MS on two cohorts of women, the largest to date, a test cohort (40 FXPOI Cases, 34 PM Controls) and a validation cohort (22 FXPOI Cases, 58 PM Controls) to identify metabolic indices of FXPOI among *FMRI* premutation carriers. Differential abundance analysis using the R-package xmsPANDA and Metabolite Set Enrichment Analyses (MSEA) via Mummichog revealed altered abundance of compounds in omega-6 fatty acid (n-6 FA) metabolism and arachidonic acid (AA) formation between females with a FXPOI diagnosis compared to female PM carriers without POI across both cohorts. Pathways downstream of FA and arachidonate metabolism were also identified, including prostaglandin synthesis and formation of pro-inflammatory metabolites from AA. Evaluation of menopausal status in controls did not implicate the menopause transition as the driver of this enrichment at the pathway level. The menopausal state of the controls was an important determinant for the direction of change for individual metabolites in the pathway. When the post-menopausal cases were compared to pre-menopausal controls, n-6 FA processing was lower. Whereas, cases compared to post-menopausal controls had increased processing of compounds through the n-6 FA and AA pathways. Intriguingly, key enzymes required for the conversion of membrane phospholipids into free FA precursors and the prostaglandins generated downstream of AA were also seen to be altered in mouse ovaries expressing *FMRI* PM alleles. Together, these data suggest altered metabolism of n-6 fatty acids is consistent across human and mouse models of FXPOI and is likely to provide critical information about the mechanism of dysfunction in PM ovaries.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2101. Molecular dysregulation in *Sox2*-expressing pituitary stem cells lacking *Prop1*

Authors:

B. Masser, S. A. Camper, L. Y. M. Cheung; Univ. of Michigan, Ann Arbor, MI

Abstract Body:

Mutations in the pituitary-specific transcription factor Prophet of Pit-1 (*PROPI*) are the most common genetic etiology of combined pituitary hormone deficiency (CPHD). CPHD is associated with short stature, attributable to growth hormone deficiency and/or thyroid stimulating hormone deficiency, as well as hypothyroidism and infertility. Pathogenic lesions impair pituitary development and differentiation of endocrine cells. We performed single-cell RNA sequencing (scRNA-seq) on pituitary stem cells from juvenile P4 female *Prop1*-mutant and control mice and observed overexpression of several genes, such as Pou Domain, Class 3, Transcription Factor 4 (*Pou3f4*), SRY-Box Transcription Factor 21 (*Sox21*), and SPARC Related Modular Calcium Binding 2 (*Smoc2*). We further performed single-cell regulatory network inference and clustering (SCENIC), which predicted activation of the *Pou3f4* regulatory gene network in *Prop1*-mutant stem cells and both *Sox21* and *Smoc2* to be downstream targets of *Pou3f4*. Therefore, we sought to elucidate the role of *Pou3f4* during pituitary development through analysis of *Pou3f4*-deficient mice, and to determine the contributions of *Pou3f4* upregulation to pituitary disease by generating double-mutant mice lacking both *Prop1* and *Pou3f4*. Here, we have shown that *Pou3f4* has a specific developmental expression pattern but is not required for pituitary organogenesis and endocrine specification. Furthermore, the *Prop1*; *Pou3f4* double-mutant mice did not show a rescue of embryonic pituitary dysmorphology, endocrine specification defects, or overexpression of *Sox21* or *Smoc2*, despite the computational prediction of the regulatory network. Collectively, these analyses have taken the initial steps in understanding the role of *Pou3f4* in the complex genetic hierarchy of pituitary organogenesis and pathophysiology. Future studies will investigate the functional significance of other *Prop1*-dependent changes in stem cell gene expression.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2102. Molecular Epidemiological Status of Group B Streptococcus in Ile Ife South Western Nigeria

Authors:

J. Omololu-Aso¹, O. O. Omololu-Aso²; ¹Obafemi Awolowo Univ., Ile Ife, Nigeria, ²Univ. Coll. Hosp. (UCH), Ibadan, Nigeria

Abstract Body:

Studies in some sub-Saharan African countries like Zimbabwe, Malawi, Kenya and Gambia revealed that Group B *Streptococcus* (GBS) is emerging as the main cause of neonatal sepsis and meningitis. However, in Nigeria, information on GBS disease prevalence remains sparse. We sourced to isolate GBS from the rectovaginal and neonatal samples that were obtained from a tertiary hospital in a populated area of Osun state and give updated information on the antibiotic susceptibility patterns, using demographic and clinical parameters. One hundred and seventy samples were collected from consenting mothers and neonates from June 2016 to January 2017. Ninety-Eight (98) GBS isolates were recovered from the vaginal, and rectal of the pregnant woman at the point of labour and the Umbilical cord of the neonate within 24hrs of birth. cultures for the isolation and identification of Group B Streptococcus (GBS) were carried out using the CDC recommended microbiological methods. The Kirby-Bauer disk diffusion method was employed to determine the antibiogram of GBS isolates in accordance with the Clinical and Laboratory Standards Institute (CLSI). The presence of resistant genes was examined using PCR. The prevalence rate of GBS maternal and neonatal colonization was 29.4% and 20.6% respectively while 4% of the colonized neonates had nosocomial GBS colonization. There was no significant association between GBS colonization status and age ($p > 0.05$), parity ($p > 0.05$), obstetric risk factors ($p > 0.05$) and sex of neonate. There was no incidence of GBS infection observed. Resistance to augmenting (88.8%), ampicillin (60.2%), penicillin (47%), tetracycline (34.7%), ceftriaxone (19.4%), clindamycin (13.3%), vancomycin (10.2%) and erythromycin (7.1%) were observed. one of the 8 representatives of the multidrug-resistant isolates harboured tetM gene while other resistant genes examined were negative in all MDR isolates. A high prevalence of maternal and neonatal GBS colonization has been established among pregnant women and neonates in the study area. Nosocomial infection was implicated in GBS colonization among neonates. However further research is called for using larger sample sizes and multiple curve studies for adequate extrapolation into the general population.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2103. Next-Generation Sequencing based pre-implantation genetic Testing in Nepal

Authors:

S. Khanal, S. Thapa, G. Joshi, A. Kunwar, N. Thakur; Kathmandu Ctr. for Genomics and Res. Lab., Lalitpur, Nepal

Abstract Body:

Preimplantation genetic testing reduces the risk of having a pregnancy with an affected fetus significantly. Screening for aneuploidy (PGT-A) is widely used as an add-on to standard IVF treatment of infertile couples around the world, though its effectiveness is heavily debated. We present our experiences in introducing NGS-based screening of embryos for aneuploidy. We emphasized on successful commencement of the NGS based screening of embryos for chromosomal aneuploidies. Baseline for analysis was created using 10 healthy male individuals. 3 days embryos from IVF were subjected to low-coverage whole genome sequencing. The analysis of the sequencing data was performed using the Ion Reporter software. The overall results from 177 total embryos analysis revealed around 28% of the embryos were euploid. However, most of the embryos possessed aneuploidies. Moreover, the results revealed complex mosaicism (mosaic in >3 embryos) being the most common anomalies in those embryos. PGT-A based on NGS is a reliable and effective technology for routine embryo screening, especially for couples who have had several miscarriages or failed embryo transfers.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2104. *Nlrp2* is a Maternal Effect Gene Required for both Placental and Embryonic Development.

Authors:

M. Sharif, Z. Anvar, I. Chakchouk, I. Van den Veyver; Baylor Coll. of Med.; Jan and Dan Duncan Neurological Res. Inst. at Texas Children's Hosp., Houston, TX

Abstract Body:

Pregnancies of women with bi-allelic inactivating mutations in NLRP2 are affected by a multi-locus imprinting disorder MLID and liveborn offspring with imprinting disorders, such as Beckwith-Wiedemann Syndrome (BWS) in children of women carrying these inactivating mutations. NLRP2 is a member of oocyte subcortical maternal complex (SCMC), required for embryonic development. We previously showed that mice with maternal loss of *Nlrp2* are subfertile with early embryonic loss and few liveborn offspring, which can have developmental defects and altered DNA methylation at selected imprinted loci. Our overarching goal is to molecularly characterize the mechanisms by which maternal loss of *Nlrp2* affects development of the placenta and embryo and genetic imprinting. To investigate this, we set up 5-14 timed matings each for the following crosses: WT x WT, maternal KO x WT, and WT x paternal KO. We used a novel application of X-ray microcomputed tomography (microCT) for comprehensive placental, embryonic and yolk sac characterization at 3 $\mu\text{m}/\text{voxel}$. We studied E11.5 conceptuses ($n=20-26$ per cross) for gross morphological anomalies, yolk sac vascularization and examined the placentas focusing on maternal decidua, junctional zone, and labyrinth. We found that placentas from *Nlrp2*-KO dams were found to be significantly smaller, had irregular lacunae, extensions and infoldings of decidua, abnormal junctional zone, and compact labyrinth with variations in vasculature. The conceptuses from *Nlrp2*-KO dams showed increased resorption ($n=25$, $P=0.0179$), abnormal yolk sac vasculature ($n=26$, 40.2%), irregular amniotic fluid volume ($n=26$, $P=0.0491$) and craniofacial anomalies ($n=22$, 37.6%) along with congenital heart defects (CHD's) ($n=22$, 32.7%). In conclusion, we show that the adverse reproductive outcomes due to maternal loss of *Nlrp2* are the result of a combination of both embryonic and extraembryonic defects. Future directions include detailed phenotypic characterization along with genomic profiling of embryos and placentas from *Nlrp2*-KO dams to study implantation (E4.5 & E5.5) and earlier stages of placentation (E9.5). This will reveal novel mechanisms linking regulation of imprinting to implantation, placentation, and embryonic development and will improve our understanding of rare imprinting disorders.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2105. Non-invasive prenatal testing (NIPT): A reliable accurate prenatal non-invasive diagnosis setting in Nepal

Authors:

S. Thapa, N. Thakur, A. Jang Kunwar, S. Khanal, G. Joshi; Kathmandu Ctr. for Genomics and Res. Lab. (KCGRL), Lalitpur, Nepal

Abstract Body:

Because of its enhanced accuracy, non-invasive prenatal testing (NIPT) for fetal aneuploidies utilizing cell-free DNA (cfDNA) has become widely used in clinical practice. The core goal of cell-free based prenatal testing is to provide minimally invasive, clinically accurate screening for fetal chromosomal aneuploidies in the early stages of pregnancy. The purpose of this study was to establish a validated NIPT workflow for cell-free fetal DNA (cffDNA) sequencing from maternal plasma for the detection of particularly autosomal trisomies (involving chromosomes 13, 18 and 21) and sex chromosome on an ion semiconductor sequencing technology. A total of ninety-one standard samples from healthy pregnant provided by Yourgene Health; their cfDNA library was prepared, perform emulsion PCR on One Touch 2 machine, enrich ISPs on One Touch ES machine, then load ISPs on an Ion 540 chip for sequencing. The sequencing output data was analyzed by using the bioinformatics pipeline of Yourgene Health. Eighty-one samples were successfully validated out of a total of 91 samples. However, 3% of samples did not meet quality, and 3% of sample libraries had low reads and failed validation. The method included a fetal DNA fraction calculation for all samples as well as additional quality indicators. After the establishment of Validated workflow, following an assessment of the continuing pregnancy's data, NIPT was offered to 174 pregnant women after the informed consent form. Maternal BMI, maternal age, gestational age along with the latest copy of ultrasound sonography (USG) was received and noted. Pre-test counseling was provided to all participants and addressed the main testing procedures, their benefits, limitations, turnaround time, and interpretation of the results. From the total clinical samples, 18 samples showed an abnormal result: 13 trisomy 21 samples, three trisomy 18 and two samples with sex chromosome abnormalities were reported. One case had to discontinue pregnancy due to complications in later pregnancy but unrelated to the NIPT results. 12 samples were needed to repeat due to the low fetal fraction (LFF) of cell-free DNA and later reported normal after the resampling and repetition of the test. During a post-test counseling session, the findings were explained. This research aims to introduce and set up Nepal's first NGS laboratory for NIPT, utilizing the Ion Torrent technology to provide a complete in-house solution for pregnant women in Nepal. The established laboratory standards for testing and reporting, as well as educational resources and counseling approaches, will contribute in the acceptance of NIPT in society and clinical practice.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2106. Ovarian subfertility genetic variants in females with unexplained infertility.

Authors:

R. Roman, L. Chorich, Z. Hawkins, M. Dougherty, M. Diamond, L. Layman; Med. Coll. of Georgia at Augusta Univ., Augusta, GA

Abstract Body:

Objective: Unexplained infertility is a common infertility diagnosis in the US, with up to 30% of patients having no identified cause after a standard evaluation. We hypothesize that abnormal ovarian follicular development may be a cause of unexplained infertility. Therefore, we sought to evaluate the overall prevalence of variants associated with primary ovarian insufficiency (POI) and ovarian dysgenesis (OD) in females with well-characterized unexplained infertility. **Methods:** Females with well-characterized unexplained infertility were recruited for the Assessment of Multiple Intrauterine Gestations from Ovarian Stimulation (AMIGOS) trial. De-identified DNA samples from 200 females were analyzed by whole exome sequencing (WES) to identify variants in twenty-nine genes associated with POI and OD listed in the Online Mendelian Inheritance in Man (OMIM) database. High quality reads were filtered to identify the prevalence of likely pathogenic variants including frameshift, splice-site, and stop-gained variants. Variant of uncertain significance (VUS) prevalence was studied, including missense variants with a Combined Annotation Dependent Depletion (CADD) score ≥ 20 and in-frame insertions/deletions. Only variants with allele frequencies < 0.01 in the gnomAD database were included. **Results:** One hundred and ninety-seven samples were adequate for WES. Five autosomal dominant likely pathogenic variants (four *ERCC6*, one *NR5A1*) were present in six patients (3%). Eighteen autosomal dominant VUS were identified in eighteen patients (9.1%), including sixteen missense variants with high CADD scores (one *BNC1*, seven *ERCC6*, four *ESR2*, one *FIGLA*, two *FOXL2*, and one *NOBOX* variant), one twenty-one base pair deletion (*ESR2*), and one three base pair deletion (*FOXL2*). Two X-linked VUS (one *BMP15* and one *DIAPH2* variant) were identified in two patients (1%). There were six autosomal recessive likely pathogenic heterozygous variants (one *FANCM*, one *GDF9*, one *HFMI*, one *MCM8*, one *XRCC1*, and one *ZSWIM7*) in eight patients (4.1%). Fourteen patients (7.1%) had two variants in genes associated with POI and/or OD. One patient (0.5%) had three variants associated with POI and OD. **Conclusion:** We have identified heterozygous likely pathogenic variants and VUS associated with ovarian subfertility in females with unexplained infertility. Future *in vitro* functional genomic studies will be needed to characterize their pathogenicity and to better understand the role of ovarian subfertility genetic variants in unexplained infertility.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2108*. Phenome and genomewide recessive scan of coding variants reveals novel associations for female infertility

Authors:

S. Ruotsalainen¹, J. Karjalainen^{2,1}, M. Kurki^{2,1}, H. Heyne^{3,1}, E. Widen¹, H. Laivuori^{1,4}, M. Aavikko¹, E. Lahtela¹, FinnGen, A. Palotie^{1,2}, M. Daly^{1,2}; ¹Inst. for Molecular Med. Finland, FIMM, Helsinki, Finland, ²Broad Inst., Boston, MA, ³Hasso Plattner Inst., Digital Hlth.Ctr., Potsdam, Germany, ⁴Dept. of Obstetrics and Gynecology, Tampere Univ. Hosp., Tampere, Finland

Abstract Body:

Identifying Mendelian diseases with recessive inheritance is challenging as most cases are caused by compound heterozygosity. Bottleneck events, such as in the Finnish population, enrich specific homozygous variants to higher frequencies and thus facilitate identification of disease associations. In the FinnGen project (n=377 277), we performed a recessive GWAS scan for 68 818 coding variants with at least 2 homozygous carriers against 2 274 phenotypes. We identified total of 570 homozygous associations (recessive p-value < 5E-8 and smaller than corresponding additive p-value) for 300 phenotypes and 229 genetic variants in 188 genes. Recessive inheritance to some phenotypes has been reported in OMIM for 71 (38 per cent) of these genes. We observed multiple recessive associations (both previously reported and not-reported in OMIM) for hearing-loss and eye diseases, including heterophoria. As a novel finding, we identified a highly Finnish enriched (over 40-fold compared to non-Finnish Europeans) stop-gained variant rs144313315 in *TBPL2* gene to be associated with female infertility in recessive GWAS (p-value from recessive model=4.75E-10, p-value from additive model = 0.289). A homozygosity in this gene has been reported in infertile female mice with anovulation. Homozygote females for this variant had significantly (p=6.33E-11) less offspring (mean=0.22) than heterozygotes or wild-type homozygotes (mean=1.73). None of the homozygous women had conceived without treatment for infertility. We identified another recessive association for female infertility for a splice donor variant rs17368310 in *PKHDILI* to have a clear recessive association with female infertility (recessive p=1.30E-18, additive p=1.34E-12). This variant is in high LD (r²= 0.79) with intronic variant rs1422 in *EBAG9* (Estrogen Receptor Binding Site Associated Antigen 9), which we hypothesize to be the actual causal gene in this case based on its more relevant biological connection to infertility as an estrogen-responsive gene.

In conclusion, our biobank-scale recessive scan of coding variants demonstrates the benefit of recessive GWAS and PheWAS scans. We found both known and novel recessive associations across a wide spectrum of phenotypes, including hearing-loss, eye diseases and female infertility, that are missed by the standard additive GWAS model.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2109. Phenomic and genomic analyses of endometriosis in the All of Us Research Program.

Authors:

D. Schlueter¹, C. Zeng², S. Goleva¹, J. Keaton³, T. Ferrara², O. Stubblefield¹, A. Williams², J. Dai¹, T. Cassini⁴, H. Mo⁵, J. Denny⁶; ¹Natl. Human Genome Res. Inst., Bethesda, MD, ²NIH, Bethesda, MD, ³Med. Genomics and Med. Genetics, Clarksburg, MD, ⁴NIH, Chevy Chase, MD, ⁵NHGRI, Bethesda, MD, ⁶NIH, Kensington, MD

Abstract Body:

Endometriosis is a disease characterized by endometrium-like tissue formation outside of the uterus, peritoneal irritation and adhesions. Endometriosis has a prevalence of roughly 10% in women of reproductive age. We leveraged electronic health records (EHRs) and patient provided information (PPI) to elucidate genetic and clinical correlates with this disease in participants derived from the All of Us Research Program. We identified cases and controls for endometriosis with two approaches and compare results from each: first through electronic health records and second through survey-based self-reported personal medical history. In our first, EHR-based approach, cases had at least one instance of endometriosis-related diagnostic codes (N=3738) and controls had none of these codes and had no record of prior laparoscopic excision or ablation procedure in their EHR (N=172366). In our second approach, we defined cases and controls using self-reported medical history at enrollment. Cases reported a prior diagnosis of endometriosis (N=4150) while controls who completed the past medical history module (excluding skip responses) and did not affirm endometriosis (N=53827). We performed phenome-wide association studies (PheWAS) for each case/control definition. A total of 374 phenome-wide significant associations were identified from the EHR-based PheWAS compared to 42 identified from the survey-based PheWAS. GWAS of the EHR-defined phenotype using whole genome sequencing (WGS) data (N=1390 cases, 5560 controls) a novel genome-wide significant locus at chr21:38534959 (OR= 5.60, P = 2.82E-8). One novel genome-wide significant result was found for the PPI-based GWAS at location chr11:15116317 (OR=1.57, P=1.12E-8) (N=2197 cases, 8788 controls). Results from the two sets of analyses are compared between the two representations of endometriosis.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2110. Placenta fraction of maternal blood cell-free RNA associates with pre-eclampsia during pregnancy

Authors:

Q. Yan¹, J. Wang²; ¹Columbia Univ. Irving Med. Ctr., New York, NY, ²Univ. of Pittsburgh, Pittsburgh, PA

Abstract Body:

Of adverse pregnancy outcomes, pre-eclampsia is the second-largest driver of maternal mortality worldwide. Although pre-eclampsia is likely a multifactorial disease, it is believed that placenta is responsible for the disease progression. However, it is challenging to monitor the health of placenta during pregnancy. Recently, a few pioneering studies showed that plasma cell-free RNA (cfRNA) from maternal blood offers an opportunity to non-invasively study the status of placenta and predict pre-eclampsia before the onset of symptoms. In this study, we hypothesize that the fraction of cfRNA released from placenta can be numerically estimated, the placenta fraction is associated with pre-eclampsia, and placenta fraction can improve the prediction of pre-eclampsia. Thus, first, we performed a tissue deconvolution of cfRNA from maternal plasma samples (GSE192902, discovery n=112 and validation n=87) with gene expression from whole blood, liver, and spleen from GTEx, and placenta from Gong et al. (2021) as references. There are four time windows, ≤ 12 weeks, 13-20 weeks, ≥ 23 weeks of gestation, and post-partum. We observed that the majority of cfRNA is derived from whole blood (0.86 ± 0.13 , mean \pm SD). The results show that placenta fractions are significantly higher during pregnancy (0.14 ± 0.12) than post-partum (0.02 ± 0.05 , $P = 6.65 \times 10^{-16}$). However, there is no difference between the three prenatal time windows. Second, we tested the association between placenta fraction and the risk of pre-eclampsia using the discovery group. The results show that placenta fraction at the second time window (13-20 weeks) is significantly associated with pre-eclampsia ($P = 4.77 \times 10^{-3}$). Third, we performed differential expression analyses of pre-eclampsia, and we identified 465 differentially expressed genes (DEGs) at the second time window, which replicated the results in Moufarrej et al. (2022). Then, we conducted prediction analyses of pre-eclampsia using support vector machine (SVM) and random forest with 10-fold cross-validations in the discovery group. SVM shows better prediction accuracy (AUC=0.98). The prediction model was further validated in the independent validation group (AUC=0.77). These results are similar to those reported by Moufarrej et al. (2022). Moreover, we added placenta fraction as an additional predictor, but the prediction accuracy is not improved, because 195 DEGs are correlated with placenta fraction ($FDR < 0.05$) and are already included as predictors. Next, we will leverage the genotype information in the deconvolution of plasma cfRNA as future work.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2111. Preeclampsia risk is influenced by apolipoprotein L1 genotype and micronutrient deficiencies.

Authors:

W. Bruner¹, R. Davis¹, C. Simpson²; ¹Univ. of Tennessee Hlth.and Sci. Ctr., Memphis, TN, ²Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN

Abstract Body:

Background: Preeclampsia (PE) is a hypertensive disorder of pregnancy that is associated with micronutrient deficiencies. Fetuses carrying two APOL1 high risk (HR) variants is also associated with PE risk. We hypothesized a potential additive effect between HR APOL1 genotype status and nutritional deficiencies would place individuals at a higher risk of developing PE. We assessed PE-associated risk of micronutrient deficiencies based on fetal APOL1 genotype in pregnant African American women.

Methods: This was a case-control study using a subset of African American mother and infant pairs collected from the Conditions Affecting Neurocognitive Development and Learning in Early Childhood cohort in Memphis, TN. We performed multiple logistic regression to examine the association of preeclampsia with 2nd and 3rd trimester plasma folate and 25-hydroxy vitamin D concentrations. Concentrations were dichotomized into high or low categories. Folate deficiency was defined as a concentration less than 15 ng/mL. 25-hydroxy vitamin D deficiency was defined as a concentration less than 20 ng/mL. Analyses assessed whether maternal or fetal apolipoprotein genotype status modified the association between folate and 25-hydroxy vitamin D association and preeclampsia. The reference group included individuals with both high folate or and 25-hydroxy vitamin D concentrations and low-risk apolipoprotein genotype.

Results: An increased risk for developing PE was found with individuals having both fetal HR APOL1 and low plasma folate concentrations in the 2nd trimester (OR 3.27; 95% CI 1.28, 7.65). Pregnancies with low 25-hydroxy vitamin D concentrations in the 3rd trimester were at an increased risk for preeclampsia (odds ratio 2.10; 95% confidence interval 1.09-4.12; P-value, 0.03). Risk for preeclampsia was greatest among pregnancies with fetal high-risk genotype and low vitamin D levels in the 2nd trimester (odds ratio, 2.79; 95% confidence interval, 1.06-6.83; P-value, 0.03) and 3rd trimester (odds ratio 6.40; 95% confidence interval 2.07-19.18; P-value, <0.01).

Conclusions: Our findings are suggestive of a potential additive effect between low 25-hydroxy vitamin D and fetal HR APOL1 genotype during the 3rd trimester. Similar potential additive effect was found between low folate and fetal HR genotype in the 2nd trimester.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2112. Prenatal and postnatal changes in chromatin accessibility and gene expression in mouse gut development for understanding Hirschsprung disease (HSCR).

Authors:

H. Chubaryov¹, A. Chakravarti²; ¹NYU, New York, NY, ²NYU Sch. of Med., New York, NY

Abstract Body:

Purpose: HSCR arises from developmental defects in the neuronal and glial cells of the enteric nervous system. Its successful formation relies on the proper migration, differentiation, and proliferation of enteric neural crest cells during embryonic development, genes for which are perturbed in HSCR. Poor outcomes in 30-50% of surgically resected HSCR patients suggests the role of postnatal developmental factors in its progression as well. In this study, the mouse was used to identify genes and their regulatory elements which are critical to prenatal and postnatal gut development. **Methods:** Previously published bulk RNA-seq whole gut data at embryonic stages E10.5, E12.5, E14.5 were combined with recently generated postnatal distal colon data at P0, P7, P21 and adult mice. Bulk ATAC-seq data was also generated for P0, P7 and adult timepoints; other timepoints are under completion. **Results:** Using maSigPro, genes were hierarchically clustered throughout development by gene expression (FPKM) across seven timepoints and functionally annotated using Enrichr. The clusters containing major genes for HSCR, *Ret* and *Ednrb*, were linked to functions involving neuronal migration and nervous system development, as expected, while the *Eno3* cluster, the only HSCR gene to increase its expression across postnatal development, was associated with mitochondrial ATP synthesis. Next, we used DESeq2, to conduct differential gene expression analyses between postnatal timepoints. Between earlier postnatal timepoints, P0 and P7, there were relatively few differentially expressed genes: 68 down- and 130 up-regulated in P7 versus P0 ($FDR \leq 0.001$ & $\text{Log}_2FC \geq 2$). The greatest change occurred between the earliest and latest postnatal timepoints: 1,572 down- and 2,241 up-regulated in adult versus P0. These changes involved upregulation of genes in the immune system and a consistent downregulation of genes in neurogenesis, in postnatal development. However, gene expression of *Ret* remained high through P7. These expression trends were mirrored for chromatin accessibility: 137 intervals had less and 319 more accessibility in P7 compared to P0 ($FDR \leq 0.01$ & $FC > 2$). The greatest changes were between P0 and adult with 20,880 greater and 21,224 with lesser accessibility in P0. In *Ret* open chromatin accessibility peaks were consistent between P0-P7, with an early peak disappearing and a new nearby peak appearing at the adult stage. **Conclusion:** This work will identify and integrate both the genes and their regulatory elements responsible for temporal gut development, eventually answering whether genetic variation in these elements contribute to postnatal disease progression in HSCR.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2113. Prenatal cytogenomic microarray analysis (CMA) reference model.

Authors:

M. Ghochani, M. Sweredoski, A. Padeganeh, A. Hajianpour, P. Rezaie, M. Moradian, R. Ramjit; Kaiser Permanente, Los Angeles, CA

Abstract Body:

Prenatal cytogenomic microarray analysis (PCMA) is used for genomic characterization of germline abnormalities in prenatal samples. In conjunction with traditional karyotyping, PCMA allows for higher resolution analysis to detect more clinically relevant genetic aberrations that can assist clinicians and families in determining the genomic health of the fetus and pregnancy. Prenatal sample types (i.e. amniotic fluid, chorionic villus sampling and products of conception) processed for PCMA have an inherent noise that is very different from the noise in postnatal blood samples. This noise could be caused by several reasons such as GC (Guanine/Cytosine) content and epigenetic differences, which may render the samples more sensitive to the wet lab processes such as fragmentation. For blood samples, the manufacturer-built postnatal reference model provided through industry benchmark (PostnatalRM) is applied, which sums up all the background noise specific to blood samples and subtracts it from all the probe signals in each sample. However, when using PostnatalRM for prenatal samples, prenatal-specific background noise remained, which resulted in artifacts that were not related to true genomic abnormalities in the fetus and could have otherwise been reported as potential false positive findings. To reduce this noise, a prenatal reference model (PrenatalRM) was built with an iterative approach. The model was built with 121 prenatal samples with normal CMA results; 25% of which had marginal quality control (QC) issues due to prenatal noise. With PrenatalRM, we reduced the number of artifacts in the PCMA results and the QC parameters showed statistically significant improvement. A comprehensive in-silico validation using 88 anonymized samples showed that > 90% of the samples that had previously failed QC with many artifact variant calls using the PostnatalRM, passed the QC when using the PrenatalRM. This improvement in result quality was because of the exclusion of artifacts and background noise from almost all PCMA samples. The validation demonstrated that the PrenatalRM had 100% sensitivity and 100% specificity in detecting real variants. Use of the PrenatalRM significantly reduced the time spent curating and signing out the PCMA cases, which ultimately resulted in improved turn-around-time and higher quality of the results. Different facilities could utilize our PrenatalRM to compare the sample-specific genomic dosages, and step-by-step procedure of this work can be used as a guideline to build reference models based on the different sample types for CMA such as prenatal samples, cancer specimens or FFPE (formalin-fixed paraffin embedded) specimens.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2114. Prenatal diagnosis of recurrent severe form of infantile galactosialidosis exemplifying a pitfall in parental carrier screening

Authors:

M. Araújo Castro, V. P. do Val, J. L. S. Duque, L. Pires, R. Honjo, G. Yamamoto, D. Bertola, C. Kim; HCFMUSP, Sao Paulo, Brazil

Abstract Body:

Galactosialidosis is an autosomal recessive inherited metabolic disease, caused by biallelic variants in the cathepsin A (*CTSA*) gene, which encodes the lysosomal protective protein, essential for the stabilization of the beta-galactosidase and neuraminidase; thus, its impaired activity leads to a phenotype with features of both GM1 gangliosidosis and sialidosis. Prenatal diagnosis is not unusual, as galactosialidosis is one of the most common inborn errors of metabolism among cohorts of non-immune fetal hydrops. Here we report one couple of Japanese and Brazilian origin with three babies affected by early infantile galactosialidosis and prenatally diagnosed only in the last gestation. Two older siblings died as newborns, both with hydrops fetalis and no etiologic diagnosis. Our patient is a female newborn, third-born child. Second trimester ultrasonography showed polyhydramnios and hydrops fetalis and thus the mother was submitted to an amniotic fluid drainage, subsequently evolving to oligohydramnios. Amniotic fluid karyotype was 46,XX. Whole exome sequencing was performed and identified two heterozygous variants: NM_000308.3(*CTSA*):c.308G>T:p.(Gly103Val) and c.1369g.A:p.(Gly457Ser). The baby was born through a c-section, at 36 weeks, and presented with respiratory discomfort and apnea. Physical examination revealed a coarse face with sparse eyebrows, palpebral fullness, anteverted nostrils and smooth, long philtrum with a short neck. Abdominal ascites and edema of the labia minora were present, as well as bilateral congenital club foot. Echocardiogram showed patent foramen ovale and patent ductus arteriosus, in addition to hypoplastic aortic isthmus and severe pulmonary hypertension. Abdominal ultrasonography showed hepatomegaly and moderate ascites with debris. Urinary sialiloligosaccharides chromatography was suggestive of Galactosialidosis. At 35 days of age the echocardiogram showed left ventricular systolic dysfunction, and thus supplemental oxygen and diuretics were introduced. She died at 65 days of age. Before this last pregnancy, parental carrier screening was performed, and only the c.1369g.A:p.(Gly457Ser) variant was reported in the father; we then analyzed the raw data and identified the c.308G>T:p.(Gly103Val) in the mother, confirming they are in trans. This case suggests that reporting variants of unknown significance (VUS) in carrier screening when a potentially deleterious variant in the same gene is identified in the partner is important to the genetic counseling and could possibly allow prenatal genetic testing for monogenic diseases in at-risk couples.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2115. Prenatal diagnostic testing in cases of cystic hygroma or increased nuchal translucency: A single center experience.

Authors:

N. Owen^{1,2}, L. Vossaert^{1,2}, R. Zemet Lazar¹, I. Van den Veyver¹, J. Smith^{1,2}, H. Dai^{1,2}, F. Xia^{1,2}, C. Eng^{1,2}, L. Meng^{1,2}, W. Bi^{1,2}, ¹Baylor Coll. of Med., Houston, TX, ²Baylor Genetics, Houston, TX

Abstract Body:

Objective: Routine prenatal diagnostic genetic testing in the setting of fetal anomalies includes chromosomal microarray analysis (CMA) and increasingly whole exome sequencing (WES). We aimed to review the diagnostic yield and spectrum for cases in which cystic hygroma or an increased nuchal translucency (NT) was observed. Traditionally these findings are associated with aneuploidies and Noonan syndrome.

Results: Retrospective review of prenatal CMA and WES cases was performed to identify cases with cystic hygroma or increased NT over a 4-year period. Cystic hygroma was identified in 69 CMA cases (of which 20 had additional fetal anomalies noted at the time of testing). Of these, 21 were positive for an aneuploidy: ten 45,X, six trisomy (T) 18, three T21, one T22 and one mosaic T13. Four cases had other pathogenic findings: a derivative chr4 (2.7 Mb 4q loss & 77.8 Mb 3q gain), a recombinant chr6 (10.7 Mb 6q loss & 1.2 Mb 6p gain), a mosaic 12p gain (Pallister-Killian), and a fourth case that was positive for both ~20% mosaic loss of X and a derivative chr6 (7.7 Mb 6q loss & 48.5 Mb 8q gain). The two cases with distal 6q deletions suggest a possible association between this region and cystic hygroma, though more cases are needed to correlate. In addition, 107 CMA cases had increased NT (29 had additional anomalies). Eight were aneuploidy-positive: three T21, two T18, one T22, one 45,X, and one mosaic T2. Other pathogenic findings were seen in three cases: a homozygous deletion of *HBA1/2*, a de novo deletion of *ARID1B*, and a de novo DGS deletion. Altogether, 29/36 (80.6%) positive cases were solved by an aneuploidy.

Prenatal WES identified 12 cases with cystic hygroma and 11 cases with increased NT. Causative variants were detected in 5 cystic hygroma cases (*CHRNA1*, *NF1*, *PTPN11*, *SMARCB1*, and *HSPG2*) and 4 increased NT cases (*NSD1*, *MYMK*, *NXK32*, and *PDHA1*). Only two (22.2%) of these diagnoses (*PTPN11* and *NF1*) fall into the Noonan spectrum of disorders.

For both CMA and WES, there was no correlation between the presence of additional anomalies (seen in 49 out of 168 total cases) and pathogenic findings: 10/29 total aneuploidies and 2/7 other pathogenic CNVs had additional fetal anomalies. For WES, 4/10 cases with isolated findings were solved versus 5/13 with additional fetal anomalies.

Conclusion: These data show that while aneuploidy and Noonan Syndrome are major genetic etiologies of cystic hygroma and increased NT, other diagnoses need to be considered indicating broad testing strategies may be beneficial. The presence of additional anomalies does not appear to affect the diagnostic yield in either CMA or WES.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2116. Prenatal onset of Spondyloepimetaphyseal Dysplasia SIK3 Type (SEMDK)

Authors:

D. Wachtell¹, M. Aubert-Mucca², J. Martin¹, A. Kot^{1,3}, J. Goldstein⁴, D. Cohn¹, S. Wong¹, J. Zieba¹, D. Krakow^{1,2,3,4}; ¹Dept. of Orthopedic Surgery, David Geffen Sch. of Med. at Univ. of California at Los Angeles, Los Angeles, CA, ²Dept. of Obstetrics and Gynecology, David Geffen Sch. of Med. at Univ. of California at Los Angeles, Los Angeles, CA, ³Dept. of Human Genetics, David Geffen Sch. of Med. at Univ. of California at Los Angeles, Los Angeles, CA, ⁴Dept. of Pathology, David Geffen Sch. of Med. at Univ. of California at Los Angeles, Los Angeles, CA

Abstract Body:

The *SIK3* gene [MIM*614776] encodes the salt-inducible kinase 3, an AMP-activated protein kinase. *SIK3* has recently been identified as responsible for an autosomal recessive spondyloepimetaphyseal dysplasia, SIK3 Type (SEMDK) [MIM#618162]. This rare, severe skeletal dysplasia shares phenotypic findings with Jansen's metaphyseal chondrodysplasia (MCDJ) [MIM#156400] which results from constitutively active heterozygous mutations in *PTH1R*. *SIK3* and *PTH1R* are involved in mTOR signaling through a mechanism by which *PTH1R* inhibits the action of *SIK3* in the growth plate. Findings common to both disorders include shortened long bones with abnormal mineralization and hypercalcemia with progressive osteosclerosis in the metaphysis of long bones, metacarpals, metatarsals, and the base of the skull. The characteristic *SIK3* phenotype includes a transverse hypoechoic gap in the long bones, intellectual disability with brain anomalies, and a severe immunodeficiency.

Here, we described the first prenatal case from a non-consanguineous union, where exome sequencing identified the following compound heterozygous variants in *SIK3*(NM_025164.6): c.1987G>A and c.3548C>T, predicting the missense protein changes p.Gly663Arg and p.Pro1183Leu, respectively. Prenatal ultrasound showed subjective poorly mineralized calvarium, shortened long bones (<1st percentile) with a distinct area of hypoechoic signal in multiple long bones. 23-week post-mortem x-rays showed undermineralization of the calvarium, irregular, widened, and flared metaphyses with an irregular ossification front, multiple transverse gaps in long bones, absence of pubic bone ossification, delayed ossification of the basal occipital bone, and increased density of the base of the skull.

A previous report on the cartilage growth plate of *Sik3*^{-/-} mice showed retained chondrocytes within bone. Human cartilage growth plate analysis showed a shortened and disrupted hypertrophic zone, cartilage bone nests, defective primary spongiosum with deficient trabeculae formation. In the human growth plate, there was marked increased and abnormal vasculogenesis in all zones, affecting column formation, not evident in *Sik3*^{-/-} mice.

These findings further our understanding of SEMDK, its prenatal presentation, and that *SIK3* alterations affect the cartilage growth plate. Prenatal exome analysis can identify rare phenotypes that may not be included in gene panel studies. Analysis of growth plates suggest differences between humans and mice due to *SIK3* mutations highlighting the importance of human studies when available.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2117. Rapid testing of congenital diaphragmatic hernia novel variants using CRISPR/Cas9 mouse embryo editing.

Authors:

E. Bogenschutz¹, S. Brown¹, C. Heffner¹, C. Carpenter¹, K. Palmer¹, K. Peterson¹, K. Snow¹, Y. Shen², F. High^{3,4,5}, P. Donahoe^{4,5}, W. K. Chung^{6,7}, S. A. Murray¹; ¹The Jackson Lab., Bar Harbor, ME, ²Dept. of Systems Biology, Columbia Univ. Irving Med. Ctr., New York, NY, ³Dept. of Surgery, Boston Children's Hosp., Boston, MA, ⁴Pediatric Surgical Res. Lab., Massachusetts Gen. Hosp., Boston, MA, ⁵Dept. of Surgery, Harvard Med. Sch., Boston, MA, ⁶Dept. of Pediatrics, Columbia Univ. Irving Med. Ctr., New York, NY, ⁷Dept. of Med., Columbia Univ. Irving Med. Ctr., New York, NY

Abstract Body:

Congenital diaphragmatic hernia (CDH) is a common and severe structural birth defect arising in 1:3,000 live births. CDH is characterized by either a weakening or partial loss of diaphragm muscle accompanied by lung hypoplasia and pulmonary hypertension, driving the associated 30-50% mortality. Many novel, damaging alleles predicted to contribute to CDH have been identified in humans, but few are functionally validated *in vivo*. This is due in part to the requirement for a mammalian model such as mice, and the high cost and time needed to generate these models. To close this technological gap, we have taken advantage of the high efficiency of CRISPR/Cas9 to create edited "F0" mouse embryos, allowing for rapid interrogation into whether the genetic alteration impacts diaphragm and lung development. Using this discovery platform we can generate both precise orthologous missense mutations via homology directed repair (HDR) using an oligonucleotide donor and insertion/deletions through non-homologous end joining (NHEJ), often leading to gene-knockouts. Diaphragm and lung defects are then scored using high-resolution micro-CT 3D imaging. From initial work with the platform, design of CRISPR/Cas9 gene targeting components to edited embryo phenotype takes an average of one to two months. Thus far, we have screened six statistically significant, predicted damaging missense mutations residing in both novel and known CDH genes discovered from CDH patient whole gene sequencing. From these six genes we have found that an allelic series in the known CDH gene *Zfp2*, a missense mutation in *Cnot1*, and an exon two deletion in *Cdc42bpb* all lead to diaphragmatic hernias in late-stage embryos and postnatal mice. The three remaining missense mutations either showed no observable structural defects in embryonic day (E)18.5 embryos, or few edited embryos were recovered at the developmental timepoint. This later cause is likely due to the increased propensity of NHEJ repair, leading to gene disrupting insertion/deletions and early embryonic lethality due to early gene loss. To improve the rate of HDR and increase the percent of embryos harboring the desired missense mutation we have begun testing multiple HDR enhancing methods and conditions *in vivo*. Treatments that increase HDR will be implemented in the embryo gene-editing platform.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2118*. Reconsidering the “advanced” maternal age for invasive prenatal testing

Authors:

I. Maya¹, L. Sagi-Dain², L. Basel-Salmon³, L. Salzer³; ¹Recanati Genetic Inst., petah tikva, Israel, ²Carmel Med. Ctr., Haifa, Israel, ³Rabin Med. Ctr., Petach Tikva, Israel

Abstract Body:

Background: Advanced maternal age, traditionally defined as maternal age over 35 years, has been used for decades to select pregnancies at increased risk for Trisomy 21. However, in the era of widely used non-invasive prenatal screening (NIPS), as well as invasive fetal testing by microarray techniques and the negligible risk for invasive testing-associated pregnancy loss, this maternal age cut-off must be re-evaluated. The objective of this study was to examine the appropriate maternal age threshold for recommendation of invasive testing for CMA. **Methods:** This retrospective cohort study was performed using database of Rabin Medical Center chromosomal microarray analysis (CMA) laboratory. All prenatal microarray tests in pregnancies with normal fetal ultrasound and recorded maternal age were included. We calculated the rate of clinically significant microarray findings per each year of maternal age, and plotted a receiver operating characteristics (ROC) curves to estimate the optimal cutoff for maternal age value. **Results:** Of the 7,033 prenatal microarray analyses, 108 (1.53%) clinically significant results were noted, 17 of these detectable by NIPS for common autosomal trisomies. ROC curve analysis failed to define a specific maternal age cut-off, in the overall cohort as well following omission of NIPS-detectable common autosomal trisomies. Only one abnormal microarray finding was found in 247 pregnancies of mothers aged 20-28 years (0.4%), vs. 21/1703 (1.23%) for mothers aged 29-34 years, 69/4195 (1.64%) for mothers aged 35-40 years, and 17/888 (1.91%) for mothers aged 41-50 years. Thus, using maternal age cut-off of 29 years for consideration of invasive testing, the majority (99.1%) of abnormal CMA findings would be detected, leaving an overall residual risk of 0.01%, while the cutoff of 35 years would detect 80% of abnormal findings, associated with a residual risk of 0.38% (one in 263). **Conclusions:** No clear maternal age cut-off could be established for the optimal detection of clinically significant microarray findings. Nevertheless, as a cut-off of 29 years enables to detect 99% of abnormal results, this might serve as the optimal cut-off, rather than the historical 35-years threshold.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2119. Recurrent constitutional chromosome 5 inversion

Authors:

M. Doco-Fenzy^{1,2,3}, E. Landais⁴, N. Gruchy^{5,3}, M. Spodenkiewick⁴, L. Herissant⁶, O. Pichon⁷, B. Cogne⁷, S. Bezieau⁸, M. Sebai⁹, M. Essid⁹, Y. Elaribi⁹, L. Lissy¹, C. Poisier¹, D. Sanlaville¹⁰, N. Chatron^{11,3}; ¹Service de génétique, REIMS, France, ²CHU Nantes, Nantes, France, ³ACLF, Paris, France, ⁴Service de génétique, CHU REIMS, REIMS, France, ⁵Service de génétique, Caen, France, ⁶Service de génétique, CHU Reims, REIMS, France, ⁷Service de génétique, CHU Nantes, Nantes, France, ⁸CHU HOTEL-DIEU, Nantes, France, ⁹Hosp. Mongi Slim, Tunis, Tunisia, ¹⁰HCL, CBPE, BRON Cedex, France, ¹¹Service de Génétique, Hospices Civils de Lyon, Bron Cedex, France

Abstract Body:

Background The recurrent pericentric inversion inv(5)(p13q13) is classically considered a polymorphism in Human with no clinical nor reproductive consequences. Indeed this inversion is described and found inherited. Surprisingly pericentric inversion, same size, on other submetacentric chromosome is described in meiotic rearrangement resulting in segmental duplication / deletion. Because few genomic data are reported in literature we investigated human families with different ethnic origins in order to update knowledge of this inv(5). **Method** We report 4 non related families with inv(5)(p13q13). - First and second inv(5) was diagnosed during pregnancy, and paternally inherited. - Third inv(5) was also discovered during pregnancy in context of elevated T21 serum markers, and found inherited. - Forth family, inv(5) was diagnosed on constitutional blood karyotype in context of blood myelodysplasia diagnosis. Inv(5) was inherited from healthy maternal grand father. The breakpoints of inv(5) were mapped in the 4 families. using Genome (WGS), Sanger sequencing, and Optical Genome Mapping (OGM). **Conclusion** To our knowledge, this study is the first molecular characterization of the inv(5)(p13q13) finding similar breakpoints in at least 3 families. We are looking for additional samples. A better knowledge of this entity will be useful to justify the decisions and prenatal genetic counselling in case of its fortuitous prenatal detection. Indeed different practice might occur facing the detection of this inv(5) in the karyotype of a foetus and its parents.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2120. Rescue of limb hemorrhage in a cohesinopathy mouse model with severe limb reduction

Authors:

A. Strasser, X. Zhou, A. Gonzalez-Reiche, M. Wu, A. Borges, B. Zhang, H. van Bakel, E. Wang Jabs; Icahn Sch. of Med. at Mount Sinai, New York City, NY

Abstract Body:

The Establishment of Sister Chromatid Cohesion N-Acetyltransferase 2 (ESCO2) acetylates the SMC3 subunit of the cohesin complex, which tethers sister chromatids together until their separation during anaphase, and regulates chromatin looping by mediating interactions between enhancers and promoters to modulate transcriptional outputs. Dysregulation of one or both processes underlie the molecular mechanism of Roberts syndrome (RBS), an autosomal recessive condition with profound growth deficiency and malformations, most notably phocomelia or severe limb reduction, which lend to its alias, pseudothalidomide syndrome. However, when and how these molecular processes are dysregulated in the developing limb to cause the RBS phenotype has yet to be elucidated. To investigate these causes, we generated an *Esco2* conditional knockout mouse line using *Prrxl-Cre* that recapitulates a human RBS loss-of-function mutation. Using bulk RNA-seq, single-cell RNA-seq, gene co-expression network, confocal microscopy, and immunohistochemistry analyses, we compared normal and mutant limb development from E9.5 to E13.5. Our results reveal a severe morphological and vascular phenotype culminating in skeletal reduction and hemorrhage of mutant limb buds by E12.5. These skeletal and vascular phenotypes are preceded by two transcriptional signatures at the onset of limb development in mutant limbs at E9.5: 1) a p53 pathway signature related to cell cycle arrest, DNA damage response, and cell death, and 2) an immune signature involving the inflammatory leukotriene signaling pathway. Given these unique, upregulated transcriptomic signatures at E9.5, we reasoned that mechanistically reversing these transcriptional signatures might in turn prevent the onset of the RBS limb phenotype. To predict potential drug candidates, we applied the Ensemble of Multiple Drug Repositioning Approaches (EMUDRA), a drug repositioning approach that matches transcriptomic signatures with drug-induced signatures. The analysis identified pifithrin-alpha, an FDA-approved p53 inhibitor, as a potential therapeutic agent. Administration of pifithrin-alpha successfully rescued the hemorrhage in mutant limbs, but not the skeletal phenotype. Taken together, our data indicate that 1) the vascular limb defects are linked to the p53 pathway, and that 2) partial morphological rescue suggests *ESCO2* might function in an additional transcriptional capacity. Further investigation of these mechanisms will significantly advance our understanding of normal and compromised limb development

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2121. Sex-specific variation in the commonly shared mothers' milk and infant gut microbiota are associated with sex disparity in childhood asthma risk.

Authors:

Inst. of Manitoba, Winnipeg, MB, Canada, ⁵Div. of Allergy and Immunology, Dept. of Pediatrics, Univ. of British Columbia, Vancouver, BC, Canada, ⁶Dept. of Pediatrics, Child and Family Res. Inst. and British Columbia Children's Hosp., Vancouver, BC, Canada, ⁷Dept. of Hlth.Res. Methods, Evidence, and Impact, Faculty of Hlth.Sci., McMaster Univ., Hamilton, ON, Canada, ⁸Dept. of Pediatrics, Univ. of Alberta, Edmonton, AB, Canada, ⁹Dept. of Pediatrics, Hosp. for Sick Children and Univ. of Toronto, Toronto, ON, Canada, ¹⁰Dept. of Med., McMaster Univ., Hamilton, ON, Canada

Abstract Body:

Gut microbiota has been known to play a critical role in childhood asthma although the mechanisms remain poorly understood. Recent studies have identified bacteria that co-occur in mothers' milk and their infants' stools, which suggest that human milk microbiota could contribute to infant gut microbial colonization. To the best of our knowledge, this is the first study to investigate the impact of microbes commonly shared between mothers' milk and infants' gut on long-term lung health of human milk-fed children. Moreover, we hypothesize that sex-related variations of microbial composition could in part explain for higher prevalence of asthma and wheeze outcomes among boys compared to girls. Sequencing of 16S rRNA from 885 human milk samples of the CHILD Cohort Study were applied to assess milk microbial composition. Genome-wide single nucleotide polymorphisms (SNPs) were genotyped in these mothers using the Illumina HumanCoreExome BeadChip. Infant genetic risk score (GRS) was previously calculated using a published genome-wide association study (GWAS) of asthma based on 44 SNPs. Gut microbial composition was determined by 16S rRNA sequencing of stool samples from human milk-fed infants at 3 months (N=323). Linear regression analysis stratified by infant sex identified the main and interaction effects of the commonly shared microbes and GRS on recurrent wheeze (ages 2-5 years). Our results indicate that male infants with a high GRS who were exposed to increased *Bifidobacterium longum* in their mothers' milk and own gut had lower recurrent wheeze prevalence (FDR-adjusted P=0.06). This trend was not found in female infants. Instead, among female infants with a high GRS, our results indicate that increasing both the milk and gut microbe *Streptococcus* spp. were independently associated with increasing prevalence of recurrent wheeze (FDR-adjusted P=0.02). Lastly, we assessed the interaction between maternal SNPs and environmental exposures on the milk microbes. Decreased abundance of *Streptococcus* spp. were significantly associated with interactions between loci in chromosome 4 and prenatal whole grain consumption (e.g., rs66976123, P = 3.4 × 10⁻⁸). This interaction result suggests that prenatal whole grain consumption could protect against infant recurrent wheeze development by modulating *Streptococcus* spp. abundance. Our study integrated human milk and infant gut microbiota while considering infant sex, and provided insight into the underlying mechanisms of sex disparity in asthma and determinants of asthma-related microbe synthesis. These results have potential to guide early life sex-specific prevention strategies for childhood asthma.

PB2122. Single-nucleus chromatin accessibility and RNA sequencing reveal impaired brain development in prenatally e-cigarette exposed neonate's brain

Authors:

Z. Chen¹, W. Chen¹, Y. Li¹, M. Moos², D. Xiao¹, C. Wang¹; ¹Loma Linda Univ., Loma Linda, CA, ²U.S. Food and Drug Admin., Silver Spring, NH

Abstract Body:

Although emerging evidence reveals that vaping alters the function of the central nervous system, the effects of maternal vaping on offspring brain development remain elusive. Using a well-established in utero exposure model, we performed single-nucleus ATAC-seq (snATAC-seq) and RNA sequencing (snRNA-seq) on prenatally e-cigarette-exposed rat brain. We found that maternal vaping distorted neuronal lineage differentiation in neonatal brain by promoting excitatory neurons and inhibiting lateral ganglionic eminence-derived inhibitory neuronal differentiation, resulting in excitatory to inhibitory neuron ratio change (E/I imbalance). By integrating gene expression and chromatin accessibility data, we recaptured the neurogenesis pseudotime course and identified the developmental widows from where e-cigarette exposure shifted the excitatory and inhibitory neuron differentiation trajectory. In addition, canonical pathway enrichment analysis revealed that synapse formation and synaptic transmission were the major biological processes effected by prenatal e-cigarette exposure. Moreover, maternal vaping disrupted calcium homeostasis, induced microglia cell death, and elevated susceptibility to cerebral ischemic injury in the developing brain of offspring. In sum, our results suggest that the aberrant calcium signaling, diminished microglial population, and impaired microglia-neuron interaction may all contribute to the underlying mechanisms by which prenatal e-cigarette exposure impairs neonatal rat brain development. Our findings raise the concern that maternal vaping may cause adverse long-term brain damage to the offspring.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2123*. Sperm mosaicism predicts transmission of *de novo* mutations to human blastocysts.

Authors:

M. Breuss¹, X. Yang², V. Stanley², J. McEvoy-Venneri², X. Xu², A. J. Morales³, J. G. Gleeson^{2,4}; ¹Univ. of Colorado, Sch. of Med., Aurora, CO, ²Univ. of California, San Diego, La Jolla, CA, ³Fertility Specialists Med. Group, San Diego, CA, ⁴Rady Children's Inst. for Genomic Med., San Diego, CA

Abstract Body:

De novo mutations underlie individually rare but collectively common pediatric congenital disorders. Some of these mutations can also be detected in tissues and from cells in a parent, where their abundance and tissue distribution can be measured. We previously reported that a subset of these mutations is detectable in sperm from the father. In addition, every male carries up to dozens of mosaic mutations in their sperm, and we predicted that ~1 in 15 males harbors such a mutation that is likely deleterious if transmitted. However, it is unclear how these detected mutations transmit to the next generation based on their measured abundance. Here, in three independent couples undergoing *in vitro* fertilization, we first identified male gonadal mosaicism through deep whole genome sequencing. We then confirmed variants and assessed their transmission to supernumerary preimplantation blastocysts (32 total) through targeted ultra-deep genotyping. Across 55 gonadal mosaic variants, 15 were transmitted to blastocysts for a total of 19 transmission events. This represented an overall predictable but slight under-transmission based upon the measured mutational abundance in sperm. We replicated this conclusion in an independent, previously published family-based cohort. Therefore, unbiased preimplantation genetic testing for gonadal mosaicism may represent a feasible approach to reduce the transmission of potentially harmful *de novo* mutations. This—in turn—could help to reduce their impact on miscarriages and pediatric disease.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2124. Successful implementation of a short turn-around time prenatal exome sequencing process in a perinatal centre.

Authors:

Sci., Univ. of Adelaide, Adelaide, Australia, ³Genetics and Molecular Pathology, SA Pathology, Adelaide, Australia, ⁴Genetics and Molecular Pathology, SA Pathology/Women's and Children's Hosp., North Adelaide, Australia, ⁵Genetics and Molecular Pathology, SA Pathology, North Adelaide, Australia, ⁶ACRF Cancer Genomics Facility, SA Pathology, Adelaide, Australia, ⁷Repromed, Dulwich, Australia, ⁸Ctr. for Cancer Biology, An alliance between SA Pathology and the Univ. of South Australia, Adelaide, Australia

Abstract Body:

Background: In 2020 we introduced prenatal exome trios for real-time clinical decision making into our diagnostic and clinical services. This testing is offered with reporting prior to 23 weeks gestation. *Aim:* We reviewed the outcomes of testing including its impact on pregnancy management for the first 18 months of offering this testing. *Methods:* An audit of the number of referrals, diagnostic outcomes and clinical outcomes was performed and we are presenting the results of this testing. *Results:* We reported 38 prenatal exome trios with an average turn-around time of 12 days from receipt of request. Diagnostic rate was 37%. Although likely pathogenic and pathogenic variants matching phenotype were generally only reported, in one pregnancy we reported suspicious compound heterozygous variants of uncertain significance in *EXOSC3* after consultation with the referring clinician. Notable diagnoses included nemaline myopathy (*NEB*), Skraban-Deardorff syndrome (*WDR26*), Smith-Lemli-Opitz syndrome (*DHCR7*), thanatophoric dysplasia (*FGFR3*), Sotos syndrome (*NSDI*), and congenital myasthenic syndrome (*RAPSN*). Noonan syndrome was also commonly diagnosed with *de novo* variants in *PTPN11* and one case with a maternally inherited *PTPN11* variant. We report on the impact of early diagnosis prior to 23 weeks gestation on pregnancy counselling and early decision-making regarding perinatal care. *Conclusion:* We have successfully expanded our prenatal genomic care to offer early trio testing to assist in real-time pregnancy counselling with a workable turnaround time of 12 days. This was possible within the context of a single-centre by streamlining the clinical referral and diagnostic testing processes without the need for on-demand sequencing, thereby demonstrating its potential for broader adoption in tertiary care hospitals and pathology laboratories.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2125. Tensor decomposition on electronic health records identifies latent subtypes of preterm birth that associate with polygenic risk scores

Authors:

S. Cruz Gonzalez¹, A. Abraham², J. Capra¹; ¹Bakar Computational Hlth.Sci. Inst., Univ. of California San Francisco, San Francisco, CA, ²Vanderbilt Univ., Nashville, TN

Abstract Body:

Phenotypic and clinical heterogeneity are hallmarks of many human diseases. Refining disease categorization by explicitly modeling phenotypic and longitudinal heterogeneity has the potential to reveal mechanistic and therapeutic insights.

To illustrate this potential, we leverage rich longitudinal phenotypic data from two electronic health record (EHR) databases to study the heterogeneity of preterm birth in over 30,000 deliveries obtained from two distinct medical systems. Preterm birth is a syndromic disease with substantial heritable risk, but limited understanding of its genetic architecture and few treatment options. We apply tensor decomposition to EHR-derived phenotypes from 28,954 individuals in the Vanderbilt EHR. The tensor decomposition identifies individuals with distinct disease traits and temporal patterns across multiple latent factors. In both white and black cohorts, we discover interpretable latent factors representing clinical subtypes dominated by morbidity along distinct disease axes, such as reproductive, mental health, and endocrine systems. The longitudinal trajectories of latent factors ranged from acute pre-pregnancy to chronic post-pregnancy. Using each individual's combination of latent factors, we are able to train accurate boosted decision tree models to predict risk of preterm birth. Integrating genetic data available for a subset of the cohort, we find that several latent factors are associated with polygenic risk scores for relevant risk factors, such as diabetes and BMI, while others do not have strong genetic associations. We then compare the latent factors derived in a separate EHR cohort of 5,978 deliveries from UCSF. Our work demonstrates that tensor decomposition can parse phenotypic heterogeneity and identify disease subtypes with distinct phenotypic and temporal signatures, enable risk prediction, and discover novel genetic associations. This approach has the potential to identify heterogeneous disease processes underlying many complex diseases.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2126. The abnormal expression of has-miR-196b-5p, FAS, and FAS-AS1 genes in Iranian patients with recurrent pregnancy loss

Authors:

S. Ghaderian, M. Ahmadi; Shahid Beheshti Univ. of Med. Sci., Tehran, Iran, Islamic Republic of

Abstract Body:

Recurrent pregnancy loss (RPL) is recognized as the most common pregnancy complication. Several factors and underlying mechanisms have been proposed; however, the exact etiology remained unclear and needed to be elucidated. Apoptosis is a vital process in the normal development of the fetus, and any aberrant expression of apoptotic genes during development probably takes part in the occurrence of RPL. Based on the comprehensive literature review, bioinformatic assessments, and the importance and crucial role of the FAS and FAS-AS1 genes and hsa-miR196b-5p during the apoptosis pathway in RPL, the present study has investigated the expression levels, correlation, and diagnostic merit of them in the blood samples of women with a history of RPL in comparison with those women with healthy fertility as the control group (n = 50, age < 35). The obtained data revealed that while the expression level of the has-miR-196b-5p was significantly decreased (P = 0.0001), the FAS (P = 0.0001) and FAS-AS1 (P = 0.01) genes were significantly upregulated in RPL women compared to the control samples. Besides, a significant positive correlation between the expression levels of FAS and FAS-AS1 (r = 0.55, P = 0.0001) and a remarkable negative association between FAS and has-miR-196b-5p (r = -0.35, P = 0.01) were disclosed. However, the observed relationship between the expression levels of has-miR-196b-5p and FAS-AS1 was not significant (r = -0.2, P = 0.19). Moreover, the results demonstrated that among these genes, the highest diagnostic value for distinguishing RPL samples from normal ones was related to the mRNA expression of the FAS gene (AUC = 0.74, P = 0.0001). In conclusion, the findings of the current report have suggested that the aberrant expression of FAS, FAS-AS1, and hsa-miR196b-5p genes in blood specimens of patients with RPL compared to their control counterparts can be considered promising biomarkers in blood specimens for the diagnosis, prognosis, and targeted therapy of the women suffering from RPL.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2127. Understanding caudal developmental abnormalities using single-nucleus multi-omics data from wild type and Danforth's short tail mouse E9.5 tailbuds

Authors:

C. Zajac¹, R. D. Albanus^{2,1}, N. Manickam¹, E. Curka¹, P. Thomas¹, C. Keegan¹, S. C. J. Parker¹; ¹Univ. of Michigan, Ann Arbor, MI, ²Washington Univ., St. Louis, MO

Abstract Body:

Caudal embryo development is important for multiple organ systems arising from all three germ cell layers, including the gastrointestinal system, genitourinary system, and the lower spinal cord. Embryonic malformations associated with caudal birth defects affect 1 in 10,000 human live births. The Danforth's short tail (Sd) mouse exhibits cessation of the vertebral column at the lumbar level and malformations of urogenital and gastrointestinal organs and provides a model to study the etiology of human caudal birth defects. The Sd mutation is caused by an endogenous retroviral (ERV) insertion 12.5 kb upstream of the *Ptfla* gene in the promoter region of the lncRNA gene *Gm13344*, a region orthologous to a human pancreatic developmental enhancer. To better understand the cell-specific regulatory landscape of the Sd mouse, we performed single nucleus chromatin profiling (snATAC-seq) from control (WT) and Sd E9.5 tailbuds that went under stringent quality control using the *ataqv* package followed by clustering. We then performed single nucleus multiome (ATAC+RNA on the same nucleus) profiling from WT E9.5 tailbuds. For quality control, we matched barcodes assigned to each modality and performed clustering based on the RNA modality. We obtained 10,428 and 10,422 high-quality ATAC profiled nuclei for WT and Sd tailbuds respectively from the first data set. Joint clustering analyses of these nuclei discovered 18 distinct clusters that represent diverse cell types, some of which have differential chromatin accessibility at key caudal embryonic developmental gene markers, including *Ptfla*. Most recently, we have generated data using single nucleus multiome (ATAC+RNA on the same nucleus) data from WT E9.5 tailbuds where initial QC revealed 7,203 high-quality nuclei that were used for clustering. This dual-modality data set generated 11 clusters at the RNA level, grouping together cells expressing important gene markers for embryonic development such as Sonic Hedgehog (Shh) and lncRNA 9030622022Rik. Preliminary results provide an insight to cluster characterization and identified transcription factors potentially responsible for changes in chromatin accessibility. The next steps in this project involve further clustering exploration and integration of chromatin accessibility modality to identify transcription factors perturbed as a result of the Sd mutation. We expect that these integrative analyses will improve our understanding of the causal cell types and regulatory networks that influence the Sd phenotype and, consequently, caudal developmental disorders in humans.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2128. Understanding the burden of clonal and non-clonal sperm mosaicism by bulk and single-cell genome sequencing

Authors:

X. Yang^{1,2}, M. Breuss³, C. Barrows¹, K. Kennedy⁴, J. Blackinton⁴, G. Harton^{4,5,6,7}, J. Gleeson^{1,2}; ¹Univ. of California, San Diego, La Jolla, CA, ²Rady Children's Inst. for Genomic Med., San Diego, CA, ³Univ. of Colorado, Sch. of Med., Aurora, CO, ⁴BioSkrbyb Genomics Inc., Durham, NC, ⁵Bryant Univ., Smithfield, RI, ⁶Eastern Virginia Med. Sch., Norfolk, VA, ⁷Univ. of Kent, Canterbury, United Kingdom

Abstract Body:

Mutations during embryonic development, aging, cellular metabolism, and environmental exposure are permanently recorded in the genomes of each cell and its daughters. Depending upon whether the mutations can be detected in regular next-generation sequencing, they are recognized as clonal or non-clonal in nature and present different features. Elucidating the patterns of these mutations and their potential to transmit to offspring is a key to understanding congenital *de novo* mutation (DNM) disorders and genetic variability across human generations. As parents age, the number of DNMs observed in the offspring increases, and with this, an increased risk of disease is caused in offspring. Although age-related DNM risks have been reported in large populations, our understanding of how paternal-specific clonal and non-clonal mosaicism contribute to offspring is still limited due to technical challenges. We recently demonstrated that a considerable portion of DNMs in children with neurological and psychiatric disorders arise from clonal mosaic mutations in the sperm and the life-long transmission risk from clonal sperm mosaicism does not increase with age (Yang and Breuss et al. Cell. 2021), resulting in congenital disorders or miscarriage in 1/300 concepti. We further aim to unravel the feature of the non-clonal gonadal mutation burden at the single-cell level. We compared the 30x genomic sequences obtained from primary template-directed amplification workflow from 14 fluorescent sorted live single human sperm cells collected from 2 healthy young men, to establish a control background. More than 80% of the single-sperm reached >1x coverage for >85% genome, with a 10% false-negative rate and 1/2 base substitution rate compared with conventional methods, allowing us to study SNVs in single sperms. The GC contents and replication timing matched the patterns in transmitted *de novo* mutations after our variant calling and filtering pipelines. We established that each sperm harbors 380 +/- 120 sperm-detectable mosaic mutations, >90% of them are non-clonal. These preliminary results help us to understand the non-clonal mosaic mutational burden in human sperm. This result will enable us to discover the non-clonal age-related genetic impacts of human sperm.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2129. Utility of preconception carrier screening in couples with unexplained infertility.

Authors:

S. Yatsenko¹, P. Ghosh¹, M. Schmitz², J. Settino³, M. Aarabi⁴, J. Sanfilippo⁵, A. Rajkovic⁶; ¹Univ Pittsburgh, Magee-Womens Hosp., Pittsburgh, PA, ²Univ. of Toronto, Toronto, ON, Canada, ³Magee Womens Res. Inst., Pittsburgh, PA, ⁴Univ Pittsburgh Med Ctr, Pittsburgh, PA, ⁵Univ Pittsburgh, Dept. of Obstetrics, Gynecology and Reproductive Sci., Pittsburgh, PA, ⁶Univ. of California San Francisco, San Francisco, CA

Abstract Body:

Diagnosis of unexplained infertility is given to ~30% of infertile couples. Patients intending to proceed with an IVF cycle frequently undergo a preconception screening for autosomal recessive and X-linked conditions associated with moderate to severe childhood manifestations, ~40% of which are also associated with neonatal and prenatal lethality. While most births after assisted reproductive technology (ART) are uncomplicated, pregnancies following ART also been reported to have an increased risk of miscarriage and congenital structural abnormalities. We hypothesize that a subset of couples with unexplained infertility may carry damaging variants in such genes. Exome sequencing was performed on DNA from peripheral blood samples of 19 couples with a diagnosis of unexplained infertility. Variants in 112 preconception screening genes recommended by the American College of Medical Genetics and Genomics (ACMG) (Tier-3) were classified according to ACMG guideline for variants interpretation. The probabilities of both partners to carry variants in the same gene were calculated based on the allele frequencies reported in the Genome Aggregation Database (gnomAD v2.0.2). Aggregate gene carrier frequencies were used to calculate the expected disease prevalence according to Hardy-Weinberg Equilibrium and compared to the observed disease prevalence in the general population. We detected 11 pathogenic, 3 likely pathogenic, and 65 heterozygous single nucleotide variants of uncertain significance (VUS) in 40 genes and three copy number variants. In four (4/19, 21%) couples, both partners were carriers of a variant in the same gene: *TNX8* (Ehlers-Danlos-like syndrome); *DHCR7* (Smith-Lemli-Opitz syndrome); *G6PC* (Glycogen storage disease type IA); and *CYP21A2* (congenital adrenal hyperplasia due to 21-hydroxylase deficiency). The observed proportion of affected couples was much higher than the highest expected 4% rate in the general population. We identified a subset of developmentally constrained genes with a much lower prevalence of affected live born individuals than expected, and a high frequency of heterozygous VUS alleles. Our findings indicate an enrichment for variants in genes associated with severe childhood conditions among individuals affected by infertility. Rare genetic variants may also contribute to infertility among heterozygote carriers due to embryonic/fetal lethality or metabolic disturbances. Further studies are necessary to determine the significance of rare coding variants in a set of preconception screening genes with respect to their functional significance for embryonic development, fetal loss and infertility.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2130. Variant reclassification in expanded carrier screening brings challenges for clinical management: experience of a Hong Kong prenatal diagnosis centre.

Authors:

Y. Zheng¹, Y. Cao¹, T. SHAM¹, A. KWAN¹, B. CHAN², C. LAU¹, J. CHONG¹, M. CHAU¹, T. LEUNG¹, K. Choy¹; ¹The Chinese Univ. of Hong Kong, Hong Kong, China, ²Hong Kong Maternal & Fetal Med. Clinic, Hong Kong, China

Abstract Body:

Expanded carrier screening (ECS) utilizing next-generation sequencing could simultaneously evaluate hundreds of genes associated with autosomal recessive (AR) and X-linked conditions. Besides reporting pathogenic (P)/ likely pathogenic (LP) variants classified by current knowledge, it also detects variants with uncertain significance (VUS) or conflicting interpretations, which have witnessed reclassification based on new evidence after the initial report. However, its clinical impact on the screened couples was unclear. Therefore, we investigated the frequency and evidence of ECS variant reclassification and evaluated its clinical impact. From April 2019 to May 2022, cases requesting ECS (covering 302 genes) with complete clinical records were recruited. Of all 978 participants, 364 were couples, 219 were single females and 31 were single males. Particularly, 44.4% (259/583) of female cases had an ongoing pregnancy at recruitment. Overall, 11.1% (109/978) of cases received reclassification alerts regarding 81 variants from 56 genes. The duration between initial and amended reports ranged from 1 to 35 months. Re-curated genes accounted for 18.5% (56/302) of the ECS panel, and 48.2% (27/56) of the genes were in the “metabolic newborn screening” catalog. Among all re-curated variants, 81.5% (66/81) were missense variants. In comparison with the variant curation in ClinVar on June 1st, 2022, 51.9% (42/81) of the re-curated variants were still of conflicting interpretations. 75.3% of reclassified variants (61/81) were upgraded from benign (B)/likely benign (LB)/VUS to P/ LP mainly due to updated patient data, *in silico* prediction data, or population data. For all four null variants upgraded from VUS to P, new evidence was derived from the establishment of a loss-of-function molecular mechanism for the gene. There were 23.5% (19/81) of variants upgraded from LP to P. Additionally, 1.2% of variants (1/81) were downgraded from LP to VUS. In consequence, additional counseling or management was needed for 3.3% (32/978) cases: 1) unscreened partners of 27 cases were recommended for ECS; 2) phasing the newly and priorly reported variants for diagnosis of an AR condition was suggested for 3 cases, and 3) 2 cases were recommended to investigate their ongoing pregnancies or offspring since their reclassified variants were for AR conditions in which their partners were also carriers. Variant reclassification was common in ECS and brought challenges to post-reclassification counseling and management of patients. These findings emphasize the importance of pre-test counseling for notifying the possibility of variant reclassification and a change in risk status.

Prenatal, Perinatal, and Developmental Genetics Posters - Thursday

PB2131. Whole genome sequencing and analysis of 4,053 individuals in trios and mother-infant duos from the Born in Guangzhou Cohort Study

Authors:

S. Huang; Guangzhou women and children's Med. center, Guangzhou Med. Univ., Guangzhou, China

Abstract Body:

Large-scale birth cohorts that recruit trios/duos families are essential resource for determining the genetic and environmental contribution to maternal-infant's health. While large-scale genomic studies of randomly chosen individuals are carried out around the world, study based on birth cohorts is scarce especially among the Chinese and the East Asian population. Here, we present the Phase I genomic study of the Born in Guangzhou Cohort Study (BIGCS) where we conduct whole-genome sequencing (~6.63x) and analysis of 4,053 Chinese participants in trios or mother-infant duos living in South China. We identify 56.23 million high-quality genetic variants, including 32% novel ones and construct a reference panel with 4,490 haplotypes that enables more accurate genotype imputation for individuals of Chinese ancestry. We characterize the population genetic structure and dissect the genetic relationship of 10 Chinese dialects in details utilizing the unique geographical and cultural composition of BIGCS participants. We investigate genome-wide associations for multiple maternal and infant traits and reveal novel genetic associations with total bile acid, gestational weight gain and lipid metabolism level in maternal peripheral or fetal cord blood. Using inter-generational mendelian randomization, we have dissected the maternal and fetal genetic effect underlying the observed associations between maternal phenotypes and fetal growth. Our findings fill the gap of the missing diversity in human genetics and demonstrate the great value of genomic study of birth cohort in advancing the worldwide maternal-infant health and genetic knowledge.

Prenatal, Perinatal, and Developmental Genetics Posters - Wednesday

PB2132. Whole-genome sequencing analysis in families with pregnancy loss

Authors:

T. Workalemahu; Univ. of Utah, Salt Lake City, UT

Abstract Body:

Background: One to two percent of couples suffer recurrent pregnancy loss and over 50% of the cases are unexplained. Whole genome sequencing (WGS) analysis has the potential to identify previously unrecognized causes of pregnancy loss, but few studies included DNA from families, including parents, losses, and live births.

Methods: We conducted a pilot WGS study of four families with recurrent pregnancy loss, including parents, losses and healthy live births. DNA was extracted from parents' saliva, buccal swabs from ten live-births, and formalin-fixed paraffin embedded placenta from eight unexplained pregnancy losses, which included an embryonic loss (<10 weeks' gestation), fetal deaths (10-20 weeks' gestation) and stillbirths (≥ 20 weeks' gestation). We used the Illumina platform for WGS and state-of-the-art protocols for DNA restoration, variant detection, and quality control. We utilized variant prioritization methods and online databases, and calculated probability of being loss-of-function intolerant (pLI) scores to evaluate pathogenicity of single nucleotide variants (SNVs), including de novo variants, and variants following autosomal dominant, compound heterozygous and X-linked recessive modes of inheritance.

Results: In samples that passed quality control (n=3 families), we identified 87 SNVs involving 75 genes in embryonic loss (n=1), 370 SNVs involving 228 genes in fetal death (n=3), and 122 SNVs involving 122 genes in stillbirth (n=2). Of these, 22 de novo, 6 autosomal dominant and an X-linked recessive SNVs were pathogenic (pLI>0.9), impacting known genes (e.g., DICER1, FBN2, FLT4, HERC1, and TAOK1) involved in embryonic/fetal development and congenital abnormalities. Further, we identified missense compound heterozygous SNVs impacting genes (e.g., VWA5B2) in two fetal death samples that were absent from live births and population controls, providing evidence for haplosufficient genes relevant to recurrent pregnancy loss.

Conclusions: In this pilot study, we identified SNVs that may be relevant to unexplained pregnancy loss, providing the justification for conducting WGS using larger numbers of families to identify embryonic/fetal-lethal variants. Our findings also warrant validation by targeted sequencing of additional families and losses. Elucidating genes causing pregnancy loss will facilitate the development of risk stratification strategies and novel therapeutics.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2133. "Grown up" minors: Recontact after withdrawal or attrition

Authors:

D. Patrinos, B. M. Knoppers; Ctr. of Genomics and Policy, McGill Univ., Montreal, QC, Canada

Abstract Body:

The participation of minors in biomedical research is critical for generating meaningful research outcomes which can translate into positive health outcomes. Many pediatric diseases are rare and heterogenous. Moreover, minors have distinct health and physiologic needs from adults. However, the participation of minors in research raises distinct ethical challenges. One such challenge is the issue of re-contact. Re-contacting minors enrolled in a research project upon their attaining the age of majority or medical maturity to seek their informed consent to continue their participation is considered an ethical requirement. This is especially relevant in the context of genomic research, where data and biological samples collected from minors may be stored, shared, and used for many years. While the issue of re-contacting minors has received significant attention in the literature, one aspect that has not received much attention has been the question of re-contacting a minor who has been withdrawn from a research project or who has been lost to follow-up, once they reach the age of majority. Indeed, the ethical permissibility of re-contact in these circumstances has not been thoroughly addressed. Our presentation will therefore analyze the ethical permissibility of re-contacting minors whose participation in research has ended, once they have reached the age of majority or maturity. Our approach identifies 3 scenarios in which the participation of a minor in a research project may end: (1) parental (or guardian) withdrawal from the research project, (2) the minor themselves asks to be withdrawn from the research project, and (3) loss to follow-up (attrition). We consider the ethical permissibility of re-contact in each scenario, based on a review of international and national research ethics guidelines and policies, as well as the relevant scholarship. We argue that re-contact is ethically permissible if it was the parent/guardian who chose to withdraw the minor or in cases where the minor was lost to follow-up. Respect for autonomy - the recognition of now-adult minor's right to choose - is the basis of this conclusion. However, where the minor themselves had asked to be withdrawn during childhood, we argue that re-contact is not ethically permissible, based on respect for their wishes and their right to be heard. Finally, we conclude with an overview of the ways in which informed consent may be sought from the now-adult participant.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2134. “Frankly, I thought this was one and done”: Patient and provider perspectives on return of reclassified variants in clinical oncology

Authors:

S. Makhnoon¹, Z. Zhao², T. Mendoza¹, R. Volk¹, S. Shete³, B. Arun⁴, S. Peterson⁵; ¹UT MD Anderson Cancer Ctr., Houston, TX, ²Univ Texas HSC Houston, Houston, TX, ³Univ Texas MD Anderson Cancer Ctr, Houston, TX, ⁴MD Anderson Cancer Ctr., Houston, TX, ⁵Univ of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract Body:

Background: Genetic variant reclassification can clarify a variant’s clinical significance and is increasingly facilitated by the availability of updated information about normal human genomic diversity. A primary challenge in genomic medicine today is accurate reinterpretation of identified variants and relaying that information to patients. Despite the prevalence of variant reclassification, the clinical and socio-behavioral consequences of reclassification for patients, or how clinicians return and manage reclassifications remains unknown. **Methods:** We conducted a qualitative study with a sample of 26 participants in two stakeholder categories: 19 patients with reclassified variants in cancer susceptibility genes, including 16 (84%) with downgraded variants and 3 (16%) with upgraded variants; and 7 key informant oncologists and genetic counselors. Participants were recruited from three geographically dispersed cancer hospitals in Texas, New Jersey, and Ohio. Semi-structured interviews were iteratively coded and analyzed for themes related to experience of receiving and returning reclassified variants, challenges, and suggested improvements. **Results:** News of reclassification, although unexpected, were received favorably by patients with understanding of the evolving evidence base in genetics and appreciation for being informed. Patients with downgraded variants reported not being able to recall receiving a reclassified result. Patients rarely communicated news of downgrades to their relatives as they believed that their relatives would not be interested in this development. Patients with upgraded variants emphasized the desire for more personalized return system including scheduled phone calls, telegenetics appointments, and in-person meetings. Key informant provider interviews revealed endorsement of the return of all variants including downgrades. However, due to the large number of downgrades and their clinical insignificance, low-touch automated methods of return were suggested to reduce workload including mailed letters and MyChart updates rather than phone calls. Rules under the 21st Century Cares Act designed to prevent information blocking was reported as facilitator of more timely return of reclassified results. **Conclusion:** Stakeholder perspectives regarding the return of reclassified genetic variants suggested several actionable changes to the return-of-results system. In the absence of established guidelines on the optimal way to recontact patients with new valuable genetic information, this work provides much needed empirical evidence from the perspectives of patients and providers.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2135. “I just wanted more”: Hereditary cancer syndromes patients’ perspectives on the utility of circulating tumour DNA testing for cancer screening

Authors:

M. Clausen¹, E. Adi-Wauran^{1,2}, S. Shickh^{1,2}, A. R. Gagliardi^{2,3}, A. Denburg^{4,2}, L. E. Oldfield⁵, J. Sam¹, E. Reble¹, S. Krishnapillai^{1,2}, D. A. Regier^{6,7}, N. N. Baxter^{8,1,2}, L. Dawson⁹, L. S. Penney¹⁰, V. Carile¹¹, M. Basik^{12,11}, S. Sun^{6,13}, K. A. Schrader^{6,13}, A. Karsan^{6,13}, A. Pollett¹⁴, T. J. Pugh^{5,15}, Y. Bombard^{1,2,15}; ¹St. Michael's Hosp., Toronto, ON, Canada, ²Univ. of Toronto, Toronto, ON, Canada, ³Toronto Gen. Hosp. Res. Inst., Toronto, ON, Canada, ⁴The Hosp. for Sick Children, Toronto, ON, Canada, ⁵Princess Margaret Cancer Ctr., Toronto, ON, Canada, ⁶BC Cancer Agency, Vancouver, BC, Canada, ⁷Univ. of British Columbia, Vancouver, ON, Canada, ⁸Univ. of Melbourne, Melbourne, Australia, ⁹Mem. Univ., St. John's, NL, Canada, ¹⁰IWK Hlth.Ctr., Halifax, NS, Canada, ¹¹Jewish Gen. Hosp., Montreal, QC, Canada, ¹²McGill Univ., Montreal, QC, Canada, ¹³Univ. of British Columbia, Vancouver, BC, Canada, ¹⁴Mount Sinai Hosp., Toronto, ON, Canada, ¹⁵Ontario Inst. for Cancer Res., Toronto, ON, Canada

Abstract Body:

Background: Hereditary cancer syndromes (HCS) predispose individuals to a higher risk of developing multiple cancers in their lifetime. However, current cancer screening strategies are limited in their ability to screen for all cancer risks. Circulating tumour DNA (ctDNA) detects DNA fragments shed by tumour cells in the bloodstream and has the potential to detect cancers early, advancing tailored clinical management. ctDNA is being integrated into care. Yet, there is a lack of evidence on patient perspectives on using ctDNA in their care.

Aim: To explore patients’ perspectives on the utility of ctDNA in their care to help inform its clinical adoption and implementation.

Methods: A qualitative interpretive description study was conducted using semi-structured phone interviews preceded by a brief background video on ctDNA with adult HCS patients recruited from CHARM, a Canadian research consortium. Participants were purposively sampled until thematic saturation was reached. Data were thematically analyzed using NVivo. Strategies such as iterative analysis, constant comparison, and double coding were used to ensure quality and rigour.

Results: Thirty HCS patients were interviewed (n=19 women, n=25 self-reported as white, age range 20s-70s). Participants were highly concerned about their risk of developing cancers, particularly those without reliable screening options for early detection. They “just wanted more” than what their current screening strategies can offer. Hence, participants were enthusiastic about ctDNA’s potential to be comprehensive (able to detect multiple cancers including those without reliable screening methods), predictive (able to detect cancers early), and tailored (lead to the personalization of their clinical management). They thought adding ctDNA as “another tool in the toolbox” would help fill gaps in current screening. That said, participants acknowledged potential limitations of ctDNA, including the risks of false positives, false negatives, and experiencing additional anxiety while awaiting results. However, they saw the potential benefits of ctDNA outweighing its limitations. Indeed, they were highly tolerant of a test that may result in further tests or procedures because of their fear of developing another cancer: “I will take anything because I know that my body can turn”.

Conclusion: Participants saw the utility of ctDNA in their care, as reflected by how their belief in ctDNA’s potential to fill gaps in current screening and improve their care overshadowed its limitations. These findings may be used to inform ctDNA’s clinical adoption and implementation.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2136*. A New System for Triageing Patients in a Medical Genetics Clinic Saves Time and Improves Quality.

Authors:

L. Randolph, C. E. F. Miers; Children's Hosp. Los Angeles, Los Angeles, CA

Abstract Body:

Background: We receive 150 referrals in Medical Genetics /month. It is time-consuming to triage them. In the past, they were printed for an MD's review. Although we strove for consistency, there was variation. This took ~7 minutes per referral, or 18 hours/month. **Methods:** We began an algorithmic approach to electronic triaging with a genetic counselor (GC) in charge. An algorithm was developed for each indication which covers which additional studies are required; the urgency; and which MD is appropriate. Each triage now takes ~4 minutes. We have developed 33 algorithms. As fragile X and CMA are first-tier tests for a child with isolated LD/ID/autism, we require those studies prior to being scheduled. If studies are declined by the insurer, we see the patient without them. If results are positive, the referral is triaged under a different algorithm (e.g., "abnormal microarray"), which allows them to be seen sooner. Sometimes, free parental testing is offered by the lab. In those cases, we require such testing prior to scheduling. This allows for more informed genetic counseling of results. Often, patients are referred to discuss abnormal testing results, but the results aren't included in the records. Previously, we cancelled appointments due to lack of results during pre-clinic review. This left open slots in our schedule that were not fillable in the short time before the clinic day. This represents lost revenue (a new visit list charge is \$645) and missed opportunities to reduce our waitlist. **Results:** We have triaged ~3500 referrals since instituting this protocol. At 50% less time required per case compared to the prior system, we spend 8 hours/mo of a GC's time on initial triage. Most of these require a second partial review to determine if the correct results or requested records have been received before scheduling can occur. Requiring prior testing in the common LD/ID/autism category of referrals has saved the clinic, patient and insurer an extra patient visit. The workup begins, and the clinic appointment occurs sooner than it would have. It also saved our MDs' and staff's time in ordering and trying to obtain authorization for these tests. Scheduling fewer visits for these patients leaves slots open for other patients and less rescheduling of appointments due to lack of test results. Our referring providers have accepted the system. **Summary:** Standardization of triaging is a fair way of booking patients with better throughput, saving patients and insurers time and money and improving patient care. A GC performs this function well with occasional input from a physician. We recommend this method to other medical offices.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2137. A Sociotechnical Analysis of Returning Genomic Informed Risk Assessments in Primary Care Pediatrics

Authors:

D. Karavite¹, S. Terek¹, J. Connolly², M. Harr³, M. Behr¹, N. Muthu¹, R. Grundmeier¹, H. Hakonarson³; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Children s Hosp. of Philadelphia, Philadelphia, PA, ³Children S Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

Background: The Electronic Medical Records and Genomics (eMERGE) network is a National Institutes of Health funded consortium conducting research in genomics, including discovery, clinical implementation, and public resources. eMERGE IV is focused on implementing a program based on polygenic risk scores and will recruit 25,000 individuals across 10 clinical sites, all of whom will receive a genomic-informed risk assessment (GIRA) that combines monogenic and polygenic determinants with social determinants, patient, and family history to delineate if participants are at high risk for any of 10 conditions, 4 of which affect children (asthma, obesity, type I diabetes, type II diabetes).

In a pediatric setting, the primary care pediatrician who receives GIRAs will play an important role in responding to caregiver questions and concerns, communicating with genetics and other specialties, and managing relevant recommendations. In developing tools and processes to support the return of results workflow, we applied a sociotechnical model, Safety Engineering in Patient Safety, to our requirements analysis to represent the human, technical, environmental, and other factors essential to the evaluation and design of information technology.

Methods: We performed a sociotechnical analysis to inform the design of systems and processes to support the return of GIRA results in a pediatric primary care network. We developed an interview format with seven phases including a review of example GIRA reports and the result workflow, 5 questionnaires (demographics, genetics experience, low-risk results, high-risk results, support systems), and semi-structured interview questions.

Results: Interviews with 20 participants revealed several important challenges. While pediatric primary care providers feel they have an important role in helping to manage genetic testing results like the GIRA, they require additional education, knowledge of evidence supporting results and recommendations, collaboration and participation of genetics, and highly efficient processes and tools to streamline communication and workflow in the highly time stressed environment of primary care.

Conclusion: Sociotechnical models provided important requirements for systems and processes that go beyond the technical requirements of the electronic health record.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2138. A systematic review of health policy guiding the identification, analysis, and management of genomic secondary findings

Authors:

S. Majeed¹, C. Johnston¹, C. Mighton¹, V. Rokoszak², S. Grewal², V. Aguda², D. Malkin³, Y. Bombard²; ¹Univ. of Toronto, Toronto, ON, Canada, ²St. Michael's Hosp., Toronto, ON, Canada, ³The Hosp. for Sick Children, Toronto, ON, Canada

Abstract Body:

Introduction: An explosion in the utilization of genomic sequencing for precision medicine over the past decade has yielded an analogous abundance in secondary findings (SFs). Existing practices within the continuum of SF identification, analysis and management are numerous, inconsistent, and sometimes contradictory across health conditions and geographic regions at a local, regional, and international levels. This widespread practice variation can lead to inconsistent care and subsequent downstream impacts on SF management and patient outcomes. As the frequency of genomic profiling continues to rise, synthesis of the SF health policy landscape is of utmost importance in order to ascertain current needs, gaps and limitations across the SF policy continuum. **Methods:** We carried out a systematic review to catalogue and appraise the current guidance established internationally directing the identification, analysis, and management of SFs for participants receiving genomic sequencing. A comprehensive search in MEDLINE, Embase and Cochrane databases was conducted. Articles were reviewed independently by two reviewers using Covidence for screening, data extraction and quality assessment. AGREE-II was used for critical appraisal and a narrative synthesis was conducted. **Results:** We screened 710 unique records and found 31 relevant studies producing guidance for SF interrogation based on our eligibility criteria, most of which were developed in North America. Preliminary results indicate that most policies focus on the SF management (97%; n = 30), but fewer provide guidance on the SF analysis (58%; n = 18) or identification (55%; n=17). Further, the most frequent topic in managing SFs is patient consent (42%, n=13), followed by the return of results (39%; n = 12) and medical actionability (n=9). Appraisal of policies revealed a low level of quality particularly for rigour of development (i.e., strength of evidence used), stakeholder involvement, and editorial independence. **Conclusions:** Our results highlight key gaps in health policy related to specific SF genes or classes used for identification and best practices for SF analysis methods. Moreover, although SF management processes like informed consent and disclosure are well described, best practices for other procedures following disclosure (such as surveillance, treatment, etc.) remain unknown. Lastly, many studies did not have adequate supporting evidence from which to base guidance, and this remains a significant limitation of the applicability, generalizability, and usefulness of these policies. Future work should focus on filling these policy gaps and supporting evidence-based practice.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2139. Access to Clinical Genetics Service and Testing for Patients with Retinal Dystrophies: a Quality Improvement Study

Authors:

Z. Shao¹, B. G. Ballios², H. Faghfoury³; ¹Univ. of Toronto, Toronto, ON, Canada, ²Dept. of Ophthalmology and Vision Sci., Univ. of Toronto, Toronto, ON, Canada, ³Dept. of Med., Univ. of Toronto, Toronto, ON, Canada

Abstract Body:

Retinal Dystrophies (RD) is a group of genetic disorders that leads to vision impairment in both pediatric and adult populations. They can be isolated or syndromic depending on the genetic etiology. Over 300 genes, both nuclear and mitochondrial, cause RD. Gene therapy for RD associated with RPE65 was approved in USA since 2017. Additional gene therapies for isolated and syndromic RD are in their final stage of clinical trials, increasing the demand for early molecular genetic diagnosis for RD. Limited clinical genetic resources are creating bottlenecks in patient care and potentially limiting access to therapeutic options for RD patients. We used quality improvement (QI) methods to identify factors impacting genetic care of RD patients. We conducted an audit of RD referrals to a tertiary hospital adult genetics clinic between September 2017 to December 2019 to investigate wait times from referral to initial assessment and time to results disclosure. Of the 316 total referrals, the time from referral to initial assessment ranged from 10 months to 24 months (mean 14 months) and the time from initial assessment to results disclosure was stable at approximately 6 months. A pilot model to mainstream genetic testing during initial assessment by ophthalmology was trialed between January-June 2022. Of 200 new referrals to an RD expert clinic, 122 were seen within this 6-month period, with approximately 80% offered a comprehensive RD genetic panel based on a clinical diagnosis of non-syndromic RD. Within this timeframe 49 genetic tests were sent and 42/49 results were disclosed to patients, with several confirmed diagnoses resulting in alterations to patient management. Challenges associated with this model include a lack of resources for coordination of sample collection and results tracking, as well as challenges in securing genetic counsellor support for patient counselling and cascade testing in family members. Further investigations are ongoing to merge the unique strengths of both clinical genetic testing models. We believe this study serves as an example of QI for optimization of clinical care for other treatable genetic conditions.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2140. Advancing Health Equity in Genomics: Reflections and Recommendations for Future Research Directions from an NHGRI Workshop

Authors:

L. Hindorff¹, E. Madden¹, A. Jackson¹, T. Akintobi², K. Baker³, R. Begay⁴, E. Burchard⁵, J. Carpten⁶, N. Cox⁷, V. Di Francesco¹, D. Dillard⁸, F. Fletcher⁹, M. Fullerton¹⁰, N. Garrison¹¹, E. Sch. of Med., Nashville, TN, ¹³Meharry Med. Coll., Nashville, TN, ¹⁴Univ. of Alaska Anchorage, Anchorage, AK, ¹⁵Icahn Sch. of Med. at Mount Sinai, New York, NY, ¹⁶Wellcome Trust Sanger Inst, Cambridge, United Kingdom, ¹⁷Univ. of Cambridge; Baker Heart and Diabetes Inst., Cambridge, United Kingdom, ¹⁸City of Hope, Duarte, CA, ¹⁹Dana Farber Cancer Inst., Boston, MA, ²⁰Univ. of Pennsylvania, Philadelphia, PA, ²¹Fred Hutchinson Cancer Res. Ctr., Seattle, WA, ²²Univ. of Alabama at Birmingham, Birmingham, AL, ²³NIMHD, NIH, Bethesda, MD, ²⁴Columbia Univ., NY, NY, ²⁵The Univ. of Chicago, Chicago, IL, ²⁶Seattle Children's Res. Inst., Seattle, WA, ²⁷Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, ²⁸Columbia Univ., New York, NY

Abstract Body:

Although advances in genomics have fueled the application of genomics to improve understanding of human health and disease, not all groups have benefitted equitably. Lack of diverse representation in genomic research and the genomic workforce impedes equitable access to and application of genomics and thus may increase health disparities disproportionately. Without improvement in research, resource allocation, and clinical practice, inequities in the benefits of genomic research and its applications will persist. The National Human Genome Research Institute (NHGRI) held a virtual public workshop in April 2022 to identify opportunities in genomics and health equity research, with over 300 attendees. The workshop objectives were to: 1) identify areas of genomic research that are important to advance health equity; 2) identify research and partnerships needed to address structural factors that impact health equity in genomics; and 3) define how success is measured within genomics and health equity. Recommendations identified from keynote speakers, panelists, breakout groups, and interactive Zoom chats will be presented. In summary: first, genomic research and the workforce need to continue to diversify. Next, additional data are needed on how lack of diversity in genomic research impacts health inequities at various stages of translation from scientific discovery to clinical and public health implementation. Research is needed on the effects of inappropriate use of race or other socially constructed traits and the underutilization of genomic markers within algorithms used for laboratory reference ranges and clinical diagnoses. To build trust and conduct equitable and ethical research, researchers should nurture long-standing relationships with communities that have been underrepresented in and harmed by biomedical research. Outreach to groups representing socially constructed traits in addition to race, such as sexual and gender minorities or individuals with disabilities, was encouraged. Metrics of health equity, such as measures of access to genomic testing, should be applied across genomic studies. The top recommendation from attendees was to support genomic workforce development by targeting Minority Serving Institutions. The next highest-ranked recommendation was to allocate

ASHG 2022 Annual Meeting Poster Abstracts

sufficient time and equitable resource distribution for community engagement. Supporting research to improve health equity in genomics aligns with NHGRI's guiding principles to strive for global diversity in all aspects of genomics research and to maximize both the usability of and the opportunities to benefit from genomics for all members of the public.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2141. Anxiety is a prominent neurobehavioral feature in Kabuki syndrome that significantly affects quality of life.

Authors:

A. Kalinousky¹, T. Rapp², H. Hijazi¹, J. Johnson³, H. Bjornsson⁴, J. Harris³; ¹Johns Hopkins Univ., Baltimore, MD, ²Univ. of North Carolina, Chapel Hill, NC, ³Kennedy Krieger Inst., Baltimore, MD, ⁴Univ. of Iceland, Reykjavik, Iceland

Abstract Body:

Background: Kabuki syndrome (KS) is a Mendelian Disorder of the Epigenetic Machinery caused by loss of function variants in either of the two genes, *KMT2D* (34-76%) or *KDM6A* (9-13%), both which are involved in the regulation of histone methylation. Previously, representative neurobehavioral deficits of KS were recapitulated in a *Kmt2d*-mouse model, emphasizing the role of KMT2D in brain development, specifically in hippocampal neurogenesis in the granule cell layer of the dentate gyrus. Interestingly, anxiety, a phenotype that is well-associated with decreased hippocampal neurogenesis, has been anecdotally reported in individuals with KS. Methods: In this study anxiety and behavior were assessed in a cohort of 63 individuals with molecularly confirmed KS diagnosis, as well as in their 25 biologically unaffected siblings, via clinically-designed questionnaires (SCARED/GAS-ID and CBCL/ABCL). Participants' age ranged from 4 to 44 years old, with 86% of participants having a pathogenic variant in *KMT2D*, and the rest having variants in *KDM6A*. In addition, data was collected on adaptive function and quality of life in participants with KS using appropriate surveys including ABAS-III and PROMIS. Survey scores were analyzed across different age groups of affected individuals and in contrast to their unaffected siblings using two-tailed paired and unpaired t-tests as well as correlation analyses. Results: Individuals with KS were found to have significantly higher anxiety scores and total behavior problem scores than their unaffected siblings ($p=0.023$, $p=0.022 \times 10^{-5}$). Moreover, a large proportion of affected individuals (23.9% children and 64.7% adults) have clinically significant anxiety that does not correlate with impaired adaptive function while negatively correlating with the quality of life ($p=0.000166$). Executive dysfunction was found to be the most prominent neurobehavioral phenotype, aside from anxiety, amongst individuals with KS, especially in younger children. Conclusions: These findings indicate that anxiety is a prominent neurobehavioral feature of KS that increases with age and is correlated with decreased quality of life. Providers should therefore carefully screen individuals with KS for anxiety in order to allow for prompt intervention. Neurobehavioral anxiety measures may also be an important outcome measures for clinical trials in KS.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2142. Assessing the performance of the Clinician-reported Genetic testing Utility InDEx (C-GUIDE): Further evidence of inter-rater reliability

Authors:

R. Hayeems^{1,2}, S. Luca¹, L. Chad^{1,2}, N. Quercia^{1,2}, A. Hossain¹, M. Meyn³, E. Pullenayegum^{1,2}, W. J. Ungar^{1,2}; ¹The Hosp. for Sick Children, Toronto, ON, Canada, ²Univ. of Toronto, Toronto, ON, Canada, ³Univ. of Wisconsin Sch. of Med., Madison, WI

Abstract Body:

Background: Genome sequencing (GS) outperforms other rare disease diagnostics, but standardized approaches to assessing its clinical utility are limited. In previous work, we developed and validated a novel outcome measure, the Clinician-reported Genetic testing Utility InDEx (C-GUIDE). C-GUIDE is a 17-item measure that operationalizes this concept from providers' perspective. It captures the utility of genetic testing related to understanding diagnosis and prognosis, informing medical management, awareness and actionability of reproductive and health risks for patients/family members, and patient/family well-being. Preliminary evidence of its inter-rater reliability was obtained through a clinical vignette study. The purpose of this study was to further assesses its inter-rater reliability using actual clinical cases.

Method: One genetic counsellor and one medical geneticist independently completed C-GUIDE Version 1.1 after genetic test results were disclosed to a shared set of pediatric patients or their family members. Raters also completed a case description questionnaire, including information about the patient's age, indication for testing and type of test chosen. Inter-rater reliability was assessed by comparing the raters' C-GUIDE scores using analysis of variance (ANOVA) to generate intra-class correlation coefficients (ICC).

Results: Of the 42 patients rated on C-GUIDE, the most common indications for testing were hearing loss (n = 18) or craniosynostosis (n = 11) and the most common tests ordered were gene panels and microarrays. Test results were diagnostic or partially diagnostic for 11 patients, potentially diagnostic for 14 patients, or non-diagnostic for 17 patients. The ICC for C-GUIDE was 0.61 (95% CI: 0.56, 0.65). When examining individual C-GUIDE items, the ICC between raters was >0.7 for 10 items, 0.5-0.7 for 1 item, and <0.5 for 6 items. Low-moderate ICCs were identified for items related to reduced diagnostic impact/medical management, the identification of future health risks, and psychosocial well-being. ICCs also varied by result type (i.e. diagnostic, potentially diagnostic, non-diagnostic). Agreement on the global item was 0.57 (95% CI: 0.33, 0.74).

Conclusion: Rater instructions for item completion will be modified to improve consistency of item interpretation. While further assessments of reliability are warranted following modifications, these findings provide additional evidence that C-GUIDE demonstrates acceptable inter-rater reliability and can be used as a strategy for measuring the value of genetic testing, as perceived by clinicians.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2143. Assessment of cancer patients using a distress thermometer to evaluate perceived and calculated stress in order to identify individuals requiring additional psychological support.

Authors:

T. Bhende¹, Q. Hasan¹, M. Srinivas¹, C. Rao²; ¹Kamineni Hosp., Hyderabad, India, ²Renovo Soumya Hosp., Hyderabad, India

Abstract Body:

Assessment of cancer patients using a distress thermometer to evaluate perceived (PS) and calculated stress (CS) in order to identify individuals requiring additional psychological support. The diagnosis and treatment of cancer drastically affects the life of individuals. The psychological stress differs from person to person and its assessment will help in identifying the type of psychological support required. To assess this, NCCN has recommended the use of Distress Thermometer (DT) as a screening measure for identifying psychological distress among cancer patients. The current preliminary study was carried out on 300 cancer patients who were undergoing treatment in two different oncology units. The distress interview was facilitated by a genetic counselor. Results indicated that Females vs males (PS= 39.66% vs 14 %) (CS= 25.7% vs 15.11%) perceive high stress & same was observed with the calculated stress. But, as the duration from time of diagnosis increased, the level of both PS & CS decreased, irrespective of gender. It was observed that, younger patients had higher stress. To our surprise, the percentage of individuals with high perceived stress was least in colorectal maybe because other categorized types were female cancers, reiterating above mentioned results. Among the 300 individuals 24% were suspected to be at a higher risk of Hereditary Cancer Syndrome and thus genetic counseling was provided to them, and it was observed that these patients had higher stress in comparison to non-hereditary, because it was compounded with their concerns about other family members, specially children. The observations of the present study indicates the important role of a genetic counselor at an oncology unit in identifying both, those who require support from psycho-oncologist and others who require genetic testing & post-test counseling.

PB2144. Assessment of reading comprehension levels of interpretation sections of genetic testing reports

Authors:

M. Gillentine, J. Narayanan, C. Paschal; Seattle Children's Hosp., Seattle, WA

Abstract Body:

With advances in technology and awareness, the number of individuals and families receiving genetic testing is increasing. Additionally, the 21st Century Cures Act allows access to test results in as little as 2 business days after completion, often without guidance from genetic counselors or clinicians. While there are efforts to increase genetic literacy in the public, diagnostic labs are responsible for providing reports with interpretation that is accessible to patients. To assess if we are meeting such a need, pediatric chromosomal microarray (CMA) and Next Generation Sequencing (NGS) panel reports were pulled from electronic medical records in Epic from 2020 to May 2022, during which time there were 3 lab directors. Nine NGS panels analyzing 10-50 genes were assessed, focused on diabetes, vascular anomalies, interstitial lung disease, differences in sex development, craniosynostosis, Rett/Angelman syndrome, and intestinal dysmotility. We analyzed 149 CMA report interpretation sections (n = 80 with pathogenic/likely pathogenic results, n = 56 with VUS, n = 8 with autosomal recessive disease risk, n = 4 with long stretches of homozygosity, n = 3 with likely benign results) and 225 NGS panel reports (n = 202 with pathogenic/likely pathogenic results, n = 28 with VUS) from 2020 to 2022 with eight different reading level tools (Flesch Reading Ease formula, Flesch-Kincaid Grade Level, Gunning Fog Scale, SMOG Index, Coleman-Liau Index, Automated Readability Index, and Linsear Write Formula). CMA and NGS reports were both above the national average reading level (7th-8th grade), with CMA reports (reading level = college level on average) written at a significantly higher grade level than NGS reports (reading level = 10th-11th grade on average). No differences were observed by sequencing panel. For NGS reports, those with pathogenic results were written at a significantly higher reading level than those with VUS. These results highlight the need to increase accessibility to genetic testing reports. We are interested in identifying strategies to provide more comprehensible reports, such as using plain language when possible and providing resources for individuals and families receiving results, especially when clinicians and genetic counselors may be unavailable at the time of test results being released into patients' charts. Future studies may investigate additional report types, such as those from exome sequencing. Increasing the comprehension of genetics reports will require input from all levels of the testing process including genetic counselors, variant scientists, lab directors, and clinicians.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2145. Awareness about rare diseases through Indian cinema

Authors:

A. Nanda; Kamineni Hosp., New Delhi, India

Abstract Body:

It is estimated that 6-8% of the world's population are affected by Rare diseases. Despite this staggering number, public awareness is limited. The aim of the present study was to analyze how RDs are depicted in popular Indian movies, given its large audience and if they are accepted by them.

In the present study, a movie search was conducted using IMDB to find multilingual movies addressing RDs, as well as a digital survey was conducted to understand the impact of movies on public understanding of RD's . From 75,000 movies made since 1913, only 49 Indian movies depicting a RD received popularity. This includes 70% Hindi, 6% Marathi, 2% Kannada, 2% Bengali, 8% Malayalam and 6% Telugu.

Analysis was confined to Hindi movies because of its popularity. Following are the movies and respective RD's. 35% of movies showed different cancer types, with none discussing hereditary cancer syndromes, an important RD, Congenital deafness (Khamoshi, 1972), Blindness (Sparsh, 1980) and speech impairment (Black, 2005) , Alzheimer's (U me aur Hum, 2008), Multiple Sclerosis (Guru, 2007), Cerebral Palsy (Margarita with a Straw, 2014), Tourette syndrome (Hichki, 2018), Autism and Asperger's syndrome (My Name is Khan, 2010), Aplastic Anemia (Rockstar, 2011) and Progeria (Paa, 2009). Some of these movies were box office hits, suggesting that people were willing to appreciate such films.

Films depicting RDs don't give sufficient information about the cause, clinical implications, prevention and management strategies to educate the audience, however the survey indicated that it can be used as a medium to improve their understanding of RDs.

PB2146. Barriers to genetic testing when indicated at diagnosis for autism spectrum disorder.

Authors:

A. Wang, I. D. Little, C. Gunter; Natl. Human Genome Res. Inst., Bethesda, MD

Abstract Body:

Multiple professional organizations recommend conducting genetic testing at the time of a diagnosis for autism spectrum disorder (ASD), but as few as 20% of individuals ever receive genetic testing for this indication. We have taken a mixed-methods approach to assess barriers to genetic testing. First, we questioned whether genetic literacy of families and patients might be a significant factor. Genetic literacy is defined as the knowledge of genetic principles and the ability to apply this information to everyday life. Higher genetic literacy is associated with greater comprehension of genetic test results and higher participation in genetic healthcare services. Previously, we developed a survey to measure three facets of genetic literacy: familiarity with genetic terms, accuracy in genetic knowledge, and skills to apply genetic information to health. We distributed this survey first to a general population sample (N=2050), allowing us to compare it to a similar sample from 2013. After adjusting for education, the 2021 sample scored significantly higher in term familiarity, but not in knowledge, although scores still fell in the “moderate” range for both facets. We then surveyed participants in SPARK (N=2023), a large genetic research study in ASD. Compared to the general population, participants in SPARK scored significantly higher in all three facets, although still in the moderate range.

To identify additional challenges with ASD genetic testing, we report on a second study interviewing healthcare providers who actively diagnose ASD to assess the needs and barriers in the process. Qualitative analysis reveals that multiple factors, including a lack of formal genetics education, parental concerns, insurance barriers, and an inability to make genetic testing referrals directly, all contribute to low rates of genetic testing usage for ASD. Overall, our findings suggest that low genetic testing uptake may be due to only moderate genetic literacy among the general population and numerous practical barriers for healthcare providers. Future research should focus on raising genetic literacy among families to help them make informed decisions, and to streamline the incorporation of genetic testing into the ASD diagnosis process.

PB2147*. Benefits, harms and costs of newborn genetic screening for long QT syndrome: estimates from the PreEMPT Model

Authors:

K. Christensen¹, P. M. McMahon², J. M. Yeh³, N. K. Stout⁴, C. Y. Lu¹, S. Stein², R. J. Hyland⁵, A. C. Wu⁶; ¹Harvard Pilgrim Hlth.Care/Harvard Med. Sch., Boston, MA, ²Harvard Pilgrim Hlth.Care Inst., Boston, MA, ³Boston Children's Hosp./Harvard Med. Sch., Boston, MA, ⁴Harvard Pilgrim Hlth.Care Inst., Boston, MA, ⁵Boston Children's Hosp., Boston, MA, ⁶Boston Children's Hosp. / Harvard Med. Sch., Boston, MA

Abstract Body:

Background: Long QT syndrome (LQTS) is a potentially lethal and highly-actionable condition that the American College of Medical Genetics and Genomics recommends for secondary findings disclosure during clinical exome or genome sequencing. Population genetic screening for LQTS is feasible, but whether its benefits would outweigh harms and justify costs is unclear, particularly among newborns. Methods: The Precision Medicine Policy and Treatment (PreEMPT) Model uses microsimulation modeling to examine the impact of newborn genetic screening. As part of the PreEMPT Model, we developed a module to compare genetic screening for LQTS against usual care in a U.S. birth cohort of 3.7 million newborns. Newborn genetic screening included surveillance of individuals with pathogenic/likely pathogenic variants or a family history of disease. Usual care included surveillance of individuals with a family history of LQTS. Outcomes included numbers of diagnosed and undiagnosed individuals; reductions in sudden cardiac death; number of individuals receiving implantable cardioverter defibrillators (ICDs); and incremental cost-effectiveness ratios. Results: Through age 20 years, newborn genetic screening would reduce the number of undiagnosed individuals from 1,412 to 620 (difference: 792, 95% uncertainty interval (UI): 266 to 1487) and the number of sudden cardiac deaths associated with LQTS from 49 to 17 (difference: 32, 95% UI: 17 to 42) but increase the numbers of children receiving ICDs from 18 to 132 (difference: 114, 95% UI, 70 to 556). Compared to usual care, newborn genetic screening costs \$91,000 per life-year saved (95% UI, \$67,000 to \$179,000 per life-year saved). Conclusions: Results suggest newborn genetic screening for LQTS would reduce undiagnosed cases and prevent deaths, but would greatly increase the number of children who receive treatment and also increase use of surgical intervention. The cost-effectiveness of newborn genetic screening for LQTS was borderline at conventional willingness-to-pay thresholds. This study demonstrates how modeling can provide insights into the tradeoffs between benefits and costs that will need to be considered as newborn genetic screening is more widely adopted.

PB2148. Cancer patients' experience of receiving variant of uncertain significance results: An Asian perspective.

Authors:

N. Ishak, T. Shaw, S-T. Li, J. Yuen, H. Goh, Z. Chua, F. V. F. Que, Z. Zhang, J. Chiang, J. NGEOW; Natl. Cancer Ctr. Singapore, Singapore, Singapore

Abstract Body:

Objective: Due to a lack of ancestry-matched, functional, or segregation data, Asians have a higher rate of having a variant of uncertain significance (VUS) reported, with up to 50% of patients receiving VUS results following panel testing. The management of VUS results has been challenging, as it has been met with increased anxiety and distress among cancer patients undergoing genetic testing. Furthermore, misinterpretation of VUS results as pathogenic has resulted in misdiagnoses and incorrect clinical management. This study aims to investigate cancer patients' experience of receiving a VUS result as an exploratory study among the Asian population.

Methods: A qualitative, semi-structured interview study was conducted to explore patients' views of receiving a VUS result. Participants who had undergone genetic testing and received a VUS result were recruited through the Cancer Genetics Service of the National Cancer Centre Singapore. Twenty participants agreed to partake. Participants' responses were transcribed verbatim and analysed using thematic analysis to identify significant themes.

Results: Thematic analysis revealed five major themes, namely: (1) VUS results are interpreted as an uncertain outcome; (2) a VUS result provides relief and encourages positive behavioural adjustments (3) fatalism and religion are used as coping mechanisms to deal with the uncertainty of the result; (4) genetic counsellors, family and the community provide reassurance and support; and (5) patients value updates to variant classifications for future management.

Conclusion: This novel study has provided unique insight into Asian patients' perspectives on receiving a VUS result. It highlights how patients manage their VUS results and uncertainty, which could improve the pre-and post-test counselling practice in Asia. Emphasis must be placed on clear communication of VUS results to dispel the possibility of misconceptions, misdiagnosis, and mismanagement in cancer care.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2149*. Challenges in incorporating polygenic risk scores in the electronic health record.

Authors:

H. Bangash, A. Miller, S. Nigbur, J. Petrzela, P. Caraballo, R. Freimuth, I. Kullo; Mayo Clinic, Rochester, MN

Abstract Body:

Purpose: In its current phase, the electronic MEDical Records and GENomics (eMERGE) Network is returning polygenic risk scores (PRSs) to participants and integrating the related discrete data into the electronic health record (EHR). We describe challenges encountered in incorporating PRS results into the EHR at Mayo Clinic Rochester, Minnesota—an eMERGE IV site.

Methods: The study team worked on 5 domains to integrate PRS data into the EHR: i) develop detailed workflows for participant recruitment, and return of PRS results supplemented with monogenic causes and family history; ii) identify relevant resources needed for the study—a development team with the expertise and capacity to build PRS data ‘parsers’ to facilitate data transfer into the EHR was assembled after interactions with multiple institutional information technology (IT) teams; iii) apply for multiple institutional committee approvals; iv) build a prototype clinical decision support (CDS) to trigger in the EHR for patients with a high PRS for any 1 of 10 diseases of interest; and v) develop PRS-related educational content to serve as a resource for clinicians.

Results: Over a 2-year span, the study team engaged with 30 different committees (e.g., clinical decision support subcommittee, clinical communications subcommittee), departments (e.g., community internal medicine, IT), and groups (e.g., Mayo Center for Individualized Medicine) across the institution to integrate PRSs into the EHR. During this time, the team encountered a number of challenges, both logistical and financial including the need to: i) obtain multiple institutional committee approvals, which delayed downstream work related to CDS development; ii) develop custom data ‘parsers’ to interface with enterprise APIs, requiring significant financial investment; iii) build a new genomic test order in the EHR to enable PRS results reports to be viewed by both patients and clinicians; iv) contract additional IT support due to limited institutional resources, which led to higher costs; v) use new technologies (e.g., Epic Registry, Ticket Scheduling) to incorporate PRSs into study workflows; and vi) harmonize institutional workflows and timelines with eMERGE Network goals.

Conclusion: We identified multiple challenges while developing workflows and processes to integrate PRS results and discrete data into the EHR. Many of the challenges were related to embedding a federally funded translational genomics research project into existing clinical, EHR and IT workflows. The lessons learned can inform the integration of PRSs into the EHR in diverse settings to enable their use in primary care.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2150. Clinical cancer and direct-to-consumer genetic test result sharing behavior among US adults: Findings from HINTS 2020

Authors:

S. Shete, S. Peterson, R. Yu, S. Makhnoon; Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract Body:

Introduction: Sharing genetic test results with different stakeholders including family members, healthcare providers, spouse, and friends is a health behavior of clinical importance in genomic medicine. Sharing behavior is perhaps most salient for results of high-risk cancer testing, which should be shared with family members as the information can inform relatives' health risk, cascade genetic testing. In addition, sharing different types of direct-to-consumer (DTC) genetic tests results can be important to raise public awareness of genetic testing. Population representative data on result sharing is sparse and limited by their lack of differentiation among types of genetic tests as sharing have been largely studied as secondary outcomes of genetic research studies. Methods: We use nationally-representative population-based data collected from the Health Information National Trends Survey (HINTS 5, cycle 4) to report prevalence and correlates of genetic test result sharing behavior for high-risk cancer tests, genetic health risk tests, and ancestry tests; for four different groups of individuals: healthcare providers and genetic counselors (HCP/GC), first degree relatives (FDR), spouse/partner, and friend/other. Results: Overall, 89.9% of those who underwent high-risk cancer genetic testing shared their results with HCP/GC. Sharers were more likely to be younger (50.1 vs 59.1 years, $p=0.018$), have \leq high school education (80.1% vs 19.9%, $p=0.036$), have a personal history of cancer (92.8% vs 7.2%, $p<0.001$), and reside in an urban area (80.1% vs 19.8%, $p=0.023$). In the multivariable analyses, adjusted for sex, race/ethnicity, income, family and personal history of cancer, females were 9 times more likely to share than males ($p=0.006$) and those with personal history of cancer were less likely to share than those without ($OR=0.025$, $p<0.001$). Of the genetic health risk test takers, 66.5% shared with HCP/GC, 38.7% with a FDR, 66.6% with a spouse/partner, 12.8% with a friend, and 14.1% did not share results with anyone. Of those who underwent ancestry testing, very few shared results with HCP/GC (2.6%), whereas modest sharing was reported with FDR, spouse/partner, friend (41.3%, 30.4%, and 20.4% respectively). 5.2% of ancestry testers did not share results with anyone. Discussion: These population representative data of sharing different types of genetic test results with various stakeholders is clinically relevant as mediators of outcomes such as proband-mediated cascade genetic testing as well as a metric for public engagement with genetic testing in the US.

PB2151. Clinical utility of returning all clinically relevant secondary findings from genomic sequencing: A systematic review

Authors:

C. Mighton^{1,2}, S. Dhaliwal^{1,3}, V. Rokoszak^{1,2}, S. Majeed^{4,2,1}, A. Sebastian², V. Aguda^{1,5}, S. Shickh^{2,1}, S. Grewal¹, D. Lightfoot⁶, Y. Bombard^{7,1}; ¹Genomics Hlth.Services Res. Program, St. Michael's Hosp., Toronto, ON, Canada, ²Univ. of Toronto, Toronto, ON, Canada, ³Western Univ., London, ON, Canada, ⁴The Hosp. for Sick Children, Toronto, ON, Canada, ⁵Cardiff Univ., Cardiff, United Kingdom, ⁶Hlth.Sci. Library, St. Michael's Hosp., Toronto, ON, Canada, ⁷Inst. of Hlth.Policy, Management and Evaluation, Univ. of Toronto, Toronto, ON, Canada

Abstract Body:

Introduction: Genomic sequencing (GS) is an effective diagnostic test, but secondary findings (SFs) complicate its clinical adoption. Most SF disclosure policies focus on medically actionable SFs. However, in practice, SF disclosure is extremely variable, and laboratories may offer a broader range of results. Furthermore, the majority of policies used to guide decisions on SF disclosure are not evidence-based, as evidence was limited at the time of their development. The field is now at a critical juncture; evidence on the outcomes of SF disclosure has accrued over the past decade, and policies will likely be updated in consideration of this evidence. There is a need for rigorous evidence synthesis and critical appraisal to guide practice and policy.

Aim: To systematically review and synthesize the literature to assess the clinical utility of returning all clinically relevant SFs across all patient populations receiving GS. This will be assessed through: 1) the yield of SFs overall and for major reporting categories (medically actionable, non-medically actionable Mendelian conditions, carrier status, pharmacogenomic results, polygenic risk), 2) clinical outcomes of SF disclosure (e.g., changes in management); and 3) the proportion of patients with phenotypic features or a family history concordant with the condition associated with their SFs.

Methods: A systematic review is being conducted. The review has been registered in PROSPERO (CRD42021254662). A search was conducted in Medline, EMBASE, and Cochrane Databases using MeSH and keywords related to SFs and GS. All articles are screened for eligibility by two reviewers in duplicate. Two reviewers will extract data on bibliographic information, genetic test information (e.g., sequencing type, variant interpretation methods), patient population (e.g., age, disease indication), and study outcomes. Two reviewers will perform quality assessment with critical appraisal tools from the Joanna Briggs Institute. Data on each outcome will be reported narratively and will be combined statistically through meta-analyses if data permit.

Results: The search returned 4401 articles. Title and abstract screening are ongoing, and to date, 173 studies have proceeded to full text screening. Full text screening, data extraction, critical appraisal, and synthesis will be completed by September 2022.

Conclusions: This will be the most up-to-date and comprehensive systematic review of the clinical utility of all types of SFs. This review will provide high-quality evidence which is necessary to inform decisions about SF reporting, disclosure, and reimbursement as GS is increasingly used across medical specialties.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2152. Communicating genetic and socioeconomic factors underlying racial health disparities in medical education

Authors:

P. Orozco Scott, C. Seah, J. Catlett, S. Leisman; Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract Body:

Despite national commitments to anti-racism, a paucity of guidance exists on how to critically appraise genetic, pathophysiological, and epidemiological findings of racial disparities with an anti-racist lens. Interpretation of racial disparities must not reinforce the notion of race as biology, but rather use nuance in attributing evidenced contributors to disease. In genetics in particular, race should not serve as a proxy for genotype, social determinants of health, or systemic healthcare barriers. Medical and graduate education should be explicit in defining race as a socioeconomic variable, taking care to warn against confounding with ancestry, and discussing how ancestral variations in genetic risk do not reflect a biological definition of race. Here, we have developed a framework for inquiry-based restructuring of scientific discussion of race in genetics research and medical education. We systematically probed medical educational materials discussing estimated glomerular filtration rate (eGFR) and HIV-associated nephropathy (HIVAN), two topics where race is routinely used and taught in clinical decision-making. We found improper attributions of disease risk to race, rather than known genetic polymorphisms, and inappropriate omissions of the historical and present systemic factors, such as systemic racism, that contribute to observed racial disparities. Through these two examples, we demonstrate that race is often attributed as a causal factor for disease, and even when genetic causes are known, imprecise approximations of ancestry and confounding of this with race are often used to justify clinical decision making and mnemonics. We suggest that critical appraisal using our inquiry-based process, applied to medical and graduate education, will allow for collaborative reframing of the way race is described in research, and used in clinical decision-making.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2153. Community data-driven approach for generating cross-ethnic population carrier screening panel

Authors:

M. Einhorn, T. Ben-Simhon, Y. Einhorn; Genoox, tel aviv, Israel

Abstract Body:

Background/Objectives: The ACMG has recently published tier-based recommendations for carrier screening. While many pan-ethnic conditions are well established, some genes carry pathogenic founder variants (PFVs) prevalent only in specific ethnic groups, and may therefore not be assigned into the correct tier or not represented at all. Using an interconnected, data-driven repository including a cohort of cases from the Israeli population we created a workflow for assistance in generating a cross-ethnic carrier screening panel. **Methods:** The dataset included de-identified WES data from a cohort of 2792 Israeli patients. Frequencies of pathogenic/likely pathogenic variants were calculated for each subpopulation and compared them with existing carrier screening panels used in Israel. Manual curation was done for suspected variants using evidence from Franklin community members. **Results:** We detected a number of relevant PFVs not included in existing carrier screening panels. These included two variants that should be included in Tier 2 (carrier frequency >1:100) and nine variants for Tier 3 (1:100-1:200). We detected two PFVs of autosomal recessive traits, a PFV in PTPN23, associated with a severe neurodevelopmental disorder (carrier frequency 1:53) as well as a PFV in WFS1 associated with Wolfram syndrome (carrier frequency 1:68). **Conclusion:**Community data-driven and sharing approaches may detect PFVs missing from currently available panels. Moreover, with the increasing use of next-generation sequencing for carrier screening, it is expected to result in a deluge of variants falsely classified as P/LP. Such data-sharing approaches will facilitate proper classification of frequent variants that have no clinical implications, thereby reducing unnecessary workload and patient anxiety

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2154. Community Engagement in genetic and genomic research in a low literate setting: Challenges and perspectives

Authors:

K. Diallo¹, A. Maiga¹, A. Yalcouyé¹, C. Guinto¹, S. Diop¹, I. Ballo², G. Landoure¹; ¹Univ. of Sci., Techniques and Technologies of Bamako, Bamako, Mali, ²Univ. of Letters and Human Sci. of Bamako (ULSHB), Bamako, Mali

Abstract Body:

Introduction: Community engagement (CE) is a process of working collaboratively with a group of persons on a common interest, and is recognized as an important component of any healthcare project. Such collaboration is particularly beneficial in genetics and genomics research (GGR) for the development of genuine partnerships with communities to build trust and incorporate local perspective into the design and conduct of research. Achieving this in a low literacy population setting is particularly challenging. **Objectives:** To address issues related to implementing community engagement strategies in genetics and genomics research in a low literacy setting **Methods:** A multidisciplinary team including geneticists, epidemiologists, anthropologists, psychologists, and CE specialists was set up and held information and education workshops and sessions throughout the countries. Interviews, focus group discussions and exchanges during the consent process were used to engage patients, their relatives and community. Both modern (radio and TV broadcasts) and traditional communication tools were used to vehiculate the purpose, the approaches, and the implications of GGR in the Malian context. The place of consanguineous and intra ethnic marriages in the occurrence of recessive diseases were highlighted **Result:** Our preliminary results showed that participants and field staff seeking consent were overall satisfied with their understanding of the study project even though most of the participants were not familiar with the concepts of GGR. Participants were less aware of the methodologies used during GGR and their implications, such as sharing the participants clinical and genomic data and the use of these data for potential secondary research. In addition, it was more difficult than anticipated to make a clear distinction between therapy and research especially those coming to healthcare centers for cure. One major issue was the language barrier. In fact, as many genetic words do not exist in our local languages, translating them was challenging. **Conclusion:** Until recently, GGR were less regarded in developing countries, overshadowed by communicable diseases. Hence, community engagement is critical in enrolling participants and in disseminating research findings for the global benefits of the community. In addition, a collaboration with local languages specialists is necessary to develop a dictionary of genetic words. Capacity building for local ethics committees to enable appropriate consideration of ethical issues raised by genomic research is likely to be necessary in many countries with limited experience of this type of research.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2155. Considerations for assessing and optimizing remote participant recruitment for a pragmatic trial of polygenic risk score testing

Authors:

C. Brunette¹, A. Antwi¹, E. Harris^{1,2}, K. MacIsaac^{1,2}, T. Yi¹, M. Danowski¹, J. Vassy^{1,2,3,4}; ¹VA Boston Hlth.care System, Boston, MA, ²Harvard Med. Sch., Boston, MA, ³Brigham and Women's Hosp., Boston, MA, ⁴Precision Population Hlth., Ariadne Labs, Boston, MA

Abstract Body:

Background: The translation of genomic medicine innovations from concept to care relies on valid and generalizable evidence, the generation of which hinges on the efficient recruitment of research participants. Here we use data from the Genomic Medicine at VA (GenoVA) Study, a pragmatic trial of polygenic risk score testing at the Veterans Affairs (VA) Boston Healthcare System, to characterize recruitment outcomes among 4499 potential research participants.

Methods: Data were recorded in real-time using a VA-developed clinical trial informatics system. Data associated with recruitment letter distribution and phone outreach between 6/1/20 and 5/16/22 involving 4531 letters and 9968 phone calls to Veterans aged 50-70 were assessed. We used Markov chains to model participant transition probabilities across 10 phone outreach attempts and 4 decision states: undecided, eligible, opt out, and accept.

Results: Overall, 723 (16.1%) participants completed an eligibility screen and accepted a study invitation, 1046 (23.2%) opted out of further contact either before or after screening, and 2730 (60.7%) were not consistently reached or remained undecided. On average, participants were called 2.2 times (range 1-20), study invitations were accepted within 4.3 calls (range 2-20) and opt out decisions were made after 1.9 calls (range 1-14). We observed higher probabilities of invitation acceptance among women (9.1% v. 7.8%), non-white/Hispanic (13.3% v. 12.8%), and participants 60 or older (21.0% v. 19.0%) than expected. End of week calls (Wednesday-Friday) yielded better invitation acceptance rates (7.4-8.5%) compared to early week calls (Monday-Tuesday; 6.0%). August, December, and January yielded the worst acceptance to opt out ratios (0.3-0.5) compared to other months (\bar{x} = 0.8). Participants were most likely to opt out (0.15, 95% CI 0.14-0.16; 0.05, 95% CI 0.04-0.06) or complete the eligibility screen (0.18, 95% CI 0.17-0.20; 0.10, 95% CI 0.09-0.11) within the first two call attempts. Opt outs occurring post-screening were low, but consistent up to the eighth call attempt (range 0.02-0.04). Invitation acceptance most often occurred between the second and seventh calls (range 0.07-0.19). Only 1.7% (95% CI 0.00-0.09) of undecided or difficult to reach participants transitioned to any other state after the fourth call attempt.

Discussion: Assessing recruitment outcomes across demographic, seasonal, and longitudinal factors is important to the operational efficiency of large genomic medicine research initiatives. Structuring outreach that focuses on optimal timing and direction of labor can help maximize participant engagement and recruitment efforts.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2156. Considerations for embedding genomic discovery research in clinical settings: Perspectives from medical geneticists

Authors:

K. Muenzen¹, H. A. Burkhardt¹, N. Reid¹, P. Tarczy-Hornoch¹, D. W. Tsuang², A. T. Chen¹, G. P. Jarvik³, D. R. Crosslin⁴; ¹Univ. of Washington, Seattle, WA, ²VAPSHCS, Seattle, WA, ³Univ. of Washington Med. Ctr., Seattle, WA, ⁴Tulane Univ. Sch. of Med., New Orleans, LA

Abstract Body:

Background: Accelerating the discovery and clinical uptake of new genomic knowledge is important for advancing genomic medicine. Adoption of new knowledge into clinical practice is hindered in part by separate norms and regulations dictating standard practices in research and clinical care. Here we explore considerations for conducting genomic discovery research within clinical environments from the perspectives of medical geneticists. **Methods:** In this IRB-approved study, we conducted 1-hour, semi-structured, remote interviews with 20 board-certified medical geneticists from the Electronic Medical Records and Genomics (eMERGE), Clinical Sequencing Evidence-Generating Research (CSER), and University of Washington (UW) networks. Interviews investigated the feasibility, utility, and challenges of clinical genomic discovery. Using Grounded Theory methods, we analyzed interview transcripts by conducting line-by-line, axial, and theoretical coding to synthesize themes that emerged from interviews. **Results:** The sample was largely white and had equal male and female representation. Participants expressed high hopes for the utility of integrating genomic research into clinical settings, but warned that feasibility was limited by the challenges of using clinical data for research, questions of consent, funding, concerns about clinical misuse of genetic testing results, healthcare system fragmentation, and conflicting goals for patients, research participants, clinicians, and researchers. Suggested requirements for implementing clinical genomic research included rigorous actionability and validity assessments of new discoveries, strong community engagement, evolved consent models, enhanced sharing and cleaning of clinical and genomic data, novel funding schemas, defined roles and responsibilities for clinicians and patients, and standards for returning research results to patients. However, participant views on how to address each of these requirements often conflicted with one another, highlighting the complexity of the issue and the challenge of developing consensus recommendations. **Conclusions:** While the potential benefits of merging research and clinical genomics are clear, the practical, ethical, social, and political considerations are extraordinarily complex. This work provides a baseline reference for the potential benefits and challenges that should be considered when integrating genomics research into clinical environments.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2157. Cultivating a data-driven computational culture within biomedical institutions by empowering graduate students with code-based data science skills.

Authors:

C. Ronkowski¹, K. Peng¹, D. Yu¹, R. Ayyala¹, S. Knyazev², M. Wu¹, I. Haworth³, J. Zaro³, S. Mangul¹; ¹Univ. of Southern California, Sch. of Pharmacy, Titus Family Dept. of Clinical Pharmacy, Los Angeles, CA, ²Univ. of California, Los Angeles, David Geffen Sch. of Med., Dept. of Pathology and Lab. Med., Los Angeles, CA, ³Univ. of Southern California, Sch. of Pharmacy, Dept. of Pharmacology and Pharmaceutical Sci., Los Angeles, CA

Abstract Body:

To address an emerging disparity between biomedical researchers' lack of computational prowess and the rising importance of massive omics datasets in translational and clinical research, we created a 2-unit graduate-level course to teach reproducible data science to Pharmaceutical and Translational Sciences (PHTS) graduate students at the University of Southern California. In our course, we emphasized data analysis, data visualization, and open data science practices using code-based assignments written within a free online Jupyter notebook environment. This framework enabled us to combine the benefits of literate programming and cloud computing to promote scientific transparency in a manner accessible to anyone with an internet connection. In addition, we implemented simplified explanations of programming fundamentals to gradually ease students into using Python libraries, empowering them with the foundational knowledge necessary to troubleshoot one's own code. We did so as a significant deterrent to adopting code-based data science solutions is the frustration of not being able to resolve errors, leading many biomedical researchers to resort to using poorly reproducible, Graphical User Interface (GUI)-based software. Moreover, we measured the effectiveness of this strategy using an anonymous Institutional Review Board (IRB)-approved survey conducted during the first and final lectures. Our findings show greater self-reported confidence, increased comprehension of the course material, and an agreement that our course was highly impactful. Based on these results, we conclude that our course framework and teaching approach represents an effective strategy for introducing the fundamentals of modern biomedical data science to students with minimal prior computer science background.

PB2159*. Delivery of an unfavorable genetic diagnosis: Developing a methodology framework

Authors:

O. Chorin^{1,2}, L. Sheelo Salzer^{3,2}, A. Koifman^{4,5}, B. Pode-Shakked^{1,6}, A. Raas-Rothschild^{1,6}, M. Tsur^{7,8,9}, I. Maya^{3,6}, ¹The Inst. of Rare Diseases, Edmond and Lily Safra Children's Hosp., Sheba Med. Ctr., Ramat Gan, Israel, ²Sackler Faculty of Med., Tel Aviv Univ., Tel Aviv, Israel, ³Raphael Recanati Genetics Inst., Rabin Med. Ctr., Petah Tikva, Israel, ⁴Med. Genetics Service, Assuta Univ. Med. Ctr., Ashdod, Israel, ⁵Faculty of Hlth.Sci., Ben Gurion Univ. of the Negev, Beer Sheva, Israel, ⁶Sackler Faculty of Med., Tel-Aviv Univ., Tel Aviv, Israel, ⁷Mitchell- Hamline Sch. of Law, Saint Paul, MN, ⁸Cardozo Sch. of Law, Yeshiva Univ., New York City, NY, ⁹Faculty of Law, Hebrew Univ., Jerusalem, Israel

Abstract Body:

Background/Objectives: Genetic counseling consists of the crucial aspect of conveying and discussing unfavorable genetic results. This event is experienced as difficult for the consulting physician, the patients, and the families. There is no structured methodology for delivering an unfavorable genetic result. **Methods:** We collaborated with "Shakla & Taria", an Israeli institute for negotiation and difficult conversations, to develop a structured methodology for delivering unfavorable genetic results in a genetic counseling setting. The principles and the different stages of the method were introduced to a team of medical geneticists and processed to form an agreed generic methodology taught to clinical geneticists in designated workshops. **Results:** The methodology consists of a preliminary questionnaire filled out by the geneticists and aims to improve the level of emotional preparation for the meeting. Additionally, preplanned details are addressed, including the timing, setting, desired participants, and atmosphere of the genetic medical encounter. The methodology for the conversation itself is structured, with a stepwise gradual delivery of the unfavorable genetic result, while affirming the patient's desire to receive the data at every stage and allowing the patient to lead the conversation. These stages are conducted sensitively and professionally, focusing on the advantages of the diagnosis and only later delving into additional medical details and offering future planning possibilities, including options for prenatal diagnosis. The last, most crucial stage consists of affirming the understanding of the data by the patient and offering the opportunity for a second meeting within a few weeks to ensure comprehension and allow for follow-up questions and care. The methodology requires delivering information while maintaining patients' autonomy, feelings, and identity inside the room and during the day after. The stages include a declaration of intent, preparation for the result, delivering the outcome itself and the medical diagnosis, discussion about the diagnosis advantages, more informative medical information, and future implications. The conversation ends after verification of the patient's understanding. **Conclusion:** We constructed a structured methodology for conveying unfavorable genetic results. We plan to incorporate these single-day workshops into the residency program for medical geneticists, genetic counselors, and other professionals in the field. Further studies are required to assess the overall satisfaction and well-being of both the patients and the geneticists from the medical genetic encounter.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2160. Designing a Comprehensive Education Program for Participants, Providers, and Research Teams: The eMERGE Consortium Experience

Abstract Body:

Polygenic risk scores (PRS) have the potential to improve healthcare by identifying individuals at risk for common, complex conditions. Use of PRS in clinical practice, however, requires careful assessment of the needs of patients, providers, and capabilities of healthcare systems. The electronic Medical Records and Genomics (eMERGE-IV) network is conducting a collaborative study, which will return PRS to 25,000 pediatric and adult participants. All participants will receive a risk report, potentially classifying them as high risk (top 2-10% per condition) for one or more of 10 conditions based on PRS. The study population is enriched by participants from diverse groups, including racial and ethnic minority populations, underserved populations, and populations who experience poorer medical outcomes. The size, scope, and novelty of the study necessitates developing comprehensive and diverse educational resources to address the needs of providers (particularly primary care providers) and participants from various backgrounds. All 10 eMERGE-IV clinical sites conducted focus groups, interviews, and/or surveys to understand the educational needs of eMERGE-IV's key stakeholders - participants, providers, and/or study staff. Together, these studies highlighted the need to develop tools that address the perceived benefit/value of PRS, types of education/support needed (including family support), accessibility of the PRS risk report, and PRS-related knowledge, understanding, and misperceptions. Based on these findings, the network followed processes to harmonize the educational initiatives across clinical sites, developed extensive training educational material and formal/informal resources, and tested them through stakeholder and community engagement. This poster summarizes the eMERGE-IV consortium's collective approach to 1) assessing stakeholders' educational needs and 2) developing educational approaches for its primary stakeholders. It addresses the challenges encountered, and solutions provided, by a large-scale and novel clinical trial and summarizes lessons-learned for similarly ambitious programs.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2161. Developing Recommendations for Direct-to-Consumer Genetic Testing

Authors:

H. Ayoubieh¹, ISCC-PEG DTC-GT Working Group, D. Messersmith², T. Weiler³; ¹Texas Tech Hlth.Sci. El Paso, El Paso, TX, ²NHGRI, Bethesda, MD, ³FIU - HWCAM, Miami, FL

Abstract Body:

Direct-to-consumer (DTC) genetic testing (GT) for health-related conditions has become easily accessible to the general public after the US Food and Drug Administration cleared a commercial company to return health reports directly to patients with information about specific pathogenic genetic variants and pharmacogenomic variants. To navigate these health reports and discuss concerns related to their results, DTC companies suggest that consumers consult with their healthcare professional. Primary care and non-genetics specialty clinicians describe encounters with patients who have questions about DTC-GT and are interested in enhancing their genetic knowledge. However, currently there are no practice recommendations for healthcare practitioners related to the application of DTC-GT. The DTC-GT Project Group of the Inter-Society Coordinating Committee for Practitioner Education in Genomics (ISCC-PEG) at the NHGRI presented a draft set of recommendations at the American College of Medical Genetics 2022 conference. The audience was asked to rate their level of agreement with the proposed recommendations and provide open-response feedback. Over 700 participants responded to the survey. The survey included Likert scale and open-ended questions. Participant responses highlight areas of agreement and disagreement. There is controversy regarding the DTC-GT-related practice expectations for both genetics and non-genetics healthcare professionals. For non-geneticists, detailed recommendations may be too onerous to recognize and implement during a brief clinical encounter. Education is needed regarding the technology used for testing by the different DTC-GT companies, how it differs from clinical testing, how different analytical tools and reporting criteria are being used to generate the reports, and how in-depth clinical evaluation and family history intake is required to appropriately counsel patients. Additionally, limiting recommendations to selected positive DTC-GT results could result in incomplete evaluations, and false negative DTC-GT-results could incorrectly reassure patients. There is also concern that these recommendations would create a bottleneck in genetic services for DTC related referrals vs referrals where genetic evaluations may be more critical and appropriate. Moreover, genetic professionals are not typically involved in pharmacogenomic testing and relevant medication prescribing. A significant matter of contention is where and how DTC-GT results should be included in the electronic medical records, as well as the legal, policy and insurance implications of the suggested recommendations.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2162*. Development and utility of a clinical research informatics application for participant recruitment and management for a return of results pilot trial in the Million Veteran Program

Authors:

T. Yi¹, C. Brunette¹, M. Danowski¹, M. Cardellino¹, J. Vassy^{2,1,3,4}; ¹VA Boston Hlth.care System, Boston, MA, ²Harvard Med. Sch., Boston, MA, ³Brigham and Women's Hosp., Boston, MA, ⁴Precision Population Hlth., Ariadne Labs, Boston, MA

Abstract Body:

Background: Clinical research informatics (CRI) is a burgeoning domain focused on using information technologies to optimize the design and conduct of translational research. In parallel, the development of workflow processes associated with re-engaging biobank participants has become necessary as genomic repositories increasingly consider the return of actionable research results. Here we describe the development and utility of a CRI application for participant recruitment and enrollment management for the Veterans Affairs (VA) Million Veteran Program Return Of Actionable Results (MVP-ROAR) Study, a randomized controlled trial returning genetic results associated with familial hypercholesterolemia. **Methods:** We leveraged the robust VA Informatics Computing Infrastructure (VINCI) to develop an end-to-end tracking system for re-contacted MVP biobank participants. The application is housed within a secure virtual server, is password protected, and accessible only to study staff. The multi-user application integrates electronic data capture, nationwide clinical and administrative data, and dashboard analytics via a combination of commercial and open-source software. Study data are queried and stored within the VA Corporate Data Warehouse, easing access and eventual trial data analysis. We use a task-based model to transition participants through the system as research staff complete study tasks in real-time. The application is developed in Python and uses the Flask microframework, providing study staff access via a standard web browser. **Results:** The application was put into production in November 2021 and includes modules for chart review, medication reconciliation, participant contact and biospecimen logging, survey recording, randomization, and documentation of genetic counseling and return of results. As of 5/18/22, a total of 2 primary users, a genetic counselor and research coordinator, and 254 Veteran participants have been integrated into the system. The application has successfully handled 1,668 task requests involving greater than 50,000 structured data points. Specifically, application users have recorded 201 chart reviews, 408 recruitment telephone calls, 84 telephone-based surveys, and 36 return of results genetic counseling sessions, among other available study tasks. **Discussion:** The development of usable, customizable, and secure CRI tools will become increasingly important as large genomic repositories begin to return research results at scale. Our work provides a proof-of-concept for using such tools to aid in managing the return of results process within a national biobank.

PB2163. Do Automated Family Histories Significantly Improve Risk Prediction in an EHR?

Authors:

X. Huang¹, D. Page², S. Hebring³; ¹Yale Univ., New Haven, CT, ²Duke Univ., Durham, NC, ³Marshfield Clinic, Marshfield, WI

Abstract Body:

We recently demonstrated that electronically constructed family pedigrees (e-pedigrees) have great value in epidemiologic research using electronic health record (EHR) data. Prior to this work, it has been well accepted that family health history is a major predictor for a wide spectrum of diseases, reflecting shared effects of genetics, environment, and lifestyle. With the widespread digitalization of patient data via EHRs, there is an unprecedented opportunity to use machine learning algorithms to better predict disease risk. Although predictive models have previously been constructed for a few important diseases, we currently know very little about how accurately the risk for most diseases can be predicted. It is further unknown if the incorporation of e-pedigrees in machine learning can improve the value of these models. In this study, we devised a family pedigree-driven high-throughput machine learning pipeline to simultaneously predict risks for thousands of diagnosis codes using thousands of input features. Models were built to predict future disease risk for three time windows. At baseline models Logistic Regression and XGBoost without e-pedigree data, we achieve average areas under the receiver operating characteristic curve (AUCs) of 0.799, 0.747 and 0.710 for 1, 6, and 24 months, and AUCs of 0.820, 0.774 and 0.713 for 1, 6, and 24 months, respectively. When adding e-pedigrees features to the machine learning pipelines, AUCs of Logistic Regression increased to 0.808, 0.761 and 0.730, and AUCs of XGBoost increased to 0.826, 0.788 and 0.736 for the same three time periods, respectively. This result emphasizes the potential value of incorporating family health history into machine learning with no further human time or input for disease risk prediction.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2164. Do digital tools support a diversity of patient values? A qualitative study using the Genetics Adviser.

Authors:

S. Krishnapillai¹, M. Clausen², D. Hirjikaka², R. Kodida², C. Mighton³, S. Shickh⁴, E. Reble⁵, J. Sam⁵, E. Adi-Wauran^{6,1}, N. Baxter⁷, J. Carroll^{8,9}, A. Eisen¹⁰, A. Eisen¹¹, C. Elser¹², G. Bombard^{1,2,18}; ¹Inst. of Hlth.Policy, Management and Evaluation, Univ. of Toronto, Toronto, ON, Canada, ²Li Ka Shing Knowledge Inst., St. Michael's Hosp., Toronto, ON, Canada, ³St. Michael's Hosp. & Univ. of Toronto, Toronto, ON, Canada, ⁴Univ. of Toronto & St. Michael's Hosp., Toronto, ON, Canada, ⁵St. Michael's Hosp., Toronto, ON, Canada, ⁶St. Michael's Hosp., Toronto, ON, Canada, ⁷Melbourne Sch. of Population and Global Hlth., Univ. of Melbourne, Melbourne, Australia, ⁸Mount Sinai Hosp., Toronto, ON, Canada, ⁹Univ. of Toronto, Toronto, ON, Canada, ¹⁰Potomac, MD, ¹¹Odette Cancer Ctr., Sunnybrook Hosp., Toronto, ON, Canada, ¹²Univ. Hlth.Network, Toronto, ON, Canada, ¹³Mem Sloan Kettering Cancer Ctr, New York, NY, ¹⁴Univ. Hlth.Network/Mt Sinai Hosp., Toronto, ON, Canada, ¹⁵Hosp for Sick Children, Toronto, ON, Canada, ¹⁶Univ British Columbia, Vancouver, NY, Canada, ¹⁷Mount Sinai Hosp./UHN, Toronto, ON, Canada, ¹⁸Ontario Inst. of Cancer Res., Toronto, ON, Canada

Abstract Body:

Background: The shared decision-making model involves patients and clinicians. Patient facing digital health can serve as a valuable adjunct to this process. Despite the well-established role of patient values in shared decision-making, there have been limited efforts to explore the range of values held by populations and how those values inform decision-making for genomic testing. Choosing to receive incidental findings (IFs) from exome sequencing (ES) is inherently complex, in part given the value-laden nature of the decision. The Genetics Adviser is a digital health application that supports patients undergoing genomic testing. **Aim:** To explore the range of values raised when deciding upon IFs to receive from ES and how these values are supported by the Genetics Adviser. **Methods:** We conducted semi-structured qualitative interviews with participants undergoing ES and choosing which IFs to receive as part of the Genetics Adviser RCT. Interviews were analyzed using interpretive description methods. **Results:** Sixteen participants were interviewed, primarily women (11/16), mean age 59 (range: 39-76 years). Participants unanimously expressed that their decision to receive all IFs available to them from ES preceded use of the Genetics Adviser. Decision-making was not described as a deliberate process for participants. Instead, their decision was predetermined and occurred within a 'black box' before using the Genetics Adviser. This 'black box' describes a complex system of motivational factors involved in decision-making. Three overarching values emerged from unpacking this 'black box', including: a sense of family stewardship, an imperative to accumulate information, and the notion of restoring and maintaining personal agency. While the Genetics Adviser did not play an active role in eliciting these values, participants appreciated having the tool to confirm their predetermined decision by clarifying, contextualizing, and instilling confidence in their decision. **Significance:** Participants entered decision-making for ES with a predetermined decision guided by three core values that motivated their decision to learn IFs: family stewardship, an information imperative, and preserving agency. The Genetics Adviser supported patients' decision-making by clarifying, contextualizing and reinforcing their predetermined decision. Further research is needed with more diverse populations including those that are frequently underserved in clinical genetics and have been historically excluded in genomics research to explore how digital tools can support a diversity of values.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2165. Early Mentoring for Medical Students in Research of Medical Genetics

Authors:

O. Samassekou¹, G. Landoure², C. Guinto¹, M. traore¹, L. CISSE³, T. Coulibaly¹; ¹USTTB, Bamako, Mali, ²CHU du Point G, Bamako, Mali, ³Teaching Hosp. of Point G, Bamako, Mali

Abstract Body:

Introduction: Research in medical genetics is at its infancy in developing countries such as Mali where a lack of human resources is the main cause of its slow. In investing in training to encourage youngsters on the path of research in medical genetics, we can reduce the gap between developed and developing countries for doing research in this field. Our research team has benefited from the H3Africa initiative, financed by the NIH, to study the genetic aspects of hereditary neurological disorders in Mali. Using some of these research funds, we have initiated a mentoring program by hypothesizing that medical genetics mentoring program for medical students would be a stepping stone to introducing them to research and opening up career opportunities for them. **Methodology:** From 2014 to 2021, we recruited graduate medical students doing thesis projects during their last two years of general medical residency at the University of Sciences, Techniques et Technologies of Bamako, Mali. We selected students based on their academic record and their motivation. We used as evaluation tools of the program, the number of scientific communications, the number of published articles, the number of awards obtained, the acquired skills, and the student satisfaction for the program. **Results:** We mentored 27 medical residents, 3 master's students, and 2 doctoral students. On average, the mentorship lasted 3 years. The students did more than 100 communications in scientific meetings, published 31 scientific papers, and won 34 awards. Among the skills acquired, in addition to theoretical and practical knowledge in medical genetics research, they have improved skills in mastering the English language, technique of scientific communications, and leadership. Over 90% of the students are pursuing a career in medical genetics or a related discipline. The students have been very satisfied with the program and want its continuation. **Conclusion:** We have implemented a mentoring program to introduce medical students to research in medical genetics. This program has had notable results that need to be encouraged and supported.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2166. Electronic health record-based recruitment for genomic research studies

Authors:

A. Miller, S. Nigbur, J. Petrzela, H. Bangash, S. Hussain, P. Caraballo, R. Freimuth, I. Kullo; Mayo Clinic, Rochester, MN

Abstract Body:

Introduction: The use of the electronic health record (EHR) as a tool for recruitment has come into focus since the onset of the COVID-19 pandemic. We established a set of EHR-based workflows to enroll patients for the Electronic Medical Records and Genomics (eMERGE) Network Phase IV project that is implementing polygenic risk scores in the clinical setting. **Methods:** A customized query of the EHR (Epic) is run weekly to identify individuals who meet study inclusion criteria (aged 3 to 74, resident of Olmsted County with a primary care provider at Mayo Clinic, and an upcoming clinical appointment). Demographic information is used to prioritize enrollment of minority participants. Study invitation messages are sent to eligible participants through the patient portal and interested patients are emailed the study consent form to review. Once consented, participants receive an email notification to complete additional study surveys in REDCap. Participants can self-schedule biospecimen collection for genetic testing and return of result appointments. Clinical variables needed for generating the study report are collected using electronic phenotyping algorithms and sent to the coordinating center via an Application Programming Interface (API). A study specific order is placed in the EHR for subsequent report upload. Discrete study data are transferred as a comma separated values (.csv) file from the Network REDCap instance to the site EHR using custom clients and institutional APIs to load the data into Epic SmartData Elements and Epic Registry to track recruitment metrics. **Results:** Recruitment workflow design began in October 2020 and was implemented in May 2022. Study investigators interacted with 28 teams and received 7 committee/group approvals for institutional support of the workflows. These teams, committees, and groups provided feedback to the study team and helped finalize the workflow outlined above. Participant recruitment began in May 2022 with the goal of enrolling 1900 adult and 100 pediatric participants over 18 months. The EHR query identified, on average, ~2000 eligible individuals in a week. A subset is sent invitations, depending on study needs. As of 6/9/2022, 1039 adults have been invited and included 62.8% female, 88.3% non-Hispanic White, with ages ranging from 18 to 75; 139 completed the prescreen survey and 39 consented to the study thus far. **Conclusion:** We describe an EHR-based recruitment workflow that includes informed consent and can be adapted for diverse research studies while maintaining privacy and confidentiality. A limitation is potential bias towards enrolling more educated, more technologically literate participants.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2167. Engagement and Feedback on Genetic Ancestry and Trait Results from >100,000 All of Us Participants

Authors:

H. Hoban¹, D. Brazel¹, C. Neben¹, C. Mbumba¹, A. Myers¹, A. Ondov¹, B. Ellis², L. Westendorf², A. Wise², S. Topper¹, A. Zhou¹, All of Us Research Program; ¹Color Hlth., Burlingame, CA, ²NIH, Bethesda, MD

Abstract Body:

The All of Us Research Program is committed to 1) creating a cohort that reflects the diversity of the US, with individuals who have been underrepresented in biomedical research (UBR), and 2) providing participants with access to their data. In November 2020, the program launched the Genetics Engagement Module (GEM), a digital platform where participants can choose to receive and view their genetic ancestry and four non-clinical trait results.

To date, 220,410 participants consented to receive their genetic results (73% UBR). Of those, 136,730 participants were eligible to receive GEM results (71% UBR). Of those, 67% elected to receive their results (67% UBR). 95% of those participants viewed their genetic ancestry results; 88% viewed at least one trait result, and 74% viewed all four trait results.

Participants provided feedback about their results through Likert-scaled questions and free text. 67% answered at least one question, and overall feedback was positive. Participants agreed with their trait results on average 4.2/5, but those levels varied, with earwax type the highest (4.7/5) and cilantro preference the lowest (3.4/5). They found their genetic ancestry and trait results very informative (3.3/4) and stated that they would like more information, specifically more precise locations for their ancestors. This matched with the 39% of participants who expressed wanting to learn more about their genetic ancestry. For trait results, participants stated their lactose intolerance results matched their lived experience best and their cilantro preference result the least, which is not surprising as cilantro preference is more heavily influenced by other genetic and non-genetic factors. Participants stated their bitter taste trait results were the most confusing because they lacked context on how other individuals' perceive taste, but they stated they "learned something" about their earwax type results, suggesting this trait was new to most participants. Finally, participants were asked if they had any additional feedback. Most participants stated that they did not, and many thanked the program for giving them access to their information. Taken together, these data show that All of Us participants are highly engaged and readily provide feedback about their genetic results in GEM. Participant interaction and satisfaction across all UBR groups drives recruitment and retention, increasing the value of the program's research database. To truly develop individualized health care based on that data, it is imperative to continue engaging with and collecting feedback from participants in this diverse cohort.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2168*. Engaging a local community & participant advisory board in a national precision medicine study: Experiences from the New York City Consortium *All of Us* Research Program.

Authors:

L. Bier¹, C. E. W. Freeland¹, J. Brown², L. Jones¹, G. M. Reyes³, L. Turner¹, A. Fuentes³, A. G. Gharavi¹, D. B. Goldstein¹, G. Hripacsak¹, R. Kaushal³, M. E. Ross³, **R. K. Trousdale**², E. G. Cohn⁴; ¹Columbia Univ. Irving Med. Ctr., New York, NY, ²NYC Hlth.+ Hosp./Harlem, New York, NY, ³Weill Cornell Med., New York, NY, ⁴Hunter-Bellevue Sch. of Nursing, City Univ. of New York, New York, NY

Abstract Body:

The All of Us Research Program (AOURP) is a nationwide NIH precision medicine initiative, which aims to enroll 1 million or more people across the United States to accelerate health research. AOURP comprises over 100 awardees and subawardees, and has a robust national governance structure which incorporates over 30 participant partners across the country. Even while participant representation is woven throughout the national program infrastructure, local community and participant engagement remains valuable, particularly as precision medicine research touches on topics around genetic research which may have complex local sociocultural implications. The New York City Consortium (NYCC), part of the AOURP, established a local Community and Participant Advisory Board (CPAB) to provide guidance and partnership around all aspects of implementing the AOURP in New York City. Here, we describe our experience of establishing a local CPAB within the context of a complex national governance structure. Initial CPAB invitations were extended in 2018 to community members with pre-existing relationships with study investigators, as well as AOURP participants nominated by local enrollment staff, with the aim of establishing a board that reflects a diversity of perspectives including social, ethnic, economic, faith-based and sexual-gender minority perspectives. The CPAB consists of approximately 15 members (membership changes over time), and meets every quarter with meetings still ongoing. Four strategies have been employed to foster engagement between the CPAB and NYCC research team, and maximize the impact of the CPAB within the AOURP: 1) Work with the CPAB to jointly set scope and goals, and develop the Board Charter; 2) Establish streamlined channels for bidirectional communication between the local CPAB and the national AOURP (both through NYCC researchers and National AOURP Participant Ambassadors); 3) Promote a reciprocal relationship between the NYCC and CPAB members, encouraging creative ways for CPAB members to contribute to NYCC activities (e.g., CPAB-led staff trainings, and CPAB feedback on questions, concerns and interests around genetic research), and how NYCC can contribute to community work of CPAB members (e.g., raising awareness of community services and events); 4) Proactively identify opportunities for the CPAB to provide feedback and guidance to national AOURP representatives. Using these strategies, the NYCC CPAB serves as a model for how a local CPAB can effectively work within a complex national program.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2169. Engaging Families and Clinicians to Advance Care Coordination and Improve Health Outcomes in Genetic Disease: The Long-Term Follow-Up Cares and Check Initiative

Authors:

K. Chan, Y. Unnikumaran, Z. Talebizadeh, R. Wiebenga, L. Barnes, C. Lumpkins, J. Taylor, A. Brower; American Coll. of Med. Genetics and Genomics, Bethesda, MD

Abstract Body:

The use of technologies to screen, diagnose, and treat newborns has accelerated a model of population-based genetic screening for diseases that benefit from early identification, are treatable but not curable, and require lifelong care and management. Each year in the United States the neonatal screening about 4 million babies leads to the identification of over 13,000 infants with a genetic condition. A key component of the NBS system is care coordination across the lifespan. In addition, some, but not all, of the genetic diseases that are identified through NBS require urgent referral for diagnosis and clinical evaluation. This requirement for rapid diagnosis coupled with life-long medical care requires coordination between a diverse group of stakeholders including birthing hospitals, state NBS programs, clinicians, and families. Although longitudinal follow-up that supports screening, counseling, and service delivery to individuals diagnosed with a condition through NBS has been a goal in the United States for many years, NBS screening is state-based with individual policies and practices that impact LTFU. For diagnosed infants, families and clinicians work together to manage care over the lifespan and the input of these two stakeholders is essential to ensuring LTFU. To develop a model of LTFU, the Health Resources and Services Administration funded the American College of Medical Genetics and Genomics to conduct a two-year effort focused on LTFU of newborns diagnosed with spinal muscular atrophy (SMA) through NBS. The Long-Term Follow-Up Cares and Check Initiative (LTFU Cares & Check) prioritizes the involvement of families and clinicians to inform which data points inform health outcomes and well-being over time. The project's overall goal is to expand the ability of state public health agencies to collaborate with families and clinicians to assure the best possible outcome for individuals with SMA. This model system consists of three main tools: (1) LTFU-Care Algorithms (LTFU-Cares) a web-based database for LTFU data collection for families, patients, clinicians, and newborn screening programs; (2) LTFU-Checklist (LTFU-Check) a checklist for LTFU monitoring, assessment, and reporting for states; and (3) LTFU-Cares Dashboard a collection of data visualization for families, patients, clinicians, and states on LTFU. Families, individuals with SMA, and clinicians who specialize in SMA will guide tool development and provide health information, while state NBS programs will receive summaries of health outcomes. The LTFU Cares & Check Initiative focuses on NBS and SMA but is a useful model for other timepoints and genetic diseases.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2170. Ensuring participant understanding of informed consent through an automated consent chatbot for a national genome sequencing study.

Authors:

E. Andrew¹, S. Savage², S. I. Berger¹, J. LoTempio¹, V. A. Fusaro², G. Mas², E. C. Delot³, E. Vilain¹; ¹Children's Natl. Res. and Innovation Campus, Washington, DC, ²Invitae, San Francisco, CA, ³Children's Natl. Res. and Innovation Campus, Washington, DC

Abstract Body:

Background: Informed consent is the cornerstone of ethical participation in biomedical research. For genomic studies, particularly with vulnerable groups and those with limited access to genetic providers, ensuring understanding of complex concepts is key. These concepts include sharing of genomic data in Federal repositories, risk of unexpected findings, and Federal legislation such as the Genetic Information Nondiscrimination Act. Traditional consenting is repetitive and time-intensive, can take weeks to schedule, and requires staff to review dense consent forms and attest that enrollees understood. Few studies audit participants' understanding of what was discussed during consent. We propose an alternative: a conversational chatbot scripted on informed consent.

Methods: We created an automated consent process using the virtual Genetic Information Assistant (Gia (R)) chatbot for the Pediatric Mendelian Genomics Research Center, an NHGRI-funded GREGoR site. Gia's script is based on the IRB-approved consent forms reviewed by study staff, rewritten and streamlined to fit text message format. Gia is informative and conversational and permits users to select the level of detail in the conversation while covering all required elements of informed consent. Gia works on a mobile device or computer and is more accessible to participants. Gia requires the completion of a short knowledge quiz prior to permitting consent. All individual responses along with actual consent are recorded. Results: Many participants opted to consent with Gia rather than traditional consenting. Participants who obtained a 100% score on a 10-question knowledge quiz within two attempts were automatically enrolled. Those who did not obtain 100% were directed to a traditional consent with study team member. Gia takes about 35 minutes to complete, compared to 60 min for the traditional consent.

Discussion: Gia chatbot-based consent for genomic sequencing studies is feasible, allows mobile access to consent, and reduces barriers. Gia ensures each participant has a uniform experience and study staff can audit understanding. Traditional consenting is challenging for large studies because the process is highly manual; Gia allows large scale population studies without increasing support staff.

PB2171. Ethical considerations for genomic newborn hearing screening from the SEQaBOO (SEQuencing a Baby for an Optimal Outcome) study.

Authors:

C. Morton¹, C. O. Mitchell¹, G. Rivera-Cruz², M. H. K. Chau³, E. Dong³, R. K. W. Choy³, K. T. Booth⁴, J. Shen⁵, S. Amr⁶, A. B. S. Giersch¹; ¹Brigham and Women's Hosp, Boston, MA, ²Boston Children's Hosp., Boston, MA, ³Chinese Univ. of Hong Kong, Hong Kong, Hong Kong, ⁴Harvard Med. Sch., Boston, MA, ⁵GeneDx, Gaithersburg, MD, ⁶Brigham and Women's Hosp., Boston, MA

Abstract Body:

Recent advances in genomic sequencing technologies have expanded our ability to provide timely, efficient, and accurate genetic diagnoses. However, with increasing genomic information clinicians are presented with ethical decisions about how and when genomic information should be disclosed to families. Currently, there is limited knowledge surrounding the benefits and burdens of implementing genome sequencing into newborn screening.

SEQaBOO is a research project offering genome sequencing for newborns who refer to diagnostic audiometry following failure of newborn physiologic hearing screening. The child's deafness and hard of hearing (DHH) is used as a paradigm for implementing genomic newborn hearing screening. SEQaBOO provides comprehensive genome sequencing and variant interpretation of DHH-associated genes, as well as optional (for parents only) ACMG secondary findings (SF) v 3.0. The analytic platform can detect chromosomal aneuploidy, copy number variants (CNVs), absence of heterozygosity, and chromosomal structural rearrangements including balanced translocations.

A comprehensive study of this nature has potential to identify genomic information that may or may not be associated with DHH phenotype. To date, 99 families have consented to receive genomic sequencing results (n=272 individuals), and of those, 81 families have been analyzed utilizing the analytic platform. This comprehensive method has identified balanced chromosomal translocations (n=4), sex chromosome aneuploidy (n=1), and pathogenic CNVs (n=11) in genes associated with DHH. While 9 had direct implications for the DHH phenotype, 7 were considered incidental findings, with no clear implications for intervention. Findings of incidental results led to obtaining further IRB approval for disclosure.

Many ethical issues need to be considered when presenting genomic data in the newborn period, including the effect of disclosing incidental findings in newborns that may be unrelated to the initial indication for genetic testing. Thoughtful deliberations of the burden and benefit of disclosing incidental findings in newborns for late-onset conditions is essential. Overall, there are vast benefits for implementing genomic newborn hearing screening but considerations for public trust in genomic science are requisite to facilitate large-scale implementation.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2172. Evaluation of out-of-province and self-pay for genetic testing in two publicly funded provincial programs in British Columbia, Canada

Authors:

A. Elliott¹, P. Grant¹, S. Langlois¹, J. Nuk², S. Mung², Q. Zhang³, GenCOUNSEL Study, L. Lynd¹, J. Austin¹; ¹Univ British Columbia, Vancouver, BC, Canada, ²BC Cancer Agency, Vancouver, BC, Canada, ³BC Children's Hosp. Res. Inst., Vancouver, BC, Canada

Abstract Body:

Background: In Canada's public healthcare system, each province determines which tests to fund by evaluating evidence of clinical utility, medical necessity and cost-effectiveness. When tests are not funded publicly, healthcare providers may discuss private pay options (e.g. self-pay) with patients. These tests are typically sent out-of-province (OOP). The Hereditary Cancer Program (HCP) and Provincial Medical Genetics Program (PMGP) provide genetic services to residents of British Columbia and the Yukon Territory and collectively see >12,000 patients/year. In 2018, there was a change in the funding authority for OOP genetic testing for PMGP.

Methods: We evaluated trends in total OOP genetic testing and self-pay for HCP and PMGP from 2015-2019. Linear and regression models were applied to HCP data to explore outcomes including the relationships between self-pay with patient and test characteristics. To examine the effect of a change in the funding authority for OOP genetic testing in 2018 for PMGP, interrupted time series linear and logistic regression models were used on PMGP data.

Results: Out-of-province genetic tests completed through HCP increased 320% from 2015 to 2019 (1027 to 3289) while self-pay increased 730%. For self-pay patients, the most frequent indications were hereditary breast and ovarian cancer (74.8%), familial pancreatic cancer (8.0%) and Lynch syndrome (7.7%). For each year studied, the mean individual income of self-pay patients was \geq \$3500 higher than in the group with funded testing ($p < 0.0001$). The total number of OOP tests completed through PMGP increased 260% from 2015-2019. After the change in funding authority in 2018, the total number of tests increased by 2.35 per-month (95% CI 1.03, 3.66), which differed from the trend before change ($p = 0.0089$). The likelihood of self-pay increased over months before the funding authority change (OR per month: 1.07; 95% CI: 1.04, 1.10); while this likelihood had an immediate 87% drop when the change occurred (OR: 0.13; 95% CI: 0.06, 0.32).

Implications: Advances in sequencing technologies with associated reductions in costs have resulted in increased uptake of genetic testing. Patients with higher incomes are more likely to self-pay. Financial barriers create disparities in clinical outcomes for patients based on their economic resources. Funding decisions can have a significant impact on uptake and rate of self-pay. There are currently no Canadian guidelines for genetic healthcare providers regarding self-pay and testing resulting in dramatic heterogeneity of access. A pan-Canadian study evaluating issues including funding approval and clinical practice is urgently needed.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2173. Evidence-Based Assertions of Clinical Actionability of Secondary Findings: Update from the ClinGen Actionability Working Group

Authors:

C. Pak¹, J. E. Bulkley¹, P. Chakraborty², M. J. Gilmore¹, A. M. Foreman³, I. Futchi³, C. L. Jenkins¹, A. Katz⁴, K. Lee³, A. Milosavljevic⁵, J. O'Daniel³, J. E. Posey⁵, N. Shah⁵, R. D. Steiner⁶, A. B. Stergachis⁷, S. Subramanian⁸, T. Trotter⁹, M. S. Williams¹⁰, A. H. Buchanan¹⁰, K. A. B. Goddard¹¹, K. Manickam¹², B. C. Powell³, J. E. Hunter¹³, ClinGen Resource; ¹Kaiser Permanente Ctr. for Hlth.Res., Portland, OR, ²Children's Hosp. of Eastern Ontario and Univ. of Ottawa, Ottawa, ON, Canada, ³Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, ⁴Horizon Therapeutics, Rockville, MD, ⁵Baylor Coll. of Med., Houston, TX, ⁶Univ. of Wisconsin Sch. of Med., Marshfield, WI, ⁷Univ. of Washington, Seattle, WA, ⁸TwinStrand BioSci.s, Seattle, WA, ⁹John Muir Hlth., San Ramon, CA, ¹⁰Geisinger, Danville, PA, ¹¹Natl. Cancer Inst., Bethesda, MD, ¹²Nationwide Children s Hosp., Columbus, OH, ¹³RTI Intl., Durham, NC

Abstract Body:

The ClinGen Actionability Working Group (AWG) uses an evidence-based framework to generate summary reports and consensus scores of the clinical actionability of secondary findings from genome-scale sequencing in adult and pediatric contexts. Recently, the AWG expanded its framework to generate assertions of actionability of gene-condition topics to inform decision-making for the return of secondary findings. The assertion process begins with a preliminary assertion of Limited, Moderate, or Strong Actionability based on consensus scores. The AWG then discusses the default actionability score-based preliminary assertion and assigns a final assertion which may differ based on the curated gene-condition evidence. The AWG may also choose an assertion of Definitive Actionability if the topic meets predetermined criteria. The AWG documents the rationale for the final assertion. To date, the AWG has finalized assertions for 108 pediatric and 135 adult gene-condition topics (www.clinicalgenome.org). The AWG changed the preliminary assertion to a higher category of actionability in 10% of pediatric and 11% of adult topics and to a lower category in 3% of pediatric and 7% of adult topics. While most assertions were unchanged, differences between preliminary and final assertions highlight nuanced factors not directly reflected in the scoring process that are nonetheless important considerations for actionability. For example, inclusion criteria used in studies could affect generalizability. In addition, when evidence is limited to descriptive or case studies, it is important to consider whether evidence from larger studies and/or controlled trials are likely forthcoming due to factors such as rarity of the condition. Importantly, our assertion process illuminates topics where gaps in available evidence makes assessment of actionability challenging. For example, *G6PD* deficiency has little published evidence for actionability, which may be related to it being common in populations traditionally underrepresented in research. This led to a preliminary assertion of Limited Actionability despite long-standing management practices, availability of clinical assessments of severity, and the likelihood of severe complications. The discussion of *G6PD* deficiency highlighted the risk of perpetuating disparities by relying on an evidence base with insufficient representation of population groups and the need to account for this representation in the assertion process. Overall, the expansion of the AWG framework to provide actionability assertions aims to facilitate decision-making around return of secondary findings from genome-scale sequencing.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2174. Expanding ethics education for trainees: creating and evaluating a course on genetics, ethics, and society.

Authors:

R. Patel, R. A. Ungar, M. Chakraborty, D. Cotter, P. Goddard, E. Greenwald, T. Mackenzie, D. O. Martschenko, A. Pyke; Stanford, Stanford, CA

Abstract Body:

Human genetics research has an ethically fraught past, with a legacy of discrimination featuring racism, classism, ableism, and exploitation. At the same time, the last decade has seen the rapid and unprecedented development of technologies capable of mapping, modeling, and manipulating genomes. Despite this troubled history and uncertain future, most training programs do not provide formal education on how to situate human genetics research within its historical and societal context. Instead, current ethics requirements largely focus on researchers' responsibilities to individuals. This narrow focus leaves most trainees ill-equipped to evaluate the broader impacts of research on society and neglects necessary dialogue about scientists' responsibilities to mitigate potential social harms. Here, we describe the curriculum for a 12 hour, discussion-based course entitled "Genetics, Ethics, and Society." Developed by a team of genetic counselors, doctoral students, and postdoctoral scholars from bioethics and genetics, the course sought to achieve the following learning goals: (1) connect the historical context of human genetics research to modern-day practices; (2) evaluate the societal and ethical implications of human genetics research; and (3) analyze how societal norms and structures, along with personal identities, biases, and responsibilities, impact the conduct of scientific research. We offered this course in May 2022, and it was attended by 16 graduate students, three undergraduate students, and one postdoctoral scholar, all of whom work in biomedical research. Using pre- and post-course surveys of enrolled trainees, we evaluate the effectiveness of this course in meeting its learning goals. We quantitatively describe the impact of the course on students' understanding of key topics, as well as their perceived importance of these topics. In addition, we report the primary motivations of trainees enrolling in this course and their main takeaways upon completion. We anticipate that this course will provide a model for how to educate trainees on the ethical and societal implications of scientific research. Our results underscore the importance of expanding ethics education to consider social risks and responsibilities.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2175. Expanding genomic testing to underserved pediatric populations

Authors:

A. S. A. Cohen^{1,2,3}, S. Davis⁴, N. J. Kane⁴, T. Zion¹, R. Moore¹, B. D. Zuccarelli⁵, C. Berrios¹, T. Pastinen^{1,3,4}, M. A. Hoffman^{3,4,6}; ¹Genomic Med. Ctr., Children's Mercy Hosp., Kansas City, MO, ²Dept. of Pathology and Lab. Med., Children's Mercy Hosp., Kansas City, MO, ³Univ. of Missouri–Kansas City Sch. of Med., Kansas City, MO, ⁴Children's Mercy Res. Inst., Kansas City, MO, ⁵Salina Pediatric Care Ctr., Salina, KS, ⁶Res. Informatics, Children's Mercy Hosp., Kansas City, MO

Abstract Body:

The “Genomic Answers for Kids” (GA4K) program at the Children’s Mercy Research Institute (CMRI) is committed to increasing access to genetic testing and finding answers for more pediatric rare genetic conditions. Patients enrolled in GA4K undergo short-read exome/genome sequencing (srES/srGS) with integrated machine-assisted strategies for rapid screening of positive cases to accelerate return-of-results. Following negative srES/srGS, an enhanced long-read GS workflow using PacBio Sequel IIe (HiFi-GS) is used to investigate variants in difficult-to-map regions and other novel variation. Despite employing diverse strategies for recruitment, we have identified **significant inequities in access to our study** that limit the reach of our pioneering methods. Patient identifiers from our cohort were used to extract data on race, ethnicity, home address, and payor type from the electronic medical record. Analysis of these variables revealed that GA4K enrollment under-represented racial and ethnic minorities and socioeconomically disadvantaged pediatric patients both within and beyond the Children’s Mercy Hospital (CMH) service area. For example, the GA4K cohort included only 5% Black and 7% Latinx children, compared to 15% and 11% respectively in the CMH patient population. These numbers didn’t include known prior inequities in access to care at CMH. **Under-representation of these groups goes beyond our study and leads to inflation of “rare” variants and reduced ability for accurate interpretation.** Geolocalization also demonstrated unequal enrollment across regions, with <25% of study participants having a home address in a rural zip code. These disparities may disproportionately impact patients from economically disadvantaged and rural communities because they rely on their local primary care providers (PCPs) for all healthcare needs. GA4K is **piloting a “direct-to-primary care provider” (DTP) strategy** to reach more rare disease patients by bringing genetic testing to their medical homes. Our strategy focuses on empowering PCPs to recognize their patients’ necessity for genetic testing and providing support for consenting, sample collection and return-of-results through the GA4K pipeline. A detailed description of our pilot strategy and preliminary results will be presented.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2176. Exploration of a Novel Cancer Genetics Learning Format: A Pilot Self-Directed Course in Genetic Cancer Risk Assessment.

Authors:

D. Tanna, P. Leung, J. M. Luna, G. Nuñez, R. Manookian, S. Dreike, S. Shehayeb, E. Sobotka, K. R. Blazer; City of Hope Comprehensive Cancer Ctr., Duarte, CA

Abstract Body:

Background: Despite efforts to integrate genetic cancer risk assessment (GCRA) services into mainstream medicine, the dearth of healthcare providers adequately trained in clinical cancer genetics remains a significant barrier to care. City of Hope delivers an annual interprofessional GCRA training program for community-based clinicians. As designed, the program cannot meet ongoing demands for GCRA training. Results of a pilot study to inform the design of a self-directed version of the training program are presented here.

Methods: A self-directed subset of the program curriculum covering Hereditary Breast and Ovarian (HBOC), Gastrointestinal (GI), and Genitourinary (GU) cancers was offered to a selected group of GCRA-practicing clinicians (n=67) who are program alumni and indicated interest in updated GCRA education. Participants could register for up to Three Course Bundles (HBOC, GI, GU), each containing video modules, quizzes, assignments, and evaluations to be completed within four months. Evaluations included Likert scale surveys to assess learning objectives and expectations, content quality, and the digital learning platform. Quantitative analysis of survey responses and qualitative assessment of open-ended feedback yielded recommendations for content and design strengths and improvements.

Results: Forty-four (17 MDs, 20 APNs, 1 PA, 6 GCs) of 67 invited participants enrolled in one or more course bundles; 56% completed all HBOC modules, 46% completed all GI modules, and 52% completed all GU modules. Participants reported that each module met stated learning objectives with HBOC scoring 4.56, GI scoring 4.51, and GU scoring 4.43 out of 5 quality points on average. Participants rated the quality and ease of use of the digital learning platform and quizzes/assignments an average of 4.30 and 4.32 out of 5 quality points, respectively.

Discussion: Achievement of learning objectives scored high, showing the self-directed curriculum to be a valuable resource for cancer genetics education. Open-ended responses suggested the need for more simplified content, additional clinical case examples, and continuous evidence-based and guideline updates. The digital learning platform was rated as user-friendly and the automated feedback on quizzes and assignments was greatly valued. Adding subtitles, improving audio/visual quality, and a mechanism to interact with faculty were recommended. Completion rates indicated the need for extended access for busy clinicians. Pilot outcomes will guide the development of a self-directed GCRA training program to scale up access to flexible GCRA training for clinicians across the spectrum of cancer care.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2177. Exploring stigma and discrimination among adults after receipt of neurodevelopmental/psychiatric genetic results in a population-based genomic screening program.

Authors:

O. Matshabane¹, K. Wain², A. Heidlebaugh³, M. Good³, K. Holdren³, B. Kikani¹, L. Walsh³, L. M. Koehly¹; ¹NIH, Bethesda, MD, ²GeneDx, Otsego, MN, ³Geisinger, Lewisburg, PA

Abstract Body:

Advances in neurodevelopmental/psychiatric disorder (NPD) genetics hold great promise for improved prevention, diagnosis and treatment. Models that increase access to NPD-related genetic information are needed. The MyCode population-based genomic screening program has returned NPD-related genetic results to 279 adults since 2017. Individuals with NPD can experience discrimination and the effects of stigma in daily life which may impact communication, coping and access to treatment. How knowledge of a genetic etiology for NPD impacts perceived stigma and discrimination experiences remains underexplored. This study utilized the Everyday Discrimination Scale and a novel adaptation of the Stigma by Association Scale to explore these concepts among adults who received a clinically relevant NPD-related genetic result from the MyCode program. In fall 2021, this study began exploring probands' communication decisions and experiences of stigma and discrimination related to a NPD genetic result amongst social networks at least 6 months after receiving results. 31 adult probands were invited to participate and 9 have participated to date (29% participation rate). Social network interviews were completed telephonically, resulting in 73 individuals, primarily family members, embedded in 9 ego-centered networks. The Everyday Discrimination Scale (5 items) assesses perceived experiences of receiving disrespectful treatment, poor service, being treated as "not smart", people acting afraid of them, and being threatened and harassed. Overall, 48% of probands report having these experiences one to four times a month. The most endorsed item (by 20%) was being "treated with less courtesy or respect than other people". The adapted Stigma by Association Scale (13 items) measures feelings, beliefs, and reactions to perceived personal, familial and associative stigma specifically related to a NPD genetic result. A total of 16.48% agreed to these stigma items. The most endorsed item was "I do not talk to others about it", by 6.35%. Network data revealed that although probands enumerated 8.11 living network members (Range: 3 - 16) through network assessments, genetic results were shared with an average of 1.78 network members (Range: 0 - 3). Results to date suggest that these participants may currently be refraining from communicating their genetic result with their social networks. Further research with larger samples exploring whether and how experiences of discrimination may be affecting the decision of communicating a NPD-related genetic result are needed to inform clinical and population-based models geared at returning these results.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2178. Exploring the ethical implications of genomic data sharing in cloud-based ecosystems: Views of developers and users.

Authors:

S. Nelson, J. Dahlquist, S. M. Fullerton; Univ. of Washington, Seattle, WA

Abstract Body:

Background: New cloud-based data storage and analysis ecosystems are being implemented to facilitate collaboration and maximize the scientific utility of costly-to-generate genomic and linked clinical data. These ecosystems differ from prior genomic data sharing efforts in bringing researchers to the data (instead of data to the researchers) to enable frictionless data search, aggregation, analysis, and dissemination. They also entail a range of user authentication and authorization processes, data access review procedures, and related oversight mechanisms that may blur responsibilities and complicate data stewardship. To gain a better understanding of these platforms and examine the ethical implications of this emerging genomic data sharing landscape, we conducted qualitative interviews with select platform developers and users, with the aim of informing researcher education and policy development. **Methods:** We conducted semi-structured confidential interviews with 20 developers and policymakers affiliated with five NIH-supported cloud platforms: the NCI Genomic Data Commons, the NHLBI BioData Catalyst, the NHGRI AnVIL (Analysis, Visualization, and Informatics Lab-space), the Kids First Data Resource Portal, and the All of Us Research Hub, as well as the NCBI database of Genotypes and Phenotypes (dbGaP) whose data access request and review systems are used by many cloud platforms. We also conducted interviews with researchers who have either shared, or made use of, data stored in these ecosystems. All interviews were recorded, transcribed, and subjected to a directed content analysis designed to identify key implications of cloud-based genomic data sharing. **Results:** Developers and policymakers described a complex array of technical and policy-based governance procedures designed to ensure data security and facilitate data sharing consistent with research participants' informed consent. Researchers making use of these new data sharing ecosystems described many advantages, but also challenges, associated with moving from local data storage and analysis to cloud-based approaches. **Conclusions:** Close analysis of the views of developers and users illustrates the complexity of these new data sharing mechanisms and suggests the need for more dialogue between users, developers, researchers, and policymakers to ensure that the promises of cloud-based ecosystems are realized.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2179. Factors contributing to preimplantation genetic testing for polygenic disorders (PGT-P) screening and recommendations by reproductive medical professionals.

Authors:

S. Shah¹, M. Quinn², J. Shamshoni¹, R. LeShay¹, R. Cantor³, C. Palmer⁴; ¹Univ. of California, Los Angeles, Los Angeles, CA, ²Univ. of Southern California, Los Angeles, CA, ³UCLA Sch Med, Los Angeles, CA, ⁴UCLA Semel Inst, Los Angeles, CA

Abstract Body:

Background: Preimplantation genetic testing for polygenic disorders (PGT-P) is a new area of research and clinical application of which is available in the United Kingdom, Scandinavia, and the United States (U.S.). No research has been published reporting the awareness, uptake, and acceptability of PGT-P among reproductive medical professionals. **Methods:** The prevalence of awareness of PGT-P among U.S. reproductive genetic counselors (GCs) was assessed by administering an online survey, designed and validated at UCLA. GCs who are currently not practicing in the U.S. or who have not counseled patients regarding preimplantation genetic testing in the last 5 years were excluded from the study. Statistical analyses were conducted to assess the impact of subject age and years of practice on provider beliefs regarding patients' access to PGT-P. Adjusted logistic regressions were performed to assess which factors would motivate GCs to consider PGT-P as an option for their patients. **Results:** Approximately 72% respondents among our sample of 83 were aware of PGT-P prior to this survey. Only 13% of the participants reported they may recommend PGT-P to their patients, and most participants felt uncertain about patients having the option of PGT-P for polygenic conditions. Currently, nearly half of all participants (48%) did not want patients to have the option of PGT-P. GCs' opinions about patients having the option of PGT-P were not significantly associated with age strata or years of practice. Factors such as use of donor egg/sperm/embryo (aOR = 3, 95% CI = 1.2, 7.5), family history of a polygenic condition (aOR = 4.4, 95% CI = 1.7, 10.9), and prior pregnancy history (aOR = 4.31, 95% CI = 1.47, 12.63) were independently and significantly associated with GCs' uncertainty regarding patients having the option of PGT-P compared to GCs' perspectives on patients not having the option. **Conclusions:** Currently, most GCs (45%) in the U.S. are unsure if patients should have the option of PGT-P compared to other types of preimplantation genetic tests. Most (72%) of them are aware of PGT-P, but 87% would not consider recommending PGT-P to their patients. In contrast, most GCs support patient access to PGT-aneuploidy (PGT-A; 100%), PGT-monogenic (PGT-M) disorders of childhood onset (99%), PGT-M for adult-onset conditions (87%), and PGT-structural rearrangements (PGT-SR; 99%). Further research is warranted to understand whether those who are unsure about their stance would consider access to PGT-P for patients in the future.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2180. Family communication choices about neurodevelopmental/psychiatric genetic results: A social-network assessment of adult participants in a population-based genomic screening program.

Authors:

K. Wain¹, O. P. Matshabane², A. Heidlebaugh¹, M. Good¹, K. Holdren¹, B. Kikani², L. Walsh¹, L. Koehly²; ¹Geisinger, Danville, PA, ²NHGRI, Bethesda, MD

Abstract Body:

Clinical genetic testing is standard of care for neurodevelopmental/psychiatric disorders (NPD) in children; yet adults are rarely offered this service. Since 2017, the MyCode population-based genomic screening program has returned NPD-related genetic results to nearly 300 adults to explore how this model can improve access. Initial responses to receiving NPD-related results have been positive and indicate an intent to share results with others. However, the extent to which participants share is not well understood. This study aimed to assess communication patterns amongst NPD-result recipients' social networks and identify factors that influence sharing. Starting in fall 2021, nine participants were recruited after 6-months from receipt of NPD-results through the MyCode program (29% participation rate). Through phone surveys, we elicited ego-centric social networks, exploring kinship/social ties, contact frequency, physical distance between individuals, and if results were shared. Descriptive statistics, using $p=0.1$ to identify potential trends are provided. On average, probands enumerated 8.11 living network members (Range: 3, 16); results were shared with an average of 1.78 network members (Range: 0, 3). A total of 16 individuals across 8 families (22% of 73 living network members) were told about results. Spouses/partners were most likely to be told (5/7, 71%), followed by siblings (4/12, 33.3%), biological parents (3/11, 27.3%) and biological children (3/14, 21.4%). Of the 57 individuals who were not told, 11 were children (Age Range: 5-36 years) and 8 were siblings (Age Range: 19-61 years). Results were more likely to be shared with immediate family than other network members (OR=8.72, $p=0.09$), but there were no differences based on physical distance (OR=1.44, $p=0.69$), frequency of contact (OR=2.47, $p=0.37$) or if the family member also had an NPD diagnosis (OR=1.84, $p=0.59$). Network members who provide emotional support (OR=4.31, $p=0.12$) or other help (OR=2.77, $p=0.21$) were not more likely to be told. However, results were shared more often with those involved in health decisions (OR=56.03, $p<0.01$) and health-related discussions (OR=7.19, $p<0.01$). Thus, despite initially reported intentions to share NPD-related results with family, participants only shared with key immediate family members who help with healthcare. Individuals with NPD may have lower health literacy or efficacy with regards to communicating genetic information, which could be addressed by engaging these key family members. Future research is needed, with larger cohorts, to more fully describe participant communication decisions and intervention opportunities.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2181. *FLCN* variant of unknown significance complicating a kidney donation process in a family with Birt-Hogg-Dubé.

Authors:

W. Geurts-Giele¹, P. J. Gundlach¹, A. C. Houweling², N. Engels³, M. A. van den Dorpel³, R. van Minkelen¹, M. F. van Dooren¹; ¹Erasmus Med. Ctr., Rotterdam, Netherlands, ²Amsterdam UMC, VU Univ. Med. Ctr., Amsterdam, Netherlands, ³Maasstad Hosp., Rotterdam, Netherlands

Abstract Body:

Background Birt-Hogg-Dubé syndrome (BHD) is a rare autosomal dominant condition caused by germline mutations in *FLCN*. It can present with a variety of clinical manifestations, including kidney tumors, pulmonary cysts, spontaneous pneumothorax and fibrofolliculomas. **Case presentation** A 49-year-old woman without pre-existing pulmonary disease was admitted to the hospital due to a spontaneous unilateral pneumothorax. Chest CT revealed bilateral basilar pulmonary cysts. BHD was suspected and genetic testing revealed heterozygosity for the variant NM_144997.5(*FLCN*):c.324C>A, p.(Ser108Arg), classified as a variant of unknown significance (VUS) based on ACMG criteria PM2, PP3 and PP4. Concurrently, several first-degree relatives of the patient applied for living kidney donor evaluation because they wished to donate a kidney to a sister (SIB1) of the index patient with end-stage kidney disease due to granulomatosis with polyangiitis. During this screening process a CT scan performed in another sibling (SIB2) of the index patient revealed a kidney tumor. SIB2 turned out to be a carrier of the same *FLCN* variant, with loss of the wildtype allele in the tumor. Fibrofolliculomas were histologically confirmed and pulmonary cysts were found. Although the *FLCN* variant was a VUS according to the ACMG guidelines, the variant allele was considered likely pathogenic for this family because the phenotype of the sisters was consistent with BHD. In agreement with the BHD expert center preferred relatives for donor nephrectomy should not carry the VUS, and no phenotypic features of BHD should be present (e.g. kidney tumors, fibrofolliculomas and pulmonary cysts). Segregation analysis for this variant was complicated due to ambiguous classification of the variant, logistic problems and different testing strategies. Finally, four siblings (including SIB1) did not carry the variant. Their 85-year-old father was a carrier of the variant, with histologically confirmed fibrofolliculomas. Based on the segregation analysis ACMG PP1_strong was applied and the variant was re-classified as a likely pathogenic variant. Non-carriers were released from follow-up screening. **Discussion** The ambiguous classification of the *FLCN* VUS complicated the living kidney donation process in this family with BHD due to the absence of clear guidelines for this situation. Time was lost due to extra screening, the necessity of this screening is open to debate. Additionally, this scenario was confusing for both the family and treatment teams. A multidisciplinary family clinic might resolve some of these issues. Finally, a brother of SIB1 was found eligible for living kidney donation.

PB2182. Fragile X syndrome: Experiences with receiving a genetic diagnosis and communicating genetic risk in a Cameroonian family.

Authors:

K. Kengne Kamga¹, N. Munung¹, N. Séraphin², A. Wonkam¹, J. de Vries¹; ¹Univ. of Cape Town, Cape Town, South Africa, ²Univ. of Yaounde 1, Yaounde, Cameroon

Abstract Body:

Fragile X Syndrome (FXS) is the leading genetic cause of intellectual disability (ID) and Autism spectrum disorder. Receiving a genetic diagnosis of FXS can have an emotional impact on the patient, parents, and the rest of the family. This paper reports on the experiences of receiving a genetic diagnosis of FXS in an extended Cameroonian family. Using an ethnographic approach, we conducted 13 in-depth interviews and one focus group discussion with members of a large family segregating for FXS. We interrogated their experiences of receiving a genetic diagnosis. Two main themes emerged from the interviews relating to psychological adaptation and communication of FXS genetic risk. First, we describe the happiness and relief that are associated with diagnostic closure. Next, we describe genetic guilt, survivor guilt, and frustrations associated with a family history of FXS and taking care of developmentally delayed children. Finally, we highlight the communication styles used by this family to convey genetic risk to extended relatives and promote resilience. Understanding the complex interaction which occurs during the return of genetic findings will help improve the quality of pre-and post-genetic counselling practices and hence minimize the risk of conflicts. Future studies should focus on designing innovative tools to enhance the process of connecting family members together once they receive a genetic diagnosis.

PB2183. Fragmented systems of care: An overview of Canadian health system care models for hereditary cancer syndromes

Authors:

J. Sam¹, M. Clausen¹, C. Mighton², S. Rajeziesfahani³, R. Gopalakrishnan¹, M. Aronson⁴, D. Bishop⁵, L. Dawson⁶, A. Eisen⁷, T. Graham⁸, J. Green⁹, M. Krahn¹⁰, J. Pauling¹¹, C. Pavao¹², C. Remocker¹², S. Savas³, N. Stjepanovic¹, S. Sun¹³, T. Tiano¹¹, A. Tilley⁵, K. Thorpe², K. Schrader¹³, H. Etchegary⁶, Y. Bombard²; ¹St. Michael's Hosp., Toronto, ON, Canada, ²St. Michael's Hosp. & Univ. of Toronto, Toronto, ON, Canada, ³Mem. Univ., St. John's, NL, Canada, ⁴Zane Cohen Ctr., Sinai Hlth.System, Toronto, ON, Canada, ⁵Patient Partner, St. John's, NL, Canada, ⁶Mem. Univ., St. John's, NL, Canada, ⁷Sunnybrook Hlth.Sci. Ctr., Toronto, ON, Canada, ⁸Univ. of Toronto & Sunnybrook Hlth.Sci. Ctr., Toronto, ON, Canada, ⁹Mem. Univ., Middle Cove, NL, Canada, ¹⁰Univ. of Toronto & Univ. Hlth.Network, Toronto, ON, Canada, ¹¹Patient Partner, Toronto, ON, Canada, ¹²Patient Partner, Vancouver, BC, Canada, ¹³BC Cancer, Vancouver, BC, Canada

Abstract Body:

Background: Hereditary cancer syndromes (HCS) are one of the most prevalent inherited diseases, accounting for 5-10% of all cancers. Patients and their family members with a confirmed genetic diagnosis of a HCS require lifelong screening and follow up since they have an increased risk for multiple malignancies in several organ systems. However, there is limited data on the accessibility and coordination of HCS care across different health jurisdictions in Canada. **Aim:** The purpose of this study is to compare the systems of HCS care in 3 provinces in Canada to support a team grant that aims to explore the indirect socioeconomic and psychosocial impacts of HCS. **Methods:** Expert leads of provincial HCS care programs in British Columbia (BC), Ontario (ON), and Newfoundland & Labrador (NL) were consulted to provide detailed information about the care systems in their respective provinces. The care system dimensions examined included an overview of populations and regions served, structure of genetic service delivery, genetic testing eligibility and panel sizes, coordination of follow up care, and gaps in care. **Results:** Access to and coordination of HCS care across all 3 provinces is fragmented. First, there are inconsistencies in genetic testing referral criteria and management recommendations for carriers. This means that some family members across the country have access to HCS medical services (e.g., genetic testing, screening, prophylactic surgery) while others do not. Accessing genetic testing is further impaired by the varied and strict eligibility criteria for testing across the provinces. Secondly, all provinces face a genetics workforce shortage, and long wait times for families to access publicly funded testing. Thirdly, provincially-organized screening and surveillance programs only exist for some organs in BC, ON, and NL. The lack of organized screening programs leaves at risk individuals and their family physicians to navigate the system of care alone. This results in inequities in medical outcomes, further exacerbated for underserved populations and rural communities. Lastly, the genetic testing offerings across the 3 provinces vary. Differences in gene panels means that at risk individuals living in different jurisdictions will have inconsistent genetic diagnoses. **Conclusions:** A fragmented and uncoordinated HCS care system may result in socioeconomic, psychosocial and health implications for HCS families. Further investigation is needed to better examine these impacts to inform evidence-based practice for a more coordinated and patient-centered health care system for families affected by HCS.

PB2184. Gender medicine, Gender-Omics and Sex-Omics: What we are dealing with?

Authors:

A. Karra^{1,2}, W. Smaoui¹, S. Kammoun¹, N. Halouani¹, N. Abdelmoula¹; ¹Med. Univ. of Sfax, Sfax, Tunisia, ²Genomics of Signalopathies at the service of Med., Sfax, Tunisia

Abstract Body:

Background: Gender medicine is viewing patients through a sex and gender lens and studying of how diseases differ between men and women. It is a novel and promising approach in terms of prevention, clinical signs, therapeutic approach, prognosis, psychological and social impact. It represents the crucial assumption for achieving the precision medicine required in this third millennium. Currently, while it is approved that biological, genetic, epigenetic, psycho-social and environmental determinants interact conjointly in defining sex/gender differences and in setting up sex/gender disparities, two new terms evolved in literature in the field of Omics Sciences: Gender-Omics and Sex-Omics. Generally, the objective of omics sciences is to identify, characterize and quantify all biological molecules that are involved in the structure, function and dynamics of a cell, tissue or organism. Here, we aim to review the objective of Sex-Omics and Gender-Omics and to sign on the role of genet/epigenetics in these entities. **Methods:** We comprehensively review the scientific literature using Pubmed and others databases to state the meaning of Gender-Omics and Sex-Omics and to delineate the role of genetics and epigenetics in these new terms. **Results:** Our bibliographic research revealed a poor literature with only two papers responding to our inquiry in PubMed and 59 papers in Google scholar. Interrogation of the 61 papers demonstrated that the term Sex-Omics is more frequently cited. The authors deal with the role of both sex and gender in physiological and pathophysiological processes of diseases using a holistic omics approach. They reported studies that consider Sex and Gender Omics biomarkers involved in various diseases. They reported also studies that consider sex-specific variations in signaling pathways and gene expression patterns in response to various health processes, pathological situations, therapeutic approaches, etc. There are also the notion of the sexome, defined as the summation of sex-biased effects on gene networks or the reporting sex differences in gene systems. For gender influence in an omics approach, there are less reports. However, Genderome may be defined as the summation of gender-biased effects on epigenetic networks or the reporting gender-associated differences in the epigenetic systems (the epigenome with methylome and the imprintome). **Conclusion:** Sex-Omics and Gender-Omics are two new omics that have been proposed in investigating sex/gender specific aspects in biomedical sciences. These omics have complex and multifaceted nature that makes it important to be approached in next years to improve precision Gendered medicine.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2185. Genetic counselors and legal recognition: a made-for-Canada approach

Authors:

M. Zawati¹, D. Patrinos¹, D. M. Lambert², B. Knoppers¹; ¹McGill Univ., Montreal, QC, Canada, ²Univ. Coll. Dublin, Dublin, Ireland

Abstract Body:

Background: Genetic counseling is a fast-growing profession in Canada. However, it lacks legal recognition in the majority of Canadian provinces and territories. Legal recognition ensures safety in the provision of healthcare services by regulating professions that pose a risk of harm to the public. Without legal recognition, any individual uses the title without the proper qualifications, and professional quality standards remain unregulated. This may potentially expose the public to risk of harm, including inaccurate interpretation of genetic testing results, incomplete risk assessment and psychological harm. We assessed the feasibility of legal models to achieve the legal recognition of genetic counselors within Canadian law. Methods: We conducted a comparative analysis of professional legislation across the three provinces with the largest workforce of genetic counsellors (British Columbia, Ontario and Quebec) to identify models of legal recognition and the level of public protection offered by each. We surveyed representatives of a Canadian genetic counseling regulation special interest group to estimate the provincial numbers of genetic counselors. Results: 3 models of legal recognition were identified: 1) constitution of a professional order, 2) inclusion in an existing professional order, and 3) delegation of specific acts from another profession. There are an estimated 484 genetic counselors in Canada, with 89% found in 4 of the 13 provinces and territories. Discussion: The first two models provide a higher level of public protection, yet are more difficult to achieve. Delegation relies on another professional body to delegate a limited number of professional acts, so is more limited in scope, but is easier to achieve, yet does not provide the same degree of public protection. The significant human and financial resources necessary to obtain legal recognition may mean that creation of a new profession of genetic counselling is beyond the reach of provinces and territories with fewer genetic counsellors. Given that genetic counseling is a relatively small profession, a balance needs to be achieved between protecting the public and leveraging the resources required to seek legal recognition. Conclusion: Though legal recognition occurs at the provincial and territorial level, we advocate for a pan-Canadian approach to develop strategies to further pursuits of legal recognition. A series of expert discussion groups of Canadian genetic counselors and other stakeholders are being formed to discuss the most effective and feasible manner of seeking legal recognition.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday
PB2186. Genetic Counselors' Attitudes Towards Religiously-Based Policies and Their Impact on Professional and Ethical Obligations in the Prenatal Setting

Authors:

L. Freedkin¹, M. Bocian¹, R. LeShay², K. Osann¹; ¹Univ. of California Irvine Med. Ctr., Orange, CA, ²Univ. of California Los Angeles, Los Angeles, CA

Abstract Body:

The National Society of Genetic Counselors (NSGC) Code of Ethics outlines the professional and ethical obligations genetic counselors have to themselves, their patients, their colleagues, and society. These guidelines stress the importance of patients' autonomy and informed consent. One interpretation of the NSGC Code of Ethics is that prenatal genetic counselors should also discuss the option of abortion with patients in order to cover all necessary facts and options. However, institutions with religiously-based policies (RBPs) that prevent genetic counselors from freely discussing abortion with patients seem to contradict the NSGC Code of Ethics. There is very little information in the current literature about genetic counselors' opinions on this potential conflict and its impacts. This study aimed to explore genetic counselors' attitudes towards RBPs, what characteristics of genetic counselors are associated with attitudes towards RBPs, and what characteristics are associated with genetic counselors' willingness to work in settings with RBPs. A survey was developed to measure genetic counselors' opinions on RBPs and interest levels in working in fictitious prenatal settings with various policies regarding abortion discussions. Overall, genetic counselors did not support the implementation of RBPs that limit abortion discussions (n=152, 86%) and believed that such policies do not align with the NSGC Code of Ethics (n=157, 90%). Most of the participants viewed abortion as moral (n=144, 77%), were comfortable counseling about abortion (n=124, 71%), and described themselves as liberal (n=134, 78%) or not very religious (n=131, 76%). These participants were more likely to express low support for RBPs ($p \leq 0.002$) and were less interested in working at institutions with policies limiting abortion discussions ($p < 0.001$). The findings of this study raise concerns for the quality and equity of genetic counseling services in settings with certain RBPs. As the political landscape shifts and abortion rights continue to be challenged, the findings of this study may encourage genetic counselors to advocate for additional NSGC guidance and ethical policies in the prenatal setting at the institutional and governmental level.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2187. Genetics education in neurodevelopmental disorders for non-genetic health professionals: A scoping review.

Authors:

C. Somerville¹, I. Peltekova^{2,3}; ¹The Hosp. for Sick Children, Toronto, ON, Canada, ²Holland Bloorview Kids Rehabilitation Hosp., Toronto, ON, Canada, ³Univ. of Toronto, Toronto, ON, Canada

Abstract Body:

Background: Clinical genetic testing is considered the standard of care for individuals with neurodevelopmental disorders (NDDs), like autism spectrum disorder, intellectual disability, and global developmental delay. Genetic tests are regularly ordered by non-genetic healthcare providers who lack formal training in medical genetics. Research has shown that these providers experience challenges in their knowledge, understanding, and management of genetic concepts and information. There is a need for structured genetics education geared towards non-genetic health care providers caring for individuals with NDDs. The aim of this scoping review was to synthesize the literature on formal genetics education interventions on NDDs for non-genetics health professionals. **Methods:** MBASE, MEDLINE, CINHAL, ERIC and PsychInfo were searched for peer-reviewed publications through November 2021. Two reviewers independently screened and extracted data from each study. Discrepancies in data analysis were resolved following joint re-evaluation. **Results:** In total, 9885 studies were screened and 72 met inclusion criteria. Study participants were largely primary care physicians, residents, medical students, and nurses. There were very few genetics education interventions specifically targeting NDDs. The topic of NDDs was mostly approached as part of broader genetics education initiatives, which largely consisted of didactic/in-person seminars or web-based learning modules (e.g., clinical case scenarios). Educational content was comprised of basic and applied genetics concepts, family history evaluation, genetic testing, and genetic services. Most studies implemented a pretest-posttest design. Outcomes included participant-reported satisfaction with the intervention and measures of genetics knowledge and confidence. However, few studies evaluated the impact on clinical care or utilization of genetic services. **Conclusion:** Although several genetics education interventions exist for non-genetic health professionals that incorporate NDDs as a topic, the development of a structured program is needed. Future research should focus on developing genetics education tools that are tailored to clinical and health system contexts, and evaluating their impact on clinical care, to help address current barriers to genetic service delivery for patients with NDDs.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2188*. Genome sequencing and preferences for secondary findings in ostensibly healthy COVID-19 positive individuals: GENCOV study Canada.

Authors:

S. Casalino^{1,2}, C. Mighton^{1,3,4,2}, M. Clausen³, E. Frangione^{1,2}, M. Chung^{1,2}, S. Chowdhary^{1,2}, G. MacDonald^{1,2}, H. Faghfoury^{1,5}, Y. Bombard^{3,4}, J. Taher^{1,4}, J. Lerner-Ellis^{1,2,4}, GENCOV Study Workgroup; ¹Sinai Hlth., Toronto, ON, Canada, ²Lunenfeld-Tanenbaum Res. Inst., Toronto, ON, Canada, ³Unity Hlth. Toronto, Toronto, ON, Canada, ⁴Univ. of Toronto, Toronto, ON, Canada, ⁵Univ. Hlth. Network, Toronto, ON, Canada

Abstract Body:

Background: Genome sequencing (GS) can identify genetic factors that influence variability in COVID-19 symptoms and outcomes. GS can also be used to screen for secondary findings (SF) about inherited predispositions to other diseases. Attitudes toward the use of GS as a screening tool in the general Canadian population is unknown, warranting exploration of individuals' preferences, knowledge, and attitudes towards GS/SF. **Aims:** Determine 1) preferences for SF from GS and 2) the impact of genetic counseling (GC) and educational tools on SF preferences and knowledge. **Methods:** Online surveys were administered to ostensibly healthy individuals previously diagnosed with COVID-19 before pre-test GC (T0), and immediately after completion of a digital genomics platform (www.geneticsadviser.com) along with pre-test GC (T1). Surveys at T0 assessed: 1) sociodemographic characteristics; 2) SF preferences; 3) knowledge of GS; 4) attitudes toward genetics/healthcare; and, 5) health literacy. Surveys administered at T1 re-assessed knowledge of GS and SF preferences. Responses were analyzed with descriptive statistics. **Results:** 605/696 responses were received for at least part of both the T0 and T1 surveys. The majority were female (56%), ≥40 years of age (54%), and had a Bachelor's degree or higher (66%). 59% indicated they were white/European. Most participants at T0 (462/599; 77%) and T1 (504/604; 83%) wished to learn all SF from GS. SF preferences were similar at T0 and T1, with the greatest interest in learning clinically actionable SF (97% at both time points), followed by polygenic risk for common conditions, drug reactions, carrier status, and other rare Mendelian conditions. Less than 1% did not wish to learn any SF. Mean scores for knowledge of sequencing limitations and benefits (n=520) improved from low at T0 (3.6 and 4.3 out of 10, respectively; Standard deviation (SD) 2.5-2.7) to moderate at T1 (5.3/10; SD 2.6-2.9). 80% (485/605) had positive/ambivalent attitudes toward genetics and 20% (120/605) had negative/ambivalent/mixed attitudes. 87% (524/605) think it is important/essential to receive the most advanced medical care. Health literacy was adequate based on a mean scale score of 18.4/20 (SD 2.4, n=596). Characteristics and predictors related to initial and post-GC SF preferences will be presented at the conference. **Conclusion:** Preliminary findings suggest that most individuals are interested in receiving SF from opportunistic GS. GC in conjunction with the digital genomics platform improves knowledge and may be an appropriate means of educating the general population about GS and SF.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2189*. Genomic knowledge, orientation, and empowerment in a demographically diverse population: Preliminary findings from the Texome project.

Authors:

C. Murali¹, R. German², T. Nguyen Dolphyn³, C. Bacino², S. Lalani⁴, H. Bellen², S. Yamamoto⁵, z. liu², M. Wangler⁶, M. Wangler⁴, P. Lupo²; ¹Texas Children's Hosp., Houston, TX, ²Baylor Coll. of Med., Houston, TX, ³Stanford Clinical Genomics Program, Stanford, CA, ⁴Baylor Coll. Med., Houston, TX, ⁵Baylor Coll. of Med., HOUSTON, TX, ⁶BCM

Abstract Body:

The Texome project provides exome sequencing for underserved Texans with undiagnosed disease. Participants lack access to clinical genomic sequencing, due to gaps in insurance coverage or cost of testing. As a result of this criterion and the racial and ethnic diversity of Texas, the participant population is more diverse than those typically recruited for studies of genomic attitudes. In this study, we measured genomic knowledge using the University of North Carolina Genomic Knowledge Scale (UNC-GKS), optimism and pessimism using the Genomic Orientation Scale (GOS), and empowerment using the Genomic Empowerment Scale (GEmS). We used unpaired T-tests to compare genomic knowledge, orientation, and empowerment scores by income level, insurance status, and self-reported ethnicity. A total of 26 survey responses were analyzed, including caregivers of children (n=10) and adults (n=8) and eight adult probands. Twelve respondents were bilingual; all endorsed speaking English comfortably. Two were primary Spanish-speakers. Two reported having a Bachelor's degree or higher and 23 reported a high school education or less. The most common self-reported race or ethnicity was Hispanic (n=16); followed by White (n=8); Black (n=4); Native American, American Indian, or Alaska Native (n=4); and Asian (n=1). Six reported having no health insurance, 16 reported a government plan such as Medicaid, and five reported private health insurance. We compared genomic knowledge, empowerment, optimism, and pessimism by income (\geq vs $<$ \$40,000), insurance status (insured vs not insured), and ethnicity (Hispanic vs non-Hispanic). Individuals earning $<$ \$40,000 per year (n=18) had higher scores on the Meaning of Diagnosis GEmS subscale compared to those earning more (n=8) (p=0.03), indicating that they felt more likely to receive a genetic diagnosis and that the diagnosis would improve the proband's life. While the difference was not statistically significant, higher earners had higher genomic knowledge (p=0.06). No significant differences were found between insured (n=20) vs uninsured individuals (n=6) or between Hispanic (n=16) vs non-Hispanic individuals (n=10). Higher genomic knowledge was moderately negatively correlated with higher genomic pessimism (r=-0.45). These preliminary findings suggest that individuals with lower income may have greater expectations and hopes for the meaning of a genomic diagnosis. While many comparisons did not yield significant differences, we were limited by small sample sizes. As the Texome project continues to accrue participants, we anticipate valuable insight into the genomic perceptions of an underrepresented population.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2190*. Healthcare provider confidence in understanding unsolicited genomic results: Insights from the eMERGE III experience.

Authors:

G. Wiesner¹, S. Ziniel², J. Madden³, S. Aufox⁴, K. B. Brothers⁵, W. K. Chung⁶, E. Clayton¹, J. Connolly⁷, R. Green⁸, K. Leppig⁹, M. Myers¹⁰, J. Ralston⁹, R. Sharp¹¹, J. Williams¹², J. Wynn¹³, C. B. Zawatsky⁸, I. A. Holm³; ¹Vanderbilt Univ. Med. Ctr., Nashville, TN, ²Univ. of Colorado Sch. of Med., Aurora, CO, ³Boston Children's Hosp., Boston, MA, ⁴Northwesterns Univ., Chicago, IL, ⁵Univ. of Louisville, Louisville, KY, ⁶Columbia Univ., New York, NY, ⁷Children's Hosp. of Philadelphia, Philadelphia, PA, ⁸Brigham and Women's Hosp./Genomes2People, Boston, MA, ⁹Kaiser Permanente of Washington, Seattle, WA, ¹⁰Univ Cincinnati, Cincinnati, OH, ¹¹Mayo Clinic, Rochester, MN, ¹²Geisinger, Danville, PA, ¹³New York Presbyterian Columbia, New York, NY

Abstract Body:

Introduction: As genomic medicine expands into all areas of medicine, health care providers (HCPs) will be confronted with interpreting unsolicited genomic test results (UGR) that the HCP did not order and that may or may not be related to the patient's health history. Research has shown that HCPs feel unprepared to understand and apply results of genomic tests. We sought to assess HCP confidence after receiving UGRs from the Electronic Medical Records and Genomics Phase III Network (eMERGE), where 21,915 participants at 10 clinical sites underwent genetic testing and return of 67 medically-actionable genes. **Methods:** 484 HCPs who received a pathogenic or likely pathogenic genomic result on an eMERGE participant within the previous 6 months were invited to complete an online survey. A composite score (low, medium, or high) was developed from the responses to 4 questions where HCPs rated their confidence in (1) knowledge of the returned variant, (2) ability to explain and (3) answer patient's questions, and (4) manage the care based on the result. Design-based Pearson's Chi Square tests were performed to account for the clustering of HCPs within eMERGE sites. The primary outcome was the confidence of HCPs in addressing the UGR with their patient. **Results:** 151 HCPs completed the survey (31% response rate). 83% were physicians, 54% female, 80% non-Hispanic White, and 63% had been in practice >10 years. Among the 95 (63%) HCPs who recalled receiving the test result, most did not feel confident in explaining it to their patients (57%), answering questions (64%), or managing patients' care based on the UGR (62%). The percentage of HCPs with a low, medium, or high composite confidence score (Cronbach's alpha: 0.96) were 25%, 40% and 35% respectively. Higher confidence was associated with HCPs who had previously ordered clinical genetic tests (p=0.014). HCPs with high confidence scores were also more likely to have a positive reaction (p=0.044) and less likely to be ambivalent (p=0.006) about the UGR. **Conclusions:** This novel study examines HCPs perceptions after receiving actual UGRs on clinic patients. Over half of our respondents self reported medium to low confidence, suggesting that HCPs do not feel prepared for UGR. We also found that a positive HCP reaction to receiving the UGR was strongly associated with higher confidence in their ability to understand and discuss the UGR with their patients. Our findings provide unique insights into the "real world" implementation of genomic medicine into healthcare that can be used in future efforts to elucidate best practices in returning UGR to HCPs. This study was supported by NHGRI R01HG010004.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2191. Healthcare providers' experiences counseling patients with results from consumer genomic testing.

Authors:

M. Trottier¹, D. Green¹, H. Ovidia¹, A. Catchings¹, J. Gruberg¹, V. Groner¹, S. Dandiker¹, A. Izhar¹, K. Blazer², J. Hamilton¹, K. Offit¹; ¹Mem. Sloan Kettering Cancer Ctr., New York, NY, ²City Hope Natl. Med. Ctr., Duarte, CA

Abstract Body:

Introduction: Consumer genomic testing (CGT) includes direct-to-consumer testing and consumer-initiated testing where individuals order a test from their physician or a laboratory-affiliated provider. CGT can include analysis of a biospecimen or raw genomic data. CGT increases genetic testing access; yet, it has limited regulatory oversight, resulting in a higher potential for error in analysis or interpretation and subsequent adverse medical and psychological risks. To assess the current state of CGT, we surveyed healthcare providers' experiences with CGT in oncogenetics and other clinical settings. **Methods:** We emailed a retrospective anonymized survey about experiences counseling individuals who obtained CGT to providers in the National Society of Genetic Counselors, the Clinical Cancer Genomics Community of Practice, and regional genetic-focused professional societies in Feb-Mar 2022. **Results:** Of 139 respondents, 123 (89%) identified as a genetic counselor (GC) and the rest as an MD/DO or other provider. Most (62%) had oncology as a clinical focus, and 88% counseled individuals after CGT within the past 3 years. When asked whether potential benefits of CGT outweigh potential harms, 21% agreed, 41% disagreed, and 38% were undecided. Those who reported seeing more CGT patients were more likely to indicate benefits outweigh harms ($p=.003$). Of respondents, 69% reported experiencing cases of raw data reports not being confirmed, 76% documented testing leading to an adverse psychosocial event, and 68% reported incorrect variant interpretation; the latter 2 events were reported more often by those who felt CGT harms outweigh benefits ($p\leq.01$). Oncology providers reported higher rates of being unable to confirm a CGT result upon repeat testing in a reference laboratory ($p=.03$). Open-ended responses identified additional CGT challenges, including patient understanding of test results, false negatives, concerns about patient communication with other providers, inappropriate medical care, testing in minors, financial concerns, and incorrect test ordered; 7 providers noted positive patient CGT outcomes. Finally, 34% of respondents consulted on circulating tumor DNA results, suggesting a new mechanism for CGT findings to be brought to clinic. **Conclusion:** GCs and other providers counseling patients for a previously obtained CGT result encounter challenges including unconfirmed results, incorrect interpretation, and adverse psychosocial sequelae. Benefits of CGT were also reported. Medical risks of CGT may be mitigated by augmented regulatory oversight of commercial laboratories providing CGT, and improved consumer and provider awareness.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2192. Homozygous *APC* p.I1307K Mutations in an Ashkenazi Jewish Female: Implications for Genetic Counseling and Clinical Management

Authors:

T. DeMarco, K. Matthijssen, M. Turner, D. Alaeddin, K. Schwarting; Inova Schar Cancer Inst., Fairfax, VA

Abstract Body:

Approximately 10% of colorectal cancer diagnoses occur in the context of an inherited cancer predisposition syndrome. One example of a condition associated with an inherited predisposition to colorectal cancer is classic or attenuated Familial Adenomatous Polyposis (FAP/AFAP), caused by mutations in the *APC* gene. It is estimated that about 10% of individuals of Ashkenazi (Eastern European) Jewish ancestry carry a founder mutation in the *APC* gene known as p.I1307K. The p.I1307K mutation does not cause FAP/AFAP, but is associated with a moderately increased lifetime risk for colorectal cancer. We present the case of an 82-year old Ashkenazi Jewish female with a personal history of multiple primary cancers, including breast cancer at the age of 59, lung cancer at the age of 71 (in the context of former smoking history), and an endometrial neuroendocrine tumor at the age of 82. In addition, the patient underwent a hemicolectomy at the age of 81 due to the presence of a significant tubulovillous adenoma. She reported a family history of breast and prostate cancer in her siblings and a gastrointestinal malignancy in her mother. In light of her personal and family history of malignancy, the patient recently underwent genetic counseling and testing utilizing a comprehensive pan-cancer panel at a commercial laboratory. The results indicated homozygous germline *APC* p.I1307K mutations. While there is a recent case series regarding four homozygous *APC* p.I1307K carriers (Rosenblum et al., Case Rep Oncology: 2021), there is no data currently available regarding the lifetime risk for cancer in these patients or appropriate medical management for these individuals. It stands to reason that this result may have been a contributor to the development of the large adenoma in this patient, but it is not clear what role, if any, it may have played in the development of her other cancers. Given the incidence of heterozygous *APC* p.I1307K mutations in the Ashkenazi Jewish population, it would be expected that the homozygous state would be reported with greater frequency than it is at present. However, there is currently a paucity of data in the published medical literature regarding *APC* p.I1307K homozygosity and the implications for cancer screening and patient-centered genetic counseling. This case contributes to the medical knowledge about the clinical variability in these patients and the need for further academic collaboration to refine cancer risks and establish mutation-specific medical management guidelines for homozygous *APC* p.I1307K mutation carriers.

PB2193. Identifying ELSI needs in newborn screening research.

Authors:

C. Lumpkins¹, A. Goldenberg², E. B. Goldman³, I. A. Holm⁴, A. Brower⁵; ¹ACMG, Bethesda, MD, ²Case Western Reserve Univ, Cleveland, OH, ³Univ. of Michigan, Ann Arbor, MI, ⁴Boston Children's Hosp, Boston, MA, ⁵American Coll. of Med. Genetics and Genomics, Dakota Dunes, SD

Abstract Body:

Introduction: Each year in the United States, 3.8 million newborns are screened for up to 81 genetic conditions, and over 12,000 are diagnosed and referred to clinical care. Discoveries of novel technologies to screen, diagnose, and treat genetic diseases have led to an ever-increasing list of conditions that are candidates for newborn screening (NBS). The NBS community of researchers, parents and families, advocacy groups, healthcare professionals, and state NBS programs play important roles in the research that leads to these advancements. Because NBS research often involves and impacts newborns and children, consideration of the ethical, legal, and social issues (ELSI) is crucial during the planning, execution, and reporting of NBS research. To better understand the ELSI concerns of NBS researchers and state programs, NBSTRN is conducting a survey to identify the specific challenges faced by those working in newborn screening.

Methods: The *Eunice Kennedy Shriver* National Institute of Child Health and Human Development (NICHD) Hunter Kelly Newborn Screening Research Program funds the Newborn Screening Translational Research Network (NBSTRN) operated by the American College of Medical Genetics and Genomics (ACMG). The NBSTRN Bioethics and Legal Workgroup developed a survey of NBS researchers and state programs with the goal of assessing the nature and scope of the ethical and legal challenges faced in their work and how those needs can best be met in the form of resources, tools and/or education. The survey included questions relating to a range of ELSI topics including, but not limited to, data sharing, consent, return of results, and including diverse perspectives in study design. The survey will be disseminated in summer 2022 to NBS researchers and state programs. Data obtained by the survey will be reviewed and used to create tools, white papers and recommendations for practice.

Results: This presentation will explore the preliminary results of the 2022 ELSI Survey and potential ways NBSTRN can address the ELSI needs of NBS researchers and state programs.

Conclusion: NBS researchers and state programs face challenges related to the ethical, legal, and social issues of newborn screening in their work. It is imperative that the nature and scope of these challenges is well understood and used to inform the development of relevant resources to support ethical NBS research. Although this effort is focused on programs related to newborns and children, our findings inform the use of genomics across the lifespan and provide a useful model for others looking to explore ELSI concerns in other areas of genomics research or care.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2194. Implementation and evaluation of digital patient-reported oncology questionnaire at the East Genomic Medicine Service Alliance

Authors:

P. Buczkowicz¹, E. Peacock¹, E. Davies², V. Kiesel³, R. N. Sandford², O. Buske¹; ¹PhenoTips, Toronto, ON, Canada, ²Cambridge Univ. Hosp.'s NHS Fndn. Trust, Cambridge, United Kingdom, ³Univ. Hosp. of Leicester NHS Trust, Leicester, United Kingdom

Abstract Body:

The East Genomic Medicine Service Alliance (E-GMSA) is undergoing a digital transformation in order to improve and standardize the delivery of genomic medicine across the region, serving a population of over 10 million. Direct patient engagement in the design and delivery of aspects of the digital transformation is fundamental to the success and widespread adoption of new and innovative solutions across genetics, other medical specialties and primary care within the region. Here we implement, gather feedback, and improve an oncology-focused family history and medical history questionnaire in preparation for region-wide deployment.

A total of 100 consented individuals from the E-GMSA who had previously filled out paper-based questionnaires as part of their referral to cancer genetics were provided access to a secure digital questionnaire. The questionnaire collected information pertaining to the patient's demographics, medical history with a focus on oncology and family history. Information from submitted questionnaires was recorded in PhenoTips software, including auto-drawn pedigree diagrams accessible to clinical staff for review and further refinement, raw questionnaire responses attached to the patient record in PhenoTips, and standardized Human Phenotype Ontology (HPO) terminology, where applicable. Furthermore, the patient-provided responses combined with available clinical data were used to test risk assessment models directly incorporated into the PhenoTips pedigree tool, including BOADICEA v5 (Cambridge Enterprise Ltd.), IBIS/Tyrer-Cuzick v8 (Cancer Research UK), GAIL (NIH National Cancer Institute) and PREMM5 (Dana-Farber Cancer Institute). Several metrics comparing respondent experience with digital versus paper-based questionnaires across various parameters, including ease of use, time to completion, comprehensibility, completion rate, time per page, average number of sessions, and net promoter score were collected. Feedback was assessed and incorporated into the oncology questionnaire prior to region-wide rollout.

The success of this pilot in the oncology setting has provided opportunities to expand to other specialties such as inherited cardiovascular conditions, and our work represents the first real-world implementation of digital questionnaires through PhenoTips as part of the E-GMSA project and demonstrates the utility of standardized pedigree and genomic data sharing in a clinical setting.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2195. Implementing human genetics training and research at a university hospital in Nairobi, Kenya.

Authors:

S. Ilovi, J. Mecha; Univ. of Nairobi, NAIROBI, Kenya

Abstract Body:

Medical Genetics in Kenya is still an underutilized service, largely driven by inadequate training of healthcare providers in medical genetics and a paucity of medical geneticists. Human genetic testing are largely carried out abroad because of low numbers; these being largely driven by prenatal genetic tests with some laboratories reporting less than five genetic tests annually for patients suspected to have genetic disorders. The bulk of genetic tests are limited to sequencing of pathogens such as SARS-CoV-2 and influenza. The University's curriculum prescribes teaching of medical genetics for both undergraduates and postgraduates. These training has been limited to cell biology with biochemistry. In 2022, we re-instituted clinical genetics teachings for medical students rotating in Internal Medicine in their fourth year and sixth year. The sessions had a reach of over 500 medical students. Similarly, we augmented clinical genetics training for first, second and third year residents in Internal Medicine. The University has recently established a Sanger based molecular laboratory which proved pivotal in management of the COVID-19 pandemic, HIV drug resistance analysis and also supporting molecular based PhD studies. We are currently instituting basic genetics research in sickle cell disease at our institution. It is envisioned that these endeavors will promote human genetics training and research in population genetics as well as improved diagnosis and management of patients with genetic and rare diseases in Kenya.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2196*. Implementing public health genomics: The familial hypercholesterolemia model

Authors:

L. Manace, R. Birnbaum, A. Avins, L. Taylor, A. Curran; The Permanente Med. Group, Oakland, CA

Abstract Body:

Background: Familial hypercholesterolemia (FH) is the most common autosomal dominant disorder, affecting 1:225 individuals worldwide. Diagnostic criteria, associated genes, and treatment guidelines are well established with proven morbidity and mortality reduction. Despite longstanding public health recommendations for health systems to identify and treat FH, only 5% of the population is currently appropriately diagnosed and managed. Population screening taking advantage of electronic medical records with referral to a specialized care-and-tracking program taking advantage of streamlined molecular genetic testing has the potential to be sustainable with cost savings based on improved outcomes. Objective: Develop and evaluate a pragmatic, phased implementation of FH as a model for precision medicine and genomics in a large integrated health system. Methods: Using the Make Early Diagnosis/Prevent Early Death (MEDPED) criteria, we created a registry of likely FH individuals 18 years and older within Kaiser Permanente Northern California enrollees (4.5 million members). This led to a pragmatic workflow for inviting members in partnership with their primary care providers to be evaluated in a specialty care program including cascade adult and pediatric relative assessment and longitudinal follow-up. Results: 93% of patients identified as likely having FH were confirmed to be affected with FH either with genotypic pathogenic or likely pathogenic variant confirmation (67%, 91% in LDLR gene 9% in APOB gene) or according to clinical diagnostic criteria including personal and family medical history with or without physical stigmata. 67% of offspring were confirmed to have inherited the causative gene variant and/or met clinical diagnosis of FH based on biochemical laboratory values. 48% of adults and 100% of affected children were on no lipid-lowering medication at the time of screening. Following initiation of therapy, there was a 41% median reduction in low-density lipoprotein cholesterol (LDL-C) levels. Conclusions: Familial hypercholesterolemia gives health systems the opportunity to realize significant primary and secondary prevention. Here we describe a pragmatic and sustainable approach to integrating genomics in a streamlined care pathway within pediatric and adult care in a model that can be adapted in other health organizations.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2197. Improving Community Based Genomics Research in Black Populations: A Review of Lessons Learned and Ideas for Need Based Solutions

Authors:

C. Whitted¹, T. Lee², F. Gilpin-Macfoy¹, R. Tawk², J. Luque², J. Reese-Smith³, L. Koehly¹; ¹NHGRI/NIH, Bethesda, MD, ²Florida A&M Univ., Tallahassee, FL, ³City of Houston Fire Dept., Houston, TX

Abstract Body:

Recruitment of historically marginalized populations in genomic research is an ongoing challenge, limiting generalizability of genomic discoveries and implementation of precision medicine initiatives. Fewer Black Americans have been recruited to participate in genomic research than White Americans, suggesting that translational discoveries from genomic research may not be generalizable to Black Americans, thereby increasing the potential for health inequities for this marginalized population. Many factors, such as historical mistrust of research due to past negative experiences, continue to impact research participation. This proposed paper perspective provides insights towards reaching Black Americans for genomics research based on lessons learned from a community-based genomics research project initiated in North Florida evaluating the Families Sharing Health Assessment and Risk Evaluation (SHARE) toolkit and ideas to help strengthen community-based research. Families SHARE aims to increase community members' understanding of the importance of family health history for their personal and family members' risk of common, complex conditions. Here, we present a review of the recruitment and community engagement methodology used to evaluate Families SHARE in North Florida Black communities and lessons learned from this experience that can guide future genomic research endeavors that aim to reach historically marginalized communities. Ideas and recommendations will be shared to improve community engagement in genomics research which includes technology needs to improve data collection, sharing of family health history and educational toolkits to improve genomic research within community settings and communities.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2198. Incidental findings in study participants: What is the researcher's obligation?

Authors:

D. Schaare, L. Boccuto, S. Sarasua, L. Ward; Clemson Univ., Clemson, SC

Abstract Body:

Background: With genomic testing becoming a standard diagnostic tool, incidental findings, or the discovery of unrelated results, have become commonplace. Due to the severity of diseases linked to specific pathogenic variants, the American College of Genetics and Genomics (ACMG) has established guidelines for clinicians to return findings on 50 plus genes associated with medically actionable conditions. However, in the research setting, the lack of a definitive guiding policy for investigators compounds ethical dilemmas that may arise when incidental findings that are clinically actionable occur in the conduct of research studies. The concern for potential loss of clinically valuable information could undermine the research subject's trust and commitment to participate in a process that offers more individual risk than benefit. **Purpose:** The analysis aimed to ascertain the most ethically valid approach to manage incidental research findings, offering a useful approach for investigators and participants. **Methods:** We performed an ethical evaluation using Wueste's Framework of Identify, Analyze, Justify, and Decide (AIJD). We then analyzed current research policies, as well as an alternative, to determine viability. **Results and Discussion:** The current policy of allowing the decision to return incidental findings up to the researcher fails the majority of ethical principles, including the consequential, deontological, and intellectual freedom perspectives. We find that by applying the ACMG guidance for clinicians to investigators resolves many of the ethical challenges and provides needed guidance to researchers. This presentation integrates suggestions from multiple organizations to establish a favorable policy for both the investigator and the research subject that will achieve the HHS aim, stated in the 2014 Joint Rule, of transitioning participants to "partners" in research.

PB2199. Individual attitudes towards identity, privacy, and health insights from personal genomics: Evidence from a full archival search on Twitter

Authors:

B. Zhao, M. Mills, E. Akimova; Univ. of Oxford, Oxford, United Kingdom

Abstract Body:

Abstract

In recent years, the massive growth of direct-to-consumer genomics testing services (DTCG) has raised public attention and posed pressing regulatory questions. However, to date, very little is known about how the newly found accessibility of personal genome information is perceived by individuals, and accompanied concerns on privacy, self-identity, and health insights. We collected all public tweets related to two major DTCG companies from 2006 to 2020 (n=1.6M, from 757,750 individual users), and analysed word, terminology, topic, and sentiment prevalence. We discovered on average most tweets are positive, even among concerning topics that are privacy related or classified as hate or offensive language. However, our content analysis identified several words clearly related to customer concerns; it is apparent that people express interest in such topics as ancestry, privacy, and risks.

Results

Monthly frequencies over the period from 2007 to 2020 shows online discussions experienced a substantial increase since 2014, in line with the steady and rapid growth of new genetic tests on the market. Percentage of organic tweets has been gradually declining over the years, negatively correlated with the annually increased DTC medical marketing spending in the US, in line with the prevalence of Western users mainly from the US and Europe.

Using most frequently used words via a simple case insensitive bag-of-words approach, we were able to identify several words that are clearly related to customer concerns such as *don't*, *fda* and *private*. In our LDA topic modelling analysis, we explored the models with topics n=8, chosen based on local maximum coherence score and visualised intertopic distances with the fewest overlapped areas.

Among the sentiment analysis on English tweets, we discovered on average most tweets are sentimentally positive, even among concerning topics that are privacy related or classified as hate speech or offensive language, possibly due to Twitter enforces relevant policies and restrictions to minimise harmful contents.

White supremacy is often behind the motivations for personal genetics testing, which may lead to racist speeches. Our preliminary analysis shows the percentage of offensive tweets remained stable until 2016, then fluctuated afterward. In comparison, hateful tweets remained low despite two significant spikes.

To understand opinions towards health risk reports, we extracted 493 terms and 378 concepts with semantic type *dsyn*. Tweets containing clinical terms has a constant increase starting 2020 with some previous spikes in 2015 and 2017. Importantly, in 2017 such tweets were negative in sentimental analysis.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2200. Integrating Predictive Genetic Testing into clinical care in the Preventive Genomics Clinic

Authors:

C. Srisukajorn^{1,2}, P. Teekakirikul¹, R. Ngathong¹, S. Kongmongkol¹, T. Viangteeravat³, J. M. Ford³; ¹Preventive Genomics Clinic and Family Check-up Services, Dept. of Med., Bumrungrad Intl. Hosp., Bangkok, Thailand, ²BIR Program, Faculty of Political Sci., Thammasat Univ., Bangkok, Thailand, ³Res. and Dev., Bumrungrad Intl. Hosp., Bangkok, Thailand

Abstract Body:

Background: Emerging insights into genomics has yield great benefits in modern medicine. Technological advancements made genetic tests readily accessible and affordable to general population. Many commercial test panels have been available to predict future disease risk in asymptomatic individuals. Yet, there are little data on how well predictive genetic testing has been integrated in the health space. **Aims:** To assess the trends of integrating genomics into healthcare at a quaternary care hospital and review how actions were taken after likely pathogenic/pathogenic variant(s) (PVs) were identified from either genetic screening test (GST) or diagnostic test (DT) panel according to the ACMG guidelines. **Methods:** The data was collected for 365 days from May 2020 using the number of index patients (PT) who received services at Preventive Genomics Clinic at Bumrungrad International Hospital. Patients were categorized in two groups: healthy and diseased. How they were referred to our clinic, types of services, management plans proposed by the board-certified geneticist, and actions taken from post-test counseling were recorded and examined. **Results:** Across the year, the clinic served 387 PT ranging from 2 to 93 years old (mean=44), 78.3% of which are healthy, the rest were diagnosed with certain disease(s) prior to the visit. We found 35.4% purchased GST panel prior to the visit while 27.9% were referred for genetic counseling from other clinics mostly by Ob-Gyn (n=21), Check-up Center (n=17), and oncology (n=16). Also, 49.6% acquired GST to see predisposition to inherited cancer and heart diseases while 26.4% received further genetic test using DT panel for various diseases including cancer. Of all population, 294 PT (76%) who obtained either GST or DT, PVs were detected in 29 PT (9.9%) from both healthy and diseased group. PVs detection rates in healthy PT were 6.9%. Post-counseling actions include follow-up (F/U) at the clinic, referring PT to other specialist(s), and cascade genetic testing (CGT) to determine heredity risks. F/U visits were appointed for 14 PT. Ten were referred to other specialist(s), 4 of which did show up for the referral visit, 1 was booked, and the rest were not indicated. CGT was recommended to all PT with PVs, only 10 of which have their family members tested, ranging from 1-14 members. Total 47 family members were presented at the clinic for F/U, 44.7% were found to have the family PVs. **Conclusion:** Predictive genetic testing has great potential for appropriate screening and preventive strategies. The results prompted appropriate surveillance, further referral to specialists, regular clinical follow-up, and follow-up family variant testing.

PB2201. International Best Practices for Genomic Data Sharing in the Health Technology Industries

Authors:

B. Knoppers, M. Zawati, Y. Joly; McGill Univ., Montreal, QC, Canada

Abstract Body:

Health technology industries play a central role in supporting the introduction of genomics into healthcare and must adapt to data sharing norms promoting collaboration, creative data re-use, and scientific reproducibility. Data sharing presents opportunities for industry, but also particular interests and challenges. Industry could therefore benefit from greater clarity and consistency over what constitutes responsible data sharing practices. An Industry Core Group was formed to develop International Best Practices for Genomic Data Sharing, consisting of representatives from 10 companies, working in partnership with the Centre of Genomics and Policy at McGill University. The Group's mission is to facilitate and promote the international harmonization and sharing of genomic and health data by industry. The effort is inspired by the Framework for Responsible Sharing of Genomic and Health-related Data developed by the Global Alliance for Genomics and Health, founded on the human rights of everyone to share in scientific advancement and its benefits, and to the protection of the moral and material interests resulting from any scientific production. The best practices are based on a systematic review of legislation, guidelines, and industry practices. Tracking the Framework's core principles, the Industry Core Group has identified 8 interrelated themes to be addressed in the best practices: Data control/sharing - how to reconcile commercial interests in data control with opportunities to generate commercial and societal value through data sharing? Identifiability - how to determine the applicability of diverse international data privacy laws and regulation? Consent - how to obtain appropriate individual permissions and to ensure commitments to patients and participants providing their data are respected when sharing internally or externally? Access - how to provide individuals and researchers access to data while protecting commercially sensitive information? Privacy and Security - how to provide for consistent and effective levels of protection for sensitive genomic and health data? Governance - how to realize commercial and societal value from data while respecting requirements from data protection law, research ethics and human rights? Partnerships - how to establish transparent, fair, and mutually beneficial partnerships involving industry, academia, as well as patient groups and publics? Intellectual Property - how to reconcile data sharing with securing intellectual property rights and commercial secrets? The Core Group seeks to dynamically engage the broader genetics community to ensure wide acceptance of the best practices.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2202*. Is it time for a paradigm shift? Design and formative evaluation of a randomized clinical trial of the sequence of genetic counseling and testing to optimize efficiency, patient empowerment and engagement, and medical adherence for cardiovascular genetic testing indications (*RESEQUENCE-GC*).

Authors:

C. Pendleton¹, C. Applegate², C. Tichnell¹, B. Murray¹, B. Rivers¹, R. McClellan¹, E. Brown¹, A. Barth¹, L. Yanek³, C. Overby Taylor⁴, J. Day⁵, C. A. James¹; ¹Div. of Cardiology, Dept. of Med., Johns Hopkins Univ., Baltimore, MD, ²McKusick-Nathans Dept. of Genetic Med., Johns Hopkins Univ., Baltimore, MD, ³Div. of Gen. Internal Med., Dept. of Med., Johns Hopkins Univ., Baltimore, MD, ⁴Dept. of BioMed. Engineering, Johns Hopkins Univ., Baltimore, MD, ⁵Dept. of Art as Applied to Med., Johns Hopkins Univ., Baltimore, MD

Abstract Body:

Genetic test (GT) results are increasingly critical to medical management. Traditional pre-test genetic counseling (GC) may facilitate informed decision making but is a constrained resource. Post-test GC can be tailored to GT results and may be optimal for adults seeking guideline-directed GT. RESEQUENCE-GC is an NHGRI-funded 3-arm trial to evaluate 2 complementary approaches to shifting the primary GC session post-test for adults with a cardiovascular GT indication. Here we describe RESEQUENCE-GC design and formative evaluation. RESEQUENCE-GC participants are randomized to 1) pre-test GC (“standard of care” arm) or 2) a pre-test genetic education video with an optional (“efficiency” arm) or 3) required (“flipped” arm) call with their GC before GT. Results are returned by phone (1) or during post-test GC (2,3). Primary outcomes are patient empowerment, psychosocial well-being, medical adherence, and GC efficiency. Preparatory to the trial, animated pre-test genetic education videos are being developed using principles from the Cognitive Theory of Multimedia Learning, with iterative professional and patient stakeholder review. The video for cardiomyopathy or arrhythmia panel GT was tested with adults from the general population recruited via a usability testing company (UserHappy) and members of a patient support group (Hope for ARVD). Participants were emailed a questionnaire link that included measures of pre-genetic education knowledge [Genomics Knowledge Scale; pilot 8-item Multidimensional Model of Informed Choice (MMIC)], the video, engagement questions [User Engagement Scale (UES); 4 items measuring trust in the video content and comfort making a GT decision], and post-genetic education knowledge. Participants (N=48) were 54% male, 42% female, 4% non-binary; 36% Black, 52% White, 4% Asian, 8% Multiracial; and 31% age 18-34, 36% 35-44, 25% 45-54, 8% ≥55; similar to the RESEQUENCE-GC recruitment pool. They had high levels of knowledge and engagement post-genetic education, averaging 7.4/8±0.9 correct MMIC responses and a 4.14±0.5 UES score (range 1-5). Trust in genetic education and comfort making a GT decision were highly rated (4.61±0.7 and 4.48±0.73 respectively); particularly among support group members (4.84±0.4 and 4.6±0.8; N=16)]. In resource-constrained environments, models to efficiently provide GT education are crucial. Our findings suggest that our theory-driven and iterative strategy has produced pre-GT education videos that are both trusted and result in high comfort making a GT decision. This finding was particularly true for cardiovascular disease patients, the target population for RESEQUENCE-GC.

Leitsalu¹²; ¹Estonian Genome Ctr., Inst. of Genomics, Univ Tartu, Tartu, Estonia, ²Inst. of Molecular and Cell Biology, Univ Tartu, Tartu, Estonia, ³Estonian Genome Ctr., Inst. of Genomics, Univ Tartu, Tartu, Estonia, ⁴Inst. of Computer Sci., Univ Tartu, Tartu, Estonia, ⁵STACC, Tartu, Estonia, ⁶Inst. for Molecular Med. Finland, HiLIFE, Univ Helsinki, Helsinki, Finland, ⁷Inst. of Clinical Med., Univ Tartu, Tartu, Estonia, ⁸Family Med. Ctr. of Medicum, Tallinn, Estonia, ⁹Inst. of Mathematics and Statistics, Univ Tartu, Tartu, Estonia, ¹⁰Estonian Res. Council, Tartu, Estonia, ¹¹Tartu Univ. Hosp., Tartu, Estonia, ¹²Estonian Genome Ctr., Inst. of Genomics, Univ Tartu, Tartu, Estonia

Abstract Body:

The Estonian Biobank has over 200 000 individuals in the cohort, which is close to 20% of adult population of the country and one objective was, in addition to genomic research, to use the data for improving the public health. The whole biobank is genotyped, has longitudinal health data and finally we are moving towards the implementation of the genomic information in the healthcare. The return of individual genomic results (ROR) to research participants is still in its early phase, and insight into how individuals respond to ROR is scarce. Studies contributing to the evidence base for best practices are crucial before the latter can be established. Here, we describe a ROR procedure conducted at a population-based biobank, followed by surveying the responses of almost 3000 participants to a range of results, and discuss lessons learned from the process, with the aim of facilitating large-scale expansion. Overall, participants perceived the information that they received with counseling as valuable, even if the reporting of high risks initially caused worry. The face-to-face delivery of results limited the number of participants who received results. Although the participants highly valued this type of communication, additional means of communication need to be considered to improve the feasibility of large-scale ROR. The feedback collected sheds light on the value judgements of the participants and on potential responses to the receipt of genetic risk information. Biobanks in other countries are planning or conducting similar projects, and the sharing of lessons learned may provide valuable insight and aid such endeavours.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2204*. Low interest and high drop off in population genetic screening of adults: Results from a "real world" pilot study.

Authors:

N. Rao, J. Kaganovsky, S. M. Fullerton, A. T. Chen, B. H. Shirts; Univ. of Washington, Seattle, WA

Abstract Body:

Population genetic screening may identify individuals at risk for preventable hereditary cancers or hypercholesterolemia and potentially address disparities in genetic testing. Learning why people may or may not engage in population screening is important to assess the acceptability of this strategy and understand if it will lead to more equitable access. We sought to understand participation rates and decision-making about screening among a diverse cohort invited to participate in the University of Washington Medical Center's (UWMC) population genetic screening study.

This study invited adults unselected for medical history who have received care at the UWMC to participate in genetic screening for hereditary cancers and familial hypercholesterolemia between June 2020 and July 2021. Email invitations contained a link to a study FAQ describing risks and potential benefits. People had the option to participate in genetic screening and provide feedback about their reasons for participating in a series of surveys. Uninterested individuals could provide reasons for nonparticipation in a free text box prior to or after the initial survey. Participation trends were compared across demographic variables and reasons for participation or non-participation were evaluated using quantitative and qualitative methods.

A total of 40,855 people were invited to participate in the study, and 2,855 (7%) people returned signed consent forms and DNA samples. The average age of enrollees was 40 years old, and 60% were female. Participation rate was lowest among Black individuals (3.33%) and highest among Multiracial or Other Race/ethnicity identifying individuals (12.99%). Learning about disease risk and identifying risk early for prevention purposes were strong motivators for receiving screening. Compared to other participants, Asian participants considered knowing more about the test and test accuracy factors of greater importance during screening decision making. Analysis of 139 survey free text responses identified 3 themes related to nonparticipation: benefits do not outweigh risks, don't want to know, and challenges with study logistics.

Uptake of genetic screening in the UWMC study is low compared to screening studies among biobank participants. However, individuals contributing to biobanks may be more interested in research and genetic findings generally. Our study may more closely mimic implementation challenges and participation outcomes in a stand-alone genetic screening program among the general population and suggests strategies that could be pursued to enhance uptake in future screening programs.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2205. Masking for whole-exome sequencing data: An analysis of the impact of masking choices in rare coding variants association tests.

Authors:

T. Nguyen¹, R. Koesterer¹, O. Ruebenecker¹, A. Moriondo¹, Q. Hoang¹, D-K. Jang¹, J. Flannick²; ¹The Broad Inst. of MIT and Harvard, Boston, MA, ²Boston Children's Hosp., Boston, MA

Abstract Body:

Whole exome sequencing (WES) has emerged as a valuable counterpart to genome-wide association studies (GWAS) because it helps implicate causal genes via rare variants associations. However, there are many different annotation algorithms and many more ways to combine rare variants to perform filters, and there is no consensus on how the results of gene-level analyses depend on grouping strategies (i.e., masks). In this paper, we analyze the impact of masking choices on association results in WES studies by conducting SKAT and burden testing and downstream analyses for various traits. Our findings suggest that as variants get rarer, higher effect sizes are observed although they cannot overcome the lack of power; in addition, masks that are more lenient than loss of function produce more gene-level associations although they may be less biologically relevant. This implies the importance of using multiple masks to aggregate variants into genes to gain more insights into trait/gene associations and ultimately, disease biology.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2206. Medical genetics and genomics services *across the lifespan*: Patient and referral trends over 17 years at the Maritime Medical Genetics Service

Authors:

M. Mackley¹, S. Goobie^{2,3}, A. Alshammari⁴, A. Miller⁴, M. Ari^{4,5}; ¹Div. of Clinical and Metabolic Genetics, Dept. of Pediatrics, The Hosp. For Sick Children, Toronto, ON, Canada, ²Dept. of Pediatrics, Dalhousie Univ., Halifax, NS, Canada, ³Maritime Med. Genetics Service, IWK Hlth.Ctr., Halifax, NS, Canada, ⁴Dept. of Med., Dalhousie Univ., Halifax, NS, Canada, ⁵Div. of Endocrinology and Metabolism, Univ. of Toronto, Toronto, ON, Canada

Abstract Body:

Following diagnostic and therapeutic advances in genomics it is expected that patterns of access to medical genetics services have changed. Adult patients—with presentations and needs distinct from their pediatric counterparts—may be increasingly accessing genetics services. Presently, however, literature documenting patterns in access is lacking. Such information is essential to facilitate resource planning and improve care delivery to genetics patients, from prenatal through adulthood.

Maritime Medical Genetics Service (MMGS), in Halifax, Nova Scotia, Canada, is a comprehensive medical genetics service offering clinical and metabolic genetics care to patients of all ages. MMGS provides all genetics services to the three Canadian Maritime provinces, uniquely affording a complete picture of access in a discrete population of nearly 2 million. To understand how services have changed and to inform future care provision we undertook a quality improvement project where we retrospectively reviewed data collected on all patients referred to MMGS over a 17-year period (January 2002 and December 2019). To assess referral trends, patient demographic, referral source, and clinic data were extracted and subjected to descriptive analysis.

Over the 17-year period, a total of 43052 patient visits were documented, of which 27865 were new patient visits. Total clinic volumes increased steadily, with an average annual growth rate of 13.1%. The proportion of adult patients grew from 61.9% in 2002 to 73.3% in 2019, and the average age of new patients increased from 24.8 to 36.5. The clinic type that saw the most growth was cancer, making up 39.1% of new visits in the final year of data (compared to 12.5% in 2002). Of note, new visits referred from internal medicine and its subspecialties, including oncology, increased more than 3-fold over the study period—increasing from 4.9% to 16.2% of new visits. In contrast, conventional sources of referrals—family medicine, pediatrics, obstetrics and gynecology—contributed proportionally less to the referral volume over time.

This quality improvement study highlights that access to genetics services at our centre has changed, necessitating a reconceptualization in local care delivery. The increasing referral volume, as well as the trend towards increasing numbers of adult patients, highlights the need for new service delivery models, particularly for adult care. Greater consideration must be given to multidisciplinary disease-specific clinics, increased numbers of medical geneticists, expanded roles of genetic counselors and nurses, and greater empowerment of non-geneticists in the delivery of genetics services.

Abstract Body:

Rare diseases (RDs) affect over 30 million people in the EU and result quality-of-life limiting and life-threatening. The RDs diagnosis is challenging, due to a multitude of different symptoms and syndromes, low prevalence, and lack of general awareness. Altogether, this leads to a lengthy and burdensome path to diagnosis, severely delayed by a “diagnostic odyssey”. Lack of timely diagnosis affects disease management and identification of potential beneficial treatments and/or clinical trials. Indeed, less than 10% of RD patients have a treatment and only 1% take advantage from approved therapy in Europe. Since 72% of RDs are genetic and 70% have an exclusively paediatric onset, strategies for genetic newborn screening (NBS) are of pivotal importance, possibly representing a particular diagnostic “check point”. The EU-IMI Research Project Screen4Care (S4C) is an international public-private collaboration of 35 partners. The 5-year project focuses on accelerating diagnosis for RDs patients through two central pillars: genetic newborn screening (NBS) and artificial intelligence (AI)-based tools. The project will drive genetic NBS in about 20.000 infants in Europe, and will design innovative gene panel including treatable (TREAT-map gene panel) and actionable (ACT-map gene panel). Whole genome sequencing (WGS) is also planned in early symptomatic infants, tested negatively during NBS. The project includes a large landscape analysis on existing knowledge about NSB worldwide and will design new Artificial Intelligence (AI)-based algorithms to identify patients using Electronic Health Records (EHR) and to build a repository “*symptom checkers*” which will allow to design an “app” user friendly for patients and healthcare providers, to help self-diagnosis and referral pathways to physicians for diagnostic workup. S4C goals will be accelerating the time to RD diagnosis and treatment, and the establishing of a digital infrastructure for families and healthcare workers. *This project has received funding from the Innovative Medicines Initiative 2 Joint Undertaking (JU) under grant agreement No 101034427. The JU receives support from the European Union’s Horizon 2020 research and innovation programme and EFPIA (www.screen4care.eu)*

PB2208. Non-inferiority of letter versus telephone genetic counseling for negative exome-based cancer genetic test results disclosure in a historically underserved population.

Authors:

M. J. Gilmore¹, M. C. Leo¹, L. Amendola², K. A. B. Goddard¹, J. E. Hunter³, G. Joseph⁴, T. L. Kauffman¹, B. Rolf⁵, E. Shuster¹, J. Zepp¹, B. Biesecker⁶; ¹Kaiser Permanente Ctr. for Hlth.Res., Portland, OR, ²Univ. of Washington, Seattle, WA, ³RTI Intl., Research Triangle Park, NC, ⁴Univ California San Francisco, San Francisco, CA, ⁵Univ. of Washintgon, Seattle, WA, ⁶RTI Intl., Washington, DC

Abstract Body:

Scalable alternative delivery models for genetic counseling are needed to realize the promise of precision medicine and ensure broad and equitable access to these services. The Cancer Health Assessments Reaching Many (CHARM) study, as part of the Clinical Sequencing Evidence-Generating Research (CSER) consortium, prioritized the evaluation of genomic medicine implementation in historically underserved populations. We assessed whether a mailed letter (n=65) was non-inferior to phone genetic counseling (n=73) in informing participants, without a personal or family history of cancer, of their negative exome-based panel results. Participants recruited earlier in the study received results by phone, and participants recruited later in the study received results by letter. Using the CHARM definition for ‘historically underserved’ (non-White, Hispanic, low-income, low-education, Spanish-speaking, resident of medically underserved area, uninsured, or LGBTQ+ identity), 76% (105/138) of participants met this criteria. Data was collected via participant surveys - follow-up 1 (FU1) at 2-30 days after result disclosure, and follow-up 2 (FU2) at 5-7 months after result disclosure. Primary outcomes and non-inferiority margins were subjective understanding of results (75% ratio of means) and test-related distress using the FACToR (Feelings About genomiC Testing Results) measure (75% ratio of means). Secondary outcomes and non-inferiority margins were related to satisfaction (80% ratio of means). The satisfaction measures, assessed at FU1 only, included questions about mode of results delivery and if the “right amount of information” was provided at results disclosure. For subjective understanding of results, letter was inferior to phone at FU1 but was non-inferior at FU2. Letter was non-inferior to phone at FU1 and FU2 using FACToR (overall score). Letter was non-inferior to phone for satisfaction with mode of results delivery. Notably, letter was inferior to phone for having the “right amount of information” provided at results disclosure. The transient inferiority of a letter for subjective understanding may be acceptable for *a priori* low-risk individuals receiving negative test results, where there are not recommended health behavior changes. Limitations include a small sample size. Future applications of this alternative delivery model could explore increasing the amount of information provided in the letter. Our work provides evidence that a letter is acceptable in conveying genetic test results to *a priori* low-risk individuals in a scalable manner to allow for more equitable access to genomic medicine.

PB2209. Parents' attitudes towards return of results from genome sequencing research for their healthy children: A qualitative study

Authors:

C. Di Carlo¹, C. Mighton^{2,3}, M. Clausen², E. Joshi², S. Casalino², T. Kim¹, C. Kowal¹, C. Birken^{3,4}, J. Maguire¹, Y. Bombard^{1,3}; ¹Li Ka Shing Knowledge Inst., St. Michael's Hosp., Toronto, ON, Canada, ²Li Ka Shing Knowledge Inst., St. Michael's Hosp., Toronto, ON, Canada, ³Univ. of Toronto, Toronto, ON, Canada, ⁴The Hosp. for Sick Children, Toronto, ON, Canada

Abstract Body:

INTRO: With widespread genomic sequencing (GS) research efforts, there is increasing impetus to return individual results to research participants. Operationalizing return of results in a healthy paediatric population is complex, as parents face decision-making conflicts regarding the manner and to what capacity to receive their child's GS results. **AIM:** We explored parental attitudes and preferences towards their healthy children's participation in GS research, expectations for return of results, and the extent of involving their child in the process. **METHODS:** Parents with children enrolled in TARGeT Kids! were recruited for participation. TARGeT Kids! is a Canadian primary care research network where healthy children are followed longitudinally to obtain and return genomic data. Parents viewed a slide show on GS prior to semi-structured individual interviews exploring expectations for return and recontact of results, attitudes towards ownership of genetic information, and perceived utility of participation. Transcripts were coded by multiple members of the research team and analysed using thematic analysis and constant comparison. **RESULTS:** There were 26 parents interviewed; 20 were aged 30-39, 22 were female, 19 self-reported as White/European, and all were college or university educated. Parental perspectives of GS centred on three themes: (1) *Downstream impacts of testing*; Parents expressed concerns of genetic discrimination and unintentional differential treatment of their child, while acknowledging clinical utility of GS with provider support. (2) *Reciprocity*; Parents preferred to receive medically actionable, childhood onset results at minimum, with the expectation to be recontacted overtime with reclassifications. (3) *Power and empowerment*; Some parents felt empowered to learn and take preventative action for their child and relatives if presented with the opportunity. Other parents felt hesitant with the decision-making power on behalf of their child, expressing concerns regarding child autonomy. **CONCLUSION:** Parents focus on downstream impacts, reciprocity and power dynamics when considering their healthy child's participation in a GS research study. Incorporating these themes in patient-facing engagement materials can optimize research and promote participation centred on the needs and expectations of parents and caretakers.

PB2210*. Partnering with patients to explore the psychosocial and socioeconomic impacts of hereditary cancer syndromes

Authors:

H. Etchegary¹, J. Sam², M. Clausen², D. Bishop³, J. Pauling⁴, C. Pavao⁵, C. Remocker⁵, T. Tiano³, A. Tilley³, C. Mighton⁶, S. Rajeziessfahani¹, R. Gopalakrishnan², M. Aronson⁷, L. Dawson¹, A. Eisen⁸, T. Graham⁹, J. Green¹⁰, M. Krahn¹¹, S. Savas¹², N. Stjepanovic², S. Sun¹³, K. Thorpe⁶, K. Schrader¹³, Y. Bombard⁶; ¹Mem. Univ., St. John's, NL, Canada, ²St. Michael's Hosp., Toronto, ON, Canada, ³Patient Partner, St. John's, NL, Canada, ⁴Patient Partner, Toronto, ON, Canada, ⁵Patient Partner, Vancouver, BC, Canada, ⁶St. Michael's Hosp. & Univ. of Toronto, Toronto, ON, Canada, ⁷Zane Cohen Ctr., Sinai Hlth.System, Toronto, ON, Canada, ⁸Sunnybrook Hlth.Sci. Ctr., Toronto, ON, Canada, ⁹Univ. of Toronto & Sunnybrook Hlth.Sci. Ctr., Toronto, ON, Canada, ¹⁰Mem. Univ., St. John's, NL, Canada, ¹¹Univ. of Toronto & Univ. Hlth.Network, Toronto, ON, Canada, ¹²Mem. Univ., St. John's, ON, Canada, ¹³BC Cancer, Vancouver, BC, Canada

Abstract Body:

Background: Patient oriented research aims to improve patient outcomes and the quality of research by focusing on patient-identified priorities and engaging patients as partners. To date, methods for meaningful patient engagement and the role of patient partners in genomics health research are not well described. **Aim:** To describe the engagement of patient partners in a large team grant in Canada exploring the economic and psychosocial impacts of hereditary cancer syndromes (HCS). **Methods:** Six patient partners from 3 provinces with a hereditary breast and ovarian cancer syndrome or Lynch syndrome were recruited from team members' networks. Regular meetings among study PIs, staff and patient partners provide consistent communication and co-development opportunities. **Results:** Patient partners were invited to engage across all phases of the study: reviewing the grant application, co-developing the study design and materials, and ultimately assisting with recruitment, data analysis, and knowledge dissemination. Offering choice in level of involvement is best practice for patient engagement and has been appreciated by patient partners as affording them flexibility around their contributions. Patient partners meet quarterly with the study team, with email communication in between, to provide feedback on study design and materials. Opportunities to review study material on their own time allows for equitable involvement when attending meetings is not always feasible. As this study involves qualitative interviews and data collection about sensitive topics (e.g., cancer journey, emotional & financial impacts), patient partners' lived experiences have informed study materials. To date, patient partners provided feedback on the content and length of interviews, probing questions, and the language to be used. Feedback on early iterations of the interview guide revealed a bias towards negative language about the impact of HCS. Partners reminded the team that there were positive impacts as well and cautioned about the use of exclusively negative language (e.g., 'burdens'). Patient partners also took part in mock interviews to finalize the interview guide and provide a training opportunity for students and study staff. **Conclusions:** To date, patient partners provided important insights on the study population and methods. Their role reflects true research co-development. Ultimately, our aim is to build a rigorous patient oriented research program in hereditary cancers, informed by patient voices, from which lessons learned are shared and the care of families affected by HCS is improved.

PB2211. Patient reported utility of cancer results from genomic sequencing.

Authors:

S. Shickh^{1,2}, M. Clausen², C. Mighton^{1,2}, E. Adi-Wauran^{1,2}, D. Hirjikaka², R. Kodida², S. Krishnapillai^{2,1}, E. Reble², J. Sam², N. Baxter^{3,4,5}, A. Laupacis⁶, Y. Bombard^{2,1,7}; ¹Inst. of Hlth.Policy, Management and Evaluation, Univ. of Toronto, Toronto, ON, Canada, ²Genomics Hlth.Services & Policy Res. Program, Li Ka Shing Knowledge Inst. of St. Michael's Hosp., Unity Hlth.Toronto, Toronto, ON, Canada, ³Univ. of Melbourne, Melbourne, Australia, ⁴Li Ka Shing Knowledge Inst., St. Michael's Hosp., Unity Hlth.Toronto, Toronto, ON, Canada, ⁵Dept. of Surgery, Univ. of Toronto, Toronto, ON, Canada, ⁶Univ. of Toronto, Toronto, ON, Canada, ⁷Ontario Inst. for Cancer Res., Toronto, ON, Canada

Abstract Body:

Background Genomic sequencing (GS) holds great promise to improve clinical utility for patients with suspected hereditary cancer syndromes (HCS), most of whom remain undiagnosed after standard panel tests. Although GS may increase HCS detection, it also generates a large volume of non diagnostic results (e.g., variants of uncertain significance; VUS), whose impact on patients is largely unknown. This limits our understanding of all possible benefits and harms of GS and the evidence available for adoption and reimbursement decisions.

Aim Explore patient-reported utility of cancer GS results, including primary and secondary VUS and low/moderate risk results.

Methods A qualitative interpretive description study, using semi-structured interviews with patients who received GS for cancer as part of the Incidental Genomics Trial. Thematic analysis employing constant comparison was used. Two coders coded transcripts, with use of a third coder to resolve conflicts.

Results Twenty-five patients participated, most of whom were female (22), >50 years (18), European or Ashkenazi Jewish (17) with breast cancer (20), and who received a variety of results including: primary & secondary VUS and pathogenic low/moderate risk variants. Patients were initially disappointed or relieved about their results but ultimately focused on clinical utility, which they described as clear follow up plans, frequent surveillance and follow up by a specialist. Their focus on clinical utility was driven by the type of GS result received. For example, when patients were provided with clear clinical actions for low/moderate risk findings, they perceived the results to be very “useful” and “reassuring” and of moderate-high utility. In contrast, when receiving low/moderate risk results or primary VUS without clear clinical follow up, patients perceived results as “concerning”, leading to potential harms such as anxiety or vigilance about cancer symptoms. Lastly, patients receiving secondary VUS interpreted their results as “negative” and not requiring any additional clinical follow up, and therefore they began to refocus on other aspects of their life and “move forward”. Overall, having a supportive family or primary care provider enhanced perceptions of utility while unsupportive families or providers diminished utility.

Conclusion From patients’ perspectives, GS for cancer may add limited utility and potentially cause harms. These findings of preliminary experiences of harms and limited utility warrant further evaluations in addition to practice interventions to support patients receiving low/moderate risk results and primary VUS from GS.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2212. Patterns and barriers to clinical trial participation for patients with primary mitochondrial disease: A survey of patients/caregivers, physicians, and pharmaceutical industry professionals.

Authors:

M. Windrem¹, P. E. Yeske², J. M. Ridgway³, A. Karaa⁴, **M. DiMatteo**¹; ¹Stealth BioTherapeutics, Needham, MA, ²United Mitochondrial Disease Fndn., Pittsburgh, PA, ³Bruno and Ridgway Res. Associates, Lawrenceville, NJ, ⁴Genetics Div., Massachusetts Gen. Hosp./Harvard Med. Sch., Boston, MA

Abstract Body:

Objective: Clinical trial recruitment is challenging, especially for rare, genetic disorders. Clinical research fails to attract the necessary level of clinical trial participation due to multiple factors. We conducted a study to better understand reduced participation in clinical trials among mitochondrial disease patients/caregivers, physicians, and industry professionals. **Methods:** Mitochondrial disease patients or caregivers, physicians treating patients with mitochondrial disease and being involved as an investigator in at least one clinical trial, and pharmaceutical industry professionals were invited via email to participate in a survey. The surveys were conducted from May 4-16, 2022. Interview topics for each group included discussion regarding clinical trial participation and recruitment as well as perceived barriers to participation in clinical trials. Results were compared between the groups. **Results:** A total of 207 surveys were completed (n=170 patients/caregivers, n=20 physicians, n=17 industry professionals). At least one clinical trial was recommended by a physician to 39% of patients surveyed, primarily being recommended by a neurologist (46%) or a geneticist (27%). Of patients surveyed, 29% participated in a clinical trial. Most physicians (85%) reported frequently recommending clinical trials for their patients. Physicians reported that most patients were either very (50%) or somewhat (35%) receptive to clinical trials. Industry professionals reported that most patients are very (23%) or somewhat receptive (59%) to participating in clinical trials. Various reasons exist for the different levels of perceived receptiveness. Travel/transportation was a common theme across all three groups as a leading barrier to patients participating in clinical trials. Other leading barriers agreed upon by more than one group included: trial site availability; not knowing how to find clinical trials; no time to participate; and not likely to qualify. **Conclusions:** Mitochondrial disease patients/caregivers, physicians, and pharmaceutical industry professionals indicate similar barriers to clinical trial participation. Increased understanding of such barriers may assist in improving clinical trial awareness and enrollment for patients with mitochondrial diseases.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2213. Personal utility in genomic medicine: what is it and can we measure it?

Authors:

E. Turbitt¹, J. Kohler², F. Angelo³, I. Miller⁴, K. Lewis⁵, K. Goddard⁶, B. Wilfond⁷, B. Biesecker⁸, M. Leo⁹; ¹Univ. of Technology Sydney, Ultimo, Australia, ²Stanford Med., Palo Alto, CA, ³Northwestern Univ., Seattle, WA, ⁴Children's Natl., Washington DC, DC, ⁵NIH, Bethesda, MD, ⁶Natl. Cancer Inst., Bethesda, MD, ⁷Seattle Children's Res. Inst., Seattle, WA, ⁸RTI Intl., Bethesda, MD, ⁹Kaiser Permanente Ctr. for Hlth.Res., Portland, OR

Abstract Body:

Rationale: It is important to understand the benefits of a medical test, as defined by those undergoing testing and receiving results. Genomic test results do not always provide information that is medically actionable. Yet, end users report benefits from receiving genomic information even if medical actions are not indicated. The ability to assess this personal utility in genomic medicine relies on a validated, patient-defined outcome measure, which is currently lacking. We aimed to construct and psychometrically evaluate a measure of personal utility - the PrU.

Methods: We used an evidence-based, operational definition of personal utility, with data from a systematic literature review and Delphi survey. This definition formed the basis from which we developed 24 items for the PrU. We piloted the PrU with 24 adults enrolled in a genome sequencing research study. The results from this pilot along with expert recommendations led to a revised PrU consisting of 17 items. We administered the PrU to adults enrolled in one of two Clinical Sequencing Evidence-Generating Research (CSER) studies after receiving genomic results ($n=841$).

Results: Most respondents were female (77.2%), educated to some post-high school or beyond (73.6%), and identified as White (37.7%), Black (28.5%), and/or Hispanic/Latino (21%). A principal-axis factor analysis suggested a three-factor solution, accounting for 66% of the variance in the items. Using the items as a guide, we labeled the three factors “self-knowledge and control” ($\alpha=.94$), “reproductive planning” ($\alpha=.89$), and “practical benefits” ($\alpha=.87$).

Conclusions: We provide strong initial evidence for the reliability and validity of three subscales of personal utility valued by adults who receive genomic test results that converge on the broader central concept of personal utility. The PrU is designed to measure the personal utility people report from receiving genomic information. Further validation of the scale in other contexts is required. The ability to measure the dimensions of utility in genomic medicine contributes to understanding patient experiences and guiding the implementation of genomics in clinical care.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2214. Population DNA screening for medically actionable conditions in young adults: The DNA Screen national pilot study

Authors:

P. Lacaze¹, J. Tiller¹, I. Winship², The DNA Screen Investigator Group; ¹Monash Univ., Melbourne, Australia, ²Royal Melbourne Hosp., Melbourne, Australia

Abstract Body:

Population DNA screening for medically-actionable conditions in early adulthood has the potential to enable timely prevention, early detection and treatment of cancer and heart disease. For medically-actionable genomic conditions such as hereditary breast and ovarian cancer (HBOC), Lynch syndrome (LS) and familial hypercholesterolemia (FH), pathogenic germline DNA variants confer high risk of developing future disease, and can be used to prompt risk management and family cascade testing. Population DNA screening for these conditions could thereby identify medically actionable genetic risk factors early, enabling timely risk-management and informed decision making, to facilitate early detection or prevention, and realise the preventative potential of genomics. Despite this opportunity, diagnostic rates for these conditions remain low, limited by restricted access to genetic testing and lack of awareness. Offering preventive DNA screening to healthy adults through a national healthcare system, with minimal or even no testing criteria using a low-cost DNA screening test, has the potential to save thousands of lives and achieve healthcare savings - if it can be delivered responsibly, cost-effectively and at scale. In Australia, a national pilot study of 10,000 adults aged 18-40 years has been funded by the Australian Government's Genomic Health Futures Mission, and begins recruitment in mid-2022. The DNA Screen national pilot study has been designed specifically to answer key implementation questions and address socio-ethical challenges associated with population DNA screening. This presentation will cover various aspects of the DNA Screen study, including: the purpose-built prospective study design; social-media driven recruitment strategy; scalable DNA screening test and assay; telehealth genetic counselling and return of results process; downstream clinical support pathways; policy, implementation and cost-effectiveness aspects; and integration into the national healthcare system. The DNA Screen pilot study is positioning Australia to take a world-first step towards offering preventive DNA screening through a national healthcare system.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2215. Predictors and Trends in Cancer Genetics Clinic Attendance Rate After the Adaptation of Telemedicine During the COVID-19 Pandemic

Authors:

A. Smullin, P. Flodman, D. Nathan, M. Smith; UC Irvine, Irvine, CA

Abstract Body:

Despite the clear benefit of cancer genetic counseling, many eligible patients never meet with a cancer genetic counselor. Several elements contribute to this, including the growing demand for genetic services, lack of genetic professionals, and patient non-attendance. Prior research in cancer genetic counseling and other medical specialties has investigated the use and outcomes of alternate service delivery models, however, little is known about the specific impact of telemedicine on patient attendance over a substantial period of time. This study analyzed demographic and clinical data from 800 adult patients seen for cancer genetic counseling before and after the adaptation of telemedicine during the global COVID-19 pandemic. The purpose of this research was to investigate telemedicine's impact on attendance rate at follow-up appointments as well as explore patient predictors of attendance status. Logistic regression analyses identified that patients were 3.54 times more likely to attend their first scheduled follow-up visit if they were in the telemedicine cohort ($p < 0.001$). Additionally, patients who had more relatives with cancer and patients of Asian descent were more likely to attend their first follow-up visit. Patients were less likely to attend their first scheduled follow-up visit if there was a greater amount of time between their initial appointment and their genetic test results report date. This research builds upon current literature on attendance status and contributes novel findings on the scope and impact of telemedicine's role in increasing attendance and access to cancer genetic counselors. Recognizing and understanding telemedicine's positive outcomes may lay the foundation for the adoption and permanence of this service delivery model in the cancer genetic counseling setting.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2216. Preferences of parents from diverse backgrounds on genomic screening in newborns.

Authors:

J. Omorodion^{1,2,3}, C. Hsu⁴, G. Rivera-Cruz^{1,5}, M. del Rosario⁵, S. Pereira⁶, S. Ziniel⁷, I. Holm^{5,8}, N. Gold^{8,9}; ¹Harvard Med. Sch. Genetics Training Program, Harvard Med. Sch., Boston, MA, ²Boston Combined Residency Program, Dept. of Pediatrics, Harvard Med. Sch., Boston, MA, ³Boston Combined Residency Program, Dept. of Pediatrics, Boston Univ. Sch. of Med., Boston, MA, ⁴Ctr. for Bioethics, Harvard Med. Sch., Boston, MA, ⁵Div. of Genetics and Genomics, Boston Children's Hosp., Boston, MA, ⁶Ctr. for Med. Ethics and Hlth. Policy, Baylor Coll. of Med., Houston, TX, ⁷Dept. of Pediatrics, Univ. of Colorado Sch. of Med., Aurora, CO, ⁸Dept. of Pediatrics, Harvard Med. Sch., Boston, MA, ⁹Div. of Med. Genetics and Metabolism, Massachusetts Gen. Hosp. for Children, Boston, MA

Abstract Body:

Newborn screening (NBS) is a long-running and successful public health initiative which has improved morbidity and mortality in infants with a range of rare disorders. The current Recommended Uniform Screening Panel specifies 35 core conditions that are suggested for inclusion in each state's NBS program. As genomic testing modalities and therapies for genetic diseases have expanded, a larger scope of disorders have been considered for NBS. Parents are key stakeholders in expanding NBS. Previous studies that have examined parental attitudes towards genomic sequencing have been largely limited to white, highly-educated populations. If genomic sequencing is to be implemented in an ethical and just manner, however, it is crucial that the perspectives of parents from a broad range of backgrounds are included. We conducted a series of semi-structured interviews and focus groups with parents from varying racial, ethnic, and socioeconomic backgrounds, which focused on several themes that may be relevant to future policymaking in NBS, including preferences regarding which genetic disorders to screen, coping with the uncertainty of genetic test results, data privacy, and barriers to pursuing follow-up care. Overall, 20 interviews (15 in English, 5 in Spanish) and 5 focus groups (4 in English, 1 in Spanish) were conducted. Emerging themes have included enthusiasm for expanded newborn screening, an appreciation for the nuances of variants of uncertainty and low penetrance disorders, and interest in shared ownership of the genetic data with the child's pediatrician. We are hopeful that by eliciting parental attitudes towards expanded newborn screening from a diverse population, and then using this data to inform its implementation, there will be maximal participation and benefit to children and families.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2217*. Priorities to promote participant engagement in cancer genomics research: A report from the Participant Engagement and Cancer Genome Sequencing (PE-CGS) Network

Authors:

Abstract Body:

Background: Engaging diverse populations in cancer genomics research is of critical importance and is a fundamental goal of the National Cancer Institute (NCI) Participant Engagement and Cancer Genome Sequencing (PE-CGS) Network. The Network sought to identify research priorities in participant engagement for the Network and strategies to address these priorities, and where possible bring medical benefit. **Methods:** The Network conducted a four-phase process with affiliated stakeholders to identify research priorities and associated strategies. The process comprised: (1) an online survey to elicit potential priorities; (2) a two-day virtual meeting, including participants and advocates from each Research Center to discuss and vote on priorities; (3) recommendations from PE-CGS External Advisory Panel to refine priorities; and (4) a one-hour virtual meeting to rank priorities and identify strategies. **Results:** Nearly 150 Network-affiliated stakeholders were engaged in the process, including clinicians, scientists, genetic counselors, funders, and patient/community representatives and cancer advocates. Six priorities in order of importance were: (i) tailor education and communication throughout the research process; (ii) identify measures of engagement; (iii) identify optimal engagement strategies; (iv) understand cancer disparities in the context of cancer genomics research; (v) personalize the return of genomics findings; and (vi) consider ethical, legal, and social implications of genomics research and participant engagement. Six associated strategies to support meaningful coordination and cooperation were: leverage Network infrastructure; develop shared models of knowledge; establish subcommittees; hold Network-wide “All Hands” meetings; securely share data and materials; and standardize and harmonize data. **Discussion:** The Network is actively pursuing these research priorities by implementing the associated strategies that support meaningful coordination and cooperation to bring direct benefit to our patients. These efforts harness the collective strengths of all Network stakeholders and position the Network to generate discoveries that advance the science of engagement in cancer genomics research.

PB2218*. Prioritizing Research in Newborn Screening: Tools from the Newborn Screening Translational Research Network

Authors:

J. Taylor, K. Chan, Y. Unnikumaran, G. Tona, C. Lorkovic, M. Lietsch, A. Brower; American Coll. of Med. Genetics and Genomics, Bethesda, MD

Abstract Body:

As advances in science and technology provide treatment options for genetic conditions, the number of diseases that could be included in newborn screening (NBS) continues to grow. A variety of stakeholders have led efforts to develop the evidence to expand NBS. A federal advisory committee reviews conditions that are nominated and evaluate the evidence of feasibility to screen and a net benefit of early identification and intervention. The increasing use of genomics and gene-targeted therapies has led to a large pipeline of conditions that are candidates for newborn screening. There are several efforts such as the Clinical Genome Resource (ClinGen) that curate the clinical relevance of genes and variants that are clinically actionable through the use of data standards and evidence frameworks. Using these efforts as a model, we developed a process for evaluating conditions that are candidates for newborn screening. We describe the process for identifying conditions, the evidence gathered to evaluate conditions and the process for prioritizing conditions that have a high potential to be nominated to the recommended uniform screening panel (RUSP). An initial list of candidate conditions was developed with a questionnaire sent to subject matter experts that included the name of the condition, analytical method, second-tier test, and available treatment(s). In 2021 NBSTRN updated the approach in consultation with the Pilot Research & Implementation Workgroup to include additional sources for identifying candidate conditions. The information about each condition was expanded to include information about research and pilot studies, incidence rates, and advocacy groups. The list was then prioritized by including criteria such as understanding of the condition (severity/urgency) test efficacy, and treatment efficacy. The new method has identified 71 conditions that are candidates for newborn screening, 21 conditions are currently a part of NBS state panels, 19 conditions may be detected in the differential diagnosis of current RUSP conditions, and 7 conditions have been nominated for addition to the RUSP. NBSTRN will continue to evaluate the evidence for NBS conditions and propose strategies to evaluate changes and improvements to NBS expansion. In conclusion, NBSTRN created a process to help researchers identify diseases for the discovery of screening, diagnostic, and therapeutic advancements. Information about these conditions can be found in the Newborn Screening Conditions Resource (NBS-CR), an interactive tool that is available online at <https://nbstrn.org/tools/>.

Hosp., Dijon, France, ³Genetics Dept., Reference Ctr. for Dev.al Disorders, HCL, Bron, France, ⁴Clinical Psychology Lab., Psychopathology, Psychoanalysis (EA4056, ED 261), Univ. of Paris, Sorbonne Paris City, Paris, France, ⁵CIC 1432 Module Épidémiologie Clinique, Université de Bourgogne, Dijon, France, ⁶Lab. of Sociology and Anthropology (LaSA, EA3189), Univ. of Burgundy Franche-Comté, Besançon, France, ⁷Genetics Dept., Reference Ctr. for Hereditary Cardiac Disorders, GH APHP, Paris, France, ⁸INSERM U1028, CNRS UMR5292, CRNL, GENDEV Team, Univ. of Claude Bernard Lyon 1, Bron, France, ⁹Genetics Dept., Reference Ctr. for Dev.al Disorders, GH APHP, Paris, France, ¹⁰Inst. of myology, GH APHP, Paris, France

Abstract Body:

The development of next generation sequencing improves the primary diagnosis but can reveal additional information (incidental findings or secondary findings (SF)). The search for secondary findings raises debates among geneticists. Faced with the contradictions in the recommendations of American and European learned societies, a national study has been set up to contribute to the evolution of French recommendations.

Our study was deployed during 18 months in 3 French reference centers for developmental diseases. Patients/parents who have undergone exome sequencing have been asked their choice to access to SF on themselves or their children for 3 categories (group 1 late onset actionable diseases, group 2 genetic counselling, group 3 pharmacogenetics)

Using a mixed, qualitative and quantitative, method, we included 344 patients or parents of children with undiagnosed developmental disorders. We studied the initial perception, the repercussion of the results at the time of the return, at 6 months and 12 months after the return via questionnaires designed for our study, and standardized scores of anxiety and depression completed. Furthermore, semi-directed interviews allowed us to deepen the impact of the results.

80% of the parents accepted the search for SF in their child, and we showed an influence of the medical discourse on the parents' choices. 52 SF were returned to 47 families, 44 families completed the questionnaires at the time of return and 38 and 39 at 6 months and 12 months. 26 families were interviewed. We show that the return of the SF has no impact on the parameters studied but the semi-directed interviews showed that the individual situation could be very different, and distress can exist. The follow-up interviews up to one year did not show regrets, but it was not without any psychological impacts in group 1.

The degree of anxiety and anguish is correlated with the nature of the result and the life context of the subjects concerned. This study highlights the importance of an interdisciplinary team to accompany this type of opportunistic presymptomatic diagnosis, the effects of which are difficult for parents to anticipate, especially since their main motivation remains the search for an etiological diagnosis of their child's disorders and potential actionability.

ASHG 2022 Annual Meeting Poster Abstracts

Our study confirms the limited impact of secondary findings reporting on patients' anxiety and quality of life.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2220. Q-A sequences in prenatal genetic counseling in Japan; conversation analytic study of NIPT and NT consultations

Authors:

M. Kawashima¹, H. Maeda², K. Horike³, A. Hayashi³, A. Tachibana³, M. Morine³, K. Hinokio³, T. Iwai⁴, K. Maeda⁴, N. Okamoto⁵, A. Kondo⁴; ¹Kyoto Sangyo Univ., Kyoto, Japan, ²Rikkyo Univ., Tokyo, Japan, ³Prenatal Med. Ctr., Shikoku Med. Ctr. for Children and Adults, NHO, Zentsuji, Japan, ⁴Med. Genetics Ctr., Shikoku Med. Ctr. for Children and Adults, NHO, Zentsuji, Japan, ⁵Osaka Women s and Children s Hosp., Izumi, Japan

Abstract Body:

Genetic counseling should be precisely tailored based on the clients' perspectives and understanding, especially when clients face serious and important decision-making. Genetic counselors are tasked with providing ample information and support for clients especially in cases like nuchal translucency (NT). This study focuses on question-answer (Q-A) sequences in prenatal genetic counseling by comparing noninvasive prenatal genetic testing (NIPT) and NT cases. Previous studies have examined linguistic strategies for establishing the supportive and non-coercive stance of genetic counselors, which enhance clients' autonomy in counseling (Sarangi & Clark 2002; Sarangi 2000). This study resides in the similar stream using conversation analysis to elucidate details of interactions based on 12 video-recordings. The recordings took place in a tertiary hospital in Japan and all genetic counseling was done by registered clinical geneticists (CGs) at this hospital. General medical encounters are quite structured with an opening/problem, presentation/history, taking/physical exam/diagnosis/treatment, and recommendation/closing (Heritage & Maynard 2006). However, we found that prenatal counseling is structured through Q-A sequences to fit with the client's knowledge and perspective. There are three major findings. First, both NIPT and NT cases involved Q-A sequences before information giving to gather clients' previous knowledge and stance toward screening tests. In NIPT cases, the CG starts with inquiries on intention for testing and previous understandings about NIPT. In NT cases, the CG starts with unpacking results from ultrasounds and asks questions on clients' perspectives and understandings. Second, especially in NT cases, both information giving and decision-making activities are sequentially initiated by clients' questions. During the CG's explanations, clients frequently ask questions on certain parts. The CG uses that occasion to include additional information, which are tailored to the client's stance and knowledge level. Third, the clients' questions are initially concerned on the given information. Clients then move to focus on decision-making autonomously in the later part. The CG can advance the decision-making process by including recommendations within the slot of answers regarding the screening test as well as based on the attitude and stance that clients can take to make a decision in the future. Through the Q-A sequences, the genetic counseling providers and clients are engaged in establishing relationships trustworthy enough to reach a decision about screening tests in prenatal genetic counseling.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2221. Raising Genetic Disease Awareness: NBSTRN Efforts to Leverage Social Media to Realize the Promise of Genomics

Authors:

Y. Unnikumar¹, K. Chan², R. Wiebenga³, G. Tona⁴, E. Wilson¹, H. Weiss¹, M. Hartnett¹, A. Brower⁵; ¹American Coll. of Genetics and Genomics, Silver Spring, MD, ²American Coll. of Med. Genetics and Genomics, Bethesda, MD, ³Newborn Screening Translational Res. Network, DELL RAPIDS, SD, ⁴NBSTRN, Bethesda, MD, ⁵American Coll. of Med. Genetics and Genomics, Dakota Dunes, SD

Abstract Body:

Social media has transformed genetics and genomics research by facilitating the global exchange of ideas among individuals impacted by disease with the researchers. This rapid transmission of information has the potential to dramatically raise awareness of newborn screening (NBS) and empower advocates to work with researchers to realize the promise of genomics to screen, diagnose, and treat babies. To realize the promise of genomics and advance NBS research, a diverse network of researchers, health professionals, families and advocacy groups, and state NBS programs need to have a mechanism to connect, collaborate and communicate the most relevant and cutting-edge research and knowledge. The Newborn Screening Translational Research Network (NBSTRN) has facilitated this new partnership, collaboration, and capacity building through the use of social media. The NBSTRN created a four-stage process of disseminating research efforts and increasing genetic disease awareness: 1) outreach, 2) engagement, 3) membership, and 4) awareness. In the Stage 1 (Outreach), NBSTRN uses website, social media, podcast, and publications; in stage 2 (Engagement), NBSTRN uses experts in their workgroup and the co-creation of data tools and resources, in Stage 3 (Membership), NBSTRN uses a forum platform to engage with stakeholders, and in Stage 4 (Awareness), NBSTRN provided specialized consultation services for grant applications, publication and study design. As of June 2022, the NBSTRN represents over 194 institutions from around the world, including 51 academic institutions, 45 for-profit institutions, 6 governmental agencies, 34 international institutions, 38 state programs, and 29 health care systems. In less than a year since conception, the Newborn Screening SPOTlight podcast has reached over 38 countries with over 1,100 episodes downloads. We will highlight the impact of NBSTRN social media awareness campaigns have made on severe combined immunodeficiency (SCID) and spinal muscular atrophy (SMA). This poster will share strategic approach using the four-stage process to engage with different stakeholders, lessons learned and unlearned in engagement activities on the different social media channels, and impact made on raising awareness of rare disease conditions. These efforts serve as an important model of how research initiatives can leverage social media to advance genomics and improve the health of all individuals with genetic disease.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2222. Real-world implementation of an efficient germline Point-of-Care Testing model in a multidisciplinary cancer center.

Authors:

K. Schaffer^{1,2}, E. Watkins³, P. Hurley^{1,2}, K. Moses⁴, M. Donahue⁴, K. E. Beckermann^{1,2}, N. Davis^{1,2}, K. K. Ancell^{1,2}, B. Park^{1,2}, T. Pal^{1,2}, K. F. Mittendorf¹, K. Lang^{1,2}, G. L. Wiesner^{1,2}; ¹Vanderbilt-Ingram Cancer Ctr., Vanderbilt Univ. Med. Ctr., Nashville, TN, ²Dept. of Med., Vanderbilt Univ. Med. Ctr., Nashville, TN, ³Vanderbilt Univ. Sch. of Med., Nashville, TN, ⁴Dept. of Urology, Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract Body:

Background: National guidelines recommend germline genetic testing for many cancers given the potential for precision therapy. Traditionally, patients see a genetic counselor (GC) for counseling and testing. NSGC has reported that a full-time cancer GC provides pre-test counseling for 10 new patients per week. Thus, limited GC availability and increasing volume of patients can delay testing and precision therapies. To address this barrier, the Vanderbilt-Ingram Cancer Center developed a novel genetic counseling and point-of-care testing (POCT) model to streamline the process. We describe a POCT pilot for patients with genitourinary (GU) cancers.

Methods: In conjunction with the Vanderbilt Hereditary Cancer Clinic (HCC), POCT protocols were developed outlining germline testing processes in medical oncology (MO) and urologic oncology (UO) clinics including patient identification, education, orders, and lab processing. Samples were sent to a national reference lab for hereditary cancer panel testing. Oversight of the program was done by a HCC GC and oncology clinicians from MO and UO. These champions were responsible for implementation, ensuring appropriate follow-up, and developing a POCT database to track results. Patients were provided a previously validated online interactive educational video focused on inherited cancer predisposition and following receipt of test results, were offered HCC referral to discuss results.

Results: POCT germline testing was completed on 356 patients with GU malignancies from April 2020 to April 2022. The majority (336; 94%) had prostate cancer, 14 (4%) had urothelial carcinoma or renal cell carcinoma, and 6 (2%) had >1 GU malignancy. 319 (98%) were male, mean age was 66 (37 - 90), 305 (86%) were White, 43 (12%) Black, 8 (2%) Other; 337 (95%) Non-Hispanic. MO completed testing for 161 (45%), UO for 115 (32%), and a multidisciplinary team for 80 (22%). Pathogenic or Likely Pathogenic variants were identified in 39 patients (11%); of these 22 (56%) had therapeutic implications and 17 (44%) accepted post-test counseling. Compared to the NSCG report, the completed tests are equivalent to 74% of a GC annual workload.

Conclusions: This pilot demonstrates the feasibility of a streamlined, multidisciplinary germline POCT model. The essential elements include designated clinician champions, coordination of POCT with other visits, and online patient education tools. The POCT model dramatically improved access to germline testing for patients undergoing cancer care, allowed patients with eligible variants to receive precision therapies, and identified those needing additional screening or cascade testing for family members.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2223. Rethinking general consent for stem cell-based embryo model research

Authors:

B. Mittleman; Stanford Univ., Stanford, CA

Abstract Body:

Advances in stem cell research now allow us to create embryo models outside the womb from stem cells originally derived from human skin. The models provide novel opportunities to understand human development, fertility, and genetics, yet bring potential ethical and legal challenges. Current ethical and legal work centers on the moral status of embryo models but no one has evaluated the complexity the new research adds to the relationship between researchers and biological material donors or between donors and the research. I argue the use of previously collected biological material for stem-cell based embryo models open novel ethical and legal concerns. Broad consent models take autonomy away from research participants in a morally controversial area of research. Current common law property doctrine would not apply easily to a dispute over stem-cell based embryo models and current statutes do not protect aggrieved research participants. This work outlines an inform consent structure for stem-cell based embryo model research that considers both research participant autonomy and possibilities for future innovation. I advocate for researchers to apply dynamic consent in their research by collecting new biological material and investing in continued relationships with donors.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2224. Return of secondary genomic findings: Experiences of sickle cell disease research participants.

Authors:

J. Floyd¹, A. Buscetta¹, G-A. Fasaye², V. Bonham¹; ¹Natl. Human Genome Res. Inst., Bethesda, MD, ²Natl. Cancer Inst., Silver Spring, MD

Abstract Body:

While the body of research investigating research participants' views on the return of actionable secondary genomic findings results (RoR) grows, there has been limited study of individuals who are living with a chronic genetic condition, such as sickle cell disease (SCD). People with SCD have historically faced discrimination and difficulty accessing treatments for their condition, which can potentially be compounded when seeking additional healthcare downstream due to RoR. As RoR is increasingly incorporated into studies, it is imperative that the views of diverse research participants be investigated and rooted in the context of health equity. This qualitative study of adult SCD research participants (n=30) was conducted in 2021-2022 with the aim of exploring views and attitudes regarding RoR. Each participant completed a semi-structured interview to ascertain perceived benefits, harms, and other implications associated with RoR. Results suggest that adults living with SCD support the return of secondary findings (SF) from genomic sequencing studies. Study findings adopt the view that already living with a chronic genetic condition may influence potential psychological burden of receipt of SF. Themes from the data include the expectation that researchers should provide referrals to medical and mental health care specialists, downstream financial support for low-resource study participants, and support with communicating results with family. Understanding the views of research participants based upon race, ethnicity, genetic condition, insurance coverage and other sociodemographic factors is important in the developing body of research on return of secondary genomic findings.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2225. Secondary findings in a large Pakistani cohort tested with whole genome sequencing

Authors:

A. Skrahin¹, H. A. Cheema², M. Hussain³, N. N. Rana⁴, K. U. Rehman⁵, R. Kumar⁶, G. Oprea¹, N. Ameziane¹, A. Rolfs¹, V. Skrahina¹; ¹Arcensus GmbH, Rostock, Germany, ²The Children Hosp., Lahore, Pakistan, ³Pakistan Inst. of Med. Sci., Islamabad, Pakistan, ⁴Children Hosp. and ICH, Multan, Pakistan, ⁵Town Women and Children Hosp., Peshawar, Pakistan, ⁶Liaquat Natl. Hosp., Karachi, Pakistan

Abstract Body:

Background. Early detection of genomic secondary findings (SFs) leads to the timely initiation of therapeutic or preventive measures. The studies in the field of SFs are diverse regarding participants' characteristics (country, ethnicity, presence of symptoms, and consanguinity); sequencing methods: whole genome sequencing (WGS) or whole exome sequencing (WES); versions of the American College of Medical Genetics and Genomics (ACMG) SFs list (v1.0, 2013; v2.0, 2016; v3.0, 2021); inclusion medically actionable SFs not yet recommended for reporting by the ACMG.

Aim and methods. Taking advantage of WGS over WES and version 3.0 ACMG SF (SFs v3.0) list over previous versions we studied SFs in individuals clinically suspected of genetic diseases at five different hospitals in Pakistan. In addition to the SFs v3.0, we have defined a list of gene/disease pairs that are not included in the SFs v3.0 list but have a clear medically actionable value if detected and reported (non-ACMG SFs), that includes e.g., Glucose-6-phosphate dehydrogenase deficient hemolytic anemia (*G6PD* gene) and Factor V Leiden thrombophilia (*F5* gene).

Results. We included 744 individuals; 91% of the participants were clinically symptomatic (n=674); 90% younger than 18 years (n = 666); 81% of the participants were reported as product of consanguinity (n = 606). The SFs v3.0 were detected in 21 (2.8%) individuals. Most of the SFs v3.0 belonged to cardiovascular diseases (CVD), 81.8% and cancer predisposition conditions, 9.1%. Non-ACMG SFs were detected in 55 (7.4%) participants. Most of the non-ACMG SFs belonged to hemolytic anemias (35.1%), followed by CVD (17.5%) and bleeding disorders (8.8%); cancer predisposition conditions accounted for 1.8% of non-ACMG SFs.

Conclusions. WGS is a reliable and easy test format to identify SFs v3.0 and non-ACMG SFs. The overall rate of SFs in the Pakistani individuals tested for genetic diseases is unexpectedly high (10.2%) due to a very high proportion of non-AGMG SFs (7.4%). The most frequent SFs were in genes associated with CVD - 81.8% (SFs v3.0), and hemolytic anemias - 35.1% (non-ACMG SFs). Our findings serve as a resource to inform decision-making in individuals undergoing genomic testing, aid the development of practice standards in genomic medicine, and drive future research efforts.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2226. Shared in Rare: Engaging stakeholders to develop a shared ELSI research agenda across rare diseases.

Authors:

C. Berrios¹, J. Garrett¹, L. Jones², N. Petersen², M. Strenk¹, Rare Voices Advisory Group; ¹Children's Mercy Kansas City, Kansas City, MO, ²Rare Voices Advisory Group, Kansas City, MO

Abstract Body:

Research on individual rare diseases presents challenges such as small sample sizes and limited funding sources, while research efforts spanning across rare diseases present difficulty in applying outcome measures to conditions with variable manifestations. Common experiences in rare disease (extended diagnostic odyssey, chronic conditions, need for advocacy, and challenges finding and managing multi-specialty care) create shared ethical, legal, and social issues (ELSI). Shared in Rare is a stakeholder engagement project to leverage the shared experiences of patients and families impacted by rare disease to develop an ELSI research agenda that is both applicable across rare diseases and guided by patient and family priorities.

A stakeholder group, Rare Voices (RV), is collaborating with ELSI and community engaged researchers to complete the project. RV includes 4 teens and 12 parents of children impacted by rare disease and 6 clinicians/researchers. This project team is working together to conduct listening sessions with diverse parents, caregivers, and teens in the rare disease community that will inform development of the ELSI research agenda.

Early engagement with RV members revealed anticipated challenges including identifying research topics across all rare diseases, communication across diverse stakeholders, moving from qualitative listening session data to research questions, and addressing stakeholder feelings about traumatic experiences surfaced by the project work. This input informed modifications to the project plan including participatory RV training in qualitative research utilizing interviews with RV parent members and collaborative development of research questions emerging from those interviews. Frequent small group work has been incorporated to facilitate communication and engagement. A trauma workgroup was formed and completed training to integrate trauma sensitive practices into all project activities.

This incorporation of stakeholder input has built a highly collaborative and engaged project team working equitably to reach the project aims. 17/22 (77%) of RV members are directly involved in the listening sessions as part of teams developing recruitment materials, drafting the discussion guide, and moderating listening sessions. The team's actions to address anticipated challenges inform future stakeholder engagement and the collaboration in every aspect of this project has poised the listening sessions to capture the voice of the rare disease community, facilitating identification of research needs that will inform a patient and family-centered ELSI research agenda to improve care for rare diseases.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2227. The future of diversity, equity, and inclusion: Achieving the vision of genetic counseling for the All of Us Research Program

Authors:

K. Onyeneho; All of Us Res. Program, NIH, Bethesda, MD

Abstract Body:

Objectives: Genetic counseling is germane to helping individuals learn about genetic contributions for developing chronic disease, including diagnosis, treatment, and prevention. The *All of Us* Research Program (“program”) seeks to achieve its vision of participant return of value and evaluation of its impact in genetic counseling. The program is poised to address practical challenges to enable genetic counseling for those who want to receive health-related DNA results, with an emphasis on diversity, equity, and inclusion (DEI) among populations known to be historically underrepresented in biomedical research (UBR). UBR groups are based on age, racial and ethnic identity, sexual and gender identity, sexual orientation, disability status, educational attainment, geography, and income. The program’s Genetic Counseling Resource will support the unique needs of UBR groups who want to receive genetic counseling for their health-related DNA results. The future of DEI in genetic counseling is pivotal for UBR groups and for the program overall in achieving its vision of providing value to its participants and evaluating its impact in research. A literature review was conducted to investigate evidence-based approaches toward increasing the efficacy of genetic counseling by understanding what types of information collected from genetic counseling sessions may be useful for returning value to research participants and for evaluation of impact. **Methods:** The literature review used PubMed and ScienceDirect 2016-2021 publications involving value and impact of genetic counseling among adults and 48 publications met inclusion criteria modeled after the Preferred Reporting Items for Systematic Reviews and Meta-Analysis based on their relevance to the review. **Results:** Efficient methods for genetic counseling that provide value to individuals and evaluation of impact include phone-based counseling accompanied by patient portals and educational tools (e.g., chatbots, videos, web-based, and printed materials); in-person counseling with visual aids; and post-genetic counseling routine patient engagement. **Conclusions:** Patient portals and educational tools enabling genetic counseling were shown to increase health and medical knowledge among individuals, especially UBR groups such as low-literacy populations and those who are not geographically in close proximity to genetic counseling services. This was significant for populations receiving access to and making use of genetic counseling services; including UBR populations, the Deaf community, and communities affected by orofacial clefts.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2228. The Million Veteran Program - Return Of Actionable Results (MVP-ROAR) Study: Participant Baseline Characteristics

Authors:

M. Danowski¹, M. Cardellino¹, C. Brunette¹, T. Yi¹, J. Vassy^{2,1,3,4}; ¹VA Boston Hlth.care System, Boston, MA, ²Harvard Med. Sch., Boston, MA, ³Brigham and Women's Hosp., Boston, MA, ⁴Precision Population Hlth., Ariadne Labs, Boston, MA

Abstract Body:

Introduction: The MVP-ROAR Study is a randomized controlled trial returning actionable genetic results associated with familial hypercholesterolemia (FH) to a subset of participants in MVP. FH is a monogenic disease characterized by a 20-fold increased risk of premature coronary artery disease due to severe elevations in low-density lipoprotein cholesterol (LDL-C). Participants are recontacted and reconsented to the study protocol. At baseline, enrollees complete a survey, provide a family history, and provide a biospecimen for LDL-C testing and clinical confirmation of the research finding, via a CLIA-certified laboratory. The genetic counselor (GC) returns the results by telephone and provides post-test counseling, including the provision of FH-related resources, facilitation of cascade testing, and documentation in the medical record.

Results: As of 5/9/22, a total of 385 participants with a suspected variant associated with FH have been recontacted and sent a study opt out letter. Of these, 11 opted out of further contact via postcard. Study staff sent a detailed mailing to 314 Veterans across 40 states. 177 were reached by phone at least once, and 65 have enrolled in the trial. Mean (SD) age of enrolled participants is 61.0 (13.3) years. 52 (80.0%) participants are men and 25 (38.5%) identify as non-white race. At enrollment, 13, 3, and 1 participants were taking a statin, fish oil, and ezetimibe, respectively. 44 participants have completed the baseline survey and biospecimen collection (blood = 39, saliva = 5). Initially 3/8 (37.5%) results were not clinically confirmed due to a high false positive call rate for rare variants on the MVP genotyping chip. After implementing an improved variant calling algorithm all subsequent results 23/28 (82.1%) were confirmed. Results have been disclosed by the GC to 28 participants. Survey data indicate some degree of medication aversion [Mean (SD) 21.4 (5.8) Beliefs About Medication] and reduced health-related quality of life among study participants, compared to the general population and those with FH [34.12 (11.12) Veterans Rand -12 Item Health Survey physical component score; 29.13 (14.25); mental component score]. 41 participants had a baseline LDL-C >70mg/dL, of whom 28 had a baseline LDL-C >100mg/dL.

Conclusion: Study participants are providing valuable information about the attitudes and outcomes of return of unanticipated genetic results within MVP. Additional data are needed to understand why participants declined to enroll after initial phone contact, but preliminary results suggest that enrollees, although with poorer baseline health, are engaged and generally receptive to receiving results.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2229. The Quebec Participatory cohort, a citizen science project for direct-to-consumer genetic testing participants

Authors:

S. Girard¹, M. Gagnon¹, C. Moreau¹, S. Gravel², M. Zawati³, Y. Joly³, H. Vezina¹; ¹Université du Québec à Chicoutimi, Chicoutimi, QC, Canada, ²Mc Gill Univ, Montreal, QC, Canada, ³McGill Univ., Montreal, QC, Canada

Abstract Body:

Direct-to-consumer genetic testing have become mainstream in the past decade. Through these tests, participants expect to learn more about their health and their ancestry. The collective investment of these participants could be further enhanced by academic efforts aiming to collect the raw data from these tests for research aiming at fostering knowledge and the public good. With this in mind, we have recently launched the pilot phase of the Quebec Participatory Cohort (CopaQ). Through this project, we aim to mobilize participants who acquired direct-to-consumer genetic testing through a private company. We first built a robust data management framework to ensure that our project will adhere to the appropriate ethical and legal policies in Canada. As expected from a citizen science project, data conservation and protection are key issues that need to be addressed in the right way. As such, we opted to develop our platform through a sustainable health hub geared toward data privacy. To collect raw genetic testing data, we built a secured web portal (<http://copaq.ca>) that provide users with a platform to collect informed consents, genotyping data as well as demographic and genealogical information. Through citizen participation, we will build a large cohort that will be made available to academic researchers. Amongst the conditions to access this cohort will be the need for the researchers to provide regular updates on the progress of their research project, in the form of a public-friendly video. Additionally, to attract and involve a large number of citizens, our team will provide participants with personalized genetic and genealogical reports. We believe that CopaQ can attract hundreds if not thousands of citizens who want to be involved in research projects. Our citizen science platform will also be a golden occasion to create a science-based community to drive citizen engagement even further.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2230*. The role of oncology nurses in the genetic counseling workflow: A literature scan

Authors:

E. Hasser¹, K. A. Leppig², N. B. Henrikson³; ¹Univ. of Washington, Seattle, WA, ²Kaiser Permanente of Washington, Seattle, WA, ³Kaiser Permanente Washington Hlth.Res. Inst, Seattle, WA

Abstract Body:

As the demand for genetic testing grows, a shortage of genetic counselors and bottleneck at the training stage limits the reach of the genetic counseling workforce. Nurses, especially infusion nurses spending extended time with cancer patients, are uniquely suited to relay genetic testing information. Training nurses in genetics could increase genetics competence and alleviate the workload burden on geneticists and genetic counselors. Minimal research has been published on the role of nurses in the genetic counseling workflow, but existing programs showed promising success. Collaboration with nurses to increase access to genetic counseling should be considered as a possible service delivery model and research area.

We conducted a literature scan and annotated bibliography to investigate the potential role of nurses in genetic counseling and to identify existing programs leveraging the nursing skill set, with a focus on oncology and infusion nurses. Combinations of terms in the categories of genetics (genetics, genomics, genetic testing, genetic counseling), nursing (nursing, nurses), and cancer (cancer, oncology) were searched in PubMed and Google Scholar. After an initial review, more specific terms such as “genetic counselor extender” and “service delivery model” were also implemented. The literature search window was Jan 2000 to May 2022. We included sources in the annotated bibliography if they contained relevant discussions about nurses in the genetic counseling workflow. We excluded sources that did not relate to nursing and genetics and those that addressed specialties other than oncology or a general care setting. We included 37 articles in the annotated bibliography. Sources discussing nurses’ knowledge of genetics were the most common (15 articles). Some articles identified that both practicing nurses and nursing students have limited training in genetics; others established core competencies for genetics in nursing curricula. Two dedicated genetics courses increased nurses’ confidence in genetics concepts. Several sources supported a potential for nurses to discuss genetic testing due to their high patient contact but did not propose a direct integration of nurses in the counseling workflow. Proposed innovative service delivery models can increase genetic counseling access and relieve administrative burden on genetic counselors. These alternatives to the traditional genetic counseling pathway included the use of telehealth genetic counseling; genetic counseling assistants; and nurses and nurse practitioners as genetic counselor extenders who actively participate in the counseling process by taking low complexity cases.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2231. The SeDeN-p2 study : Perceptions of French health professionals on the extension of newborn screening with or without genetics as a first-line test.

Authors:

C. Level^{1,2,3}, F. Huet^{4,3,5}, D. Salvi¹, C. Thauvin-Robinet^{1,3,2}, C. Binquet^{6,3}, E. Simon⁷, Inter-Filières de Santé Maladies Rares, France, Association Francophone de Génétique Clinique, Société Française de Médecine Prédictive et Personnalisée, C. Peyron^{8,3}, L. Faivre^{1,2,3,9}; ¹Ctr. de Génétique et Ctr. de Référence Anomalies du Développement et Syndromes Malformatifs, CHU Dijon Bourgogne, Dijon, France, ²Equipe Génétique des Anomalies du Développement, INSERM UMR 1231, Université de Bourgogne-Franche-Comté, Dijon, France, ³FHU TRANSLAD, Dijon, France, ⁴Service de Pédiatrie Multidisciplinaire, Hôpital d'Enfants, CHU Dijon Bourgogne, Dijon, France, ⁵Société Française de Dépistage Néonatal, National, France, ⁶Ctr. d'Investigation Clinique - Epidémiologie Clinique, INSERM UMR 1432, CHU Dijon Bourgogne, Dijon, France, ⁷Service de gynécologie obstétrique et médecine fœtale, CHU Dijon Bourgogne, Dijon, France, ⁸Laboratoire d'Économie de Dijon, Dijon, France, ⁹Filière de Santé Natl.e AnDDI-Rares Anomalies du Développement avec ou sans Déficience Intellectuelle de causes Rares, Dijon, France

Abstract Body:

Context: The recent modifications of the French bioethics law, the therapeutic progress and the massive development of advanced genetic techniques (such NGS) with a rapid decrease in costs imply to question the extension of newborn screening (NBS) to new actionable pathologies and the acceptable and relevant methods for its possible expansion. International studies are beginning to determine the potential place of NGS in NBS. In this perspective, the SeDeN project aims to fully assess the social acceptability of these issues by measuring the diversity and consistency of expectations of health professionals, parents and public policy makers. **Material and method:** The component of the SeDeN project presented here focuses on the opinions of professionals. This part is composed of a qualitative exploratory phase (12 interviews), a quantitative investigation phase based on a questionnaire survey and a qualitative in-depth phase. The online questionnaire, carried out by University Hospital Federation TRANSLAD in partnership with the French Society of Newborn Screening, was distributed via networks and learned societies to pediatricians, geneticists, genetic counselors, midwives, gynecologists, and molecular biologists in mainland France and the French overseas territories. Only the results of this questionnaire are presented here, with particular emphasis on the differences in responses between geneticists and other professionals. **Results and discussion:** The questionnaire was distributed from June 22 to December 20, 2021. 1199 professionals have completed all or part of the questionnaire and nearly 20% are geneticists or genetic counselors. Professionals expressed concerns about the use of genome-wide techniques in NBS and preferred the use of target panels. Concerns about the wider use of genetic techniques include ethical issues, potential anxiety for families, organizational difficulties in implementation, and lack of trained professionals. When practitioners were asked about adding different disease groups (childhood onset with no available treatment; adult onset with treatment or not; or able to provide information to relatives) to NBS, geneticists and genetic counselors were the most reluctant, as they were particularly aware of the impacts of genetic disease announcement. The same is true for the transmission of uncertain results. These data are important to better understand the opinion of French health professionals in a logic of decision support for health policies.

Bellen^{9,2,10,8}; ¹Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, ²Jan and Dan Duncan Neurological Res. Inst., Texas Children's Hosp., Houston, TX, ³Texas Children's Hosp., Houston, TX, ⁴Baylor Genetics Lab., Houston, TX, ⁵Stanford Clinical Genomics Program, Stanford Hlth.Care, Stanford, CA, ⁶Dept. of Pediatrics, Baylor Coll. of Med., San Antonio, TX, ⁷Dept. of NeuroSci., Baylor Coll. of Med., Houston, TX, ⁸Program in Dev.al Biology, Baylor Coll. of Med., Houston, TX, ⁹Dept. of Molecular and Human Genetics, Baylor Coll. Med., Houston, TX, ¹⁰Howard Hughes Med. Inst., Houston, TX

Abstract Body:

The Texome Project provides crucial genetic testing, advanced bioinformatics analysis, and functional modeling to diagnose and study genetic disease in minority and underserved populations. National programs providing comprehensive genomic medicine have demonstrated the utility of genetic analysis on rare and complex undiagnosed disease. However, underserved groups and ethnic minorities have not equally benefited from large-scale genomics research and are largely underrepresented in genomic databases. To reach this population within Texas, we partnered and promoted enrollment with safety-net hospitals and community health clinics. To maximize accessibility to genetics services among our cohort, we offer virtual appointments via telemedicine, remote sample collections, and multilingual recruitment. The Texome Project also includes longitudinal follow-up which seeks to uncover the attitudes and feelings towards genomic medicine from an understudied population. At present, the Texome Project has received referrals for 55 ethnically and socioeconomically diverse families, 39 of whom we accepted. We completed enrollment for 28 families and whole exome sequencing (WES) for 14. A definitive diagnosis has been determined in 4 cases. Two of our solved cases are caused by previously reported variants in *ATPIA3* and *ASXL3* while the other two diagnostic variants in *DNMT3A* and *RPGR* are novel and not well studied. This gives our WES analysis a diagnostic yield of 29% to date. The clinical and molecular data provided by these patients contribute to new scientific discovery about the phenotypic spectrum and pathogenicity of specific variants. One significant challenge in genetic testing for our population is the availability of family members who may be separated by national borders, interpersonal issues, or premature mortality. This leads to some participants being analyzed on a proband or duo basis (n=10, 36%) instead of a more ideal trio analysis (n=18, 64%). For cases with non-definitive WES findings (n=10, 71%), further bioinformatic and functional modeling in *Drosophila* is ongoing which may implicate new gene-disease relationships. Preliminary findings of the Texome Project highlight the need and value of including underserved and underrepresented patients to provide equitable care and further scientific discovery.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2233. Transforming genetics service delivery: Genetics providers' perspective on integrating digital tools into clinical practice.

Authors:

W. Lee^{1,2}, D. Hirjikaka³, S. Grewal³, M. Clausen³, **S. Luca**¹, Y. Bombard^{3,2}, R. Hayeems^{1,2}, Genetics Navigator Study Team; ¹Program in Child Hlth.Evaluative Sci., The Hosp. for Sick Children, Toronto, ON, Canada, ²Inst. of Hlth.Policy, Management, and Evaluation, Univ. of Toronto, Toronto, ON, Canada, ³Genomics Hlth.Services Res. Program, Li Ka Shing Knowledge Inst., St. Michael's Hosp., Toronto, ON, Canada

Abstract Body:

Background: eHealth tools can provide scalable solutions to current challenges of access, efficiency, and equity in genetic service delivery. Various digital tools have been integrated into one or more stages of the genetic service pathway and have contributed to improving access to genetic services. Yet, genetics providers' perspectives on and comfort with digital tools are not well characterized. We explored providers' perspectives on the integration of digital tools into practice for both pediatric and adult patient populations. **Method:** Healthcare providers from genetics clinics across Canada were recruited via professional networks and snowball sampling. Using an interpretive description approach, key informant interviews were conducted. The interviews were transcribed and analyzed using thematic analysis. **Results:** Eleven geneticists and 21 genetic counselors across five provinces were interviewed (yrs in practice: 3 to >25). Participants had generally favorable attitudes towards digital tool integration as a strategy for alleviating pressures and inefficiencies in triaging, clinical assessment, pre-test counseling and education, thereby allowing providers to practice at the top of their scope. While many were hesitant, some providers noted that digital tools can be used for return of results in less complex cases (e.g., negative results). However, they expressed concerns that digital tools may create unintended burdens on providers' workloads associated with managing new digital applications. In addition, providers described ways in which digitization of genetics services could both enhance and compromise the patient-provider relationship. For example, some providers expected that the increased efficiency in practice would allow them more time to better address patient needs, while others worried that using digital tools would interfere with building patient/caregiver rapport. Finally, providers felt that digital tools could empower patients in their medical care, but they were concerned that this benefit may be limited to patients with adequate access to and proficiency with technology. **Conclusion:** Providers considered digital tools to be a potential solution for improving access, efficiency, and patient-centered care. However, successful integration of digital tools into care delivery requires careful consideration, evaluation and research of their potential unintended impacts related to digital burden for providers, compromised patient rapport, and widening the inequity that already exists in patient access to genetic services.

PB2234*. Tribal community perspectives on genomics research and data sharing: a mixed-methods study.

Authors:

K. S. Tsosie^{1,2,3}, J. Kim², J. J. Vasquez⁴, J. M. Yracheta^{2,5}, J. Li-Pook-Than⁴, M. Snyder⁴, L. G. Rosas⁴; ¹Arizona State Univ., Tempe, AZ, ²Native BioData Consortium, Eagle Butte, SD, ³Vanderbilt Univ., Nashville, TN, ⁴Stanford Univ. Sch. of Med., Palo Alto, CA, ⁵Missouri Breaks Industries Res., Inc., Eagle Butte, SD

Abstract Body:

Purpose: Precision medicine will likely fail to redress health disparities without equitable approaches for the collection and sharing of genomics and health data from American Indian and Alaska Natives. **Methods:** Convergent mixed methods characterized Tribal members' perspectives on genomics research and data privacy, sharing, and deposition. Survey data were collected from adult (median age=40.0 years) enrolled members of the Cheyenne River Sioux Tribe (N=125) recruited from Tribal district health fairs to assess positive-negative motivators contributing to trust and study participation. Respondents were purposively selected for focus group (total N=20, 3 cohorts) interviews, coded for content and thematic analyses. **Results:** Survey respondents expressed increased willingness to participate in studies led or partnered with the Indian Health Service (IHS; 72.8%) or nonprofit organizations (70.4%), compared to non-IHS federal institutions (52.8%) or pharmaceutical companies (36.8%). Respondents with higher educational attainment were more likely to be concerned about who can access their genetic data ($P=0.023$) and fate of biological material at the end of a study ($P=0.010$) compared to those without college experience. Focus group participants expressed concerns that removing individual identifiers would not adequately mitigate risks of hacking, re-identification, and reification of racial purity assumptions about Tribes. Intriguingly, Tribal participants called for increased transparency in who is accessing their data, which could be a pathway for building trust. Trust is intrinsically linked to derived utility of Tribal data back to communities. Participants stressed the importance of having data sharing protocols codified under Tribal law before Tribal data is collected. **Conclusions:** Trust is an important factor for Tribal members on whether to participate in research, as contextualized by contentious relationships between Tribal nations and federal agencies. Tribal members are wary of research motives, particularly for-profit interests, and open data sharing contributing to commercialization and privatization of Indigenous data. **Policy:** These findings inform data policies (e.g., National Institutes of Health Genomic Data Sharing Policy) and Tribal engagement. A model was developed encapsulating themes of data sharing, access, security, and stewardship with embedded histories of trust and distrust which, in turn, relate to facilitating direct community benefits and long-term Tribal data governance. Hence, fostering Tribal data agency can dismantle power imbalances and encourage Tribal research participation.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2235. Understanding views towards gene editing in Switzerland

Authors:

K. Ormond, S. Gächter, E. Vayena; ETH-Zurich, Zurich, Switzerland

Abstract Body:

Although the debate about modifying human genetics has been going on for several decades, the discussion about gene editing remains heated. Several large groups have presented views of experts and/or the general public, but through this work it is also clear that views vary from country to country, due in part to cultural and religious variation as well as existing legal frameworks. In Switzerland, in addition to having ratified the Oviedo Convention, there are a number of laws that restrict the genetic manipulation of embryos or reproductive germ cells, which would subsequently prohibit human germline gene therapy. In contrast, somatic gene therapy research can be carried out when approved. In this study we present data from semi-structured interviews with Swiss experts. The potential participants included basic research and translational scientists, physicians, lawyers and bioethicists. A list of ~150 potential expert participants were identified based on their roles at the major Swiss Universities, University Hospitals and Children's Hospitals, including professionals working specifically in genetics, genomics and the field of rare disease. We also utilized lists of board certified (FMH/FAMH) medical geneticists in the country, and individuals who participated in a Swiss Expert Committee for Biosafety (SECB) Gene Therapy Working group, the Swiss National Ethics report on gene editing, or TA-Swiss, the Foundation for Technology Assessment. Interviews are underway as of June 2022 and will be conducted until data saturation is reached. Data will be recorded, transcribed, and coded using an inductive coding method. From this, themes will be identified and presented through discussion with the research team and a feedback and deliberation process with study participants. Their views will be compared with already published literature in this area, and presented with a summary of relevant laws that exist in Switzerland. The results from this interview project will inform a country-wide survey of the general public (planned for Fall 2022) and a deliberative democracy event in early 2023. We aim to incorporate social, cultural, religious, and traditional aspects unique to Swiss society among other things that might play a role in defining bioethics, policy-making, and regulatory practices of gene editing for the therapy of hereditary diseases in Switzerland.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2236. Users' evaluation of artificial intelligence-based diagnostic program in pediatric rare diseases

Authors:

I. Choi¹, J. Kim¹, G-H. Kim², B. Lee^{2,1}; ¹Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of, ²Asan Med Ctr, Seoul, Korea, Republic of

Abstract Body:

Since the early 2000s, with the advent of the next generation sequencing (NGS) technique, genome sequencing using the NGS technique, such as whole-exome sequencing (WES) or whole genome sequencing (WGS), showed higher clinical utility than the traditional tests. Furthermore the artificial intelligence (AI)-based genetic diagnostic program has been applied to genome sequencing to facilitate the diagnostic process. The Korean version of the artificial intelligence (AI)-based diagnostic program utilized big data obtained from whole-exome sequencing (WES) performed by next-generation sequencing to shorten the time required for pediatric rare disease diagnosis. This project was a Korean government-driven project to develop the AI-based medical service in South Korea, which has been named as “Dr. Answer 1.0.” It was started in 2018 to support clinical treatment and diagnosis using medical big data. It aims to provide precision medical services through early diagnosis and personalized gene treatment using genetic diagnosis. The objective of the current study was to evaluate the experience and level of satisfaction with the program for patients, guardians, and physicians who participated in the AI-based genetic diagnostic program for rare pediatric genetic diseases. The study period was from April 2020 to March 2021. A survey was designed to assess their experience and level of satisfaction. A total of 30 physicians and 243 patients and guardians (199 neurodevelopmental disorders and 44 hearing impairments) completed the survey. DNA samples of the subjects were collected through buccal swabs or blood collection: 211 subjects (86.8%) through buccal swab and 29 subjects (11.9%) through blood collection. Average turnaround time for result receipt was 57.54 ± 32.42 days. As a result of the AI-based diagnostic program, the diagnostic rate of neurodevelopmental disorder was found to be 40.1% and that of hearing impairment was 52.3%. The level of satisfaction of the two groups participating in the AI-based diagnostic program was 8.31 ± 1.71 out of 10 in the patient and guardian group and 8.42 ± 1.23 in the physician group. As the number of AI-based health care solutions will increase in the medical genetics field, genetic counseling will be considered more important. In future studies, the awareness and satisfaction survey on genetic counseling service provided to patients with rare diseases will be investigated. * It was written by referring to a article of the same author that had been accepted for publication through Medicine journal at April, 2022.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2237*. Using variant databases to estimate disease prevalence for rare recessive disease

Authors:

S. Baxter¹, M. Singer-Berk¹, J. Wood¹, N. Watts¹, M. Wilson¹, H. Rehm², A. O'Donnell-Luria³; ¹Broad Inst. of MIT and Harvard, Cambridge, MA, ²Massachusetts Gen. Hosp./Broad Inst. of MIT and Harvard, Boston, MA, ³Broad Inst. of MIT and Harvard/Children's Hosp. of Boston, Cambridge, MA

Abstract Body:

Prevalence of a condition is an important factor in decision-making by researchers and pharmaceutical companies to determine goals and resource allocation toward the condition, yet the prevalence of the vast majority of rare diseases is unknown. Increased knowledge about the prevalence of a condition, both globally and in specific sub-populations (e.g. Ashkenazi Jewish, East Asian), is important to advocacy groups and organizations that aim to extend outreach, support and to build a network that includes as many affected individuals and families as possible. Over the last 2 years our team has partnered with a network of patient organizations to estimate prevalence for 15 rare autosomal recessive conditions in the RareAsOne network. We collected pathogenic (P) and likely pathogenic (LP) variants from databases like ClinVar and the Human Gene Mutation Database (HGMD), as well as all predicted loss of function (pLoF) variants in gnomAD. All LP and P ClinVar/HGMD variants that are present in gnomAD were re-curated following modern ACMG/AMP curation guidelines and pLoF were curated following our own internally-developed loss of function curation protocol. Carrier frequency and disease prevalence were estimated for all populations in gnomAD with over 2,000 alleles, using the Hardy-Weinberg equation and gnomAD allele frequencies (AFs). The results were returned directly to the patient organizations and their experts on 90 minute zoom calls, accompanied by written materials. Across the 15 genes assessed, global carrier frequencies ranged from 1/284 to 1/11,891 and prevalence from 1/322,831 to 1/565,546,084. For some genes, we were able to identify populations with increased carrier frequencies that had not been previously recognized in the literature (ex. TANGO2, PLA2G6). Two of the key factors impacting the estimates were formal classification of the variants and time since gene discovery. Including high frequency variants with weak or minimal evidence for pathogenicity would overinflate the estimates, highlighting the importance for having conservative standards for which variants are included. Conversely, genes that were more recently associated with disease typically had lower estimated prevalence due to fewer LP/P variants in ClinVar, underlining the need for including these genes on panels and functional studies to resolve variants of uncertain significance. Groups used this data for a variety of purposes including but not limited to publications, patient recruitment, and outreach to pharmaceutical companies. A future goal of this project is to release an aggregate frequency calculator utilizing gnomAD data for use by the community.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2238. Utilizing chatbots for family communication: Uptake and engagement among familial hypercholesterolemia probands from a prospective, pragmatic trial.

Authors:

N. Walters¹, Z. T. Lindsey Mills¹, A. Brangan¹, G. Campbell-Salome¹, S. Savage², T. Schmidlen², K. M. Morgan¹, E. P. Tricou^{1,3}, M. N. Betts^{1,4}, L. K. Jones¹, A. Sturm^{1,5}; ¹Geisinger, Danville, PA, ²Invitae, San Francisco, CA, ³Family Heart Fndn., Pasadena, CA, ⁴WellSpan Hlth., York, PA, ⁵23andMe, Sunnyvale, CA

Abstract Body:

Background: Familial hypercholesterolemia (FH), a CDC Tier 1 condition, significantly increases one's risk for early heart attack and stroke. FH is treatable but vastly underdiagnosed, making it imperative that probands share risk information with relatives to identify more cases. Chatbots, internet-based conversational agents, can aid in family communication. A Family Sharing Chatbot (FSC) was sent to FH probands identified through Geisinger's MyCode® Community Health Initiative. The FSC allows probands to send relatives a link to a Cascade Chatbot (CC) that explains their FH risk and recommends action steps. This study examined uptake of and engagement with the FSC. **Methods:** Probands included in a prospective, pragmatic trial were sent three messages prompting use of the FSC via email, text, and/or the patient electronic health record (EHR) portal. An opt-out methodology was used. Data on chatbot engagement from 7/1/2021 through 5/12/2022 was collected from the EHR and the chatbot's HIPAA-secure web portal. Statistical analyses were conducted using SPSS version 26. **Results:** Of the 175 included probands, 21 (12%) opted out of receiving the FSC. A logistic regression was performed to examine the effects of age on the likelihood that probands would opt out, which was statistically significant ($\chi^2(7, 154) = 10.35, p < .001$). Older probands were more likely to opt out than younger probands [$\text{Exp}(B) = .942, (.909, .977)$]. No significant differences between sex and opt-out status were found. Communication preferences varied among the 154 (88%) remaining probands; most chose to receive the FSC via the patient EHR portal (91/154, 59%), followed by email (40/154, 26%), text (21/154, 14%), and both email and text (2/154, 1.3%). Seventy-five (49%) probands clicked the FSC link, 62 (40%) started the FSC, and 36 (23%) shared a CC link with at least one relative. More females shared (24/89, 27%) than men (12/65, 18%). The average age of probands who shared ($M = 52$ years) was lower than those who did not ($M = 56$ years). Probands who read two or more invites on the patient EHR portal shared more (20/69, 29%) than those who read one or none (1/22, 4.5%). Probands who had multiple contacts with the study team (genetic counseling, study follow-up calls) shared more, with 6/42 (14%), 23/90 (26%), and 7/22 (32%) completing one, two, and three contacts respectively. **Conclusions:** The FSC can help FH probands facilitate family communication with at-risk relatives. It is essential to offer alternatives (e.g., family letters) as these may be more desirable for older probands who were more likely to opt out of the FSC. Reminder messages and additional contacts may help increase engagement with the FSC.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2239*. Validation of automated electronic health record (EHR) data capture of hereditary breast and ovarian cancer and Lynch syndrome phenotypes

Authors:

J. Savatt¹, C. J. Buoy¹, S. M. Ney¹, C. R. Kelsey¹, A. H. Buchanan¹, N. Banet², M. A. Kelly¹, R. Puttagunta¹, H. Ramey¹, W. Fairbrother³, N. T. Strande¹; ¹Geisinger, Danville, PA, ²Cleveland Clinic, Cleveland, OH, ³Brown Univ., Providence, RI

Abstract Body:

Electronic health record (EHR)-linked genomic biobanks offer a wealth of data that can be leveraged to increase understanding of genetic disease. The power of such data to expand our understanding relies on capturing accurate phenotypic information. Yet, EHR International Classification of Disease (ICD 9/10) codes alone may not accurately reflect patient phenotypes. While manual chart reviews enable more reliable phenotyping, they are low throughput and often not feasible for large scale studies. We assessed the performance of EHR data extraction for 14 cancer and precancerous phenotypes associated with hereditary breast and ovarian cancer (HBOC) and Lynch syndrome in Geisinger's MyCode Community Health Initiative. MyCode is a biobank of blood and other samples from over 312,000 unselected participants who consent to health-related research including exome sequencing linked to EHR data. To identify phenotypes of interest, diagnosis codes (ICD 9/10 and Epic Diagnostic Grouper (EDG)) and diagnoses from the Geisinger tumor registry that collects data for all individuals diagnosed or treated in the health system for the National Cancer Database were annotated for inclusion and exclusion using clinician generated phenotype definitions. Data were then extracted for 7,710 MyCode participants. For each phenotype, blinded manual EHR reviews were completed for the first 50 phenotype positive participants, if available, and at least 100 phenotype negative individuals. Discrepancies between the extracted data and manual review were re-reviewed and diagnoses were added or removed from pulls, as needed. Sensitivity and specificity were determined for diagnostic codes alone, tumor registry data alone, and combined diagnostic code and tumor registry data abstraction. Eight phenotypes had at least 50 participants flagged as positive by the data pull. Combined diagnostic code and tumor registry data abstraction had a median sensitivity of 99.4% and median specificity of 98.6%. Combined data extraction for 10 phenotypes had sensitivities and specificities that were both greater than 95%; abstraction of rare and noncancerous phenotypes had poorer performance. Diagnostic codes alone had fewer false negatives compared to tumor registry data alone, however tumor registry data had higher specificity. While our data are promising for EHR phenotype extraction, systems that lack tumor registries may need additional EHR elements to enhance specificity. These results show most HBOC and LS phenotypes can be accurately identified using a combination of diagnostic codes and tumor registry data facilitating phenotype collection for future large scale genomic studies.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2240. Voices from the online right: A qualitative study of race and genetics discourse.

Authors:

O. Sommers¹, J-H. Yu², D. Bowen¹; ¹Univ. of Washington, Seattle, WA, ²Univ. of Washington Sch. of Med., Seattle, WA

Abstract Body:

Background: Scientific racism maintains unjust racial hierarchies by portraying racial inequality as an inevitable result of innate differences between races. Proponents of modern scientific racism often cite geneticists' ability to predict racial categorization from genetic ancestry as proof that there are significant biological differences between races. These ideas are often spread through online discourse and have been used to support White Supremacist "replacement" theories and justify racial violence. Methods: To investigate the prevalence of scientific racism in "civil conversations" online, semi-structured interviews were conducted with 9 adult individuals, recruited from the social media site Reddit, who reported having conversations about race and genetics online. Results: Most participants had concordant explanations about the relationship between race and genetics. There was disagreement about the primary cause of health differences between black and white Americans. Discrimination was either ranked as an important environmental factor or dismissed completely. Among those who dismissed discrimination, socioeconomic factors within the environment were given as more important than genetic factors in determining health differences; however, those socioeconomic factors were then explained by references to innate racial differences, thus naturalizing existing racial hierarchies. Conclusion: Despite variation in participants' articulation on the causes of racial health differences, the logics of those actively involved in online race and genetics discourse ultimately endorse racial differences as innate. Further analysis will explore how discussions about scientific racism shape what is considered "common sense" (i.e., taken for granted) in online communities.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Wednesday

PB2241. Whole-exome sequencing in Puerto Rican patients: approach to diagnosis in complex traits.

Authors:

E. Albino¹, C. Buxo², C. Chapel-Crespo³, S. Carlo⁴, A. Cornier⁵, Z. Powis⁶; ¹Univ. of Puerto Rico, Med. Sci. Campus, Sch. of Hlth.Professions, San Juan, PR, ²Univ. of Puerto Rico, Med. Sci. Campus, Sch. of Dental Med., San Juan, PR, ³Univ. Pediatric Hosp. Dr. Antonio Ortiz, Sch. of Med., Univ. of Puerto Rico, San Juan, PR, ⁴Ponce Hlth.Sci. Univ., Cabo Rojo, PR, ⁵San Jorge Children s Hosp./ Ponce Hlth.Sci. Univ., San Juan, PR, ⁶Quest Diagnostics, Kalamazoo, MI

Abstract Body:

Whole-exome sequencing (WES) has become the first diagnostic option, especially in populations with difficult access to genetic tests. The use of WES in diagnosis will accelerate the management in Hispanic Puerto Rican patients undergoing a diagnostic odyssey; however, interpretation can be complex as Puerto Ricans are poorly represented in genomic databases. In addition, due to the differences in the medical system in Puerto Rico, exome testing is often ordered as a first-tier test and as proband-only testing due to the reduced cost to the family. Our objective was to evaluate the use and diagnostic yield of genetic tests analyzed in a diagnostic reference laboratory for Puerto Rican patients with complex traits.

We retrospectively reviewed consecutive results and clinical information of 50 Puerto Rican probands undergoing WES. WES included intronic variants, copy number variant analysis, and mitochondrial genome sequencing. Statistical analysis was performed using Fisher's exact test.

WES reports from 50 Puerto Rican probands between 16 months to 36 years were evaluated. WES was the test choice for these probands who have many heterogeneous neurogenetic phenotypes and a normal chromosomal microarray result. WES positive results were reported in 12 of 50 (24.0%) of probands; 15 of 50 (30.0%) probands had an uncertain result. The remainder of results of probands; 23 of 50 (46%) were negative. While the positive and uncertain rates trended towards higher numbers than probands from other regions of the United States (for the same time period), differences were not statistically significant ($P = 0.0453$). All uncertain results were due to variants of uncertain significance in clinically relevant genes. Of 27 probands, 11 (40.7%) had a variant of uncertain significance reported in addition to the primary positive or VUS finding.

Almost a quarter (24%) of patients received positive results from WES in this cohort of Puerto Rican patients with complex traits and 30% of the probands had a variant of uncertain significance. As diversification occurs in population genomic databases and variant data is shared in knowledge bases like ClinVar, the number of reported VUSs is hypothesized to decrease; the trends in this study suggest the study population may be underrepresented in these databases, though larger studies are needed. Such studies may also aid in variant classification and add to the knowledge of genetics for Puerto Rican patients with complex traits.

Genetic Counseling, ELSI, Education, and Health Services Research Posters - Thursday

PB2242. Your genes & you: patient motivations regarding secondary findings from genomic studies

Authors:

P. Brock¹, S. Hovick¹, L. Byrne¹, L. Peterson², G. Brock¹, I. Lattimer¹, J. Lin¹, R. Webber¹, L. Woodruff¹, M. Towne³, C. Milliard³, K. Sweet¹; ¹The Ohio State Univ., Columbus, OH, ²Loyola Univ. Med. Ctr., Chicago, IL, ³Ambry Genetics, Aliso Viejo, CA

Abstract Body:

Genomic sequencing provides opportunity to identify pathogenic variants unrelated to the primary testing indication. These secondary findings (SF) may be actionable and detected in the absence of any signs of disease, and individuals and families may benefit from increased preventive care and/or management based on these results. Most guidance on returning SF comes from expert recommendations. In this study, we assessed participants' interests, attitudes, and motivations regarding SF, as well as perceived disease risk, risk-related beliefs, and informational needs. Following standard genetic counseling and clinical multigene panel testing, patients at our cardiology and hereditary oncology clinics are offered enrollment in the Genomic Medicine Initiative (GMI) biobank study for further genomic investigation including research exome analysis and return of actionable SF results. A REDCap survey that assessed interests, attitudes, and motivations regarding SF, as well as perceived disease risk, risk-related beliefs, and information needs was emailed to 315 GMI participants. We received a total of 109 responses (35% response rate) from patients who underwent testing for a personal history of cancer (N=103) or heart disease (N=6). Of the respondents, 63% were male and 95% were White with an average age of 59 years (range 30-82). The most common primary motivation for enrolling in the GMI was to have the most up-to-date genetic information to provide family members (44%) followed by contributing to scientific knowledge and understanding (23%). Participants strongly agreed that they enrolled for scientific information (>90%), to provide information for their family (>90%), to change their health care (80%), and/or to gain additional explanations for their health condition (81%). Just 36% "strongly agreed" that they signed up because they were encouraged by a health care professional. Participants who enrolled primarily to provide information for family members were more likely to be older (mean=63.75, SD=10.77) compared to participants who enrolled primarily to contribute to scientific knowledge (mean=54.28, SD=14.06, p=0.016). Two separate descriptive disease scenarios addressed interest in receiving SF for either cancer or heart disease, and respondents reported equal interest in both types of SF. These results provide important insights into the motivations and interest in genomic research with the possibility of the return of SF results. Most participants report hoping to provide information for their family over information for themselves, and personal motivations may have a bigger impact than encouragement from health care providers.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2243. A calibrated automated patch clamp assay can interpret any VUS in *KCNH2*.

Authors:

C. Ng^{1,2}, R. Ullah³, J. Farr^{1,4}, A. P. Hill^{1,2}, **J. I. Vandenberg**^{1,2}, B. M. Kroncke³; ¹Victor Chang Cardiac Res. Inst., Darlinghurst, Australia, ²Sch. of Clinical Med., UNSW Sydney, Darlinghurst, Australia, ³Vanderbilt Univ. Med. Ctr., Nashville, TN, ⁴Sch. of Computer Sci. and Engineering, UNSW Sydney, Kensington, Australia

Abstract Body:

Introduction: Pathogenic *KCNH2* variants can cause long QT syndrome (LQTS) and increase the risk of sudden cardiac arrest. More than half of the nonsynonymous variants in *KCNH2* listed in the ClinVar database are classified as variants of uncertain significance (VUSs). *In vitro* functional assays can provide evidence to strengthen the case for reclassifying VUS as either likely benign or likely pathogenic. **Aim:** To use an automated patch clamp assay, calibrated according to the recommendations published by the ClinGen SVI working group, to assess the function and provide evidence for VUS reclassification for *KCNH2* variants identified in this cohort. **Method:** A cohort of 216 nonsynonymous missense variants in *KCNH2* were collated from LQTS cohorts in France, Italy and Japan (Kozek et al., 2021). Heterozygous *KCNH2* variants were expressed in HEK293 cells and characterised using an automated patch clamp electrophysiology platform. Variants were classified as functionally normal or abnormal based on previously established current density and gating parameters established for this assay (Jiang et al., 2022). **Results:** Out of the 216 unique missense variants identified from this cohort, 188 were identified in individuals with clinically confirmed LQTS whereas 28 in individuals with suspected LQTS. 172 of the 188 variants in clinically confirmed LQTS were found to be functionally abnormal compared to 15/28 variants in suspected LQTS cases. 154 of the 216 variants have been previously classified in ClinVar database; 58 classified as (likely)pathogenic, 79 VUSs, 17 with conflicting classification. 54/58 ClinVar variants classified as (likely)pathogenic were found to be functionally abnormal. Furthermore, 58/79 VUS and 14/16 conflicting variants were also functionally abnormal. Most of the variants in the voltage sensor domain, pore domain and cNBH domain are functionally abnormal; whereas only a minority of variants located within the proximal N and distal C terminus are functionally abnormal. Variants from the EAG domain can have normal and abnormal function. **Conclusion:** Our *in vitro* functional genomics assay for *KCNH2* variants can provide the additional evidence needed for VUS reclassification. This is invaluable, as reclassifying a VUS can facilitate cascade screening of the extended family. **Reference:** 1. Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2244. A Case of Concurrent 3p26.3-p25.3 Deletion and 9q34.2-q34.3 Duplication in Monozygotic Twin Males: A Case Report.

Authors:

T. Maini¹, J. Black¹, I. Cherrick², N. Brescia³, J. A. O'Malley², R. Lebel¹; ¹Section of Med. Genetics, SUNY Upstate Med. Univ., Syracuse, NY, ²Dept. of Pediatrics, SUNY Upstate Med. Univ., Syracuse, NY, ³Dept. of Neurology, SUNY Upstate Med. Univ., Syracuse, NY

Abstract Body:

Monochorionic diamniotic male twins were vaginally delivered at 33 weeks, to a 32-year-old G3P2 mother. The union was non-consanguineous. Intrauterine growth restriction of twin B had been noted. Both were small for gestational age and required ventilatory support. Both twins displayed micrognathia, hypotonia, bilateral ptosis, unilateral cryptorchidism and hydronephrosis, and gastric anomalies. Twin A had an atrial septal defect and a left SVC. Both failed a newborn hearing screen; twin A in both ears and twin B on the right side only. Twin A developed seizures soon after birth and twin B developed them later. Microarray revealed a 10,138 kbp deletion of 3p26.3-p25.3 and a 4,031 kbp duplication of 9q34.2-q34.3, in both boys. Karyotype confirmed 46,XY,der(3;9)(p25.3;q34.2) in both. The 3p anomaly overlaps with that of 3p deletion syndrome, with features including low birth weight, microcephaly, ptosis, micrognathia, hypertelorism, hypotonia, psychomotor and growth delay, hearing deficits and intellectual disability. Congenital heart disease, gastric and renal abnormalities are also commonly seen. The 9q34 duplication is a much rarer finding, and is associated with developmental and speech delay, poor feeding, and musculoskeletal abnormalities. Both twins remained in the NICU for an extended period. Six days after discharge from the NICU, twin A was readmitted to the pediatric ICU due to seizures. Twin B was transferred to the PICU from the NICU. Recurrent admissions followed for twin B, due to apneic episodes and feeding difficulties. He was found to have advanced pulmonary dysfunction and expired at 9 months; his autopsy showed pulmonary interstitial fibrosis, a dilated pulmonary artery, and right ventricular hypertrophy and dilation. Examination of the brain demonstrated acute on chronic diffuse hypoxic and ischemic damage and a mal-rotated right hippocampus lacking a dentate gyrus. Twin A had a similar but less fulminant course notable for apneic episodes, failure to thrive and seizures. He was transferred to comfort care, and expired at 14 months. No autopsy was performed. While 3p distal deletion syndrome is well established in the literature, 9q duplications are seldom reported. The combination of both has not been reported to date, and its occurrence in monozygotic twins is extraordinary.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2245. A combination of exome sequencing and optical genome mapping unveils a dual molecular diagnosis in a case with an unknown neurodevelopmental disorder.

Authors:

A. Acharya¹, N. Lin¹, S. Leal¹, J. Posey², I. Järvelä³, I. Schrauwen⁴; ¹Columbia Univ., New York, NY, ²Baylor Coll. of Med., Houston, TX, ³Biomedicum, Espoo, Finland, ⁴Columbia Univ., NYC, NY

Abstract Body:

An affected female with an apparent unknown syndrome that includes moderate intellectual disability, microcephaly, almond-shaped eyes, short philtrum, small chin, thin and dysmorphic fingers with a brachydactylic 4th finger and arachnodactylic 5th finger on the left, a slender habitus and mild epilepsy was investigated to determine the molecular etiology. We first performed exome sequencing, which revealed a 12bp deletion in the *GRIN2A* gene [p.(Ile151_Ala155delinsThr)] that was inherited from her father who also had mild epilepsy during childhood, that resolved similarly as previously seen in *GRIN2A* cases. The additional features of the daughter were unlikely due to the *GRIN2A* variant; therefore, we investigated this case further via optical genome mapping (OGM), a technology that utilizes long, linearized DNA to detect genomic structural variants (SVs) such as deletions, duplications, insertions, inversions and translocations. Optical genome mapping identified 6199 SVs, of which 44 were ultrarare (MAF<0.005) and 31 unique to the proband. The latter included a heterozygous 7kb insertion affecting *H3F3A*. Variants in this gene cause Bryant-Li-Bhoj neurodevelopmental syndrome 1, an autosomal dominant disorder with a variable phenotype including features seen in our case, such as intellectual disability, microcephaly, dysmorphic features including an abnormal philtrum, and distal skeletal defects. The variant is currently being further reconstructed via targeted long-read sequencing and Sanger sequencing, which will be presented at the meeting. In conclusion, via comprehensive molecular testing including exome sequencing and optical genome mapping, we identified a dual molecular diagnosis in an affected individual with an apparent unknown syndrome.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2246. A framework designed to improve the evaluation and reporting of incidental findings: Implementation and experience of a clinical laboratory in the first 15 months.

Authors:

C. M. Brown, L. M. Amendola, A. Chandrasekhar, A. J. Coffey, A. Kesari, R. J. Taft, D. L. Perry; Illumina Inc., San Diego, CA

Abstract Body:

Introduction: The Illumina Clinical Services Laboratory offers genome sequencing (GS) for rare disease and returns incidental findings (IFs), defined here as variants unrelated to testing indication not in genes on the American College of Medical Genetics and Genomics secondary findings list, that impact medical management. Lack of professional guidelines prompted us to design a framework for IF evaluation and return. Here we describe this framework and outcomes of its integration into our workflow.

Methods: Necessary properties of reportable IFs were defined and a stepwise process to evaluate potential IFs, with stopping points at which variants are deemed reportable or not, was developed. We assessed the number and types of IFs returned between January 2021 and March 2022.

Results: Clinical significance of the genotype and actionability of the associated disorder were identified as key features of reportable IFs. Single gene variants meet clinical significance criteria if they are in the correct zygotic state, classified as pathogenic (P) or likely pathogenic (LP), and have a gene-disease relationship of strong or definitive. For mitochondrial variants, heteroplasmy level is also considered. Multigene copy number variants must be classified as P or LP. Expanded repeats are not returned as IFs. Actionability criteria are met if ClinGen actionability scores for the relevant disorder are at least moderate (total score ≥ 7) with evidence of effective interventions (effectiveness score > 0). If scores are low, or unavailable, the literature is searched. IFs are returned if pre-symptomatic surveillance, interventions or circumstances to avoid are described. Variants in genes associated with disorders with palliative treatments not specific to the genotype, or management strategies in early stage clinical trials, are not returned as IFs.

Over 15 months, 726 individuals had GS. IFs were returned in 31 individuals from 30 families (4.3%) and were mostly associated with disorders of the blood and blood forming tissues (2.1%), cancer predisposition/neoplasm (1.2%), and renal or cardiac disorders (both 0.3%). Variants in the following genes were reported at least

once: *APRT*, *CHEK2*, *CLCN1*, *DDX41*, *F11*, *G6PD*, *HBB*, *HNFI1A*, *HOXB13*, *MT-RNR1*, *NF1*, *PKD1*, *RAD51C*, *SDHA*, *TTN*, *TTR* and *WRN*. Of the 17 associated disorders, actionability was established using ClinGen data for 7 and the literature for 10.

Discussion: This framework was successfully incorporated into our laboratory workflow and led to the return of actionable findings in 4.3% of patients. It could serve as a model for other groups considering standardization in the return of IFs encountered during genomic testing.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2247. A heterozygous de novo VUS (p.M130I) in candidate gene PSMC5 in a male with autism, mild developmental delay, speech deficiency, dysmorphic features, hypospadias and chordee.

Authors:

M. Hajianpour¹, C. Kois², J. A. Lundberg¹; ¹Albany Med. Coll./ Div. of Med. Genetics and Genomics, Dept. of Pediatrics, Albany Med. Ctr., Albany, NY, ²Nemours Children's Hosp., Wilmington, DE

Abstract Body:

Proband is a 23-month-old male with autism spectrum disorder, mild developmental delay and speech deficiency, hypospadias, and chordee (status post chordee repair, meatotomy and scrotoplasty). He was born FT, BW: 6lbs 1oz, BL: 18 inches. Developmental milestones were mildly delayed: He walked at 18 months, talked in single word at 9 months and in 2-3 words sentences at 21 months of age. He is receiving PT, OT, and ST. He has now a vocabulary of ~100 words, counts to 20, and knows alphabets. **Physical exam** (at 23m): Ht: 28th%ile, Wt: 40th%ile, HC: 60th%ile for age. He was not cooperative during the exam. He had occasional hand flapping when excited. **Dysmorphic features:** Mild positional plagiocephaly (prominent on the left), dolichocephaly, prominent mid-forehead; slightly posteriorly rotated ears; down-slanted palpebral fissures, epicanthal folds, long eyelashes; low/ broad nasal bridge and root, anteverted nares; thin upper vermillion; mild microretrognathia; hypoplastic nipples; mild clinodactyly of the 5th fingers, and bilateral clinodactyly of 2nd toes laterally overlapping the 3rd toes. **CNS:** CN II-XII are grossly intact. Good muscle tone. **GENETIC WORK-UP:** [1] Chromosome microarray (CMA) analysis: A Paternally inherited 580 Kb duplication at chromosome 17q25.3: a variant of uncertain significance (VUS): Not contributing to the phenotype. [2] Fragile X studies: Normal, 31 CGG repeats. 3. Molecular studies: GeneDX expanded Autism/ID panel TRIO (2500 genes): (i) A heterozygous maternally inherited VUS in KDM1A gene: p.A197T, Autosomal dominant - not contributing to phenotype. (ii) A hemizygous maternally inherited VUS of gene **ZNF674**: p.E150K A candidate gene/ may contribute to phenotype. (iii) A heterozygous, de novo VUS in candidate gene **PSMC5**: c.390 G>p.M130I: May contribute to the phenotype (**under investigation/ research**). *No PSMC5-related disorder is listed in OMIM.*
PSMC5: Member of the AAA (ATPases Associated with diverse cellular Activities) gene family. It may be involved in the regulatory subunit of the 26S protease. *PSMC5 (Proteasome 26S Subunit, ATPase 5) is a Protein Coding gene.* Reported diseases associated with PSMC5: Mulibrey nanism and Ogden syndrome. Patient does not currently have features of these two conditions.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2248. A multiomics approach to resolving small supernumerary marker chromosomes

Authors:

C. Grochowski¹, M. Ghandi², H. Du³, M. Mehaffey², K. Park², J. Rosenfeld³, S. Darilek¹, J. Eisfeldt⁴, M. Pettersson⁴, L. Potocki⁵, J. Lupski³, C. M. B. Carvalho²; ¹Baylor Coll. Med., Houston, TX, ²Pacific Northwest Res. Inst., Seattle, WA, ³Baylor Coll. of Med., Houston, TX, ⁴Karolinska Inst.t, Solna, Sweden, ⁵Baylor Col Med/TX Child Hosp, Houston, TX

Abstract Body:

Small supernumerary marker chromosomes (sSMC) are chromosomal fragments that are inherently challenging to characterize due to their small size, abnormal genetic structure, frequent occurrence of breakpoints within centromeric sequence as well as their heterogeneous and mosaic nature. Markers are hypothesized to be formed due to a trisomy rescue event resulting in incomplete degradation of DNA contained within micronuclei structures that are generated from aberrant anaphase chromosome separation and/or through a chromoanasythesis repair process. They display sporadic Mendelian inheritance patterns and the clinical consequence when they are identified remains elusive. We sought to fully resolve the architecture and infer the mechanistic origins through a multiomics approach including custom high-resolution array comparative genomic hybridization (aCGH), short-read whole genome sequencing (WGS) as well as optical genome mapping (OGM). Our heterogeneous cohort includes four families that were referred for genetic testing due to various clinical presentations that identified a *de novo* sSMC during G-banded karyotyping studies. The probands included 1 boy and 3 girls with markers that were derived from chromosomes 2 (N=1), 17 (N=2) and 19 (N=1). Further characterization using custom aCGH revealed an apparent size distribution of 4Mb to 10Mb with a log₂ ratio confirming the suspicion of mosaicism in at least 2 probands. Visualization of copy number gains in short-read WGS and the bioinformatic tool *VizCNV* revealed complexities not previously identified. One sample revealed a complex sSMC with a triplication embedded within duplications involving genomic material from chromosome 19. Subsequent analysis using OGM revealed the triplication to be inverted within this sSMC's architecture. In all samples studied, further analysis of the breakpoint regions within the proband in comparison with both parental samples will help to elucidate the final structure, dosage sensitive genes contained on the sSMC as well points of genomic instability that may have mediated the event. As previous studies (Grochowski *et al.*, 2018 (PMID:29696747) and Bodkin *et al.*, 2019 (PMID:31279534)) have highlighted, the complete architectural mapping of an sSMC is crucial in understanding the phenotypic presentation in a patient and targeting therapies in the pursuit of precision medicine.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2249. A multiple congenital anomalies newborn with coexistence of extra der(22) chromosome marker and balanced t(11;22) maternally inherited

Authors:

M. Albalwi¹, R. Alahmadi², D. Al-Bardisi², K. Alshalan², M. Siraj², A. Alzaid², N. Aldawsari², M. Alfadhel³, M. Alshammari⁴; ¹Dept. of Pathology & laboratory Med., King Abdulaziz Med. City, Riyadh, Saudi Arabia, ²Dept. of Med. Lab., King Khalid Univ. Hosp., King Saud Univ. Med. City, Riyadh, Saudi Arabia, ³Genetics & Precision Med. Dept., King Abdullah Specialist Children's Hosp., Riyadh, Saudi Arabia, ⁴Med. Genetics Div., Pediatrics Dept., King Khalid Univ. Hosp., King Saud Univ. Med. City, Riyadh, Saudi Arabia

Abstract Body:

Supernumerary derivative 22 [der(22)] syndrome is a rare chromosomal genomic disorder that is associated with multiple congenital anomalies, congenital heart defects, renal anomalies and male genital abnormalities. Here, we describe a one month male newborn with extra supernumerary derivative 22 marker and a balanced translocation t(11;22) inherited from his mother [47,XY, t(11;22)(q23.3;q11.1)mat, +der(22)t(11;22)(q23.3;q11.1)]. Coexisting of extra der(22) and balance t(11;22) rarely reported or not seen in the literature. Proband clinical features was associated with distinctive feature of deep-set eyes, relatively large ears with preauricular tag and cleft palate. Also, he has a congenital heart defects, absent unilateral kidneys and bilateral undescended testis. His genetic analysis abnormalities were also confirmed by FISH and chromosomal microarray analysis. Proper clinical evaluation and laboratory investigations are important for a proper family planning and genetic counseling particularly in a highly consanguineous population.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2250. A national initiative working toward equitable translational genomic research for Canadian Indigenous families: Early findings indicate the need to reduce uncertainty in variant interpretation.

Authors:

A. Mohajeri¹, **K. Jacob**¹, S. McIntosh¹, J. mwenifumbo², T. Maroilley³, V. Avramovic³, F. Bernier⁴, K. Boycott⁵, L. Badalato⁵, O. Caluseriu⁶, L. Chad⁷, G. Costain⁷, I. De Bie⁸, C. Greenberg⁹, A-M. Med., Vancouver, BC, Canada, ³Cumming Sch. of Med., Univ. of Calgary, Calgary, AB, Canada, ⁴Alberta Children's Hosp., Calgary, AB, Canada, ⁵Children's Hosp. of Eastern Ontario, Ottawa, ON, Canada, ⁶Univ. of Alberta, Edmonton, AB, Canada, ⁷The Hosp. for Sick Children, Toronto, ON, Canada, ⁸Montreal Children's Hosp., Montreal, QC, Canada, ⁹Children's Hosp. of Winnipeg, Winnipeg, MB, Canada, ¹⁰Dept. of Pediatrics, CHU Sainte-Justine, Montreal, QC, Canada, ¹¹McGill Univ. Hlth.Ctr., Montreal, QC, Canada, ¹²Univ. of Western Ontario, London, ON, Canada, ¹³Mem. Univ. of Newfoundland, St. John's, NL, Canada, ¹⁴UNBC, Prince George, BC, Canada, ¹⁵Univ. of Calgary, Calgary, AB, Canada

Abstract Body:

Problematic barriers to health care for Indigenous populations in Canada (First Nations, Inuit and Métis People) affect Indigenous participation in clinical trials and translational precision health studies, including projects to improve genomic diagnosis. Furthermore, under-representation of Indigenous individuals in genomic research has led to a lack of background reference information and less precise genomic interpretation, compounding inequities for those with rare genetic disease. The Silent Genomes Project aims to reduce gaps in access to accurate diagnosis, genomic resources and genomic health parity for Indigenous families through several projects which strive to prioritize Indigenous cultural safety, including a translational diagnostic genome-wide sequencing study only open to enrollment for those identifying as Indigenous, who have not obtained a diagnosis through routine clinical care. A majority of medical genetics clinics across Canada are participating. At the time of submission, 56 families have undergone whole genome sequencing, and results are available for 47 families. Reported candidate variants were categorized according to overall diagnostic relevance after conferencing among multiple clinical experts; categories included Definite, Probable, Uncertain, and Negative Diagnosis, as well as Research Candidate, and Incidental Finding. “Research” variants were typically in genes not yet firmly established as causative of human disease. Eleven families (23%) had no reportable findings (negative). Twenty-four families had only one reported candidate variant, and 12 families had more than one. Overall, we reported 60 candidate variants including 14 definite, 5 probable, 21 research candidates, and 20 uncertain. There were also 3 incidental findings in two families. Sixteen families (34%) received at least one diagnosis. The fact that the majority of reported variants (41 of 60; 68%) introduced uncertain possibilities—either in known or novel disease genes—speaks to the need for improved analytical precision. Deeper knowledge of the frequency of alleles in Indigenous populations should substantially reduce the number of uncertain variants being returned to families.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2251*. A new neurodevelopmental disorder with microcephaly and neural tube defect Loss of NARS1 leads to microcephaly and neural tube defects

Authors:

S. Temel^{1,2}, E. Oruç^{3,4}, A. Kahraman^{3,4}, S. Ozemri Sag¹, E. Eren⁵, M. Ergoren⁶, S. Gul⁷, MarmaRare Group, E. Deniz⁸, A. Fuss^{3,4}; ¹Bursa Uludag Univ., Faculty of Med., Dept. of Med. Genetics, Bursa, Turkey, ²Bursa Uludag Univ., Inst. of Hlth.Sci., Dept. of Translational Med., Bursa, Turkey, ³Bogazici Univ., Dept. of Molecular Biology and Genetics, Istanbul, Turkey, ⁴Bogazici Univ., Ctr. for Life Sci. and Technologies, Istanbul, Turkey, ⁵Bursa Uludag Univ., Faculty of Med., Dept. of Pediatric Endocrinology, Bursa, Turkey, ⁶Near East Univ., Faculty of Med., Dept. of Med. Genetics, Nicosia, Cyprus, ⁷Biotechnology Div., Dept. of Biology, Istanbul Univ., Istanbul, Turkey, ⁸Yale Univ., Sch. of Med., Dept. of Pediatrics Critical Care, New Haven, CT

Abstract Body:

Aminoacyl-tRNA synthetases (ARSs) are enzymes that attach the appropriate amino acid onto its corresponding tRNA and are essential for protein translation. Mutations in ARS genes have been implicated in various human diseases, including neurological, autoimmune, and cancer. One of the thirty-seven ARSs Asparaginyl-tRNA synthetase1 (NARS1) functions in the cytoplasm responsible for asparagine tRNA charging and implicated in neurodevelopmental delay with microcephaly due to toxic gain-of-function and partial loss-of-function effects. **Here**, we report a family with a ten-month-old deceased boy who presented with microcephaly and dysmorphic features. He was the second-born from a consanguineous marriage at 33+5 week gestational age. He presented with resistant epilepsy, neurodevelopmental delay, neonatal diabetes, inguinal hernia, hydrocele testis humoral immunodeficiency, congenital heart disease (VSD, pulmonary stenosis), and multiple cavernous malformations in the brain. The sibling was the third-born female who presented with microcephaly and encephalocele. She also deceased on her first day of birth. Exome sequencing revealed a homozygous missense mutation c.866A>G, (p.Tyr289Cys) in the NARS1 gene, the segregation in the family was confirmed by Sanger sequencing. We turned to animal models to investigate the role of NARS1 in development and bolster the evidence that the variant is disease-causing. We used the frog *Xenopus* model for loss of function assays. We depleted *nars1* using the CRISPR/ CAS9 system targeting three non-overlapping exons. We analyzed brain size and the neural tube defects using optical coherence tomography imaging and showed that *Xenopus* NARS1 mutation leads to microcephaly and neural tube defects recapitulating our patient's phenotype. Next, to test the pathogenicity of the identified NARS1 variant, we used the fly *Drosophila melanogaster* as a model. Using a Gal4 line, we show that the fly orthologue of NARS1, AsnRS, is expressed in the larval and adult central nervous systems and in a subset of neurons. We have generated a mutant for AsnRS and transgenic fly lines expressing wild-type and mutant NARS1.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2252. A novel FAME1 repeat configuration in a European family identified using a combined genomics approach

Authors:

T. Maroilley^{1,2,3,4}, M-H. Tsai^{5,6,4}, R. Mascarenhas^{3,7}, C. Diao^{1,2,3}, M. Khanbabaei⁷, S. Kaya⁸, C. Depienne⁸, M. Tarailo-Graovac^{1,2,3,9}, K. Hosp., Taiwan, Taiwan, ⁶Sch. of Med., Coll. of Med., Chang Gung Univ., Chang Gung, Taiwan, ⁷Dept. of Clinical NeuroSci.s, Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada, ⁸Inst. of Human Genetics, Univ. Hosp. Essen, Univ. of Duisburg-Essen, Essen, Germany, ⁹Equal, Senior Authors, AB, Canada

Abstract Body:

Familial adult myoclonic epilepsy (FAME) is an autosomal dominant, neurological disease characterized by adult-onset of cortical tremors and infrequent generalized tonic-clonic seizures. Recently, using long-read sequencing, FAME was found to be caused by a pathogenic pentanucleotide repeat expansion, a combination of a TTTCA repeat expansion associated with a polymorphic TTTTA repeat. Thus far, six intronic loci with this pentanucleotide repeat combination have been described, suggesting that the repeat itself plays the main role in the pathogenesis of the disease regardless of the locus/gene where the repeat is located. Common ancestral founder effects may play a role as individual loci expansions have been only associated with specific populations. For example, the *SAMD12* expansions (FAME1) have only been reported in patients of Asian descent. Importantly, a recent detailed analysis performed in the FAME1 families revealed that the repeats have variable size, configuration, and composition. The TTTCA repeats can be very long (> 1000 repeats), but also very short (14 being the shortest identified); and of different configurations and compositions, suggesting a complex relationship between the combination of repeat expansions and disease manifestation. Here, we report two siblings (brother and sister) of European descent with a clinical diagnosis of FAME, yet negative repeat-primed PCR (RP-PCR) test. Using short-read whole genome sequencing (srWGS), we identified a pentanucleotide expansion in intron 4 of *SAMD12*. We used Optical Genome Mapping (OGM) to validate our findings, which confirmed the 4.1kb expansion in *SAMD12*. We also used Cas9-mediated enrichment and long-read sequencing, which confirmed a novel (not previously reported) configuration of the repeat: (TTTTA)₋₈₀₀(TTTCA)₃(TTTTA)₇(TTTCA)₇. Our study is the first to associate the *SAMD12* locus in European FAME patients and currently represents the shortest identified TTTCA expansion, which explains why it was missed using the RP-PCR test. These results also show that we are still learning about FAME and integrating additional genomics approaches (e.g., OGM and srWGS) may help facilitate the discovery of novel configurations and thus mechanisms of this disease.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2253. A rare association of congenital hypohydrotic ectodermal dysplasia, secondary hypogonadism, and severe iron deficiency anemia.

Authors:

D. Selvarajan¹, N. Raman¹, P. Jayapal²; ¹Thiruvarur Med. Ctr., Thiruvarur, India, ²Lucile Packard Children's Hosp., Stanford Univ., Pal Alto, CA

Abstract Body:

A 16-year-old male presented with breathlessness for the past one month. He was short for his age, severely pale, and non- edematous on examination. His secondary sexual characteristics were poorly developed with thin scalp hair, sparse axillary hair, absent pubic hair, micropenis, poorly developed testes, and atrophic nails with grade 1 clubbing. He also had partial anodontia. His bone age was less than chronological age. He gave a history of heat intolerance and absent sweating since childhood. He was born to non-consanguineous parents by full-term delivery. He attained milestones on time. His scholastic performance had been good. His sibling was normal. No other family member had a similar illness. On evaluation, he was found to have severe iron deficiency anemia with Hemoglobin of 6 g/dl. He had low testosterone, FSH, and LH which are suggestive of secondary hypogonadism. A clinical exome test was done to analyze the genes associated with anemia, ectodermal dysplasia, and hypogonadotropic hypogonadism, which showed a heterozygous pathogenic variant involving exon 12 of the EDAR gene indicative of Hypohydrotic ectodermal dysplasia. The other pathogenic genes for hypogonadotropic hypogonadism and iron deficiency anemia were negative. To the best of our knowledge, this is the first case of Hypohydrotic ectodermal dysplasia reported in association with secondary hypogonadism and severe iron deficiency anemia. This combination could be a new syndrome as such.

PB2254. A recurrent *AFF3* pathogenic variant associated to KINSSHIP syndrome in a Mexican patient

Authors:

L. Flores Gallegos¹, V. GUEVARA SANCHEZ¹, C. JUARISTI MANRIQUE², R. MORALES TOQUERO¹; ¹Hosp. Angeles Puebla, PUEBLA, Mexico, ²CENTOGENE, ROSTOCK, Germany

Abstract Body:

KINNSHIP syndrome was defined in 2021, as an autosomal dominant disorder characterized by a recognizable pattern of anomalies caused by *the novo* missense heterozygous mutations in the degnon of *AFF3* gene within chromosome 2q11. Voisin et al, proposed that this variants are likely to weaken or prevent binding to the ubiquitin ligase motif located in exon 6. [Voisin et al 2021]

Anomalies found in KINSSHIP syndrome are horseshoe kidney, mesomelic dysplasia, seizures, hypertrichosis, intellectual disability and pulmonary involvement as cardinal features. Bilateral fibular agenesis, feet in a marked equinovalgus position, subcortical brain atrophy and ambiguous genitalia are also reported. [Shimizu et al 2019]

We present a 2 year old female mexican patient with bilateral equino valgus position, mesomelic bone dysplasia, sacral dimple, failure to thrive, global developmental delay, camptodactyly, external genital hypoplasia and hypertrichosis. MRI showed cortical atrophy and corpus callosum hypoplasia. Normal karyotype was reported.

A next-generation sequencing exome panel (CentoXome Solo) identified an heterozygous pathogenic variant in *AFF3* gene NM_002285.2:c.691C>T (p.Pro231Ser) that was previously reported. The carrier status test of both parents confirmed a *the novo* event.

To our knowledge this is the first Mexican patient report of KINSHIPP syndrome and one of the few reported in global literature. Interestingly, has the c.691C>T that appears to be a recurrent variant in the degnon of *AFF3*. In our country the access to NGS studies is cost limited, but correct genetic counseling and dedicated patient care could be the difference in the correct diagnosis, management and counseling for the patient and their relatives.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2255. A robust NGS detection workflow for the *IKBKG* gene

Authors:

H-Y. Yen, J. Zdrodowski, I. Zelaya, A. Zhong, M. Fileto, S. Rammohan; Fulgent Genetics, Temple city, CA

Abstract Body:

IKBKG is associated with incontinentia pigmenti (IP), an X-linked (XL) dominant disorder impacting the skin, hair, teeth, nails, eyes, and CNS primarily affecting females and, rarely, males with 47,XXY or low-level mosaicism for the condition. The most distinctive features are evolving skin lesions, starting with blistering at birth and transitioning to wart-like rash, swirling hyperpigmentation, and, in some cases, linear hypopigmentation. Milder variants in *IKBKG* are associated with XL recessive immunodeficiency with or without hypohidrotic ectodermal dysplasia, typically affecting males.

IKBKG (formerly *NEMO*) encodes the regulator gamma subunit of the IKB kinase (IKK) complex. IKK-gamma, in complex, activates NF-kappaB, which protects against the apoptosis induced by tumor necrosis factor alpha, and regulates proinflammatory responses and ectodermal development.

IKBKG analysis is complicated by the presence of a highly homologous pseudogene, *IKBKGP1*, also on the X chromosome. This results in difficulties evaluating the gene by NGS as many reads suffer from multiple-mapping issues, wherein one read matches multiple locations, resulting in a lack of unique reads to call variants. As such, analysis typically includes LR-PCR for a common 11.7-kb deletion and LR-PCR and sequencing for variants in all 10 exons. In order to promote an efficient approach in the laboratory, we propose an NGS detection workflow for *IKBKG*.

We started our analysis with NGS and misalignment analysis for the common deletion, as a screen. Next, we evaluated the multi-mapping BAM file in the regions of high homology (e3-10) for variants with 25% allele fraction (AF) for germline variants in females, 50% for males, or lower AF for potential mosaic variants. Variants identified were confirmed by LR-PCR alone (common del) or LR-PCR and Sanger sequencing targeting the SNV detected. If no variants were identified, no further testing was performed. Eighty-six consecutive orders for *IKBKG* testing submitted to our laboratory were tested using the workflow (70 females). 45.3% had diagnostic results and 3.5% had VUS. Among diagnostic cases, 74.4% were the common deletion (including one mosaic) and 10 were other variants.

Given the management and surveillance options for patients, as well as prognostic and recurrence information, accurate diagnostic testing of *IKBKG* and other genes with highly homologous regions is necessary to avoid false negative and false positive results. We demonstrated a workflow to accurately evaluate the *IKBKG* gene to produce reliable results for patients while improving lab efficiency by utilizing NGS and confirmatory testing by orthogonal methods, as needed.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2256. A variant interpretation framework based on probabilistic graphical modeling that provides continuous high-resolution estimates of variant pathogenicity with improved interpretation accuracy over current discrete five-category frameworks

Authors:

R. Nussbaum, T. Manders, J. Nicoludis, A. Nampally, K. Nykamp, Y. Kobayashi, A. Colavin; Invitae, San Francisco, CA

Abstract Body:

As genetic testing expands to larger panels and exome analysis, laboratories face an increasing burden of interpreting variants while clinicians are forced to sort through expanding lists of variants of uncertain significance (VUS). Current variant interpretation systems rely on rules-based frameworks such as the ACMG/AMP guidelines (Richards et al. *Genet. Med.* 2015) and Sherlock (Nykamp et al. *Genet. Med.* 2017) that use pre-defined heuristic weighting of quantitative and qualitative data of various evidence types to support either a pathogenic or a benign interpretation. While these systems bring consistency and reproducibility to variant classifications, valuable information is lost when rules-based approaches incorporate inherently quantitative data such as population allele frequencies or in silico algorithms as discrete categories. Insufficient or conflicting evidence results in more than 50% of observed variants in disease-associated genes being classified as VUS. This leaves many patients with uncertainty about their disease risk or diagnosis and how those results should influence their care. Here we introduce a novel variant interpretation framework based on probabilistic graphical modeling and machine learning that applies domain expert-informed causal reasoning about the pathogenesis of disease. This framework has several advantages compared to current rules-based systems. First, instead of treating different types of evidence as independent and relying on manually-defined weights, it provides a compact representation of the complete joint probability distribution for the domain to assess the value of information in the context of other information. We demonstrate that this approach can substantially decrease the number of missense VUS observed at our lab by up to 25%, even when using a limited set of distinct data types. Second, the graph structure facilitates incorporation of additional types of quantifiable evidence, such as functional analyses and clinical phenotype information. Third, this approach supports reasoning about the relationship of evidence to interpretation so that the pieces of information that will most effectively increase the certainty of a variant being pathogenic or benign can be identified. Lastly, by estimating quantitative probabilities of pathogenicity instead of relying on a 5-tier classification, the framework provides a continuous high-resolution estimate of variant pathogenicity, which we believe will empower and encourage the medical community to implement more informed, personalized management guidelines that will lead to better patient care.

PB2257. Accurate Total and Allele-Specific Copy Number Quantification of the Cardiovascular Disease-Associated Lipoprotein (a) Kringle-IV Type-2 Tandem Repeat Using Illumina Sequencing

Authors:

J. Belyeu¹, S. Behera², X. Chen³, N. Q. H. Nguyen⁴, V. K. Menon⁵, C. M. Ballantyne⁶, C. Rodriguez⁷, R. C. Kaplan⁷, G. Metcalf⁵, B. Yu⁸, E. Boerwinkle⁸, M. A. Eberle⁹, F. Sedlazeck⁵; ¹Illumina, Inc., San Diego, CA, ²Baylor Coll. of Med., Houston, TX, ³Pacific BioSci.s, Richland, WA, ⁴Sch. of Publ. Hlth., Univ. of Texas Hlth.Sci. Ctr., Houston, TX, ⁵Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX, ⁶Dept. of Med., Baylor Coll. of Med., Houston, TX, ⁷Dept. of Epidemiology and Population Hlth., Albert Einstein Coll. of Med., Bronx, NY, ⁸Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, ⁹Pacific BioSci.s, San Diego, CA

Abstract Body:

Transcript length of the human LPA gene, which encodes lipoprotein (a) (Lp(a)), has been associated with increased cardiovascular disease (CVD) risk. The transcript length of LPA is primarily driven by the number of copies of a 5.5kb tandem repeat known as Kringle-IV Type-2 (KIV-2). Quantification of KIV-2 has been challenging with sequencing due to the length of the repeat and its extreme variability, with 2-60+ copies of the region in each allele and greater than 95% heterozygosity in most populations. Here we present a computational strategy to determine KIV-2 copy number from Illumina whole-genome sequencing (WGS). The method successfully identified total copy number (summed copy number of both alleles) in all 3,202 samples from the 1000 Genomes Project. The approach utilizes SNV markers to determine the phased copy number (individual length of each allele) in ~47% of these samples. We performed an analysis of call accuracy against orthogonal long-read and optical mapping technologies in a subset of 46 samples for total copy number and 39 alleles for phased copy number calls. This analysis revealed high accuracy, with average agreements in total and allelic copy number of 98.2% and 98.6% respectively. We then analyzed KIV-2 copy number in a set of approximately 3,000 additional genomes collected in the USA from European, African, and Hispanic ancestries, with matching Lp(a) protein level measurements. In this analysis we found significant trends of higher Lp(a) levels associated with low KIV-2 copy number across all three ancestral groups.

The LPA calling method, which will be made available on Illumina's DRAGENTM Bio-IT platform*, will enhance characterization of KIV-2 copy number and enable the detection of alleles that increase CVD risk from WGS with vast utility in research applications.

*For Research Use Only. Not for use in Diagnostic Procedures.

PB2258. Advancing Biobanking in the Genomics Era: Development of Molecular Omics Approaches for Interrogating the Diversity of Population Genetics for Early and Late-Stage Human Disease Prevention

Authors:

M. Sheldon, S. Nahas; Sampled, Piscataway, NJ

Abstract Body:

Precision medicine has demonstrated improvements in the quality of life for people who are at risk for or present with a given disease and its complications. Development of targeted, molecular-based assays and companion treatments that provide early detection and inform effective therapeutic approaches for a number of serious conditions often relies on access to large numbers of high quality biospecimens and associated clinical data. For these reasons, biobanks are poised to play a role in supporting many aspects of clinical research, including clinical trial management, discovery and development of assays and therapies. At Sampled, we taken the next step in the evolution of the modern biobank. The Sampled model is that of a SMART lab, providing a comprehensive suite of sample Storage, Management, Analysis, Research and Transportation services to clients large and small in a range of academic and commercial sectors. In this presentation, we will consider a number of initiatives at Sampled to develop tools for the advancement of the diagnosis and treatment of human genetic disorders. One such example is polygenic risk score (PRS) testing. PRS tests for diseases like Alzheimer's, breast cancer, and even severe COVID have been developed and brought to market by Sampled in collaboration with commercial partners. These tests are designed using Genome Wide Association Study (GWAS) data to identify candidate risk alleles and associated clinical data that can be combined to give a risk score. This score is then be combined with that of the population within the patient's demographics, to assess potential risk for a particular disorder. For example, the Alzheimer's PRS Test can aid in stratification of clinical trials for new treatments or facilitate early detection of subjects at high risk. It includes over 112,000 loci of interest, including the "VIP" APOE loci. Initial applications will be for physicians assessing new patients, with cognitive complaints, to assess their future risk of cognitive decline due to Alzheimer's disease. It can also provide greater insight into the risk of cognitive decline in existing patients. Additionally, the Alzheimer's Risk Test will be used in clinical study recruitment strategies to identify patients most suitable to enter trials of investigational Alzheimer's drugs, including those patients with mild cognitive decline who are most at risk of subsequent decline within the timescale of the study. In addition to working with partners to clinically validate these tests on the ideal platform, Sampled offers the ability to scale up for high throughput testing in its high-complexity CLIA laboratory.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2259. Analysis of mRNA and protein expression levels of MECP2 in missense mutant iPSC and lymphoblast lines against isogenic controls

Authors:

T. Thiruvallur Madanagopal¹, S. Pastore¹, T. Muhammad¹, A. Mikhailov¹, J. Vincent²; ¹Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada, ²Ctr. for addiction and mental Hlth., Toronto, ON, Canada

Abstract Body:

Background Mutations in MECP2 (methyl CpG binding protein 2) have found to cause Rett syndrome (RTT), as well as autism spectrum disorder (ASD), schizophrenia, and X-linked intellectual disability (XLID). About 33% of all RTT patients have missense mutations, and mainly in the methyl-CpG-binding domain (MBD) that binds to DNA and forms chromatin associated protein complex. Some of these mutations interfere with the binding and some others disrupt the clustering of chromatin. A similar proportion of RTT patients have nonsense mutations that truncate the MECP2 protein, leading to protein degradation resulting in insufficient levels in the cell. Studies have suggested this degradation might also be true for missense mutations. Hence understanding changes in MECP2 expression in mRNA and protein would shed light on better understanding of the role of MECP2 mRNA and protein degradation towards the clinical manifestations. **Methods** MECP2 mutant and isogenic iPSC (induced pluripotent stem cells) and lymphoblasts were provided by the Rett Syndrome Research Fund or purchased from Coriell Institute for Medical Research, USA. RNA and protein were isolated from these cells. mRNA levels of MECP2 was analyzed using RT-qPCR from complimentary DNA (cDNA) synthesized from RNA. Protein levels were quantified using ELISA and western blot. The mRNA expression levels of MECP2 for the mutants iPSC and lymphoblasts lines were analysed against isogenic controls. **Results** While mRNA levels were not significantly affected, some mutants showed significantly less protein expression compared to its isogenic controls (R225X, R133C). However, other mutants like R306C and R106W did not show a significantly change in protein expression compared to its isogenic control. **Conclusion** The knowledge on the levels of MECP2 protein and mRNA expression could help develop approaches to recover the mutant MECP2 protein and stabilizing it. This would be beneficial to develop personalized therapeutic approaches for MECP2-related clinical phenotypes.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2260. Anthropometric parameters in males with chromosome 9p microdeletion syndrome in the first years of life: preliminary evidence.

Authors:

S. Pajouhanfar, R. Starosta, V. Tate, Y-C. Hou, F. Cole, T. Turner, P. Dickson; Washington Univ. Sch. of Med., Saint Louis, MO

Abstract Body:

Introduction: Chromosome 9p microdeletion syndrome (“9p- syndrome”) is a rare syndrome with a spectrum of expressivity including dysmorphic features, intellectual disability, hypotonia, psychiatric illnesses, metopic craniosynostosis, male-to-female sex reversal, neonatal hypoglycemia, congenital heart disease, and ocular abnormalities. To date, there has been no investigation of the anthropometric data in 9p- patients, and in practice their parameters are plotted in typical growth charts such as the ones published by the World Health Organization (WHO) or the Centers for Disease Control and Prevention (CDC), which have not been validated for this population. Objective: A retrospective study with chart reviews of anthropometric parameters was performed to compare growth curves of males with 9p- syndrome to the general population. Methods: Anthropometric data from clinical visits until age 3 years were collected from all participants. Data were compared to the WHO growth charts for weight, length, and head circumference at 2, 4, 6, 9, 12, 15, 18, and 24 months of age, and to the CDC growth charts for weight, height, and head circumference at 36 months of age. Due to the low sample size, only descriptive statistics were performed. Written informed consent was obtained from the parents or legal guardians of all participants. This study was approved by the Washington University in Saint Louis IRB. Results: Eleven patients (male = 7) with a documented diagnosis of 9p- by karyotype or chromosomal microarray were included in this study. Due to the low female sample size (n = 4) in the study, only males (were analyzed. Mean percentiles for height at 2, 4, 6, 9, 12, 15, 18, 24, and 36 months were 66%, 83%, 86%, 78%, 88%, 81%, 80%, 84%, and 75%, respectively. Mean percentiles for weight at 2, 4, 6, 9, 12, 15, 18, 24, and 36 months were 70%, 92%, 90%, 68%, 68%, 71%, 67%, 68%, and 84%, respectively. Mean percentiles for head circumference at 2, 4, 6, 9, 12, 15, 18, 24, and 36 months were 28%, 71%, 83%, 70%, 67%, 57%, 73%, 73%, respectively. Discussion/Conclusion: Despite the small sample size, on a visual inspection of the data there is an apparent trend toward higher percentiles for height during the first 3 years of life in males with 9p- syndrome compared to normative data. This trend was accompanied by weight during the first year of life, with a relative decrease in weight percentiles afterward. There was no perceived deviation from normality in head circumference values, which may have been confounded by trigonocephaly but may also represent a small degree of relative microcephaly. We are currently enrolling more individuals with a diagnosis of 9p- syndrome to expand this analysis.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2261*. B-allele frequency based approach to detecting absence of heterozygosity using optical genome mapping.

Authors:

A. Raksi, W. A. Sherman, N. Miller, A. R. Hastie, S. Shams; Bionano Genomics, San Diego, CA

Abstract Body:

Introduction: Copy-neutral loss of heterozygosity can be caused by uniparental disomy, associated with meiotic errors resulting in developmental diseases and cancer, or be a result of identity by descent (IBD), when the parents are close relatives or from a bottleneck population. These events have traditionally been identified using SNP microarray and microsatellite analysis. Previously, we described a method to detect the absence or loss of heterozygosity (AOH/LOH) using high-resolution optical genome mapping (OGM) results from the Bionano Genomics Saphyr platform, based on information about structural variant (SV) call zygosity. Here we describe a method for AOH analysis based on the B-allele frequency (BAF) observed at label sites overlapping with known SNP positions, which enables the detection of AOH events at low allelic fractions. **Methods:** DNA was processed on the Bionano Genomics Saphyr instrument and analyzed using the Bionano Solve pipeline. The labels used in OGM attach to a specific nucleotide sequence motif in the genome. SNPs overlapping the sequence will cause a lack of fluorescence at that point. The B-allele frequency is calculated as the ratio of molecules with missing labels to the total number of molecules aligned to the position. Label sites were filtered to those overlapping known SNPs with a minor allele frequency greater than 5% in the population. Data from 180 control samples were used to identify labels for which the BAF values clustered into three well-formed clusters corresponding to the AA, AB, and BB alleles, indicating that heterozygous and homozygous SNPs could be differentiated. Next, BAF values were normalized for the query sample at each SNP position. Finally, AOH regions were called using the NxClinical software's SNP-FASST3 algorithm for segmenting and calling events. **Results:** By filtering data for labels overlapping known SNPs and those that clustered well, 3867 informative label sites were identified using the DLE1 labeling enzyme. The method was validated in a small cohort of constitutional and cancer samples with known AOH/LOH events. We were able to detect a wide range of events ranging from small 20Mb events to as large a whole chromosome. We also demonstrated and validated a 55Mb low level mosaic detection of a CN-AOH at 16% allele fraction. **Conclusions:** Our results show that it is possible to detect AOH/LOH regions at low allele frequency using optical genome mapping alone. This expands the utility of the method to analyzing tumor samples. The software will be made available as part of NxClinical v7.0.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2262. Beyond NGS: RNA-based functional evaluation improves ACMG classification of VUS with potential Loss of function

Authors:

J-L. Blouin^{1,2}, T. RIO FRIO¹, A. VANNIER¹, M. ABRAMOWICZ^{1,2}; ¹Univ. Hosp. of Geneva, Geneva, Switzerland, ²Univ. of Geneva-Sch. of Med., Geneva, Switzerland

Abstract Body:

NGS in clinical practice allows screening an ever increasing number of genes that has improved the portion of elucidated cases, but also creates a dramatic increase of variants of unknown significance. Current variant filtering strategies and interpretation guidelines by the ACMG focus on amino-acid level identify but filter out other non-coding or synonymous variants that may however have a biological and clinical significance. We have implemented an analytical pipeline to assess the variants-of-uncertain-significance (VUS) predicted to impact gene transcript with the aim to decipher their pathogenicity. After selection of pre-filtered variants by an interdisciplinary team, molecular investigations based on techniques of targeted transcript regions that are fast and affordable were performed on RNA extracted from patients blood. Besides confirmation of predicted impact on splicing, sequence or structure of some variants, a number of unexpected effects were also observed in a number of other variants. For example, a variant in an intronic canonical splicing signal of DNAH11 predicted to induce in-frame exon skipping, and, or partial intronic retention ultimately leads to premature polyadenylation of mRNA. Also, a variant in an intronic cis- regulatory splicing element of NEB produces an unexpected broad range of alterations of the sequence, the structure and the balance of alternative isoforms. We also demonstrated the utility of RNA analysis in a prenatal diagnosis in RNA from fetal amniocentesis in the context of ultrasonography abnormalities for a IVS+5 variant of FBN1 that was upgrades to class 5 in the fetus. We demonstrated that such targeted RNA-based analytical approach had the ability to clarify a number of DNA-based interpretation of variants. It was far-more cost-effective than total RNAseq that needs complex analytical process that would not be necessary in a number of such situation where VUS are identified and could explain the phenotype. All variants, within various genes, analyzed through this pipeline so far could thus be re-classified, either upward (pathogenic) or downward (benign) following ACMG guidelines. In addition we found that all the genes assessed until now could be assessed on RNA from blood although some of them were not necessary predicted to be expressed in such easily accessible tissue according to GTEx.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2263. Challenges of characterisation of medically relevant tandem repeats in whole genome sequencing data

Authors:

I. Lojova^{1,2}, M. Kucharik^{3,4}, Z. Pös^{1,4,3}, A. Zatkova¹, E. Tarova^{1,5}, J. Styk^{4,3,6}, J. Budis^{4,3,7}, L. Kadasi^{1,2}, T. Szemes^{4,2,3}, J. Radvanszky^{1,4,2}; ¹Inst. of Clinical and Translational Res., BioMed. Res. Ctr. of the Slovak Academy of Sci., Bratislava, Slovakia, ²Dept. of Molecular Biology, Faculty of Natural Sci., Comenius Univ., Bratislava, Slovakia, ³Geneton Ltd., Bratislava, Slovakia, ⁴Comenius Univ. Sci. Park, Bratislava, Slovakia, ⁵Faculty of Ed., J. Selye Univ., Dept. of Biology, Komarno, Slovakia, ⁶Inst. of Med. Biology, Genetics and Clinical Genetics, Faculty of Med., Comenius Univ., Bratislava, Slovakia, ⁷Slovak Ctr. of Scientific and Technical Information, Bratislava, Slovakia

Abstract Body:

Following the introduction of massively parallel sequencing and dedicated bioinformatic tools, genotyping of tandem repeat motifs (TRs) from these datasets are becoming commonplace too. Effective and reliable TRs characterisation for medical reasons, for example of those connected to repeat expansion disorders (REDs), however, still poses several challenges, specifically when considering the vast variability and complexity of TRs. We aimed, therefore, to characterize some of the potentially relevant TR detection challenges. For this we used whole-genome sequencing (WGS) data (BGI-DNB-SEQ; Paired-End 150bp; PCR-free library preparation) generated for 52 individuals. Altogether, over 50 manually selected and described (according to the actual HGVS nomenclature) medically relevant TR loci were genotyped and characterized from each WGS using the modified version of our previously published tool Dante (Budis et al., 2019). The data set consisted of patients having three different types of REDs (10 DM1, 7 DM2 and 5 HD) and 30 controls. The main challenges identified were: 1) Correct dissection of clinically relevant parts of TR loci and their flanking sequences, especially if they are parts of complex motifs (connected to the use of unified allele nomenclature; e.g.HGVS); 2) Correct allele identification and sizing, affected by the: i) achieved read depth and usable reads; ii) possible complexity of motifs (expected and unexpected complexity, including unexpected sequence interruptions or loss of normally present interruptions); and iii) stutter effects (largely eliminated by PCR-free approaches); 3) Sizing limits, i.e. the maximum allele length determinable from the spanning reads (connected to read-length/motif-length characteristics); 4) Identification of the presence of alleles exceeding the detection limit (expansion detection exploiting partial reads); 5) Correct allele phasing when considering complex motifs consisting of several adjacent simple motifs. Results of our work proved the potential of short-read WGS in the field of TRs characterization, however, with certain limitations, which require further studies, modifications, specific quality control metrics, or at least which should be kept in mind when evaluating TRs in individual patients. The presented work meets the relevant ethical standards and informed written consents were obtained. Financial support: Slovak Research and Development Agency (APVV-18-0319), Scientific Grant Agency (VEGA_2/0167/20, VEGA_2/0040/20) and by the OP Integrated Infrastructure co-financed by the European Regional Development Fund (ITMS: 313011V578, 313011W428).

PB2264. Child with Rhabdomyosarcoma and unusual features: suspected Rasopathy.

Authors:

S. Charaya¹, I. Panigrahi², A. Tyagi¹, S. Gupta¹; ¹Post graduate Inst. of Med. education and research, Chandigarh, India, ²PGIMER, Chandigarh, India

Abstract Body:

Case description: 8-month-old female child with intermittent fever episodes for 20 days and gradually progressive left cheek swelling. On examination had failure to thrive, microcephaly, right facial nerve palsy (upper motor neuron) and dysplastic ears. Local examination showed 8cmx8cmx6cm swelling over face, firm in consistency with few nodular surfaces. Skin over swelling- tense, red with raised temperature. Skin examination showed café au lait macule over trunk and lower limb, melanocytic nevi, nevus spilus, Mongolian spots over back, Inflammatory linear verrucas epidermal nevus, scarring alopecia. FNAC of swelling showed predominantly scattered tumor cells with few clusters of many bizarre multinucleated tumor cells s/o malignant neoplasm. Immunohistochemistry from FNAC cells showed desmin, myogenin and MyoD1 positive Rhabdomyosarcoma. MRI Brain showed exophytic heterogeneously enhancing lesion in left masticator space. Exome sequencing studies were performed keeping a possibility of Rasopathy or Genodermatoses.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2265. Chromosomal and molecular investigations of Senegalese children bearing disorders of sex development.

Authors:

H. Younoussa^{1,2}, M. SOUMBOUNDOU³, R. DIAGNE⁴, R. M'kacher⁵, M. GADJI¹; ¹Service of Biological Hematology & Oncology-Hematology (BHOH), Faculty of Med., Pharmacy and Odontostomatology, Cheikh Anta Diop Univ. of Dakar (UCAD), Natl. Ctr. of Blood Transfusion (NCBT), Dakar, BP5002 PtE, Senegal, Dakar, Senegal, ²Cell-Environment, Paris, France, ³Med. Diagnostic Lab., Diarniadjò Hosp., UFR-Santé de Thiès, Iba Der THIAM Univ. of Thiès, Senegal, Thiès, Senegal, ⁴Med. Diagnostic Lab., Diarniadjò Hosp., UFR-Santé de Thiès, Iba Der THIAM Univ. of Thiès, Senegal, Dakar, Senegal, ⁵Cell Environment, Paris, France

Abstract Body:

Disorders of sex development (DSD) are among the most common congenital malformation syndromes in Africa. They are defined as conditions associated with atypical chromosomal, gonadal or anatomical sex development. The incidence and prevalence of these anomalies remain very high in Africa despite of diagnostic difficulties compared to the rest of the world. Indeed, diagnosis and management of these abnormalities in this African continent remain very limited. In order to set up and improve postnatal diagnosis of DSD for a better patient clinical management, we aimed to investigate the epidemiological, genetic and molecular profile of children with DSD in Senegal. A retrospective and prospective study in a multicenter survey of DSD in Senegal was conducted from 2014 to 2021 with 91 included DSD patients. The survey data were entered into Excel and exported to R software version 4.1.3 for statistical analysis. Chromosomal investigations were performed using constitutional cytogenetics (G-banding) and molecular FISH techniques for the search of the SRY gene as well as telomere and centromere labeling followed by M-FISH for the search of other chromosomal aberrations that would be the cause of these abnormalities. The mean age of the patients was 33.16 ± 48.97 with extremes from 2 days to 178 months. The median age was 12 months. The percentage of parental consanguinity was 54%. Karyotype and FISH analyses were performed in the majority of the population. Among the 91 DSD patients, 48.88% had 46,XY karyotypic profile, 31.11% with 46,XX karyotype, 1.1% with 46,XX/45,X mosaic karyotype, 1.1% of 46,XY/45,X karyotype and 17.77% did not have karyotype. The most frequent etiological causes of DSD were congenital adrenal hyperplasia, androgen insensitivity syndrome in the studied population. A few cases of ovotestis and mosaicism were also observed. These preliminary results, allowed us to continue further molecular and genetic investigations using whole genome sequencing in order to fully characterize DSD-patients. This study will pave the way to define the gonadal mechanisms that may be involved in the DSD Senegalese population.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2266*. Chromosome conformation capture to detect structural variation in medical diagnostics

Authors:

S. Holwerda¹, P. Krijger², M. Versteegen², H. Ploos van Amstel¹, W. de Laat², M. van Kempen¹, K. van Gassen¹; ¹Univ. Med. Ctr. Utrecht, Utrecht, Netherlands, ²Hubrecht Inst., Utrecht, Netherlands

Abstract Body:

Genomic aberrations, including structural variations (SVs), are a major cause of human genetic diseases. Routine detection of SVs in clinical diagnostics mostly relies on standard cytogenetic techniques like karyotyping and fluorescent in-situ hybridization (FISH). The current standard-of-care cytogenetic techniques have proven to be highly successful but they are labor intensive, require highly specialized personnel, provide low resolution data and are low throughput. Here, we perform a study to implement SV detection by a chromosome conformation capture technique, HiC, into our diagnostic pipeline. HiC has been used to detect SVs and copy number variation (CNVs) in a genome wide (unbiased) manner, and could be a high throughput / high resolution alternative to SV detection by karyotyping. Its compatibility with NGS, sample requirements and DNA isolation ease allows implementation in current diagnostic flows. Despite some advantages, certain SVs have not yet been reported in literature, and implementation in daily medical diagnostics has not been reported. Our HiC-study initially focusses on the detection of several unreported SVs, such as: Robertsonian translocations and ring-chromosomes. To this purpose we use patient derived cell lines from the Coriell biobank to test our hypothesis: HiC can detect SVs across centromeres. Furthermore we strive to implement HiC with our current diagnostic exome capture, potentially providing SNV and SV calls in one test. Towards a 'one test fits (almost) all', as a bonus, chromosome conformation capture data will provide structural data, such as topologically associated domain (TAD) boundary information, that could explain disease mechanisms behind structural aberration of our genome.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2267. Clarifying genetic disease with long range sequencing: Tipping the balance for structural variant detection in SMAD3.

Authors:

S. Safgren¹, J. Morales-Rosado², R. Aleff¹, M. Bockol¹, J. Smadbeck¹, N. Hoppman¹, Z. Stephens¹, M. Dehankar¹, S. Phillips³, S. Mantia³, E. Wieben¹, K. Wierenga³, E. Klee¹; ¹Mayo Clinic, Rochester, MN, ²Vanderbilt Univ. Med. Ctr., Nashville, TN, ³Mayo Clinic, Jacksonville, FL

Abstract Body:

A maternally inherited duplication of uncertain significance in the last 3 exons (7-9) of *SMAD3* was identified by exome sequencing in a patient with a previous clinical diagnosis of Marfan syndrome. No additional relevant variants were identified. While it was clear that this VUS had pathogenic potential, the molecular mechanism was unclear. Exome and genome sequencing accurately identify most single nucleotide variants (SNV), but balanced copy number variants (CNV) or translocations are routinely missed or incorrectly characterized. Mate-pair sequencing was used to determine the orientation and location of the duplication. Interestingly, the Mate-pair results revealed a larger duplication of 4 exons (6-9), as well as a deletion of exon 6. However, it could not be determined if this complex structural variant (SV) was in cis or in trans. Long-read sequencing using PacBio and Oxford Nanopore was used to further characterize this event. This analysis confirmed a deleterious deletion of exon 6 in cis with a non-deleterious tandem duplication of exon 6 through 9. The deletion breakpoints in introns 5 and 6 were manually defined from the long-read data because of SINE repeat sequences in this region. The duplication event was located beyond the 3'UTR of the gene and has the same intron 5 breakpoint observed in the deletion event. In this patient, long-read sequencing aided in understanding the deleterious in-frame loss of exon 6 that was obscured in the exome sequencing by the in cis duplication of exons 6-9 (a balanced duplication/deletion of exon 6 where n=2). The exome sequencing report from the affected mother indicated the same VUS and provided evidence this complex variant was inherited on a single allele. The impact for the patient and family includes a refined diagnosis from Marfan to Loeys-Dietz syndrome - which can have a more severe phenotype, with more extensive surveillance recommendations. This illustrates a unique molecular pathogenic mechanism, which resulted in a certified molecular diagnosis of Loeys-Dietz syndrome, and allowed for molecularly informed care recommendations.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2268. Clinical description of patients with CNV in the 15q11.2 region: What do we know?

Authors:

H. Chaparro Solano¹, M. Arcos-Burgos², L. Rodriguez-Salazar³, G. Ardila Patiño³, P. A. Rueda³, C. Estrada Serrato⁴, O. Londoño⁴, Y. D. Carrillo Rincón³, J. J. LOPEZ RIVERA⁵; ¹Clínica Colsanitas, Bogota, Colombia, ²Inst. de Investigaciones Médicas, Univ. de Antioquia, Medellín, Colombia, ³Laboratorio Especializado, Clínica Univ.ria Colombia, Bogota, Colombia, ⁴Clínica Univ.ria Colombia, Bogota, Colombia, ⁵Clinica Univ.ria Colombia, Bogota, Colombia

Abstract Body:

Introduction: Copy number variants (CNVs) between breakpoints 1 and 2 (BP1 and BP2) of 15q11.2 region, and involving *CYFIP1*, *NIPA2*, *TUBGCP5* and *NIPAI* genes, have been associated with diverse phenotypes and incomplete penetrance. While microdeletions that meet the described characteristics have been associated with Burnside-Buttler syndrome, the absence of phenotype or the presence of variable expressivity in patients with the same, or very similar CNV characteristics, has led to the fact that their interpretation, reporting and follow-up become a challenge. A similar scenario occurs with microduplications contained within this same region. The aim of this study is to describe the clinical characteristics of Colombian patients with this type of CNV, in order to achieve an adequate characterization of the conditions associated with them and to contribute to the delineation of the phenotype and its understanding in prognostic terms.

Methodology: A retrospective cross-sectional study was performed. Clinical and paraclinical variables were collected from Colombian patients (n=26) with deletions or duplications between BP1 and BP2 of 15q11.2 region, identified thru comparative genomic hybridization (CGH). All samples were processed, including its classification, between 2017 and 2021, by a single laboratory. The current study was endorsed by the Research Ethics Committee of Fundación Universitaria Sanitas.

Results: 32% of the CGH were ordered for autism spectrum disorder and 28% for neurodevelopmental delays. Other causes were cardiopathies, immune disorders, obesity, epilepsy and dysmorphism. Sixty-five percent (n=17) of the patients were male and 35% (n=5) were female. The mean age of the patients was 8.54 years (min 2 - max 24 SD 5.41). Among the prenatal history, only 19% (n=5) presented prematurity. In relation to clinical history, 65% (n = 17) registered behavioral disorder, 77% (n = 20) language delay and 58% (n = 15) motor neurodevelopmental delay. Heart disease was present in 23% (n = 6) of the participants and central nervous system malformations in 8% (n = 2). Fifty-four percent of the CNVs identified corresponded to gains and 46% to deletions. The average size of CNVs was 0.51 Mb (min 0.31 - max 0.855 SD 0.19).

Discussion and conclusions: Results are consistent with other scientific evidence, and demonstrate that there is still significant genetic and clinical heterogeneity associated with CNVs in the 15q11.2 region, making their analysis and classification difficult. Further studies, with larger sample sizes, are required to deepen the phenotypes related to this type of variants in order to achieve a better understanding of their pathogenicity.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2269*. Clinical long-read genome sequencing: Analytical performance of germline small variant detection using HiFi genome sequencing

Authors:

N. Hammond¹, L. Liao¹, P. Tong¹, Z. Ng¹, C. Ho¹, Y. Yang^{2,1}, S. A. Scott^{2,1}; ¹Clinical Genomics Lab., Stanford Hlth.Care, Palo Alto, CA, ²Dept. of Pathology, Stanford Univ., Stanford, CA

Abstract Body:

Long-read sequencing has the ability to detect structural variants, interrogate homologous regions, and phase variants; however, short-read sequencing is more commonly implemented for clinical testing based on its higher throughput and accurate detection of single nucleotide variants (SNV) and insertions/deletions (indel). Given the recent advances in long-read single molecule real-time HiFi sequencing chemistry and variant calling practices, we analytically validated HiFi genome sequencing to assess its performance for clinical testing. HiFi genome sequencing (average 32X) was performed on DNA from six GIAB cell lines, and results were compared to short-read genome sequencing data (average 52X). HiFi genome sequencing small variant calling was accomplished using pbmm2 v1.7.0, DeepVariant v1.3.0 and WhatsHap v1.4, and short-read sequencing variant calling using DRAGEN v10.3.4. Small variant calls were benchmarked against the GIAB v4.2.1 truth set using hap.py v0.3.15, including comprehensive interrogation across genomic regions as defined by GIAB v3.0 stratifications. HiFi genome sequencing outperformed short-read genome sequencing on overall SNV accuracy (99.9% recall, 99.9% precision vs. 99.4% recall, 99.8% precision); however, short-read genome sequencing outperformed on overall indel accuracy (99.6% recall, 99.7% precision vs. 99.3% recall, 99.2% precision). Importantly, HiFi genome sequencing significantly outperformed short-read genome sequencing in segmental duplication regions for both SNVs (98.2% recall, 99.0% precision vs. 91.6% recall, 95.6% precision) and indels (98.7% recall, 99.1% precision vs. 92.8% recall, 95.6% precision), and in low mappability regions for both SNVs (98.8% recall, 99.5% precision vs. 90.7% recall, 97.2% precision) and indels (98.6% recall, 99.3% precision vs. 88.3% recall, 95.7% precision). HiFi genome sequencing reproducibility was assessed by measuring non-reference genotype concordance between GIAB data from independent sources, which was >99.9% for SNVs/indels in non-difficult regions. These results indicate that HiFi genome sequencing is highly accurate and robust, outperforming short-read sequencing across the majority of GIAB genomic regions, which supports the use of this technology for clinical diagnostic testing.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2270. Clinical utility of parental testing for the reclassification of likely pathogenic and uncertain copy number and sequence variants in a pediatric neurodevelopmental disorders cohort.

Authors:

C. Bilancia, A. Baxter, M. Martin, A. Ortega; Bionano Genomics, San Diego, CA

Abstract Body:

Genetics professionals frequently recommend parental testing when a child has a variant of uncertain significance identified on genetic testing, with the belief that knowing parental inheritance will impact understanding of the clinical significance. The clinical utility of parental inheritance for variant classification in a pediatric neurodevelopmental disorder population is complicated by variability expressivity, reduced penetrance, and limited parental clinical history. This analysis describes the experience of parental inheritance testing by a commercial lab in a pediatric population for variants identified from clinical chromosomal microarray analysis or whole exome sequencing testing. For cases where parental testing was completed following identification of an uncertain or likely pathogenic copy number variant in the child, 74% of cases had some available clinical or phenotype information for a parent. Of those with clinical information available, 43% had an overlapping feature similar to the child's. Due to complications in assessing parental phenotype and challenges with copy number variants often involving multiple genes, less than 2% of cases received a reclassification following parental testing. In comparison, parental testing for sequence variants resulted in 33% of cases receiving a reclassification, highlighting the importance of trio analysis for whole exome sequencing. This conclusion is further supported by our retrospective analysis showing that 67% of proband-only sequencing cases had a variant of uncertain significance compared to 58% of cases when one or both parents were available for analysis. Examples of chromosomal microarray cases where parental inheritance was informative included novel copy number variants involving 7q36.1 and 19q13.33. For whole exome sequencing, parental inheritance enabled reclassification by identifying *de novo* variants and phasing multiple variants in a gene linked to a recessively inherited disorder. The information presented from this analysis provides guidance for education and counseling about the benefit of parental testing for reclassification of variants associated with neurodevelopmental disorders.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2271. Clinical validation of end-to-end whole genome sequencing and interpretation applied to both panel-based and diagnostic genome testing.

Authors:

A. Salman¹, K. A. Lafferty¹, D. M. Toledo¹, K. C. Lewis¹, E. B. Malolepsza¹, M. V. Harden¹, K. L. Larkin¹, V. Mistry², E. Frise², W. He², J. McCarthy², S. B. Gabriel¹, M. G. Reese², H. L. Rehm^{3,1}, N. J. Lennon¹; ¹Broad Inst. of MIT and Harvard, Cambridge, MA, ²Fabric Genomics, Oakland, CA, ³Massachusetts Gen. Hosp., Boston, MA

Abstract Body:

The Clinical Research Sequencing Platform (CRSP) at the Broad Institute is a CLIA-licensed and CAP-accredited clinical laboratory that to date has provided clinical whole genome sequencing to partner laboratories and clinical research programs. Currently, customers are provided with raw data (CRAM) or secondary analysis outputs (VCF) for use in their external pipelines. Here, we describe a plan to support and validate panel-based or indication-based interpretation, enabling launch of an end-to-end whole genome service with genomic interpretation.

To enable high-throughput interpretation services, CRSP intends to make use of the Fabric Genomics interpretation platform. Panel-based testing is facilitated by Fabric's AI Classification Engine (ACE), which assists in the auto-application of certain types of evidence according to ACMG/AMP criteria, highlighting potentially pathogenic variants for further review by a variant analyst. The ACMG version 3.1 secondary findings list of 73 genes was used for ACE validation. Indication-based testing is facilitated by Fabric's GEM algorithm, which prioritizes all variants in a genome by their likelihood of causing a given phenotype with subsequent review by a variant analyst and signing geneticist.

To validate this service, we have assembled a cohort of both clinical and reference samples in which variants of interest exist. The variant spectrum is represented by the inclusion of single nucleotide variations (SNVs), small insertions and deletions (indels), and larger copy number and structural variants. Between 20-25 samples of each variant type were identified, using unique samples for the ACE and GEM algorithms, resulting in ~136 validation samples.

We present here the results of the validation study. The validation assessed whether the variant of interest was detected and prioritized for review as expected and where the variant ranked within the GEM algorithm. We also assessed the time for review for each case to understand analyst resources required to support the Fabric Genomics platform. Samples in which the variant of interest was appropriately prioritized for review were considered to have passed this stage of the validation. We also reviewed the automated and manual variant analysis steps for each classified variant to assess accuracy of the automated portion of the classification, as well as time for manual variant review. The algorithm was also assessed for repeatability and the platform was assessed for security. The full outcome of this validation will be presented.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2272. Clinical whole-genome sequencing of oral samples and microbial contamination

Authors:

N. Ameziane¹, A. Kumar¹, V. Skrahina¹, A. Rolfs², G. Oprea¹; ¹Arcensus Diagnostics, Rostock, Germany, ²Albrecht-Kossel-Inst., Univ. of Rostock, Rostock, Germany

Abstract Body:

The oral cavity is an excellent source of biological sampling for clinical genetics and genomics. This is because oral sample collection is quick, easy-to-access, and non-invasive, compared to blood or other tissue collection methods. We have set-up a whole genome sequencing-based clinical genetic testing approach for suspected patients with hereditary disease. During routine molecular diagnostic analysis, some samples suggested the presence of non-human DNA sequences at varying percentages.

We explored the fraction of non-human reads sequenced from buccal swabs and saliva, type of microbial genomes from which they originated, and impact on molecular classification of the subjects. Read sequences not mapped to human reference genome, were aligned to completed reference microbial reference sequences from the National Center for Biotechnology Information's (NCBI) RefSeq database using KRAKEN v2.

A total of 973 samples (860 buccal swabs and 113 saliva samples) were analyzed. For 97% buccal swabs and 74% saliva samples, more than 5% of the sequenced reads were non-human. The most common contaminant was caused by *Streptococcus mitis* and *Rothia mucilaginosa*, which were identified in 288, and 35 of the buccal swabs and in 15 (5,2%) and 5 (14.3%) of the saliva samples, respectively.

Importantly, by comparing contaminated to non-contaminated samples, the presence of non-human DNA contamination did not demonstrate an impact on the diagnostic yield.

PB2273. Comparing the analytical performance of exome sequencing and traditional panel testing in a cancer population

Authors:

E. Reble¹, J. Sam¹, R. Kodida¹, M. Clausen¹, S. Shickh^{2,1}, C. Mighton^{2,1}, J-M. Capo-Chichi³, E. Greenfeld^{4,2,5,6}, A. Noor^{4,2,5,6}, R. H. Kim^{4,2,3}, J. Lerner-Ellis^{4,2,5,6}, Y. Bombard^{1,2,7}; ¹St. Michael's Hosp., Toronto, ON, Canada, ²Univ. of Toronto, Toronto, ON, Canada, ³Univ. Hlth.Network, Toronto, ON, Canada, ⁴Mount Sinai Hosp., Toronto, ON, Canada, ⁵Dept. of Pathology and Lab. Med., Sinai Hlth., Toronto, ON, Canada, ⁶Lunenfeld-Tanenbaum Res. Inst., Sinai Hlth., Toronto, ON, Canada, ⁷Ontario Inst. for Cancer Res., Toronto, ON, Canada

Abstract Body:

Background: The use of genomic sequencing (GS), including exome and genome sequencing, is increasingly being used as a diagnostic tool over traditional panel testing. With the ability to assess many more genes than traditional panel testing, GS can test for the same well-known genes as traditional panel testing while also testing for more preliminary evidence genes, and may act as an important health tool that can be reanalyzed as new genes and evidence comes to light. However, little is known as to whether GS is a valid and useful diagnostic tool over traditional panel testing. The analytical performance of GS is an important measure of validity that must be determined to inform health technology assessment of GS. **Aim:** To assess the analytical performance of exome sequencing (ES) to detect small single nucleotide variants (SNVs), insertions, and deletions compared to traditional panel testing in a cancer population. **Methods:** We assessed the analytical performance of ES in 277 individuals with a history of cancer or polyposis who received both traditional panel testing and ES. Cancer panels included BRCA1/2 testing (2 genes), Lynch syndrome testing (5 genes), cancer-specific (ex. breast, renal or colon) panels (14-24 genes), or expanded cancer panels (30-70+ genes). For all individuals (n=277), the analytical performance of ES was determined by assessing the concordance rate for all potentially clinically relevant sequence variants previously reported in the cancer panel test was evaluated. For a subset of individuals (n=75) with additional variant data, the sensitivity and specificity of all sequence variants (including likely benign/benign and high frequency variants) identified by ES and the panel in overlapping regions were evaluated. **Results:** 102 variants (VUS or P/LP variants in the region of interest) were identified by cancer panels in the 277 individuals; all 102 of these variants were also detected by ES, resulting in a concordance rate of 100%. For the subset of individuals (n=75) with additional variant data, preliminary analysis in 45 individuals demonstrated high analytical performance of ES compared to panel testing (all variants: sensitivity = 99.69%, specificity = 99.99%; substitutions: sensitivity = 99.69%, specificity = 99.99%; small insertions and deletions: sensitivity = 100%, specificity = 100%). **Conclusions:** Based on preliminary analysis, we have demonstrated high analytical performance of ES compared to traditional panel testing in a cancer population. This is a critical step to allow for ES and GS to be integrated effectively into clinical care as an important diagnostic tool.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2274. Comparison of chromosomal inversions in three different datasets

Authors:

T. Bozkurt¹, M. G. Mehaffey², U. Sezerman¹, C. M. Carvalho^{2,3}, Z. Coban-Akdemir^{4,3}; ¹Acibadem Mehmet Ali Aydinlar Univ., Istanbul, Turkey, ²Pacific Northwest Res. Inst., Seattle, WA, ³Baylor Coll. of Med., Houston, TX, ⁴Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX

Abstract Body:

Introduction: Inversions (INVs) are underexplored copy-neutral structural variations that involve a change in orientation of a DNA segment often generated by non-allelic homologous recombination. The role of INVs has been well-established in primate evolution and speciation. However, current knowledge of INVs' functional effects involving their role in human disease is still limited. This is mostly due to the fact that it is challenging to identify INVs since they i. present a high rate of false-positive and false-negative errors, ii. are challenging to resolve given their balanced nature, and iii. have breakpoints lying in complex repeat regions. Next-generation sequencing technologies including short-read sequencing, long-read sequencing, Strand-seq, and BioNano optical maps, have provided valuable contributions to the global discovery and catalogues of INVs. However, we are still in need of a cross-comparison of those catalogues involving INVs detected by different technologies. **Method:** Here, we investigate the INVs available from three different datasets: the dataset in the study of Ebert and Audano *et al.* (PMID: 33632895), the Genome Aggregation Database (gnomAD), and the Database of Genomic Variants (DGV). gnomAD and DGV data were directly used in the hg19 version, while INVs were converted to hg19 coordinates for the dataset of Ebert and Audano *et al.* We applied the Bedtools intersect function with the 0.5 fraction option to compare each dataset pairwise. **Results:** There are 737 INVs in gnomAD (59 bp-74.35 Mb, with a median of 1.117 kb), 3,349 INVs in DGV (51 bp-9.73 Mb with a median of 2.639 kb), and 367 INVs in Ebert and Audano *et al.* (300 bp-5.3 Mb with a median of 21 kb). 91.3% and 4.2% of the gnomAD INVs overlapped with the DGV and Ebert and Audano *et al.* INVs, respectively. On the other hand, 48.3% and 16.3% of the DGV INVs intersected with the gnomAD, and Ebert and Audano *et al.* 61.7% and 33.9% of Ebert and Audano *et al.* INVs overlapped with the DGV and gnomAD INVs. Next, we investigated whether INVs disrupt genes associated with any human disease phenotype in Online Mendelian Inheritance in Man (OMIM). Our analysis revealed 54 disease genes (27 AR, 17 AD, 6 AD/AR) overlapping gnomAD INVs (67 bp-0.7 Mb with a median of 711 bp), 172 disease genes (78 AR, 59 AD, and 23 AD/AR) overlapping DGV INVs (53 bp-1.064 Mb with a median size of 1.272 kb), and 23 disease genes (13 AR, 7 AD, and 2 AD/AR) overlapping INVs in the study of Ebert and Audano *et al.* (547 bp-0.110 Mb with a median of 9.562 kb). **Conclusion:** Databases such as gnomAD, DGV, and published datasets provide valuable resources to scientists studying INVs. To our knowledge, we present the first study comparing INVs in these datasets.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2275. Comparison of diagnostic yield between exon-targeted microarray and standard microarray for patients with congenital heart defects (CHD).

Authors:

S. Sulpizio, V. Cawich, A. Morton, A. Dikeman, S. Sackmann, A. Flage, B. Torchia; Allele Diagnostics Inc, Spokane, WA

Abstract Body:

In an effort to increase the diagnostic yield of a standard chromosome microarray (CMA) for patients with congenital heart defects (CHD), we designed a whole genome (CGH+SNP) CMA (the CHD array) with enhanced exon-level coverage in 356 genes associated with CHD. As with our laboratory's standard CMA, process improvements for DNA extraction, labeling, and hybridization were made to provide results in as little as 2 days.

To evaluate the diagnostic yield of the CHD array, 499 deidentified samples from patients with CHD indications were processed. Data was interpreted by an ABMGG Cytogeneticist and classified using ACMG guidelines. Reportable variants (Pathogenic, Likely Pathogenic, VUS) were then categorized based on likelihood of a causative link with the specific type of CHD in the patient and likelihood of being detected by our standard CMA.

In 499 samples, 108 had variants strongly associated with CHD and 30 had variants where the relationship with CHD was uncertain. Therefore, the diagnostic yield of the CHD array was 27.7%. Variants potentially associated with CHD, that would not have been identified by standard CMA, were detected in five samples. These included 6 deletions within autosomal recessive disease genes, ranging in size from 521 bp to 8.2 kb, which were confirmed by dPCR. Thus, for this cohort, there was an increased diagnostic yield of 1.0% for the CHD array over the standard CMA.

A cohort of 8079 samples submitted for diagnostic testing by standard CMA was evaluated against the CHD array design *in silico* using genomic coordinates of the identified variants. Three cases run on standard CMA had pathogenic or likely pathogenic variants that were strongly associated with CHD and would not have been identified by the CHD array. One of these variants, detected in two patients, involved a gene that has a clear but infrequent association with CHD. The other involved a gene only recently associated with CHD, demonstrating the importance of frequent gene curation and periodic updates to the array design.

In conclusion, a CMA platform with enhanced exon-level coverage of genes associated with CHD increased the diagnostic yield of reportable variant types by detecting smaller alterations within the targeted regions. Although a small number of CHD-related alterations may not be detected by an exon-level array, the more targeted design clearly identified additional exon-level alterations. In combination with a rapid turnaround time, the increase in diagnostic yield could significantly impact the care of patients with structural heart defects.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2276. Comparison of positive findings between CMA/exome combo and Whole Genome Sequencing: Aclinical lab experience

Authors:

X. Zhao^{1,2}, X. Luo^{1,2}, J. Lattier², P. Liu^{1,2}, L. Meng^{1,2}, C. Eng^{1,2}, F. Xia^{1,2}, H. DAI^{1,2}, W. Bi^{1,2}; ¹Baylor Coll. of Med., Houston, TX, ²Baylor Genetics, Houston, TX

Abstract Body:

Introduction: CMA and WES have been utilized as genetic diagnostic tests over the last decade for patients with suspected underlying genetic disorders. However, the conventional phenotype-driven and stepwise approach can be time consuming and often lead to inconclusive results. In contrast, WGS offers the potential of a single test that captures nearly all genomic variation in an unbiased manner. As WGS becomes more clinically available, it is often asked whether and when the patients would benefit the most if WGS is ordered as the first-tier diagnostic test. To provide insights into this question, a comprehensive comparison of WGS and WES+CMA is conducted at Baylor Genetics. **Method:** We compared the positive findings, turnaround time (TAT), and diagnostic rate among patients with concurrent orders of CMA and WES (the Combo) and patients who had clinical WGS test in the same period of time. Patients who received a diagnosis with WES or CMA alone and did not proceed with the combo test were not included. CMA was performed using a comprehensive custom designed array with SNP probes and exon-targeted coverage for >4,200 disease genes or candidate disease genes. **Result:** Overall, 206 patients with diagnostic findings were included in this study (145 combo, 61 WGS). The average TAT of the Combo is 33.0 days with a median of 25.4 days. 29.0% of cases received results within 2 weeks (42/145). On the other hand, the average TAT of WGS is 26.3 days. Among these, 37.7% of cases were reported within 5 days (23/61). Of the aberrations detected by WGS, 16% of positive WGS cases (10/61) could potentially be missed. Six findings would definitely be missed by the Combo, including two deep intronic variants, two mitochondria variants, one complex structural rearrangement, and one short tandem repeat (STR) variant. In addition, three of the four <10kb CNVs may be detectable by our comprehensive array because of using exon-targeted array, but all of these four small CNVs may be missed by a clinical array without enhanced coverage for disease genes. Majority of the positive WGS cases were rapid test from NICU patients who have one or more of the following clinical indications (60.7%, 37/61): seizures, congenital heart disease, and respiratory failures. **Conclusion:** We reported here a comparison between the use of WGS versus ordering WES and CMA in clinical settings. In addition to the variants detectable by the combo, WGS may detect small CNVs, deep intronic variants, mitochondrial variants and balanced chromosome rearrangements. In addition, TAT as short as 5 days may be provided by WGS. Our studies support that WGS is a rapid diagnostic tool for diverse genetic aberrations.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2277. Copy Number Variations (CNVs) detected in 14% of patients presenting with peripheral neuropathies in a French cohort.

Authors:

A-S. Lia^{1,2,3}, I. Pyromali¹, F. Miressi¹, N. Benslimane¹, A. Nizou¹, P. Derouault³, P. Chazelas^{1,2}, F. Favreau^{1,2}, F. Sturtz^{1,2}, C. Magdelaine^{1,2}; ¹NEURIT-UR20218-Limoges Univ., Limoges, France, ²Laboratoire Biochimie Génétique Moléculaire - Limoges Hosp., Limoges, France, ³Unité Fonctionnelle de Bioinformatique - Limoges Hosp., Limoges, France

Abstract Body:

Introduction: Inherited Peripheral Neuropathies, such as Charcot-Marie-Tooth Disease (CMT), Hereditary Motor Neuropathies (HMN) and Hereditary Sensitive Neuropathies (HSN) are characterized by damages of motor and/or sensory peripheral nerves. To date, more than hundred genes are known to be responsible for these diseases. Classically, investigations are performed by Next-Generation-Sequencing (NGS) allowing the easy and fast detection of Single Nucleotide Variants (SNVs) or short indels. The goal of this study was to analyze differently these NGS data in order to detect unbalanced Structural Variations (SVs), also called Copy Number Variations (CNVs).

Materials and Methods: DNA from 919 patients presenting with peripheral neuropathies were studied by NGS using either an amplicon-targeted sequencing panel or a capture-targeted panel. NGS data were then analyzed by the bioinformatics tools Cov'Cop and CovCopCan, developed in our laboratory, in order to detect CNVs. To characterize more precisely the pointed out unbalanced SVs, qPCR, CGH and/or Sanger sequencing have been initiated.

Results: We found that 130 of the 919 patients harbor CNVs (14.1%): 87 duplications and 43 deletions. A quarter of these CNVs are large (involving more than three exons). We initiated the molecular characterization of these 130 CNVs. The first results allowed involving a large deletion in *SACS* in Charlevoix-Saguenay spastic ataxia, two *KIF5A* large deletions of respectively 5 and 14 exons, but also the deletion of a single exon in *SH3TC2* in Charcot-Marie-Tooth disease. In addition, we showed the non-pathogenicity of a partial *REEP1* duplication in spastic paraplegia 31, but we could not clearly concluded about the involvement of the complete *AARS* duplication in Charcot-Marie-Tooth disease. The analysis of the other CNVs is in progress and it is currently difficult to estimate the amount of pathogenic CNVs within the 130 CNVs identified.

Conclusions: By analyzing our NGS data with specific bioinformatics tools allowing the detection of CNVs, we identified unbalanced SVs in 14.1% of our patients. Interestingly, the first analyses showed that some of them are pathogenic and can explain the symptoms of the patients. This approach helps us to increase the positive diagnosis rate of our patients presenting with peripheral neuropathies and we suggest molecular biologists and geneticists to use this strategy for all inherited diseases to improve the diagnosis.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2278. CREBBP related Rubinstein Taybi syndrome: Report of 3 patients

Authors:

I. Panigrahi, P. Srivastava; PGIMER, Chandigarh, India

Abstract Body:

Rubinstein Taybi syndrome (RSTS) is a cause of intellectual disability and postnatal growth retardation. The genes associated with this phenotype include *CREBBP* and *EP300*. We report 3 children diagnosed with RSTS and were found to have single nucleotide variants or copy number variant (CNV) involving the *CREBBP* gene. The three children were 1-2 year old and evaluated in the Genetic Clinic. All three presented with developmental delay and dysmorphism, one child had broad thumbs. Two patients were found to harbor single nucleotide variants (SNVs) in the *CREBBP* gene and one was detected to carry heterozygous deletion, a CNV on chromosome 16p13.3 identified on MLPA. Of the SNVs, both variants were truncating variant in exon 10 and exon 22 of the gene respectively. In one patient, MRI brain revealed agenesis of corpus callosum, and in another micro-hemorrhages in left basal ganglia and right cerebellar hemisphere with loss void in straight sinus and right transverse sinus were observed. Thus, RSTS is a relatively common cause of developmental delay or intellectual disability. We discuss the clues and approach to early diagnosis in RSTS. Appropriate evaluation can help in early diagnosis and appropriate genetic counseling in the affected families.

PB2279*. Deciphering the genetic etiology of idiopathic male infertility by low-pass mate-pair genome sequence analysis.

Authors:

J. Qian¹, T. Law^{1,2,3}, M. Chau^{1,2,3}, Y. Cao^{1,2,3,4}, S. Tong¹, Y. Kwok^{1,2,3}, T. Leung^{1,2,3,5}, J. Chung^{1,2,3,4}, K. Choy^{1,2,3,4,5}, Z. Dong^{1,2,3,4}; ¹Dept. of Obstetrics and Gynaecology, The Chinese Univ. of Hong Kong, Hong Kong, China, ²Shenzhen Res. Inst., The Chinese Univ. of Hong Kong, Shenzhen 518057, China, ³Hong Kong Hub of Paediatric Excellence, The Chinese Univ. of Hong Kong, Hong Kong, China, ⁴The Fertility Preservation Res. Ctr., Dept. of Obstetrics and Gynaecology, The Chinese Univ. of Hong Kong, Hong Kong, China, ⁵The Chinese Univ. of Hong Kong-Baylor Coll. of Med. Joint Ctr. for Med. Genetics, Hong Kong, China

Abstract Body:

Objective: The genetic etiology of idiopathic male infertility contributed by copy-number variant (CNV), structural variant (SV), and absence of heterozygosity (AOH) is yet to be established. We aimed to investigate the genetic contributions in male infertility with negative results from routine genetic tests by applying our in-house low-pass mate-pair genome sequencing (GS). **Methods:** This is a retrospective cohort study of 101 patients (mean age = 36) (63 with non-obstructive azoospermia and 38 with severe oligospermia) with primary infertility and negative results from Y-microdeletion detection and karyotyping analysis. Low-pass mate-pair GS (4X) was performed in each subject for identifying clinically significant CNVs, SVs, and regions with AOH using in-house analytical pipelines. High read-depth GS (40X) was subsequently performed in five cases with intragenic deletions affecting autosomal recessive (AR) genes that related to male infertility or cases with multiple regions of AOH. **Results:** Candidate molecular etiologies were identified in 20 of 101 cases (19.6%). Firstly, 12 likely clinically significant CNVs were identified and subclassified into four groups: (1) three pathogenic deletions/duplications showed direct evidence to explain the infertility; (2) three pathogenic microdeletion/duplication syndromes with limited evidence of male infertility (22q11.2 duplication syndrome, 16p13.11 microdeletion syndrome, and terminal deletion of 5p); (3) two pathogenic deletions in AR manner (genes *IFT74* and *LDLR*); and (4) four variants of uncertain significance involving male infertility related genes. In addition, three inversions and six complex insertions involving OMIM disease-causing genes or genes curated by GeneReviews were reported. For instance, *DMRT1*, deletion of which leads to nonsyndromic 46, XY disorders of testicular development, was directly disrupted by a cryptic insertion. Furthermore, multiple regions with AOH were identified in three cases indicating parental consanguinity (n=2) and uniparental disomy (UPD; n=1). Lastly, high read-depth GS excluded any pathogenic mutations in two cases with intragenic deletions affecting AR genes and one with suspected UPD, but indicated pathogenic homozygous point mutations in two cases suspected parental consanguinity. **Conclusions:** Our study provides a landscape of various types of chromosomal abnormalities in idiopathic male infertility by applying our in-house low-pass mate-pair GS. Most importantly, the clinically significant variants potentially contributed to male infertility in approximately 20% of the cases, underappreciated by the standard care.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2280. Deep exome sequencing to detect mosaic variants in craniofacial microsomia

Authors:

N. Parmalee¹, J. Gustafson¹, D. Jensen¹, V. Dmyterko¹, R. Bly¹, J. Perkins¹, M. Cunningham², D. Luquetti³, K. Sie¹, C. Heike³, J. Bennett⁴; ¹Seattle Children's Res. Inst., Seattle, WA, ²Univ. of Washington and Seattle Children's Res. Inst., Seattle, WA, ³Univ. of Washington, Seattle, WA, ⁴Seattle Children's Res. Inst., Seattle, WA

Abstract Body:

We conducted deep exome sequencing to a depth of >1000x in multiple tissues from probands with craniofacial microsomia (CFM), an isolated birth defect. We sequenced multiple tissues, as well as blood from the proband and blood or saliva from both parents. Our goal was discovery of mosaic variants in causative genes in which variants are present in affected tissues and either absent from proband blood or present at lower levels in blood and absent from both parents. Deep sequencing allows us to detect variants that would be missed with a standard exome.

Isolated structural birth defects are congenital anomalies that affect the morphology of a single region or tissue as opposed to complex or syndromic anomalies that may span multiple tissues or involve multiple systems. We focused on CFM in which craniofacial features including the mandible and maxilla are underdeveloped and the ear may be underdeveloped or absent. A constellation of other morphological signs may be present; CFM has a high degree of phenotypic variability. Presentation is generally asymmetrical with the right side affected more often. The prevalence of craniofacial microsomia is 1:3500-1:4000 births. CFM is thought to arise in early embryogenesis as a defect in neural crest cell migration into the 1st and 2nd pharyngeal arches. The cause for this is unknown.

We are investigating postzygotic somatic mutations that lead to genetic mosaicism and may be causative in isolated structural birth defects. We hypothesize that some percentage of unsolved genetic conditions may be due to mosaicism in which the mutation is not present in the blood and thus not detected with a standard exome. In this study we selected CFM as a model; while some patients have family history, in large part CFM cases are sporadic. We hypothesize *de novo* variation and we are investigating the hypothesis of postzygotic mutation that leads to developmental defects in patterning. It is not known what tissue may harbor a causative mutation. We selected CFM as a model in part because multiple tissues are discarded during reconstructive surgeries and are available for sequencing, including preauricular tags, cartilage, bone, teeth, and soft tissue.

Based on expertise in the lab with mosaicism in other conditions we expected that the variant allele frequency (VAF), the percentage of sequencing reads supporting a true mosaic variant, may be very low in an affected tissue. We routinely detect mosaic variants in known causative genes with a VAF of less than 1% that are confirmed with orthogonal assays. We report results from our search for mosaic variants at low VAF that would not be detected with a standard coverage exome that present in tissue and not in the blood.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2281. Development and analytical validation of an innovative 397 gene genome-based inherited kidney disease panel

Authors:

K. Weymouth¹, V. Charu², N. Hammond¹, S. White¹, R. da Silva Francisco, Jr.², J. Kohler³, P. Tong¹, Z. Ng¹, C. Ho¹, K. Dumas¹, D. Fisk¹, C. Hale¹, T. Nguyen Dolphyn¹, C. Reavey¹, E. E. Smith¹, W. Qiao^{1,2}, Y. Yang^{1,2}, N. Kambham², S. A. Scott^{1,2}; ¹Clinical Genomics Lab., Stanford Hlth.care, Palo Alto, CA, ²Dept. of Pathology, Stanford Univ., Stanford, CA, ³Dept. of Pediatrics, Stanford Univ., Stanford, CA

Abstract Body:

Chronic kidney disease (CKD) is an important cause of morbidity and mortality, which can progress to end stage renal disease necessitating dialysis and renal transplantation. Monogenic causes of CKD are increasingly recognized, as evidenced by diagnostic yields in adults and children that range from ~10-30%, supporting the implementation of genetic testing to guide management and transplant considerations. Diagnostic panel and exome testing often employ enrichment-based sequencing; however, technical advantages using genome sequencing include unbiased coverage, copy number variant (CNV) detection, and flexible interrogation of clinical regions of interest (ROI). Therefore, we developed an innovative inherited kidney disease (IKD) panel based on genome sequencing (NovaSeq 6000; $\geq 40X$) that includes 397 clinically significant genes implicated in a spectrum of monogenic kidney disorders and selected syndromic diseases with abnormal nephrology phenotypes. Clinically relevant non-coding variants (ClinVar, HGMD) were also included in the ROI, and the panel was subsequently validated by measuring performance with detecting single nucleotide variants (SNVs), insertions/deletions (indels), and CNVs. Small variants (SNV/indel) were called using DRAGEN v3.9.5 and benchmarked for accuracy against the GIAB v4.2.1 truth set using hap.py, which resulted in $\geq 99.9\%$ recall and precision across the high confidence regions of the IKD genome panel. Moreover, small variant precision across all assessments (inter-run, intra-run, inter-instrument, inter-side, inter-flow cell) were 100% in the non-difficult regions of the IKD genome panel, indicating that the assay was robust and precise. Clinical specimens (blood, saliva, assisted saliva, fibroblast) were also validated using paired samples and measuring non-reference genotype concordance across the IKD genome panel, which resulted in SNV/indel concordance $\geq 99.9\%$. Clinical performance was assessed by testing ≥ 30 samples with known clinically significant small variants and/or CNVs, which previously had undergone orthogonal testing using other methods. Taken together, these results support the validation and implementation of this novel IKD genome panel for clinical testing among adults and children with abnormal nephrology phenotypes.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2282. Development and clinical implementation of genome-based germline exome testing.

Authors:

K. Dumas¹, D. Fisk¹, C. Hale¹, N. A. Hammond¹, C. Ho¹, L. Liao¹, Z. Ng¹, T. Nguyen Dolphyn¹, Y. Park¹, C. Reavey¹, H. Shi¹, E. E. Smith¹, T. Tan¹, P. Tong¹, N. Watson¹, K. S. Weymouth¹, S. White¹, L. Hudgins², E. Ashley³, J. A. Bernstein², E. Spiteri^{1,4}, W. Qiao^{1,4}, S. A. Scott^{1,4}, Y. Yang^{1,4}; ¹Clinical Genomics Lab., Stanford Hlth.Care, Palo Alto, CA, ²Dept. of Pediatrics, Stanford Univ., Stanford, CA, ³Stanford Ctr. for Inherited Cardiovascular Disease, Stanford, CA, ⁴Dept. of Pathology, Stanford Univ., Stanford, CA

Abstract Body:

Exome sequencing is widely used as a diagnostic test for children and adults with suspected Mendelian disease, and typically employs enrichment-based sequencing targeted to all coding exons; however, limitations of this approach include the additional steps of enrichment, fixed test content, and interpretation limited to coding region and splice variants. Given the quality advantages and potential utility of using genome sequencing for clinical exome testing, we developed a novel genome-based exome assay that was validated and implemented as a clinical test. The Stanford genome-based exome reportable range was defined by coding regions of human RefSeq genes, GENCODE, CCDS, as well as all clinically relevant non-coding variants, as defined by ClinVar likely pathogenic/pathogenic, and HGMD disease- and likely disease-causing. Validation of the genome-based exome was accomplished by sequencing >90 samples (NovaSeq 6000; ≥40X) that were strategically selected to measure accuracy, precision, clinical performance, and other required elements of assay development. Small variants (single nucleotide variants (SNVs) and insertions/deletions (indels)) were called using DRAGEN v3.8.4 from seven GIAB samples and benchmarked for accuracy against the GIAB truth set using hap.py, which resulted in >99.9% recall and precision across the high confidence regions. Moreover, small variant precision across all assessments (inter-run, intra-run, inter-instrument, inter-side, inter-flow cell) were >99% in GIAB non-difficult regions, indicating that the assay is robust and precise. Clinical specimens (blood, saliva, assisted saliva, fibroblast) were also validated using paired samples and measuring non-reference genotype concordance, which resulted in SNV/indel concordance of ~99%. Clinical performance was assessed by testing 29 samples with known clinically significant small variants, which resulted in a clinical accuracy of 100% (95% CI: 99.7-100%). To date, the genome-based exome has been performed on 86 patients (trios and probands), which resulted in a positive diagnostic rate of 20.9% across indications. These results support the validation and implementation of this novel genome-based exome assay for clinical testing among children and adults with suspected Mendelian disease.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2283. Development of a comprehensive whole genome sequencing test for cardiovascular disease patients.

Authors:

L. Amendola¹, A. Coffey¹, S. Strom¹, A. Kesari¹, J. Avecilla¹, J. Lowry¹, S. Thacker¹, C. Brown¹, K. Golden-Grant¹, M. Brown¹, B. Milewski¹, J. Belmont², D. Perry¹, R. Taft¹; ¹Illumina Inc, San Diego, CA, ²Genetics & Genomics Services, Inc, Houston, TX

Abstract Body:

Guidelines for genetic assessment in individuals with cardiovascular disease (CVD) are inconsistently followed, in part due to the complexity of the recommended testing regime. In an effort to build a single scalable, and future-proof, molecular testing platform that can meet the needs of CVD patients, we have developed a clinical whole genome sequencing (WGS) test that includes an in-silico CVD gene panel, CVD risk alleles, PRS for coronary artery disease and pharmacogenomic findings. Here we focus on the selection and curation of gene-disease relationships and variant types related to CVD as a fundamental component of robust molecular test development. The broad primary CVD indications we considered included aortopathy, arrhythmia, cardiomyopathy, dyslipidemia, hypertension, and thrombophilia. Genes and genomic variation associated with these CVD indications were identified through comprehensive literature review, assessment of commercially available panels, expert interviews, and review of relevant ClinVar and HGMDTM variants. Gene-disease relationships curated as Definitive or Strong were included on the CVD gene panel, and an internal knowledge base of relevant variant classifications was developed to reduce curation burden at the time of testing. WGS performance was assessed across all genes and variants of interest. Of the 309 gene-disease pairs identified, 132 had been previously curated as having a Definitive or Strong relationship and were included in the in-silico CVD gene panel. All remaining genes (n=177) were prospectively curated based on the ClinGen framework, leading to the inclusion of an additional 57 genes, and a final in-silico panel size of 189 genes. Potential or known pathogenic genomic rearrangements were identified in 155 genes, with 37 having more than one such variant smaller than 10 kb. Short tandem repeats were included for 3 genes (*DMPK*, *CNBP* and *FXN*) where they are an established mechanism for conditions with CVD phenotypes. WGS performance was assessed across all 189 genes and associated variants, including repeat expansions, which showed both high sensitivity and specificity and overall performance acceptable for a broad population screen. Variants identified as major contributors to genetic CVD were manually curated for the knowledge base. A CVD-focused WGS test may be able to address challenges related to the underutilization of and variability in CVD genetic testing by providing a single multifaceted molecular diagnostic platform. These data demonstrate that the development of an evidence-backed in-silico WGS CVD testing panel component of such a test is tractable.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2284. Diagnosis of genetic causes of intellectual disability and multiple congenital abnormalities in center of excellence for human genetics in Egypt

Authors:

A. Mohamed¹, A. kamel¹, M. Eid², O. eid¹, M. Mekkawy¹, M. Zaki¹, E. Ashaat¹, G. Abdelsalam¹, M. Aglan¹, M. issa¹, S. Housein¹, s. Gharib¹, M. Elruby¹; ¹Natl. Res. Ctr., Cairo, Egypt, ²Natl. research center, Cairo, Dokki, Egypt

Abstract Body:

Aim: the aim of this study is the application of different cytogenomic technique in diagnosis of genetic causes of intellectual disability (ID)/multiple congenital abnormalities (MCA), and genotype/phenotype correlation. This work was done in the Centre of Excellence of Human Genetics, National Research Centre, Egypt. The center is funded by the STDF (project 5253). **Methods:** The total referral patients (ID/MCA) were 2170 through years 2016 to 2020, karyotype was don for all patients, FISH, multiple ligation probe amplification (MLPA) and array CGH technique were performed not to all patients due to high cost of the kits. **Results:** chromosomal abnormalities found in 6.6% of the referred patients. FISH was performed for 324 patients, 226 patients diagnosed as microdeletion syndromes, 98 had chromosomal abnormalities or marker chromosome. The MLPA technique was performed for 160 patients who had ID/MCA, we used probe mix for MR, subtelomere and microdeletion syndromes. 26 patients (16%) had positive results. Array CGH were performed for 90 patients. Out of the 90 sampled there are 44 samples (49%) had large copy number variations, deleted and/or duplicated segments. Some of these copy number variations involved two chromosomes copy number variation or complex rearrangements which involved more than two chromosomes. Negative patients need whole exome or genome sequencing. The array CGH is the 1st tier for the diagnosis of genetic cause of ID/MCA and for genotype/phenotype correlation.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2285. Diagnostic approach of transthyretin amyloidosis in a Colombian patient

Authors:

J. Estela-Zape¹, L. Moreno Giraldo^{2,3}, D. Arturo-Terranova², J. Satizabal-Soto²; ¹Fundación Univ.ria María Cano, Cali, Colombia, ²Univ. del Valle, Cali, Colombia, ³Univ. Libre, Cali, Colombia

Abstract Body:

Transthyretin amyloidosis (ATTR) is characterized by the deposition of amyloid fibrils, especially affecting cardiomyocytes and peripheral nerves. In Colombia, to date 43 cases of ATTR have been confirmed, and due to its low prevalence it has been included in the list of orphan diseases, according to resolution 5265 of 2018, however, its clinical presentation is heterogeneous and the delay in diagnosis does not allow a timely approach. We present the case of a 5-year-old patient, product of the third pregnancy of non-consanguineous parents, who from the age of 20 months presented regression of developmental milestones, muscular atrophy, hypotonia, gait disturbance, cardiomyopathy, and gastrostomy. Given the complexity of the clinical picture and in order to determine the etiology of the disease, whole exome sequencing was performed. The heterozygous variant in the transthyretin gene (TTR) was identified: c.424GxA, (p.Val142Ile) (classically Val122Ile), with pathogenic clinical significance. This variant is commonly reported in patients with ATTR. Functional studies have shown that this variant renders the TTR complex unstable, leading to protein cleavage and decreased stability in retinol transport. New treatments have been developed in order to stop or delay amyloid deposition by transthyretin, stabilizers of the TTR gene molecule that reduces the rate of amyloid deposition, drugs that act by inhibiting hepatic expression of transthyretin by interfering ribonucleic acid or by antisense oligonucleotides that block the transcription of the messenger RNA of the TTR gene, drastically reducing hepatic production of TTR. In addition, advances in treatment show the use of CRISPR technology to edit the human genome in vivo and produce a chronic silencing of TTR expression in hepatocytes through a single intravenous administration. All these advances will allow timely therapy to be addressed in those diagnosed for the disease. The timely identification of the disease allows to provide an adequate genetic counseling, recognizing available treatments for the management of the pathology.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2286. Diagnostic Utility and Lessons Learned from Deep Sequencing Vascular Malformations

Authors:

C. Myers¹, C. R. Paschal^{2,3}, M. Gillentine^{4,1}, D. Sternes^{5,6}, Z. Nelson⁷, J. Perkins^{5,8}, J. Bennett^{9,10,2}; ¹Dept. of Lab., Seattle Children's Hosp., Seattle, WA, ²Dept. of Lab., Seattle Children's Hosp., Seattle, WA, ³Dept. of Lab Med. and Pathology, Univ. of Washington, Seattle, WA, ⁴Univ. of Washington, Seattle, WA, ⁵Seattle Children's, Seattle, WA, ⁶Patient-centered Lab. Utilization Guidance Services (PLUGS), Seattle Children's Hosp., Seattle, WA, USA, Seattle, WA, ⁷Seattle Children's Hosp., Seattle, WA, ⁸Dept. of Otolaryngology/Head and Neck Surgery, Univ. of Washington, Seattle, WA, ⁹Seattle Children's Res. Inst., Seattle, WA, ¹⁰Div. of Genetic Med., Dept. of Pediatrics, Univ. of Washington, Seattle, WA

Abstract Body:

Now recognized to be primarily caused by tissue-restricted somatic mutations, disorganized morphogenesis of blood vessels results in vascular malformations. Mutation identification increasingly drives targeted medical therapies but requires specialized diagnostic approaches. Here we report results on over 300 individuals using VANSeq, a clinical sequencing assay for vascular malformations. Over two years, we performed 319 clinical tests on 306 individuals. The most common clinical indication was isolated vascular malformation (lymphatic or venous), followed by vascular malformation with overgrowth. Of the 319 samples tested, 57% had pathogenic or likely pathogenic findings, 2% had variants of uncertain significance, 37% were negative (no variants reported), and 4% of testing could not be completed due to insufficient or poor-quality DNA. DNA was extracted from formalin-fixed paraffin-embedded (FFPE) tissue (41%), fresh-frozen tissue (33%), peripheral blood (22%), or saliva (4%). Diagnostic yield was highest when affected tissue was tested. Increasing the number of samples tested increased the diagnostic yield. Nine of 13 patients that had repeat testing had diagnostic results after the first test was non-diagnostic. The variant allele frequency (VAF) was less than 5% in nearly half of samples with a mosaic pathogenic variant identified (43%, n=143). Across the cohort, variants were reported in 25 of the 44 genes tested; *PIK3CA* accounted for the majority of positives (n=86), followed by *TEK* (n=18), *GNAQ* (n=10), *MAP2K1* and *RASAI* (n=8, each). Nearly half of patients with a *TEK* pathogenic variants had co-occurrence of a second somatic *TEK* variant (n=8/18). Four individuals had coexisting somatic activating mutations in two separate genes (ex: *BRAF* and *GNAQ*). Concomitant mutations frequently coexist with driver mutations in cancer, but this has not been well-documented for vascular malformations. Our experience highlights several considerations unique to clinical testing of vascular malformations.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2287. Diagnostic utility of the targeted next generation sequencing panel test for suspicious genetic glomerular diseases

Authors:

J. Kim, H. Lee; Dept. of Internal Med., Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Abstract Body:

Background: A substantial proportion of glomerular diseases has genetic background, but there is no solid guideline concerning genetic work-up. The targeted next-generation sequencing (NGS) gene panel can identify possible mutations causing genetic glomerulopathies. We evaluated the diagnostic utility of targeted NGS panel for glomerular diseases. **Methods:** Patients who received targeted NGS panel from 2017 to 2021 were included. Our NGS panel covered 23 variants causing genetic glomerulopathies including collagenopathies (COL4A3, COL4A4, COL4A5, and MYH9), genetic nephrotic syndrome (ACTN4, ADCK4, ANLN, COQ2, COQ6, EMP2, INF2, NPHS2, NUP107, PLCE1, and TRPC6), and other syndromic diseases (NPHS1, LAMB2, LCAT, LMX1B, PAX2, SMARCAL1, WDR73, and WT1). Variants were classified according to American College of Medical Genetics and Genomics 2015 guideline. Diagnostic yield was calculated as positivity rate of pathogenic or likely pathogenic variants. **Results:** A total of 111 patients were included. The median age of disease onset and of receiving test was 9.0 [3.0;22.5] and 17.0 [7.5;33.0] years. Among them, 50 had family history of kidney disease and 3 had congenital anomalies. Seventy-three patients received percutaneous kidney biopsy for their pathologic diagnosis. Overall diagnostic yield of targeted NGS panel was 36% and higher in patients with younger onset age (<18 years) than those older [44.7% vs 17.1%, p=0.03]. It was associated with previous kidney biopsy (adjusted odds ratio (aOR), 6.23; 95% confidence interval (CI), 1.21-32.06), hematuria (aOR, 4.68; 95% CI, 1.32-16.56), systolic blood pressure (aOR, 0.94; 95% CI, 0.88-0.99) and absence of edema (aOR, 0.05; 95% CI, 0-0.66) even after covariate adjustment. Among 40 patients with positive gene test results, 16 changed their diagnosis from initial pathologic diagnosis and 13 patients received new genetic diagnosis. **Conclusion:** Targeted NGS panel test for genetic glomerular diseases was useful in genetic diagnosis with a modest diagnostic yield of 36%. Previous kidney biopsy, hematuria, low systolic blood pressure and absence of edema were associated with higher positivity rate.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2288. Diagnostic yield of trio and individual Whole Exome Sequencing in a group of colombian patients with a suspected monogenic disease.

Authors:

E. Rodriguez-Alvarino¹, S. Bello Uyaban², D. Otero Rodríguez², M. Galvez²; ¹Univ. Natl. de Colombia, Bogota, Colombia, ²Gencell - Genuino Group, Bogotá, D.C, Colombia

Abstract Body:

Introduction: During last years, Whole Exome Sequencing (WES) has had great acceptance for the evaluation of genetic disorders. Due to the access to next-generation sequencing (NGS), bioinformatics tools, and professionals' experts, these molecular tests represent a first- tier diagnostic tool for many genetic diseases. **Objective:** To compare the diagnostic yield of singleton and trios WES in a Colombian cohort with clinical suspicion of a genetic disease, as well as the yield per phenotype groups, between June 2020 to May 2021. **Methodology:** A cross-sectional descriptive, retrospective study, approved by an ethics board, was carried out. Medical records were reviewed to obtain phenotypic data and trio WES was performed. Variant calling was done using *GATK* best practices, with subsequent annotation and filtering using Human Phenotype Ontology (HPO) terms and variants were classified using the American College of Medical Genetics and Genomics (ACMG) 2015 guidelines. Analysis as singleton exome and trio exome were performed in every case. Cases were considered positive when pathogenic (P) or likely pathogenic (PP) variants were identified, with a mechanism of inheritance explaining the patient's phenotype. Additionally, cases were stratified by groups according to the main clinical phenotype, to evaluate the specific yield of the test. **Results:** A total of 100 cases were included. The average age was of 8,6 years, and seven cases were born of consanguineous parents. The diagnostic yield was 26% for singleton and 31% for trio WES. Among positive cases, 18% had an autosomal dominant disease, 8% an X-linked, 4% autosomal recessive, and 1% a digenic inheritance disorder. Two cases had incidental findings in *PMS2* and *MSH6* genes, and two other cases had concomitant monogenic conditions. The most prevalent phenotype was neurodevelopmental delay in 47% individuals, with a yield of 36,1%. The highest yield was found for paralysis (71,3%), followed by hypoacusis (55,5%) microcephaly (50%), pulmonary hypertension (50%) and hematologic alterations (50%). Abnormal movements had the lowest diagnostic rate (10%). **Conclusion:** This study showed a 5% better yield for trio exome in comparison to singleton. This is mainly explained by the identification of *de novo* variants and confirmed compound heterozygous mutations, which cannot be established in singleton exomes. WES showed the best performance in neurological phenotypes, especially paralysis.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2290. Does a larger gene panel size change the mutation detection rate in hypertrophic or dilated cardiomyopathy ?

Authors:

S. Fokstuen¹, P. Meyer², E. Hammar¹, M. Beghetti³, F. Masclaux¹, M. Guipponi¹, J. Wacker³, A. Py², J. Schwaiger⁴, M. Abramowicz¹, S. Suchet¹, C. Gruner⁴, J-L. Blouin¹; ¹Genetic Med., University Hospitals of Geneva, Switzerland, ²Cardiology, University Hospitals of Geneva, Switzerland, ³Pediatric Cardiology, University Hospitals of Geneva, Switzerland, ⁴Cardiology, University Hospitals of Zürich, Switzerland

Abstract Body:

Implementation of next generation sequencing (NGS) has led to a rapid expansion in the number of genes included in diagnostic genetic testing for cardiomyopathies. This tendency is changing with the evidence-based assessment of genes conducted by ClinGen. Our aim was to evaluate the mutation detection rate and the involved genes in patients with isolated hypertrophic or dilated cardiomyopathy (HCM and DCM) according to the gene panel size. Our NGS approach consists of targeted exome sequencing. Before September 2019, we have used in-house gene panels including 65 resp. 78 cardiomyopathy genes. Since October 2019, we switched to Genomics England PanelAPP, including 144 resp. 140 high-evidence based genes causative for the different subtypes of cardiomyopathy. A total of 141 patients with non-syndromic HCM (109) or DCM (32) underwent molecular testing. Our mutation detection rate was 47 % (35/74) with the in-house panels, 39 % (26/67) with the PanelAPP panels and 43 % (61/141) overall. The use of the larger PanelAPP panels did not show any difference in the genes found with causative variants. All the genes with pathogenic or likely pathogenic variants identified with the larger PanelAPP panels were already included in our smaller in-house panels. Our results confirm the lack of major clinical benefit of large panels in isolated HCM or DCM and support the recommendations of the 2021 European Society of Cardiology heart failure guidelines, which suggest to use small evidence-based panels and to consider additional large panels only if there is a clear family history or a specific phenotype.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2291. *DST* variants are responsible for neurogenic arthrogryposis multiplex congenita confirming the large clinical spectrum of type VI hereditary sensory autonomic neuropathy

Authors:

Y. Capri^{1,2}, L. BOURMANCE², C. DUPONT³, M-H. SAINT-FRISON⁴, F. Guimiot^{5,4}, S. GROTTTO⁶, A. LAQUERRIERE⁷, Y. CHITRIT⁸, J. Melki²; ¹Genetic Dept.-Univ. Hosp. APHP-Nord Robert Debré, Paris, France, ²INSERM-UMR1195, University-Paris Saclay-Le Kremlin Bicêtre, France, ³Cytogenetic Unit-APHP-Hosp. Robert Debre, Paris, France, ⁴Foetopathology Unit-Univ. Hosp. APHP-Nord Robert Debré, Paris, France, ⁵INSERM UMR1141, University-Paris Nord, France, ⁶Univ. Hosp. APHP-Ctr. Hosp. Cochin, Paris, France, ⁷Normandie Univ.-INSERM UMR1245, Rouen, France, ⁸Obstetric Dept.-Univ. Hosp. APHP-Nord Robert Debré, Paris, France

Abstract Body:

Arthrogryposis multiplex congenita (AMC) is a developmental condition characterized by multiple joint contractures resulting from reduced or absent fetal movements. Through whole-exome sequencing combined with high resolution array-CGH from DNA of a fetus presenting with early onset AMC, we identified biallelic loss-of-function mutations in *DST* with a stop gain variant (NM_001144769.5:c.12208G to T: p.Glu4070*) on one allele and a 149 kb microdeletion including exons 26 to 83 of the *DST* gene (arr[GRCh37] 6p12.1(56323554_56472573) x1) on the other allele. Transmission electron microscopy of the sciatic nerve revealed abnormal morphology of the peripheral nerve with severe hypomyelination associated with dramatic reduction of fiber density which highlight the critical role of *DST* in peripheral nerve axonogenesis during development in human. Mutations in *DST* cause hereditary sensory and autonomic neuropathies (HSAN) type VI which has been reported in several unrelated families with highly variable age of onset from fetal to adult onset. Our data enlarge the clinical spectrum and disease mechanisms of neurogenic AMC.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2292. Evaluate using artificial intelligence and machine learning in to predict deletion detection possibility in a cohort of chromosome 22q11.2 deletion syndrome cases

Authors:

I. Alabdulkareem¹, M. Addam², A. Alkhalidi², M. Albalwi³; ¹SDAIA, Riyadh, Saudi Arabia, ²King Abdulaziz Med. City, Riyadh, Saudi Arabia, ³Natl. Guard Hosp, Riyadh, Saudi Arabia

Abstract Body:

Chromosome 22q11.2 deletion syndrome (DiGeorge syndrome) is a neurodevelopmental illness that has been intensively investigated to elaborate more on the connection between chromosomal microdeletion, brain development, cognitive function, and psychiatric signs. It is a rare genetic disorder that is characterized by a wide range of clinical manifestations presented with distinctive facial features, common congenital heart disease, immune deficiency, and learning difficulty. The majority of 22q11.2 deletion cases are due to de novo heterozygous deletion with the minority of familial inherited deletion. Cytogenetically, large deletion cases may be detected easily with G-banding high-resolution karyotyping and FISH analysis in 85%. Here, we evaluate using artificial intelligence and machine learning in to predict deletion detection possibility in a cohort of chromosome 22q11.2 deletion syndrome cases. The analysis pipeline is built on AI/ML image-based diagnostics undertaking the 450-655 banding level of chromosome 22 using analyzed CytoVision image karyotypes of the subjects followed by recalling and linking DiGeorge FISH probe signal images for the same subject(s). A subsequent AI algorithm was used composed of chromosomes images and FISH images obtained with high sensitivity in predicting Chromosome 22q11.2 deletions. Our finding looks promising in supporting and helping in both fast and urgent results and to the naïve cytogenetic laboratories who are constrained with providing advanced approach technology such as CGH array and provide a crucial cytogenetic diagnostic decision on their patients.

PB2293. Evaluating the potential for using internal data in assigning benign classification to variants of uncertain significance.

Authors:

J. Wang, E. Choo, C. Lo, H. Tadepally, T. Smart, B. Gall, R. Munch, N. Sanapareddy, Y. Sha, V. Souter; Natera, Inc., Austin, TX

Abstract Body:

Variants are classified as variants of uncertain significance (VUS) when current evidence is not sufficient to assign either a benign or pathogenic classification to them. However, since a definitive clinical interpretation is not available for common VUS, their frequent reevaluation often increases the workload for clinical labs. When a variant is seen in healthy individuals homozygous for a recessive disorder, a strong benign criterion (American College of Medical Genetics and Genomics (ACMG) BS2) can be applied to potentially reclassify it as likely benign (LB), thereby minimizing its frequent reevaluation. Our study objective was to evaluate the potential for using internal data in reclassifying VUS occurring in presumably healthy individuals homozygous for these variants. Following ACMG/Association for Molecular Pathology guidelines, we evaluated the potential for reclassifying VUS to LB using presumably healthy individuals homozygous for these variants who underwent carrier screening with the Horizon™ 274 gene panel between March 2020 to March 2021 (38401 cases). Only genes associated with early-onset recessive disorders (defined by MedlinePlus) were included in this study. Genes associated with autosomal dominant and X-linked phenotypes were excluded. Based on our screening and internal data curation, 58 VUS variants across 44 genes were identified in presumably healthy individuals homozygous for these variants. Of these, 12 variants across 11 genes could be reclassified as LB based on ACMG BS2 criterion. These 12 variants were found in a total of 2647 cases processed by our lab since April 2018. All our proposed classifications due to homozygosity on carrier screening were consistent with current benign (B)/LB classification in ClinVar. In contrast, only 7 out of 58 variants were reported for their homozygosity in healthy individuals in the public database gnomAD. None of the 58 VUS variants were submitted as pathogenic or likely pathogenic in ClinVar. Our results demonstrate that homozygosity data from presumably healthy individuals retrieved from an internal variant database may be useful for VUS reclassification of genes associated with early-onset recessive disorders. Additionally, findings here highlight the importance of internal databases carrying homozygosity data of variants from healthy individuals in improving the reporting efficiency of clinical labs. However, while internal data may be utilized to improve reporting efficiency, careful review of clinical data for these individuals should be conducted first.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2294. Evidence review of the use of first-line genome sequencing to diagnose rare germline disorders

Authors:

K. Wigby^{1,2}, D. Brockman³, G. Costain⁴, C. Hale⁵, S. Taylor⁶, J. Belmont⁷, D. Bick⁸, D. Dimmock², S. Fernbach⁹, J. Greally¹⁰, V. Jobanputra¹¹, S. Kulkarni⁹, E. Spiteri⁵, R. Taft⁶, Medical Genome Initiative; ¹Univ. of California San Diego, San Diego, CA, ²Rady Children's Inst. for Genomic Med., San Diego, CA, ³Massachusetts Gen. Hosp., Boston, MA, ⁴The Hosp. for Sick Children, Toronto, ON, Canada, ⁵Stanford Hlth.Care, Palo Alto, CA, ⁶Illumina Inc, San Diego, CA, ⁷Genetics & Genomics Services, Inc, Houston, TX, ⁸Genomics England Ltd., Gig Harbor, WA, ⁹Baylor Coll. of Med., Houston, TX, ¹⁰Albert Einstein Coll. of Med., Bronx, NY, ¹¹New York Genome Ctr., New York, NY

Abstract Body:

Background: Genome sequencing (GS) has evolved as clinically validated assay with robust capabilities to identify rare genetic disorders. Recently published guidelines and health technology assessments have sought to identify patient populations that would benefit most from exome or genome sequencing. Questions remain, however, regarding when to apply GS as a first-line diagnostic test for rare germline disorders. To address this question, the Medical Genome Initiative conducted a focused literature review as part of a framework to develop patient selection recommendations.

Approach: The purpose of the literature review was to appraise the evidence focused on the use of first-line GS for the diagnosis of rare germline disorders. Studies published from January 2011 - December 2021 that reported on the diagnostic yield (DY) or clinical utility of GS were included. Studies on fetal, microbiology, oncology and healthy cohorts were excluded. Study characteristics, DY, and clinical utility were abstracted by two independent reviewers. To assess study quality, we adapted criteria for diagnostic studies from the American College of Radiology which grades study design and measures to reduce sources of bias.

Results: Sixty-three studies met inclusion criteria, comprising over 2700 patients who received GS in one of the following settings: acute care pediatric inpatients, pediatric outpatients, adult outpatients, or mixed. GS was the first-line genetic test in 41% of studies analyzed. For pediatric acute care studies, the proportion of studies using GS as a first line test was considerably higher at 78.5%. The proportion of high quality first-line GS studies was greater than non-first line GS studies (23% vs 2%, p=0.017). Most studies (61.5%) of first-line GS involved mixed phenotype patient populations. The mean DY of first-line GS was 45.2% (14-73%) compared with 39.3% (6-86%) in studies with cohorts that received prior genetic testing and 33.5% (9-60%) in exome-negative cohorts. Clinical utility was assessed in 33% of studies, the majority of which used GS as a first-line test.

Discussion: These studies suggest that first-line GS is appropriate in certain patient populations, but additional high-quality studies are needed to further assess the use of first-line GS for indications beyond pediatric acute care patients. Heterogeneity among study design and variant reporting limits comparability of DY across studies and underscores the need for additional metrics to assess utility of GS. The learnings from this literature review combined with the clinical expertise of the expert panel will be used to develop recommendations for first-line GS.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2295. Examining the factors impacting molecular diagnosis during clinical exome sequencing re-analysis

Authors:

A. Chan¹, K. Wood¹, J. Knoblauch¹, K. Pechter², K. Cao³, J. Wang⁴, J. Murrell⁵, L. Conlin¹; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²The Children's Hosp. of Philadelphia, Philadelphia, PA, ³Children's Hosp. of Philadelphia, Philadelphia, PA, ⁴Children's Hosp. Philadelphia, Philadelphia, PA, ⁵The Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

The use of clinical exome sequencing (CES) has been increasing due to its comprehensive and diagnostic capacity. However, most individuals who receive CES remain undiagnosed. With the rapid increase in gene-disease associations, evolving clinical presentations and analysis pipelines, the diagnostic utility is expected to increase over time, making it crucial to reanalyze non-diagnostic CES results. We conducted a retrospective study to examine the factors impacting molecular diagnoses during CES reanalysis. Re-analyses of 182 CES were ordered at the Children's Hospital of Philadelphia between July 2018 and May 2022, of which 20 CES were diagnostic after reanalysis (11%). Of these 20 diagnostic cases, the initial CES result was negative in six, diagnostic in one, and non-diagnostic in 13. CES reanalysis was ordered on the diagnostic case to identify a molecular cause for the other features not explained by the original variant. In the majority of cases (80%, n=16), a molecular diagnosis was made after CES re-analysis due to new published information at the gene (10 new disease or candidate disease genes), variant (five with additional case reports), and phenotype levels (one phenotype expansions). This newly published information resulted in additional variants being reported at the time of reanalysis in 12 of the 16 cases, upgrade in variant classification in three cases, and no change in variant classification for one case. Four of the 16 cases with newly published information also had evolving clinical presentations that facilitated phenotype correlation. The elapsed time between the original CES and the newly published information that impacted interpretation ranged between 3.2 months and 3.6 years, with the median time elapsed being 2.1 years. In the remaining four exomes, diagnostic variants were identified in two cases (10%) as a result of an updated pipeline; another had an upgraded classification of a previously reported variant; and the remaining reanalysis reported the same diagnostic variant as the original report with additional information. In summary, this study highlights the utility of CES reanalysis for previously non-diagnostic results. Factors leading to diagnostic findings include new information about genes, variants or disorders, updated patient-specific clinical information, and technical improvements, such as an updated bioinformatics pipeline and analysis strategy. Exploring other outcomes from CES reanalysis (e.g., inconclusive CES that became negative after re-analysis) will help to determine the circumstances which reanalysis is most useful.

PB2296. Gabriella Miller Kids First Data Resource Center (DRC): Collaborative Platforms for Accelerating Pediatric Research

Authors:

D. Higgins¹, J-P. Thibert², M. Mattioni³, J. DiGiovanna³, R. L. Grossman⁴, S. L. Volchenboum⁴, D. M. Taylor^{5,6}, V. Ferretti², A. P. Heath¹, A. Resnick¹, Gabriella Miller Kids First Data Resource Center; ¹Ctr. for Data Driven Discovery in Biomedicine, Children's Hosp. of Philadelphia, Philadelphia, PA, ²CHU Sainte-Justine Res. Ctr., Montreal, QC, Canada, ³Seven Bridges, Cambridge, MA, ⁴Univ. of Chicago, Chicago, IL, ⁵Dept. of Pediatrics, Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, ⁶Dept. of BioMed. and Hlth.Informatics, Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract Body:

Children born with certain structural birth defects have an increased risk of developing cancer before they turn 18 years old. Structural birth defects and pediatric cancer share a context of altered developmental biology and their co-occurrence suggests underlying genetic pathways responsible for both of these. Investigating pediatric cancer and structural birth defects together will help facilitate discoveries into their genetic causes and spur advancement in prevention, detection, and therapeutics which can improve patient outcomes.

The Gabriella Miller Kids First Pediatric Research Program (GMKF) is an NIH Common Fund initiative focused on providing large-scale clinically annotated genomic data for pediatric cancer and structural birth defect cohorts, including tumor- and germline whole genome sequencing (WGS), trio based joint-genotyping, and paired RNA sequencing of somatic tissues. The GMKF Kids First Data Resource Center is charged with generating these datasets and empowering collaborative discovery on its data resource platforms. 24 Kids First studies are released on the Kids First Data Resource Portal, representing more than 20,000 participants and more than 1.0 PB of data, with additional datasets being released yearly. Here we present an overview of the Kids First Data Resource Center's data and platforms. Our harmonized clinical and genomic datasets and platforms are interoperable with other NIH-supported consortia, allowing investigators to easily incorporate Kids First data into their research projects. The Portal's Variant Search feature allows users to query variants or genes of interest present in Kids First datasets quickly, guiding them toward specific studies and participants. The Portal's integration with the CAVATICA cloud analysis platform allows users to run large-scale bioinformatic workflows as well as notebook-based analyses in R Studio and Jupyter Lab, all within their browser window. Overall, we show how the Kids First Data Resource can help investigators of all types access and analyze genomics-scale pediatrics data as part of their research.

PB2297. Generic genome sequencing: one lab flow for all

Authors:

G. Schobers^{1,2}, R. Derks¹, E. Bosgoed¹, D. Hellebrekers³, N. de Leeuw¹, A. Stegmann³, E-J. Kamsteeg¹, A. Paulussen³, M. Ligtenberg¹, A. van den Wijngaard³, C. Gilissen^{1,4}, R. Blok³, H. Brunner^{1,2,3}, H. Yntema^{1,2}, M. Nelen¹, L. Vissers^{1,2}; ¹Radboudumc, Nijmegen, Netherlands, ²Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands, ³MUMC+, Maastricht, Netherlands, ⁴Radboud Inst. for Molecular Life Sci., Nijmegen, Netherlands

Abstract Body:

Background Genetic laboratories maintain numerous workflows to diagnose the full spectrum of hereditary and congenital diseases, including traditional approaches and advanced technologies. A single generic workflow would increase efficiency quite dramatically. We therefore assessed whether genome sequencing (GS) can replace all existing workflows supporting germline genetic diagnoses. **Methods** We performed GS (NovaSeq6000TM; 37x mean coverage) on 1,000 cases with 1,271 clinically relevant variants, selected from 1 year's diagnostic yield in a tertiary referral center, identified through 15 different workflows. Variants were binned by size and type: small variants (SNVs and indels <50 bp), large variants (CNVs and repeat expansions) and other variants (SVs and aneuploidies). VCFs were queried per variant and assessed in Trusight Software Suite (DRAGEN Germline Pipeline, TSS, Illumina). **Results** Overall, 93.9% (1,194/1,271) of variants were detected with GS. Detection rates differed per type, with small variants detected in 95.2% (825/867), large variants in 91.9% (328/357), and other variants in 87.2% (41/47). Importantly, variants were identifiable through routine clinical interpretation strategies, including disease-based clinical filters or gene-specific searches in TSS. Variants that remained undetected were located in homologous/repetitive regions, or mosaic. **Conclusion** GS is an efficient generic workflow to capture clinically relevant germline variants in a 'one-test-fits-all-strategy'. No new challenges in variant detection were identified, besides those known for short-read sequencing. GS can therefore not only replace exome sequencing, but also >99% of Sanger sequencing, smMIP, MLPA, and array analysis, allele specific PCRs, and cytogenetic analyses including karyotyping and FISH. These results provide perspective on how genetic laboratories will evolve.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2298. Genetic Testing Interpretation Consult (GTIC): A Novel Electronic Health Record (EHR) Support Tool to Further Characterize Variants of Interpretation for the Nongenetic Provider to Support Their Clinical Practice.

Authors:

J. Talbert¹, J. Cogan², **R. Hamid**³; ¹Vanderbilt Univ. Med. Ctr., Nashville, TN, ²Vanderbilt Univ, Nashville, TN, ³Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract Body:

Introduction: Exponential growth in next-generation sequencing has fueled an increase of genetic testing beyond clinical genetics and made it accessible to nongenetic specialties. Inherently the progress has resulted in variant classification discrepancies between laboratories despite ACMG guidelines and a glut of variants of uncertain significance (VUS) leading to ambiguous results, leaving nongenetic providers especially perplexed. The clinical impact of VUS' include missed diagnoses, lack of follow up testing or over testing, all leading to poor outcomes for patients and provider frustration. To support our nongenetic providers and deter from "curbside consults" for interpretation of VUS', we created a genetic testing interpretation consult (GTIC) via EHR Econsult with the goal of providing next steps for the clinician to follow. **Methods:** We designed an Econsult tool integrated into our EHR (EPIC). Nongenetic providers were trained to use this tool utilizing a web-based training module. Nongenetic providers requested further interpretation of genomic test results via this Econsult as an orderable. A dedicated team of genetic counselors, MD and PhD geneticists received the order along with limited clinical and family history and the molecular test report. The VUS' in the report were analyzed via a customized protocol utilizing variant specific bioinformatic tools, literature reviews, phenotyping databases, VUMC biobank data and phenotyping databases. A report was generated highlighting discrepancies, directing specialists for clinical correlation based on gene/phenotype with suggested next steps to further clarify etiology. The report was returned via the EHR to the requesting provider. **Results:** From 14 unique nongenetic specialties, 57 Econsults were ordered between Feb 2021-May 2022, variants analyzed totaled 195. Of the 57 cases, 24 resulted in alternate interpretations. Of the 24 cases, 19 variants were changed to VUS-possibly pathogenic and 25 were deemed VUS-possibly benign, revealing a 22.6% rate of discrepancy with the performing lab (44/195). **Conclusions:** We were able to provide further clarity for the VUS' in question for 24 cases (42%) and recommend specific next steps. With Econsult in place providers felt more confident and supported in ordering genomic testing.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2299. Genetic testing of *STRC* for hearing loss: a clinical lab's approach to pseudogenes

Authors:

M. Luo¹, M. Diaz-Miranda¹, T. Hartman¹, E. Bedoukian¹, I. Krantz¹, L. Conlin¹, J. Balciuniene²; ¹The Children's Hosp. of Philadelphia, Philadelphia, PA, ²PerkinElmer Genomics, Pittsburgh, PA

Abstract Body:

Pathogenic *STRC* variants cause DFNB16, a common type of autosomal recessive childhood-onset hearing loss (HL). *STRC* has a highly homologous pseudogene, *STRCP1*, located nearby that renders this region prone to non-allelic homologous recombination, leading to copy number (CN) changes, gene conversions, and fusion genes. The most common pathogenic *STRC* findings are large deletions, while disease-causing sequence variants (e.g. SNVs) are rarely reported due to analytic challenges caused by *STRCP1* on conventional sequencing tests. Therefore, a subset of patients with *STRC* diagnoses are missed and the scope of *STRC* pathogenic variants is not well explored. We use exome-based NGS and array CGH platform to screen a panel of 121 genes associated with pediatric ostensibly non-syndromic HL. This testing also includes an *STRC*-specific module which uses long range PCR followed by NGS and droplet digital PCR for integrative analysis of SNVs and CN variants in the *STRC* locus. Our testing of 479 unrelated probands with HL yielded diagnostic findings in 45% (216/479). *STRC* positive findings were identified in 5.6% (27/479), accounting for 12.5% of all diagnoses. Only 33% (9/27) of the *STRC* diagnoses were due to biallelic *STRC* deletions. A heterozygous *STRC* deletion and a hemizygous SNV accounted for 26% (7/27) and compound heterozygous SNVs accounted for 22% (6/27) of *STRC* diagnoses. In 7 of these patients, the SNVs were of *STRCP1* origin indicating focal or multi-exonic gene conversion events. More complex *STRC* findings were identified in the remaining 18.5% (5/27) patients. Two individuals carried a deletion on one allele and a non-functional *STRC-STRCP1* fusion on another allele. In three individuals, an apparently homozygous pathogenic variant was identified by NGS; however, the integrated *STRC* data were consistent with the presence of *STRC* deletion on one allele, and *STRC* duplication on the other allele with one *STRC* copy carrying a pathogenic SNV, and the second copy representing a non-functional *STRC-STRCP1* fusion. While some pathogenic variants in *STRC* can be detected by standard NGS and array CGH, the inclusion of this *STRC*-specific testing resulted in a doubling of the number of *STRC*-related diagnoses. Without the *STRC*-specific testing, diagnoses would have been completely missed in 5 individuals, and 8 individuals would have yielded inconclusive results. This integrative *STRC* testing approach uncovered signatures and potential mechanisms of complex genomic changes in the *STRC-STRCP1* locus and can serve as a model of cost-effective testing strategy for other similar pseudogene-containing genes.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2300. Genetic testing of the *ATP7B* gene for patients with suspected Wilson disease.

Authors:

M. Kyriass, H. Cox; PreventionGenetics LLC, an Exact Sci. company, Marshfield, WI

Abstract Body:

Wilson disease (WD) is an autosomal recessive inborn error of copper metabolism. Clinical disease occurs due to pathogenic genomic variants in the *ATP7B* gene, which encodes the transmembrane ATPase Cu(I) transporting β polypeptide. This leads to a disruption of copper homeostasis, which results in the accumulation of copper in the liver, nervous system, corneas, and other tissues (Weiss 2016. PubMed ID: 20301685; Chanpong and Dhawan. 2022. PubMed ID: 35042319; Dev et al. 2022. PubMed ID: 35586338). Typical features of WD include liver disease, neurologic abnormalities, and psychiatric disturbances. Kayser-Fleischer rings, which occur due to a high level of copper storage throughout the body, are often present in the eyes (Weiss 2016. PubMed ID: 20301685; Chanpong and Dhawan. 2022. PubMed ID: 35042319). Biochemically, low serum ceruloplasmin concentrations and low serum copper levels may be observed, while 24-hour urinary copper levels may be elevated. Additionally, copper levels in the liver are generally elevated (Weiss 2016. PubMed ID: 20301685; IEMbase v2.0.0 at <http://www.iembase.com/disorder/201>). Diagnosis is based on the combination of clinical and biochemical features, and/or biallelic pathogenic *ATP7B* variants identified by molecular analysis (Weiss 2016. PubMed ID: 20301685). However, the clinical picture and age of onset for WD patients can be highly variable. This clinical variability, along with the fact that other diseases and environmental factors can lead to a WD-like phenotype, can complicate diagnosis (Weiss 2016. PubMed ID: 20301685; Sánchez-Monteagudo et al. 2021. PubMed ID: 34572285). Our lab has been analyzing the *ATP7B* gene for over a decade in patients with a suspected diagnosis of Wilson disease, as well as in at-risk family members. During that time, over 200 variants with an interpretation of uncertain significance, likely pathogenic, or pathogenic have been observed. Of the nearly 800 single gene tests performed analyzing *ATP7B*, we reported a diagnostic molecular result in over 20% of cases. In addition to the clearly positive cases, an indeterminate outcome was observed in an additional ~12% of cases while nearly 70% of cases were reported as negative. Overall, these results highlight the benefit of molecular genetic testing for diagnosis of WD patients, while also emphasizing the fact that biallelic *ATP7B* pathogenic variants may not be identified in all patients with a clinical suspicion of WD. Further molecular, laboratory, and/or clinical analysis may be warranted in patients with a clinical suspicion of WD but without any pathogenic variants identified in the *ATP7B* gene.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2301. Genome sequencing enables parent of origin analysis of the X chromosome in probands with Klinefelter syndrome

Authors:

B. Seifert¹, R. Duncan¹, S. Li¹, R. Gore¹, L. S. Schaffer², E. N. Torres², M. N. Similuk¹, W. Bi³, H. Dai³, A. J. Oler¹, R. Ghosh¹, A. Raznahan², M. A. Walkiewicz¹; ¹Natl. Inst. of Allergy and Infectious Diseases, NIH, Bethesda, MD, ²Natl. Inst. of Mental Hlth., NIH, Bethesda, MD, ³Baylor Coll. of Med., Houston, TX

Abstract Body:

Background: Klinefelter syndrome (47,XXY) is characterized by tall stature, hypogonadism, delayed pubertal development, lack of secondary sexual characteristics, and varying neurodevelopmental phenotypes such as learning difficulties and social challenges. Among individuals with a 47,XXY karyotype, prior studies have shown maternal meiotic nondisjunction accounts for approximately 51% of cases, and paternal meiotic nondisjunction accounts for approximately 49% of cases. Whether the majority of sex chromosome nondisjunction occurs in meiosis I or meiosis II is less well understood. Here, we analyzed the parent of origin of the X chromosome via genome sequencing (GS) in individuals with a known diagnosis of Klinefelter syndrome. **Methods:** Trio Parentage/UPD Studies (TRIPS) analysis was conducted on 40 trios undergoing GS and clinical oligonucleotide SNP chromosomal microarray analysis (SNP-CMA). All probands of each trio had a 47,XXY karyotype previously diagnosed through chromosome analysis. Parents of each proband were included for trio GS analysis. Genome sequencing was performed by short-read sequencing and clinical SNP-CMA performed by comprehensive high-resolution array that detects uniparental isodisomy (UPiD), regions of homozygosity (ROH), and copy number variants (CNVs) underlying neurodevelopmental disorders. **Results:** Among 40 trios undergoing GS and clinical SNP-CMA analysis, 17/40 probands (42.5%) showed X chromosome aneuploidy consistent with paternal meiotic nondisjunction. Twenty-one of 40 (52.5%) probands showed X chromosome aneuploidy consistent with maternal heterodisomy. Two of 40 probands (5.0%) showed X chromosome aneuploidy consistent with maternal isodisomy, suggestive of a maternal meiosis II or post-zygotic mitotic error. The results showing maternal isodisomy were confirmed by clinical SNP-CMA. Within the individuals with maternal heterodisomy of the X chromosome, 1 individual (2.5%) showed marker patterns suggestive of segmental isodisomy within the short arm of the X chromosome, which is currently under investigation. **Conclusions:** Similar to previous studies, our analysis showed ~52% of probands with a 47,XXY karyotype to result from maternal meiotic nondisjunction and ~43% to result from paternal meiotic nondisjunction. Our data demonstrate the power of genome sequencing in determining the parent of origin of the extra X chromosome in individuals with Klinefelter syndrome. Ongoing work aims to correlate neurodevelopmental phenotypes in probands with the parent of origin of the additional X chromosome in these probands with Klinefelter syndrome.

Molecular and Cytogenetic Diagnostics Posters - Wednesday

PB2302. Genome Sequencing Enables Precision Clinical Care in Genetic Leukoencephalopathies

Authors:

K. Muirhead¹, J. L. Hacker¹, F. Gavazzi¹, S. Woidill¹, O. Sherbini¹, G. Helman¹, J. Kramer-Golinkoff¹, G. H. Velasquez², A. Pizzino¹, J. Schmidt¹, R. Taft³, A. Vanderver¹; ¹Children's Hosp. of Philadelphia, Philadelphia, PA, ²Univ. of California San Francisco, San Francisco, CA, ³Illumina Inc, San Diego, CA

Abstract Body:

OBJECTIVE: Leukoencephalopathies are rare, heritable white matter disorders with variable presentations that encompass more than thirty distinct phenotypes. While recent studies have shown the efficacy of genome sequencing (GS) in this population, the impact of a GS diagnosis on clinical care has not yet been investigated. **METHODS:** The cohort consisted of 165 individuals with clinically ascertained leukoencephalopathies who were subsequently enrolled in the IRB-approved Myelin Disorders Biorepository Project and received clinical GS. Clinical data from pre- and post-GS office notes was extracted and assessed for etiologic-specific screening, treatment and referrals to specialist providers after achieving a GS diagnosis to assess for outcomes of care. **RESULTS:** As a result of GS, 68 individuals (41%) achieved a positive test finding, 28 individuals (17%) had suspicious variants in a gene(s) of interest reported and 69 individuals (42%) had negative or non-diagnostic results. Of the 68 individuals who achieved a definitive diagnosis, 57 had sufficient clinical data available to investigate the impact of a GS diagnosis on clinical care. Within this group, 54 (95%) were referred to specialist providers for disease monitoring, 38 (67%) received additional targeted screening and 12 (21%) were eligible for disease-specific treatment. **CONCLUSIONS:** Individuals with clinically ascertained leukoencephalopathies who achieved a diagnosis via GS received precision clinical care inclusive of specialist referral, screening and condition-specific treatment. These data suggest that GS should continue to be considered as a first-line test for this population. Future implementation studies may be necessary to understand barriers to adoption and widespread deployment.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2303. Genome-wide investigation of potentially pathogenic copy number variants & mechanisms fomenting their origins.

Authors:

Z. Dardas¹, R. Duan¹, D. Marafi², D. Calame¹, J. Fatih¹, M. Dawood¹, H. Du¹, C. M. Grochowski¹, J. E. Posey¹, C. M. B. Carvalho³, J. R. Lupski¹; ¹Baylor Coll. of Med., Houston, TX, ²Kuwait Univ., Safat, Kuwait, ³Pacific Northwest Res. Inst., Seattle, WA

Abstract Body:

Deletions and duplications of chromosomal segments (copy number variants, CNVs) are a major source of variability between personal genomes and are a significant contributor of pathogenic rare variants to genomic disorders, as well as to both human gene & genome evolution. Despite these significant roles, the contribution of CNV to human disease and their underlying mechanisms are not fully understood. Herein, we aim to uncover the contribution of CNVs to a variety of rare Mendelian diseases in a large cohort of patients (>13,000) and better unfold the molecular mechanisms driving their formation. Moreover, as there is a possibility that genes in a family may have derived from one ancestral gene which became duplicated into different copies (paralogs) during evolution, we also aim to identify CNV in gene families including the tubulin superfamily. Using bioinformatics tools for CNV prediction from exome data (XHMM and HMZ/HTZ Dup/Del Finder), we identified a total of 50 potentially pathogenic novel exonic CNVs in neurodevelopmental disease (NDD) cohort (homozygous (16) duplications, *de novo* heterozygous (20) deletions and (14) duplications). A custom designed high-density array comparative genomic hybridization (aCGH) was utilized to further validate the presence of the predicted CNV and better delineate its precise genomic interval (start and stop positions) and breakpoint junction sequence. Of note, 9 candidate novel NDD-associated genes were identified among the identified CNVs including *SYNRG*, *DDX15*, *HNF1B*, *DUSP14*, *CYP4F11*, *CYP4F2*, *NID1*, *NEDD4*, and *C21orf57*. Interestingly, several genes that are members of gene families were detected within the candidate CNVs including *DDX15*, *HNF1B*, *CYP4F11*, *CYP4F2*, *KIF1A*, and *TUBB4A*. Additionally, multiple *de novo* large deletions and duplications were predicted by XHMM on chromosomes 5 and 18, respectively, in an unsolved NDD case. Array CGH revealed a terminal 14.4 Mb deletion in Chr5p and a terminal 21.5 Mb duplication in Chr18q suggesting a novel unbalanced translocation between Chr5p and Chr18q. Moreover, we fully characterized the CNV structure in three cases in which we confirmed to be tandem duplications with blunt fusion suggesting non-homologues end joining (NHEJ) as their driving mechanism. We also detected a complex genomic rearrangement (CGR) involving an apparent quadruplication-quintuplication event, which warranted further investigation by other technologies including long-read whole genome sequencing and optical mapping. This work has helped to reveal new potentially disease-causing genes, the disease pathogenesis, and provide insight into their associated SV mutagenesis mechanisms.

Brigham/Harvard Med. Sch., Boston, MA

Abstract Body:

A growing fraction of the population is receiving genetic testing, yet DNA sequencing often uncovers variants of uncertain significance (VUSs). Physicians and patients are often ill-prepared to manage VUSs and insurers are concerned about downstream costs. To understand the contribution of panel-based and genomic (exome and genome) testing to the generation of inconclusive results, data on rates of VUS return and diagnostic yield were collected from over 1.5 million tests from 19 clinical labs from Jan 2020 - Dec 2021. Results were delineated by panel size (2-10, 11-25, 26-50, 51-100, 101-200, >200 genes) or trio vs. less-than-trio for genomic testing, and for a subset, disease area across 12 broad indications. We found a larger and statistically significant difference ($p < 0.0001$) in the rate of inconclusive test results due to VUSs from multi-gene panel tests (32.4%; 470,834/1,452,897) compared to the rate from genomic tests (30.1%; 11,100/36,845). For panel tests, the rate of inconclusive results correlated with panel size ranging from 5.9% for 284,953 panel tests of 2-10 genes to 76.2% for 76,800 panel tests >200 genes. The rate of inconclusive results due to VUSs from less-than-trio genomic testing (36.8%; 5,903/16,049) was statistically significantly ($p < 0.0001$) higher than the rate from trio-based genomic testing (25.0%; 5,197/20,796). Although an increased rate of inconclusive results were observed in genome tests (32.4%; 1,646/3,432) compared to exome tests (29.8%; 9,454/22,313), this correlated more strongly with testing laboratory as most only ran one platform (exome or genome) and inconclusive rates per lab ranged from 16.2% to 72.5%. Although inconclusive rates for most disease areas directly correlated to panel size, rates were higher than expected for panel size for hematology/rheumatology/immunology tests (61%; average 21 genes) and lower than expected for panel size for cardiology tests (36%; average 68 genes). In contrast, little correlation to panel size was observed for diagnostic yield which ranged from a low of 7% for germline cancer (92,560/1,236,963; average 21 genes) to a high of 36% for dermatology (195/536; average 4 genes). In summary, the largest source of inconclusive results was multi-gene panel testing and was lower when deploying genomic testing. This is best explained by current practices of obligatory reporting of all VUSs in panel-based testing compared to genomic testing where correlation with phenotype constrains which VUSs are reported. These results may inform future reporting practices and payer coverage in genetic and genomic testing and a heightened appreciation for genomic testing interpretation methods.

PB2305. GMCK-RD a success story: Implementation of genomic medicine in Stockholm healthcare region, update on first 10,000 samples

Authors:

A. Lindstrand¹, H. Stranneheim², K. Lagerstedt Robinson¹, N. Lesco¹, M. Kvarnung¹, D. Nilsson², M. Engvall¹, J. Eisfeldt², H. Malmgren¹, C. Chiara², A. Jemt², S. Vonlanthen¹, P. Marits¹, M. Johansson Soller¹, A. Nordgren¹, V. Wirta², A. Wedell¹, GMCK-RD; ¹Karolinska Inst.t, Stockholm, Sweden, ²Karolinska Inst.t / SciLifeLab, Solna, Sweden

Abstract Body:

In healthcare clinical genetics is transitioning to clinical genomics and especially rare disease diagnostics is increasingly done through panel, exome and whole genome sequencing. At Karolinska we have formed Genomic Medicine Center Karolinska Rare Diseases (GMCK-RD), a joint unit between healthcare and academia, enabling large-scale genome sequencing of patients. Our transition to genomic medicine has been a success with over 10,000 individuals across a broad spectrum of rare diseases analyzed, enabling a diagnosis as well as personalized prediction, prognosis, and treatment in thousands of patients. GMCK-RD brings together experts from various medical disciplines with clinical geneticists, bioinformaticians and researchers. To facilitate implementation, we have developed a number of bioinformatic tools and processes covering steps as variant calling, workflow management, variant prioritization and interpretation, data sharing and quality assurance. Challenges include big data processing, ethical and legal issues as well as rigorous quality control while at the same time enabling continuous development of analysis pipelines and tools. Our analysis covers detection and interpretation of SNVs, INDELS, uniparental disomy, CNVs, balanced structural variants, and short tandem repeat expansions. Ongoing developemet projects include: (i) detection of mobile elements, (ii) Implementation of RNA-seq for diagnostic multiomic analyses and (iii) exploring novel reference genomes. The rapid increase in genomic testing also brings along a high need for scaling up interpretation, including through recruitment and training of highly specialized “genomicists” and development of new support solutions. We also need integrated units where highly specialized clinicians work closely together with laboratory experts, enabling patient selection, correct interpretation and validation of findings, and rapid translation to individualized treatment. This interactions have also enabled a large number of new disease gene discoveries. By overcoming these issues, we at GMCK-RD have moved healthcare in our region towards precision diagnostics and precision medicine.

PB2306. High diagnostic yield from clinical genome sequencing supports genome sequencing as first-tier genetic test: Evidence-based from 2002 index cases

Authors:

F. Guo, R. Liu, A. Mathur, C. Da Silva, B. Nallamilli, C. Collins, L. Bean, N. Gurujju, X. Chen-Deutsch, R. Yousaf, Z. Ma, J. Balciuniene, M. Hegde; PerkinElmer Genomics, Pittsburgh, PA

Abstract Body:

Genome sequencing (GS) is one of the most comprehensive tests that interrogate single nucleotide variants (SNV), copy number variants (CNV), mitochondrial variants, repeat expansions, and structural variants in one single assay. Despite the clear technical superiority, few studies are available regarding the diagnostic utility of its clinical application. In this study, we systematically evaluated 2002 consecutive clinical GS cases performed in our laboratory since 2017 to explore the diagnostic utility of clinical GS. Among these 2002 clinical GS cases, there were 1429 pediatric patients (633 singleton and 796 trios) and 573 adult patients (393 singletons and 180 trios). Whole blood, saliva, isolated DNA, and dry blood spot (DBS) samples accounted for about 25.6%, 48.2%, 12.0%, and 14.1% of samples, respectively. Saliva was the most common sample type, accounting for 41% and 55.4% in pediatric and adult cases, respectively. In contrast, DBS was the most common sample type for the pediatric cohort with 36.5% and 17.3% in pediatric singleton cases and all pediatric cohorts, while 6.7% of the adult samples were DBS. Overall, more than 30% of cases were previously tested by another laboratory but still undiagnosed. The overall assumed diagnostic yield was 38.1% (762/2002), with 40.3% (255/633) in pediatric singleton cases, 40.5% (322/796) in pediatric trio cases, 30.3% (119/393) in adult singleton cases and 36.7% (66/180) in adult trio cases. In addition, a relatively higher diagnostic yield of 40.4% in pediatric cases versus 32.3% in adult cases was observed in our cohort. Among the diagnostic findings, 82.3% of cases had SNVs only, including 83.9% in the pediatric cohort and 75.7% in the adult cohort; 13.2% of cases had a CNV ranging from a single exon deletion to aneuploidy in 12.3% of the pediatric cohort and 15.7% of the adult cohort. Eighteen cases had one SNV and one CNV in the same gene associated with recessive diseases consistent with the patient's clinical findings. Fifteen cases had diagnostic findings in the mitochondrial genome consistent with mitochondrial disease. We also detected two pediatric cases with SMA and three pediatric cases with positive repeat expansion screening consistent with the patient's clinical findings, which would have been missed by other sequencing platforms like exome sequencing. Importantly, around 3% of diagnostic cases had findings consistent with multiple different clinical diagnoses.

In summary, we demonstrate the clinical utility of GS within a large-to-date clinical GS cohort along with consistency in the use of DBS cards which are widely used in newborn screening.

Molecular and Cytogenetic Diagnostics Posters - Thursday

PB2307. Identification of a small duplication in the upstream noncoding enhancer of *SOX9* in a family with 46,XX disorder of sexual development by clinical whole genome sequencing.

Authors:

S. Sajan¹, C. Brown¹, L. Davis-Keppen², K. Burns², E. Royer², A. Kesari¹, D. Perry¹, R. Taft¹; ¹Illumina Inc, San Diego, CA, ²Sanford Children's Hosp., Sioux Falls, SD

Abstract Body:

Patients with rare undiagnosed genetic disease often undergo years of testing before receiving definitive molecular diagnoses. Here, we describe a family with multiple individuals with *SRY*-negative 46,XX testicular disorder of sexual development (DSD) referred for clinical whole genome sequencing (cWGS) through the Illumina's iHope program, comprising the affected proband, the clinically unaffected mother, and an affected maternal uncle. Both affected individuals identify as male. The proband is a 9-year-old male with ambiguous genitalia at birth, elevated testosterone levels, proximal scrotal hypospadias, phallus length of 2.6 cm, and palpable gonads. Also noted were urinary infections, short stature, ADHD and anxiety, whereas development was normal and intelligence in the superior range. A previous 64-gene panel test for ambiguous genitalia was negative. The mother's 30-year-old brother also has *SRY*-negative 46,XX testicular DSD with features including perineal hypospadias, bifid scrotum, palpable gonads with dysgenetic testes, mullerian structures in the scrotum, as well as hypogonadism and short stature. Trio case analysis for this particular family structure did not identify any clinically relevant variants using the standard clinical laboratory protocol. However, a detailed literature review revealed noncoding copy number variants upstream of the *SOX9* gene known to cause DSD that were excluded from the original analysis. We therefore manually inspected the cWGS data upstream of *SOX9* which resulted in the identification of a small ~3.5 kb duplication of 17q24.3, seq[GRCh37]dup(17)(q24.3)chr17:g.69480152_69483631dup, located about 634 kb upstream of the *SOX9* gene impacting the well-known XYSR enhancer of this gene. The smallest duplications of this enhancer that had previously been reported were 23.9 kb and 24.2 kb in two patients whose minimal critical region of overlap was ~5.2 kb containing experimentally validated binding sites for the testis-specific transcription factors SOX9 and SF1. The 3.5 kb duplication reported in our proband is entirely contained within this minimal critical region and is the smallest such duplication reported to-date in patients with 46,XX DSD. This duplication was present in everyone in the trio including the unaffected mother, which is consistent with one previous report of incomplete penetrance. These data show that cWGS as a first-tier test can benefit patients with suspected genetic disorders and also underscores the importance of analyzing cWGS noncoding variants.
